## Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

*With pleasure and appreciation we dedicate this book to our spouses and children, who made it possible for us to bring this text to fruition and who taught us what was really important in development over the lifespan. It is impossible to adequately describe the value of their encouragement and support. We also would like to express our appreciation to the Elsevier editorial staff who are extremely talented and helpful in keeping track of all the details necessary to complete such a task as well as their judicious editorial skills. Furthermore, no dedication of a book embracing this field would be meaningful without a tribute to the courage and perseverance of neurologically impaired children and their caretakers.*

# Preface to the First Edition

It is concurrently tiring, humiliating, and intellectually revitalizing to compile a book containing the essence of the information that embraces one's life work and professional preoccupation. For me, there is a certain moth-to-the-flame phenomenon that cannot be resisted; therefore this new book has been produced.

Pediatric neurology has come of age since my initial interest and subsequent immersion in the field. Concentrated attention to the details of brain development and function has brought much progress and understanding. Studies of disease processes by dedicated and intelligent individuals accompanied by a cascade of new technology (e.g., neuroimaging techniques, positron emission tomography, DNA probes, synthesis of gene products, sophisticated lipid chemistry) have propelled the field forward. The simultaneous increase of knowledge and capability of pediatric neurologists and others who diagnose and treat children with nervous system dysfunction has been extremely gratifying.

Although once within the realm of honest delusion of a seemingly sane (but unrealistic) devotee of the field, it is no longer possible to believe that a single individual can fathom, much less explore, the innumerable rivulets that coalesce to form the river of knowledge that currently is pediatric neurology. Streams of information in certain areas sometimes peacefully meander for years; suddenly, when knowledge of previously obscure areas is advanced and the newly gained information becomes central to understanding basic pathophysiologic entities, a once small stream gains momentum and abruptly flows with torrential force.

This text is an attempt to gather the most important aspects of current pediatric neurology and display them in

a comprehensible manner. The task, although consuming great energies and concentration, cannot be accomplished completely because new conditions are described daily.

The advancement of the field necessitated that preparation of this text keep pace with current knowledge and present new and valuable techniques. My colleagues and I have made every effort to discharge this responsibility. Because of continuous scientific progress, controversies are extant in some areas for varying periods; wherever possible, these areas of conflict are indicated.

This book is divided into four unequal parts. Part I contains a discussion of the historic and clinical examination. Part II contains information concerning laboratory examination. Chapters relating to the symptom complexes that often reflect the chief complaints of neurologically impaired children compose Part III. Part IV provides detailed discussion of various neurologic diseases that afflict children.

Although every precaution has been taken to avoid error, bias, and prejudice, inevitably some of these demons have become embedded in the text. The editor assumes full responsibility for these indiscretions.

It is my fervent hope that the reader will find this book informative and stimulating and that the contents will provide an introduction to the understanding of many of the conditions that remain mysterious and poorly explained.

**Kenneth F. Swaiman, MD**  
**Autumn 1988**

# Preface to the Sixth Edition

In 1975, a little over 40 years ago, the first two-volume reference text concerning Pediatric Neurology was published. In 1971, Dr Swaiman was approached by an executive editor of C.V. Mosby to discuss publishing a book on pediatric neurology based on papers he had read from a University of Minnesota Continuing Medical Education Course. This was a year before the first Child Neurology Society meeting and thus before the formal organization of pediatric neurologists. Drs. Ken Swaiman and Frank Wright began this project, immediately facing the challenge of delineating the field. At that time, the importance of neurochemistry and genetics was being emphasized, there were questions as to whether learning disabilities or autism were legitimate components of child neurology, and recruiting authors for various chapters was difficult as sub-specialties of the discipline were in their infancy or under- or undeveloped.

The first edition preface of *The Practice of Pediatric Neurology* stated, "We have aspired to create a well-illustrated book that stresses the mainstays of modern pediatric neurology—the staggering array of neuromuscular and metabolic diseases described in the past 30 years, the relationship of embryology to congenital malformations, the growing number of recognized but yet unexplained degenerative diseases of childhood, and higher cortical function as related to learning capabilities of the child." The book and the subsequent 1982 edition were internationally well received. *Pediatric Neurology* and subsequently *Swaiman's Pediatric Neurology* were first published in 1989 and then in 1994, 1999, 2005 and 2012. Elsevier succeeded C.V. Mosby as the publisher in 2012. The growth of the discipline is documented by the fact that the number of pages and chapters has grown greatly: from 40 chapters/1082 pages in 1975 to 108 chapters/2290 pages in 2012.

This sixth edition of *Swaiman's Pediatric Neurology: Principles & Practice* reflects the remarkable increase in knowledge and complexity of the field since the fifth edition. Keeping abreast of all new information required us to increase the size and scope of this book from 108 to 170 chapters. To avoid publishing an overwhelming and oversized tome, we meticulously curated the most immediately necessary information and guidance in the print book, while providing the full text, our most comprehensive edition ever, online. We are proud of our mobile-optimized, downloadable e-book, which is included with your print purchase, and which provides easy and complete searchable and annotatable access to the content. Between the portable print book and the expansive online text, this reference offers a remarkable collection of well written chapters on topics of importance to professionals around the world who care for children with neurological disorders.

To accomplish these goals, we have increased the number of editors from four in the last edition (Ken Swaiman, Stephen Ashwal, Donna Ferriero, Nina Schor) to eight by adding four new and accomplished individuals with expertise in specific

areas: Andrea Gropman (neurogenetics and metabolic disorders); Richard Finkel (neuromuscular disorders); Phillip Pearl (pediatric epilepsy); and Michael Shevell (neurodevelopmental disabilities). We also had some unofficial expert guidance for specific sections of the book on neurodevelopmental malformations (Bill Dobyns); pediatric movement disorders (Jon Mink); and pediatric neurooncology (Roger Packer).

Major changes in the book that the reader will find of interest include:

- Completely new sections on pediatric immune mediated nervous system disorders (4 chapters), cerebrovascular diseases (6 chapters), neurooncology (13 chapters), neuromuscular disorders (18 chapters), and clinical care of the child with neurologic disorders (11 chapters).
- Major expansions of the sections on perinatal acquired and congenital disorders (7 chapters), neurodevelopmental disabilities (11 chapters), pediatric epilepsy (23 chapters), and nonepileptiform paroxysmal disorders and disorders of sleep (7 chapters).
- Three new chapters for the section on emerging concepts in child neurology including topics related to the developmental connectome, stem cell transplantation, and cellular and animal models of neurological disease.
- Updates of all remaining chapters by an international group of authors who are experts in their respective fields.
- Other new chapters in different sections of the book include: neuropsychological assessment; development of a neonatal neurointensive care unit; neonatal traumatic brain, spine and peripheral nervous system injury; an overview of the conceptual framework of the developmental encephalopathies; an overview of how to evaluate patients with a suspected metabolic disorder; a review of conditions associated with vitamin metabolism; and a chapter on nutrition and malnutrition and the developing brain.

We hope that the reader will find this book a useful resource and that the information will benefit the many children who suffer from these conditions. It is our wish that the greater world community will increase support for the care of neurologically impaired children and the research necessary to provide further understanding of, and improved treatment and preventive measures for, neurologic diseases. This support will improve the survival and quality of life of these brave children and their families.

**Kenneth F. Swaiman**  
**Stephen Ashwal**  
**Donna M. Ferriero**  
**Nina F. Schor**  
**Richard S. Finkel**  
**Andrea L. Gropman**  
**Phillip L. Pearl**  
**Michael I. Shevell**

# Acknowledgments

We wish to thank all of the authors who graciously gave of their time to prepare and review their chapters, as well as the editorial and publishing staff at Elsevier, especially Charlotta

Kryhl, Humayra Rahman Khan, Joshua Mearns, Andrew Riley and many others. Without their diligence and persistence, we would have never been able to complete this project.

# Contributors

*The editors would like to acknowledge and offer grateful thanks for the input of all previous editions' contributors, without whom this new edition would not have been possible.*

 Professor of Pediatrics  
 Children's Learning Institute and the  
 Division of Child, Adolescent  
 Neurology  
 University of Texas Health Science  
 Center  
 Houston, TX, USA

**Richard S. Finkel, MD**  
 Chief, Division of Neurology  
 Nemours Children's Hospital;  
 Professor of Neurology  
 University of Central Florida College of  
 Medicine  
 Orlando, FL, USA

**Paul G. Fisher, MD**  
 Professor, Neurology and Pediatrics,  
 and by courtesy Neurosurgery and  
 Human Biology;  
 Beirne Family Professor of Pediatric  
 Neuro-Oncology;  
 Bing Director of Human Biology  
 Stanford University  
 Stanford, CA, USA

**Kevin Flanigan, MD**  
 Robert F. and Edgar T. Wolfe  
 Foundation Endowed Chair In  
 Neuromuscular Research  
 Professor of Pediatrics and Neurology,  
 The Ohio State University;  
 Director, Center for Gene Therapy  
 The Research Institute of Nationwide  
 Children's Hospital  
 Columbus, OH, USA

**Nicholas K. Foreman, MB.ChB. MRCP**  
 Seebaum-Tschetter Chair of  
 Neuro-Oncology  
 Professor, Department of Pediatrics;  
 University of Colorado  
 Denver, CO, USA

**Israel Franco, MD, FACS, FAAP**  
 Director Yale New Haven Children's  
 Bladder and Continence Program  
 New Haven, CT, USA;  
 Professor of Urology  
 New York Medical College  
 Valhalla, NY, USA

**Yitzchak Frank, MD**  
 Clinical Professor  
 Pediatrics, Neurology, Psychiatry  
 Icahn School of Medicine at Mount  
 Sinai  
 New York, NY, USA

**Douglas R. Fredrick, MD**  
 Clinical Professor  
 Department of Ophthalmology  
 Byers Eye Institute  
 Stanford University  
 Palo Alto, CA, USA

**Hudson H. Freeze, PhD**  
 Director  
 Human Genetics Program  
 Sanford Burnham Prebys Medical  
 Discovery Institute  
 La Jolla, CA, USA

**Cristina Fuente-Mora, PhD**  
 Research Scientist  
 Department of Neurology  
 New York University School of  
 Medicine  
 New York, NY, USA

**Joseph M. Furman, MD, PhD**  
 Professor  
 Departments of Otolaryngology and  
 Neurology  
 University of Pittsburgh  
 Pittsburgh, PA, USA

**Renata C. Gallagher, MD, PhD**  
 Associate Professor of Clinical  
 Pediatrics;  
 Director, Biochemical Genetics  
 Department of Pediatrics  
 UCSF Benioff Children's Hospital  
 San Francisco, CA, USA

**Catherine Garel, MD**  
 Hôpital d'enfants Armand-Trousseau  
 Department of Radiology  
 Paris, France

**Emily Gertsch, MD**  
 Referring Physician  
 Raleigh Neurology Associates  
 Raleigh, NC, USA

**Donald L. Gilbert, MD MS FAAN FAAP**

Professor of Pediatrics and Neurology;  
Program Director;  
Child Neurology Residency Director  
Tourette Syndrome and Movement  
Disorders Clinics Director  
Transcranial Magnetic Stimulation  
Laboratory  
Cincinnati Children's Hospital Medical  
Center  
Cincinnati, OH, USA

**Elizabeth E. Gilles, MD**

Pediatric Neurologist  
Child Neurology Solutions, PLLC  
Saint Paul, MN, USA

**Christopher C. Giza, MD**

Physician  
Pediatrics, Pediatric Neurology  
Ronald Reagan UCLA Medical Center  
Los Angeles, CA, USA

**Carol A. Glaser, MD**

Chief, Encephalitis and Special  
Investigations Section  
Division of Communicable Disease  
Control  
Richmond, CA, USA

**Hannah C. Glass, MDCM, MAS**

Associate Professor  
Departments of Neurology, Pediatrics  
and Epidemiology, Biostatistics  
University of California, San Francisco  
San Francisco, CA, USA

**Tracy Glauser, MD**

Associate Director, Cincinnati  
Children's Research Foundation;  
Director, Comprehensive Epilepsy  
Center;  
Co-Director, Genetic Pharmacology  
Service  
Cincinnati Children's Hospital Medical  
Center  
Cincinnati, OH, USA

**Joseph Glykys, MD, PhD**

Instructor in Neurology  
Department of Neurology  
Division of Child Neurology  
Massachusetts General Hospital  
Harvard Medical School  
Boston, MA, USA

**Amy Goldstein, MD**

Director, Neurogenetics, Metabolism;  
Assistant Professor of Pediatrics  
University of Pittsburgh School of  
Medicine  
Division of Child Neurology Children's  
Hospital of Pittsburgh  
Pittsburgh, PA, USA

**Hernan Dario Gonorazky, MD**

Clinical and Research Neuromuscular  
Fellow  
Division of Neurology  
Genetics and Genome Biology Program  
PGCRL, Hospital for Sick Children  
University of Toronto  
Toronto, ON, Canada

**Rodolfo Gonzalez, PhD**

Principal Scientist  
International Stem Cell Corporation  
Carlsbad, CA, USA

**Howard P. Goodkin, MD, PhD**

The Shure Professor of Neurology and  
Pediatrics  
Department of Neurology  
University of Virginia  
Charlottesville, VA, USA

**John M. Graham, Jr., MD, ScD**

Professor Emeritus  
Department of Pediatrics  
Cedars-Sinai Medical Center and  
Harbor-UCLA Medical Center  
David Geffen School of Medicine at  
UCLA  
Los Angeles, CA, USA

**Alexander L. Greninger, MD, PhD**

Laboratory of Medicine  
University of Washington  
Seattle, WA, USA

**Gary Gronseth, MD**

Professor and Vice-Chairman  
Department of Neurology  
University of Kansas Medical Center  
Kansas City, KS, USA

**Andrea L. Gropman, MD**

Chief, Neurogenetics and  
Neurodevelopmental Disabilities  
Department of Neurology  
Children's National Medical Center  
George Washington University of the  
Health Sciences  
Washington, DC, USA

**Richard Grundy, MD**

Professor of Paediatric Neuro-Oncology  
and Cancer Biology  
Children's Brain Tumour Research  
Centre  
University of Nottingham  
Nottingham, UK

**Renzo Guerrini, MD, FRCP**

Professor and Head  
Neuroscience Department  
University of Florence and Children's  
Hospital Anna Meyer  
Florence, Italy

**Nalin Gupta, MD, PhD**

UCSF Benioff Professor in Children's  
Health  
Departments of Neurological Surgery  
and Pediatrics  
University of California San Francisco  
San Francisco, CA, USA

**Jin S. Hahn, MD**

Professor  
Department of Neurology and  
Pediatrics  
Stanford University, School of Medicine  
Stanford, CA, USA

**Milton H. Hamblin, PhD**

Assistant Professor  
Department of Pharmacology  
Tulane University School of Medicine,  
New Orleans, LA, USA

**Abeer J. Hani, MD**

Assistant Professor of Pediatrics and  
Neurology  
Lebanese American University  
Beirut, Lebanon

**Sharyu Hanmantgad**

Department of Radiology  
Memorial Sloan-Kettering Cancer  
Center  
New York, NY, USA

**Mary J. Harbert, MD**

Director of Neonatal Neurology  
Sharp Mary Birch Hospital for Women  
and Newborns;  
Assistant Professor of Neurosciences  
University of California San Diego  
San Diego, CA, USA

**Chellamani Harini, MBBS, MD**

Instructor  
Department of Neurology  
Boston Children's Hospital  
Boston, MA, USA

**Andrea M. Harriott, MD**

Fellow  
Department of Neurology  
Brigham and Women's Hospital  
Massachusetts General Hospital  
Boston, MA, USA

**Chad Heatwole, MD, MS-CI**

Associate Professor of Neurology  
Department of Neurology  
University of Rochester  
Rochester, MN, USA

**Andrew D. Hershey, MD, PhD, FAHS**

Endowed Chair and Director of  
Neurology;  
Director, Headache Center  
Cincinnati Children's Hospital Medical  
Center;  
Professor of Pediatrics and Neurology  
University of Cincinnati, College of  
Medicine  
Cincinnati, OH, USA

**Deborah G. Hirtz, MD**

Professor  
Neurological Sciences and Pediatrics  
University of Vermont School of  
Medicine  
Burlington, VT, USA

**Gregory L. Holmes, MD**

Professor of Neurological Sciences and Pediatrics;  
Chair, Department of Neurological Sciences  
University of Vermont College of Medicine  
Burlington, VT, USA

**Barbara A. Holshouser, PhD**

Professor  
Department of Radiology  
Loma Linda University School of Medicine  
Loma Linda, CA, USA

**Kathleen A. Hurwitz, MD**

Physician  
Hurwitz Pediatrics  
Murrieta, CA, USA

**Eugene Hwang, MD**

Attending, Pediatric Neuro-oncology  
Director, Clinical Neuro-oncology Immunotherapeutics Program  
Center for Cancer and Blood Disorders  
Children's National Medical Center  
Washington, DC, USA

**Rebecca N. Ichord, MD**

Associate Professor, Neurology  
University of Pennsylvania School of Medicine;  
Director, Pediatric Stroke Program  
Philadelphia, PA, USA

**Paymaan Jafar-Nejad, MD**

Assistant Director  
Department of Neuro Drug Discovery  
Ionis Pharmaceuticals, Inc.  
Carlsbad, CA, USA

**Sejal V. Jain, MD**

Associate Director of the Sleep Center;  
Director, Neurology-Sleep Program;  
Assistant Professor of Pediatrics and Neurology  
Cincinnati Children's Hospital Medical Center  
Cincinnati, OH, USA

**Lori Jordan, MD, PhD**

Assistant Professor  
Departments of Pediatrics and Neurology  
Vanderbilt University Medical Center  
Nashville, TN, USA

**Marielle A. Kabbouche, MD, FAHS**

Professor of Pediatrics and Neurology  
University of Cincinnati, College of Medicine;  
Director, Inpatient Headache Program  
Department of Pediatrics and Neurology  
Cincinnati Children's Hospital Medical Center  
Cincinnati, OH, USA

**Joanne Kacperski, MD**

Assistant Professor of Neurology and Pediatrics  
University of Cincinnati, College of Medicine  
Department of Pediatrics and Neurology  
Cincinnati Children's Hospital Medical Center  
Cincinnati, OH, USA

**Peter B. Kang, MD**

Associate Professor of Pediatrics and Chief, Division of Pediatric Neurology  
Department of Pediatrics  
University of Florida College of Medicine  
Gainesville, FL, USA

**Matthias A. Kariannis, MD, MS**

Associate Professor of Pediatrics and Otolaryngology  
Division of Pediatric Hematology/Oncology  
NYU Langone Medical Center and Perlmutter Cancer Center  
New York, NY, USA

**Horacio Kaufmann, MD**

Felicia B. Axelrod Professor of Dysautonomia Research  
Department of Neurology  
NYU School of Medicine  
New York, NY, USA

**Harper L. Kaye, MD**

Neurologist  
Clinical Neuromodulation  
Boston Children's Hospital  
Boston, MA, USA

**Robert Keating, MD**

Chief  
Neurosurgery  
Children's National  
Washington, DC, USA

**Colin R. Kennedy, MBBS, MD**

Professor in Neurology and Paediatrics  
Faculty of Medicine  
University of Southampton  
Southampton, UK

**Yasmin Khakoo, MD**

Child Neurology Director;  
Associate Attending Pediatric Neurologist/Neuro-oncologist  
Memorial Sloan Kettering Cancer Center  
New York, NY, USA

**Adam Kirton, MD, MSc, FRCPC**

Associate Professor  
Pediatrics and Clinical Neurosciences  
Cumming School of Medicine  
University of Calgary Alberta Children's Hospital Research Institute  
Calgary, AB, Canada

**John T. Kissel, MD**

Professor of Neurology, Pediatrics, Neuroscience;  
Chairman, Department of Neurology  
The Gilbert and Kathryn Mitchell Chair in Neurology  
The Ohio State University Wexner Medical Center  
Department of Neurology  
Columbus, OH, USA

**Kelly G. Knupp, MD**

Associate Professor of Neurology and Pediatrics  
University of Colorado School of Medicine Children's Hospital  
Colorado Aurora, CO, USA

**Bruce R. Korf, MD, PhD**

Wayne H. and Sara Crews Finley Chair in Medical Genetics;  
Professor and Chair, Department of Genetics;  
Director, Heflin Center for Genomic Sciences  
University of Alabama at Birmingham  
Birmingham, AL, USA

**Eric H. Kossoff, MD**

Professor  
Departments of Neurology and Pediatrics  
Johns Hopkins Hospital  
Baltimore, MD, USA

**Sanjeev V. Kothare, MD**

Director, Pediatric Sleep Program  
New York University Langone Medical Center;  
Pediatric Neurologist and Epileptologist  
NYU Comprehensive Epilepsy Center  
Department of Neurology  
New York, NY, USA

**Oren Kupfer, MD**

Assistant Professor of Pediatrics  
Pediatric Pulmonary Medicine  
University of Colorado School of Medicine  
Children's Hospital Colorado  
Aurora, CO, USA

**W. Curt LaFrance, Jr., MD, MPH, FAAN, FANPA, DFAPA**

Director  
Neuropsychiatry and Behavioral Neurology  
Rhode Island Hospital  
Providence, RI, USA

**Beatrice Latal, MD, MPH**

Professor  
Child Development Center  
University Children's Hospital Zurich  
Zurich, Switzerland

**Steven M. Leber, MD, PhD**

Professor  
Departments of Pediatrics and  
Neurology  
University of Michigan  
Ann Arbor, MI, USA

**Jean-Pyo Lee, PhD**

Assistant Professor  
Department of Neurology  
Tulane University School of Medicine  
New Orleans, LA, USA

**Ilo E. Leppik, MD**

Professor of Neurology and Pharmacy  
University of Minnesota  
Minneapolis, MN, USA

**Tally Lerman-Sagie, MD**

Professor  
Neurosurgery  
Edith Wolfson Medical Center  
Jerusalem, Israel

**Jason T. Lerner, MD**

Associate Professor  
Division of Pediatric Neurology  
David Geffen School of Medicine at  
UCLA  
Los Angeles, CA, USA

**Richard J. Leventer, MD**

Professor  
Division of Medicine  
The Royal Children's Hospital  
Melbourne  
Melbourne, Australia

**Daniel J. Licht, MD**

Associate Professor of Neurology;  
Director of the Wolfson Family  
Laboratory for Clinical and  
Biomedical Optics  
Department of Neurology  
The Children's Hospital of Philadelphia  
Philadelphia, PA, USA

**Uta Lichter-Konecki, MD, PhD**

Visiting Professor of Pediatrics  
Director of the Metabolism Program  
Division of Medical Genetics/PKU  
Program  
Children's Hospital of Pittsburgh  
Pittsburgh, PA, USA

**Zvi Lidar, MD**

Consultant Physician  
Neurosurgery  
Herzliya Medical Center  
Tel Aviv-Yafo, Israel

**Djin Gie Liem, PhD**

Senior Lecturer  
School of Exercise, Nutrition Sciences  
Deakin University  
Burwood, NSW, Australia

**Tobias Loddenkemper, MD**

Director of Clinical Epilepsy Research;  
Associate Professor, Harvard Medical  
School  
Division of Epilepsy and Clinical  
Neurophysiology  
Boston Children's Hospital  
Boston, MA, USA

**Roger K. Long, MD**

Associate Professor  
Department of Pediatrics  
University of California, San Francisco  
San Francisco, CA, USA

**Quyên N. Luc, MD**

Clinical Assistant Professor of  
Neurology  
Keck School of Medicine  
University of Southern California  
Los Angeles, CA, USA

**Mark Mackay, MBBS, PhD, FRACP**

Director, Children's Stroke Program  
Department of Neurology, Royal  
Children's Hospital;  
Honorary Research Fellow, Clinical  
Sciences Theme,  
Murdoch Childrens Research Institute;  
Honorary Professorial Research Fellow  
Florey Institute of Neurosciences and  
Mental Health  
University of Melbourne  
Melbourne, VIC, Australia

**Annette Majnemer, MD**

Professor; Director and Associate Dean  
School of Physical and Occupational  
Therapy  
McGill University  
Montreal, Canada

**Naila Makhani, MD, MPH**

Assistant Professor  
Departments of Pediatrics and  
Neurology  
Yale University School of Medicine  
New Haven, CT, USA

**Gustavo Malinger, MD**

Associate Professor  
Obstetrics and Gynecology  
Tel-Aviv University  
Tel-Aviv, Israel

**David E. Mandelbaum, MD**

Professor  
Neurology, Pediatrics  
Brown University  
Providence, RI, USA

**Stephen M. Maricich, PhD, MD**

Mellon Foundation Scholar  
Assistant Professor  
Department of Pediatrics  
Division of Neurology  
Pittsburgh, PA, USA

**Kiran P. Maski, MD**

Instructor, Harvard Medical School  
Department of Neurology  
Boston Children's Hospital  
Boston, MA, USA

**Mudit Mathur, MD, MBA, FAAP, FCCM**

Associate Professor  
Department of Pediatrics, Division of  
Pediatric Critical Care  
Loma Linda University School of  
Medicine  
Loma Linda, CA, USA

**Dennis J. Matthews, MD**

Professor; Chairman  
Physical Medicine and Rehabilitation  
University of Colorado  
Denver, CO, USA

**Kelly McMahan, MD**

Genetic Counselor  
University of Rochester Medical Center  
Rochester, NY, USA

**Megan B. DeMara-Hoth**

Clinical Research Associate (Volunteer)  
Neurology  
Medical College of Wisconsin  
Milwaukee, WI, USA

**Bryce Mendelsohn, MD, PhD**

Assistant Clinical Professor  
Department of Pediatrics, Division of  
Medical Genetics  
University of California  
San Francisco, CA, USA

**Julie A. Mennella, PhD**

Member  
Monell Chemical Senses Center  
Philadelphia, PA, USA

**Laura R. Ment, MD**

Professor, Departments of Pediatrics  
and Neurology;  
Associate Dean  
Yale School of Medicine  
New Haven, CT, USA

**Eugenio Mercuri, MD**

Professor of Pediatric Neurology  
Catholic University Sacred Heart  
Rome, Italy

**David J. Michelson, MD**

Assistant Professor  
Departments of Pediatrics and  
Neurology  
Loma Linda University Health  
Loma Linda, CA, USA

**Mohamad A. Mikati, MD**

Wilburt C. Davison Professor of  
Pediatrics;  
Professor of Neurobiology;  
Chief, Division of Pediatric Neurology  
Duke University Medical Center  
Durham, NC, USA

**Fady M. Mikhail, MD**

Co-Director  
Department of Genetics  
University of Birmingham  
Birmingham, AL, USA

**Steven Paul Miller, MDCM, MAS**

Division Head and Professor of  
Pediatrics  
Bloorview Children's Hospital Chair in  
Pediatric Neuroscience  
Department of Pediatrics (Neurology)  
The Hospital for Sick Children,  
University of Toronto  
Toronto, ON, Canada

**Jeff M. Milunsky, MD**

Co-Director, Center for Human  
Genetics;  
Director, Clinical Genetics;  
Senior Director, Molecular Genetics  
Center for Human Genetics  
Cambridge, MA, USA

**Jonathan W. Mink, MD, PhD**

Frederick A. Horner, MD Endowed  
Professor in Pediatric Neurology  
Departments of Neurology,  
Neuroscience, and Pediatrics  
University of Rochester  
Rochester, NY, USA

**Ghayda M. Mirzaa, MD**

Assistant Professor  
Center for Integrative Brain Research  
Children's Research Institute  
Seattle, WA, USA

**Wendy G. Mitchell, MD**

Professor, Clinical Neurology  
Keck School of Medicine  
University of Southern California  
Children's Hospital Los Angeles  
Los Angeles, CA, USA

**Michael A. Mohan, MD**

Department of Sleep Medicine  
Boston Children's Hospital  
Beth Israel Deaconess Medical Center  
Boston, MA, USA

**Payam Mohassel, MD**

Clinical Fellow  
National Institutes of Health, National  
Institute of Neurological Disorders  
and Stroke  
Bethesda, MD, USA

**Mahendranath Moharir, MD, MSc, FRACP**

Pediatric Neurologist and Associate  
Professor  
Division of Neurology, Department of  
Pediatrics  
The Hospital for Sick Children and  
University of Toronto  
Toronto, ON, Canada

**Umrao R. Monani, PhD**

Associate Professor  
Pathology, Cell Biology  
Columbia University Medical Center  
New York, NY, USA

**Michelle Monje Deisseroth, MD, PhD**

Anne T. and Robert M. Bass Endowed  
Faculty Scholar in Pediatric Cancer  
and Blood Diseases  
Assistant Professor of Neurology, and  
by courtesy, Neurosurgery, Pathology  
and Pediatrics  
Stanford University  
Palo Alto, CA, USA

**Manikum Moodley, MD, FCP, FRCP**

Staff Pediatric Neurologist  
Center for Pediatric Neurology  
Neurological Institute, Cleveland Clinic  
Cleveland, OH, USA

**Andrew Mower, MD**

Neurology  
Children's Hospital of Orange County  
Orange County, CA, USA

**Richard T. Moxley III, MD**

Professor of Neurology and Pediatrics  
University of Rochester Medical Center  
School of Medicine and Dentistry  
Rochester, NY, USA

**Sabine Mueller, MD, PhD, MAS**

Associate Professor  
Department of Neurology,  
Neurosurgery and Pediatrics  
University of California, San Francisco  
San Francisco, CA, USA

**Alysson R. Muotri, PhD**

Associate Professor  
Departments of Pediatrics and Cellular,  
Molecular Medicine  
University of California San Diego  
La Jolla, CA, USA

**Sandesh C.S. Nagamani, MBBS, MD**

Assistant Professor  
Molecular and Human Genetics  
Baylor College of Medicine  
Houston, TX, US

**Mohan J. Narayanan, MD**

Barrow Neurological Institute  
Phoenix, AZ, USA

**Vinodh Narayanan, MD**

Medical Director  
Center for Rare Childhood Disorders  
The Translational Genomics Research  
Institute (TGen)  
Phoenix, AZ, USA

**Ruth D. Nass, MD**

Nancy Glickenhau Pier Professor of  
Pediatric Neuropsychiatry;  
Professor, Department of Child and  
Adolescent Psychiatry;  
Professor, Department of Pediatrics  
NYU Langone Medical Center  
NYU Child Study Center  
New York, NY, USA

**Jeffrey L. Neul, MD, PhD**

Chief of Child Neurology;  
Professor and Vice Chair  
Department of Neurosciences  
University of California  
San Diego, CA, USA

**Yoram Nevo, MD**

Professor and chair  
Institute of Neurology  
Schneider Children's Medical Center of  
Israel  
Tel-Aviv University  
Tel Aviv, Israel

**Bobby G. Ng, BS**

Scientist  
Genetic Disease Program  
Sanford - Burnham - Prebys Medical  
Discovery Institute  
La Jolla, CA, USA

**Katherine C. Nickels, MD**

Assistant Professor  
Department of Neurology  
Mayo Clinic  
Rochester, MN, USA

**Graeme A.M. Nimmo, MBBS, MSc**

Resident  
Clinical and Metabolic Genetics  
The Hospital for Sick Children  
University of Toronto  
Toronto, ON, Canada

**Michael J. Noetzel, MD**

Professor of Neurology and Pediatrics;  
Vice Chair, Division of Pediatric and  
Developmental Neurology  
Washington University School of  
Medicine;  
Medical Director, Clinical and  
Diagnostic Neuroscience Services  
St. Louis Children's Hospital  
St. Louis, MO, USA

**Lucy Norcliffe-Kaufmann, PhD**

Assistant Professor, Physiology and  
Neuroscience  
NYU Langone Medical Center  
New York, NY, USA

**Douglas R. Nordli, Jr., MD**

Chief of the Division of Pediatric  
Neurology and co-director of the  
Neuroscience Institute  
Children's Hospital Los Angeles  
Los Angeles, CA, USA

**Ulrike Nowak-Göttl, MD**

Professor;  
Deputy Director Campus Kiel  
Institute of Clinical Chemistry  
Universitätsklinikum  
Schleswig-Holstein  
Kiel, Germany

**Hope L. O'Brien, MD, FAHS**

Associate Professor of Pediatrics and Neurology  
University of Cincinnati, College of Medicine;  
Director, Young Adult Headache Clinic;  
Program Director, Headache Medicine Education  
Department of Pediatrics and Neurology  
Cincinnati Children's Hospital Medical Center  
Cincinnati, OH, USA

**Joyce Oleszek, MD**

Associate Professor  
Department of Rehabilitation  
University of Colorado at Denver  
Denver, CO, USA

**Maryam Oskoui, MDCM, MSc, FRCPC**

Assistant Professor  
Departments of Pediatrics and Neurology/Neurosurgery  
McGill University  
Montreal, QC, Canada

**Alex R. Paciorkowski, MD**

Assistant Professor  
Department of Neurology  
University of Rochester Medical Center  
Rochester, MN, USA

**Roger J. Packer, MD**

Senior Vice-President, Center for Neuroscience and Behavioral Medicine;  
Gilbert Family Neurofibromatosis Family Distinguished Professor in Neurofibromatosis;  
Director, Brain Tumor Institute;  
Director, Neurofibromatosis Institute Children's National Health System;  
Professor, Neurology and Pediatrics  
George Washington University  
Washington, DC, USA

**Seymour Packman, MD**

Professor Emeritus  
Department of Pediatrics, Division of Medical Genetics  
University of California  
San Francisco, CA, USA

**Jose-Alberto Palma, MD**

Assistant Professor, Department of Neurology;  
Assistant Director, Dysautonomia Research Laboratory  
NYU Langone Medical Center  
New York, NY, USA

**Andrea C. Pardo, MD, FAAP**

Assistant Professor  
Department of Pediatrics and Neurology  
Ann and Robert H. Lurie Children's Hospital of Chicago  
Northwestern Feinberg School of Medicine  
Chicago, IL, USA

**Julie A. Parsons, MD**

Associate Professor of Pediatrics and Neurology  
Child Neurology  
University of Colorado School of Medicine  
Aurora, CO, USA

**John Colin Partridge, MD**

Professor, Emeritus  
Pediatrics (Neonatology)  
University of California San Francisco UCSF Benioff Children's Hospital  
San Francisco, CA, USA

**Gregory M. Pastores, MD**

Clinical Professor, Medicine (Genetics)  
University College Dublin  
Dublin, Ireland

**Marc C. Patterson, MD**

Chair, Division of Child and Adolescent Neurology  
Professor of Neurology, Pediatrics and Medical Genetics  
Director, Child Neurology Training Program  
Mayo Clinic  
Rochester, MN, USA

**William J. Pearce, PhD**

Professor of Physiology  
Center for Perinatal Biology  
Loma Linda University School of Medicine  
Loma Linda, CA, USA

**Phillip L. Pearl, MD**

Director of Epilepsy and Clinical Neurophysiology  
Boston Children's Hospital;  
William G. Lennox Professor of Neurology  
Harvard Medical School  
Boston, MA, USA

**Melanie Penner, MD, FRCP(C)**

Clinician Investigator and Developmental Pediatrician  
Holland Bloorview Kids Rehabilitation Hospital  
Toronto, ON, Canada

**Leila Percival, RN**

Clinical Research Nurse  
NYU Langone Medical Center  
New York, NY, USA

**Marcia Pereira, PhD**

Instructor  
Department of Neurology  
Tulane University School of Medicine  
New Orleans, LA, USA

**Stefan M. Pfister, MD**

Professor of Pediatrics  
Division of Pediatric Neurooncology  
German Cancer Research Center (DKFZ)  
Heidelberg, Germany

**John Phillips, MD**

Professor and Director of Child Neurology  
Department of Neurology  
University of New Mexico Health Science Center  
Albuquerque, NM, USA

**Barbara Plecko, MD**

Professor  
Department of Child Neurology  
University Children's Hospital Zurich  
Zurich, Switzerland

**Sigita Plioplys, MD**

Head, Pediatric Neuropsychiatry Program  
Child and Adolescent Psychiatry;  
Associate Professor of Psychiatry and Behavioral Sciences  
Northwestern University Feinberg School of Medicine  
Ann & Robert H. Lurie Children's Hospital of Chicago  
Chicago, IL, USA

**Annapurna Poduri, MD, MPH**

Associate Professor  
Department of Neurology  
Boston Children's Hospital, Harvard Medical School  
Boston, MA, USA

**Sharon Poisson, MD**

Assistant Professor  
Neurology Clinic  
University of Colorado Hospital  
Aurora, CO, USA

**Scott L. Pomeroy, MD, PhD**

Bronson Crothers Professor and Chairman  
Department of Neurology  
Harvard Medical School  
Boston, MA, USA

**Andrea Poretti, MD**

Assistant Professor  
Division of Pediatric Radiology  
Russell H. Morgan Department of Radiology and Radiological Science  
The Johns Hopkins University School of Medicine  
Baltimore, MD, USA

**Scott W. Powers, PhD, ABPP, FAHS**

Professor of Pediatrics and CCRF Endowed Chair  
University of Cincinnati College of Medicine;  
Director of Clinical and Translational Research  
Cincinnati Children's Research Foundation;  
Co-Director, Headache Center;  
Director, Center for Child Behavior and Nutrition Research and Training  
Division of Behavioral Medicine and Clinical Psychology  
Cincinnati Children's Hospital Medical Center  
Cincinnati, OH, USA

**Michael R. Pranzatelli, MD**

Courtesy Professor of Neurology  
University of Central Florida College  
of Medicine  
Orlando, FL, USA;  
Adjoint Professor of Neurology  
University of Colorado School of  
Medicine  
Founder and President  
National Pediatric Neuroinflammation  
Organization, Inc.  
Orlando, FL, USA

**Allison Przekop, DO**

Associate Professor  
Pediatrics, Division of Pediatric  
Neurology  
Loma Linda University Children's  
Hospital  
Loma Linda, CA, USA

**Malcolm Rabie, MB BCh, FCP (SA) (Neurol.)**

Staff Physician  
Institute of Neurology, Schneider  
Children's Medical Center of Israel  
Tel Aviv University  
Tel Aviv, Israel

**Sampathkumar Rangasamy, PhD**

Research Assistant Professor

## 1

## General Aspects of the Patient's Neurologic History

*Kenneth F. Swaiman and John Phillips*

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

When presented with a challenging patient in 1885, with students Josef Babinski, Sigmund Freud, and others looking on, Dr. Charcot used the most important tools he had at his disposal: a careful history and a detailed examination. If he were alive today, Dr. Charcot would use those same tools.

There is no substitute for an accurate and thorough history. The patient or parent begins with an explanation of his or her concern. In most medical settings this opening statement lasts less than 60 seconds if not interrupted, as it unfortunately generally is, by the physician (Beckman and Frankel, 1984). More focused questions follow as a differential diagnosis is developed. In some cases language can be a barrier, particularly with the growing multiculturalism in the United States and other countries, and it is important that the interview be conducted in the native language of the patient. This may require the use of interpreters. Using a nonprofessional or poorly trained medical interpreter should be avoided because this has a much higher risk of causing clinically significant errors than using an experienced professional interpreter (Flores et al., 2012). In addition, an effective medical interview requires eye contact to help establish patient rapport (Cole and Bird, 2014), and the near-ubiquitous presence of computers in examination rooms, with an electronic medical record at the physician's fingertips, can be a problem. Compared with using paper medical records, there is now significantly more time spent looking at the medical record (now on a computer screen) and less time looking at the patient (Asan et al., 2014). However, although there is no turning back on the electronic medical record, and the pressure to see more patients may be increasing, the balance of new technology is certainly favorable. Once adopted, the electronic medical record improves physician's productivity and portable telemedicine equipment allows access to virtually any language needed in a medical setting (Cheriff et al., 2010).

Arriving at an appropriate differential diagnosis is an active process. As information is obtained suggesting specific disease categories, further questioning helps narrow the possible diagnostic possibilities. This process is assisted by considering general groups of neurologic diseases. Memory aides are often used to recall differential diagnostic categories—VINDICATE and VITAMIN C are two common examples (Table 1-1). Overlap exists between categories, and within each disease category are multiple subcategories and then specific diseases that become more or less likely as the patient interview proceeds. For example, recurrent strokes from MELAS (a disorder of energy metabolism) could be considered both a vascular and a metabolic process. The important issue is that, if focal weakness is the presenting concern, then the patient interview continues in an effort to discern whether the weakness is recurrent or triggered by fever or dehydration (which might make

a metabolic disorder more likely). Further questioning may disclose a history of lactic acidosis that narrows the differential diagnosis further to a possible mitochondrial disorder such as MELAS, which can then be confirmed with genetic testing. The point is to begin broadly. Cast a wide net. Consider all disease categories until a more focused differential diagnosis is possible based on the detailed history.

Part of clarifying the history of the current illness is to answer four basic questions:

1. Is the process acute or insidious?
2. Is it focal or generalized?
3. Is it progressive or static?
4. At what age did the problem begin?

The order in which disease findings develop and the precise age of onset of symptoms and signs may be critical factors in the process of accurate diagnosis. Many degenerative disorders have specific ages of onset that can help narrow the differential diagnosis; cognitive regression in an 8-year-old may raise the question of adrenoleukodystrophy, whereas in a 2-year-old one might consider neuronal ceroid lipofuscinosis. The presence of repeated episodes or associated phenomena should also be determined. For example, although the clinical manifestations of cerebrovascular events such as an acute stroke normally develop over minutes to hours, the underlying process may be long-standing; therefore, acute onset of vascular symptoms may be the result of a subacute or chronic process. On the other hand, infections, electrolyte imbalances, and toxic processes (such as exposure to over-the-counter drugs, prescription medications, insecticides, and other toxins found around the home) usually progress over a day to several days before maximum symptoms occur. More chronic are degenerative diseases, inborn metabolic disorders, and neoplastic conditions that usually progress insidiously over weeks to months.

Evaluation of whether a condition is **focal or generalized** is central to the diagnostic process. A focal neurologic lesion is not necessarily one that causes focal manifestations but is one that can be related to dysfunction in a circumscribed neuroanatomic location. For example, a focal lesion in the brainstem may cause ipsilateral cranial nerve and contralateral corticospinal tract involvement. If the problem is not focal, it usually results from a generalized process or from several lesions (i.e., multifocal). Neoplastic and vascular diseases frequently result in focal processes; occasionally, trauma results in such abnormalities. Generalized or multifocal conditions are usually associated with degenerative, congenital, metabolic, or toxic abnormalities.

In child neurology, it is particularly important that the clinician always attempt to determine whether the condition

**TABLE 1-1** Disease Category Acronyms

Vindicate	
V	Vascular
I	Inflammatory
N	Neoplastic
D	Degenerative
I	Infectious
C	Congenital
A	Allergy or autoimmune
T	Trauma or toxin
E	Endocrine
Vitamin C	
V	Vascular
I	Infectious
T	Trauma
A	Autoimmune
M	Metabolic
I	Idiopathic
N	Neoplastic
C	Congenital

is **progressive or static**. This is best accomplished by taking a detailed developmental history. Documenting the age of acquisition of major motor, language, and social milestones allows characterization of a child's developmental progress compared with age-based norms. To address the critical issue of developmental regression, questions are posed that determine whether the child is no longer capable of motor or intellectual activities that were previously performed. This information is essential to the diagnosis of progressive disease, which is usually preceded by a period of normal development. Occasionally, prior formal neurologic and psychometric evaluations may be available that help enormously in providing objective documentation of prior developmental status. Reviewing family photographs, videos, baby books, or old Facebook postings can be helpful. In progressive conditions, such as those caused by metabolic or neoplastic disorders, documentation of increasing loss of normal function or an increase in any symptoms is essential. Static conditions can be the result of traumatic or anoxic injury, a congenital abnormality, or perhaps a resolving acute toxic ingestion.

Reviewing the **medical history** is an essential part of any interview and often provides information that is critical in arriving at an appropriate diagnosis, extending information gleaned from the history of current illness. In child neurology, medical history begins with the moment of conception. Was conception achieved with reproductive technology, the long-term consequences of which are not clear? Was the mother older than 35 years at the time of conception, a possible risk factor for adverse outcome? During gestation, were there exposures to toxins such as alcohol, nicotine, or prescription or illicit drugs? Was the pregnancy planned and was the mother healthy throughout gestation? At what point was fetal movement first noted (i.e., quickening), which should be at approximately 4 to 5 months' gestation, and did it continue throughout the entire pregnancy? Were there problems with poverty, nutrition, or exposure to violence and stress? Obtaining some of this important information could be difficult because of privacy concerns, and may require a confidential interview with mother.

Details of the delivery are critical and may not be entirely recalled by parents; therefore, reviewing birth records if available is important. Information such as duration of labor, medications or assistive devices (forceps and vacuum extraction) used, presence of meconium at delivery, and gestational age may have direct relevance to later brain development. The

general status of the newborn immediately after delivery should also be understood. Objective information is important such as birth weight, Apgar scores, head circumference, and any neonatal complications encountered. Obtaining accurate information may require interviewing all caregivers, particularly with children whose mothers had pregnancy-related health problems and may have been sick. An enormously important piece of information that needs to be confirmed and not just assumed is the status of neonatal screening. Depending on the state or country of birth, most children are screened as a public health measure for certain treatable metabolic conditions. In the United States (<http://www.babysfirsttest.org/newborn-screening/states>) and Canada (<http://raredisorders.ca/documents/CanadaNBSstatusupdatedNov.112010.pdf>), it varies by state and province, but all screen for at least some disorders of amino acid metabolism, fatty acid oxidation diseases, organic acid conditions, and hemoglobin and endocrine disorders.

**Family history** is particularly important as many disorders encountered by the clinician may have a genetic basis. Begin by asking if any family members suffer from the same problems that affect the patient. Autosomal-dominant traits may be present in successive generations, although the degree of expressivity may vary. Autosomal-recessive traits often do not manifest in successive generations but may be present in siblings. Consanguinity must be considered when autosomal-recessive disease is part of the differential diagnosis, even if it is not forthcoming from interviewing parents (the incidence of false paternity has been reported to be from 1% to 30% depending on the population studied).

Cognitive and behavioral development is influenced by the child's home environment. A social history helps identify whether risk factors such as exposure to poverty, violence, parental depression, or bullying are present. Some clinics find the SEEK parent screening questionnaire helpful to identify potential challenges in the home environment (Fig. 1-2).

Caregivers should be questioned carefully about the nature and results of previously performed tests, including electrodiagnostic tests, brain-imaging studies, biochemical studies (e.g., quantitative assays of amino acids, organic acids, lactic acid, and lysosomal enzymes), biopsies, and chromosomal or gene studies. It is particularly important to review the full report of prior comprehensive genetic tests such as microarray analysis, exome sequencing, or genome-wide association studies (GWAS). Even when these tests fail to establish a clear diagnosis, they usually identify abnormalities of unknown clinical significance, and what was once unclear may have over time been found to have clear clinical implications. Therefore it may be helpful to perform an updated review of abnormalities identified on prior genetic testing. Use of prior medication should also be documented, including those medications that may have been prescribed but not taken, with note made of results of such therapies. If prior imaging has been performed, reviewing the study and not simply relying on the report is helpful to confirm findings (this is particularly important if the radiology interpretation is by someone without pediatric experience, or whose experience is not known as may occur with an on-call teleradiology service).

Thus, history taking is an active process. Beginning with a presenting complaint, the clinician broadly considers multiple diagnostic categories, which are narrowed as open-ended questions and followed by more specific queries. An exhaustive, all-encompassing neurologic history is impossible to obtain, particularly under the time constraints most clinicians face in today's environment. Therefore a skilled clinician is able to focus the interview on relevant information, often following up details that are more important than the patient or caregiver is aware of, and likewise, gently steering the conversation

***SEEK Parent Questionnaire***  
***A Safe Environment for Every Kid***

No. \_\_\_\_

1

Dear Parent or Caregiver: **Being a parent is not easy.** We want to help families have a safe environment for kids. We are asking everyone these questions. Please answer the questions about your **child being seen today** for a check-up. They are about issues that affect many families. If there's a problem, we'll try to help.

Today's Date: \_\_\_\_/\_\_\_\_/200\_\_  
 Child's Date of Birth: \_\_\_\_/\_\_\_\_/\_\_\_\_  
 Sex of Child:       Male       Female

**PLEASE CHECK**

- Yes     No      Do you need the telephone number for **Poison Control**?
- Yes     No      Do you need a **smoke alarm** for your home?
- Yes     No      Does **anyone** smoke **tobacco** at home?
- Yes     No      Is there a **gun** in your home?
- Yes     No      In the last year, did **you** worry that your food would **run out** before you got money, or food stamps to buy more?
- Yes     No      Do you worry that your **child** may have been **physically** abused?
- Yes     No      Do you worry that your **child** may have been **sexually** abused?
- Yes     No      Lately, do **you** often feel **down, depressed, or hopeless**?
- Yes     No      Do **you** often feel **lonely**?
- Yes     No      During the past month, have **you** felt **little interest** or **pleasure** in the things you used to enjoy?
- Yes     No      Do you often feel your **child** is **difficult** to take care of?
- Yes     No      Do you wish you had more **help** with your **child**?
- Yes     No      Do **you** feel so **stressed** you can't take another day?
- Yes     No      Do **you** sometimes find you need to **hit/spank** your child?
- Yes     No      In the past year, have **you** or **your partner** had a problem with **drugs** or **alcohol**?
- Yes     No      In the past year, have **you** or **your partner** felt the need to cut back on **drinking** or **drug use**?
- Yes     No      Have **you ever** been in a relationship in which you were physically **hurt** or **threatened** by a partner?
- Yes     No      In the past year, have **you** been **afraid** of a partner?
- Yes     No      In the past year have **you** thought of getting a **court order** for protection?
- Yes     No      **Are there any problems you'd like help with today?**

***Please give this form to the doctor or nurse you're seeing today. Thank you***

away from trivial discussion. Carefully listening to what is stated and how it is stated is important. Directly questioning the child when possible provides unique information, particularly if done at the onset of the interview before the adults start talking. Documenting exact quotes, using the vocabulary of the child or caregiver, improves accuracy of the medical record and avoids relying on an observer's interpretation of events when first-hand information is available. Bringing this information together is then the job of the clinician, who assembles all relevant facts into a cogent story that characterizes the neurologic process.

A child's developmental status is critically important in any neurologic assessment, and using a valid developmental screening test is helpful. Several assessment tools are available. These can be divided into provider-administered tools, such as the **Denver developmental screening test-II (DDST-II)** (see Fig. A-1ab in Appendix A), and parent questionnaires (Tervo, 2005), such as the **ages and stages questionnaire** and the **parents' evaluation of developmental status**.

Using the DDST-II, development is plotted over four broad domains of gross motor, fine motor, personal-social, and language skills from birth through 6 years of age. The age distribution for passing at the 25th, 50th, and 90th percentile is noted for each of 125 items. The DDST-II can be performed in a busy office setting; however, it is only a screening test, and any concerns should be followed up with more extensive developmental assessments. Also, adaptations must be made based on the cultural context. For example, the DDST-II items "using a spoon and fork" and "playing board games" are not relevant in cultures in which no one does these activities, and may need to be substituted by more appropriate developmental items. Concerns have been raised about the lack of validity of the DDST-II, and in the United States some states do not recommend using the DDST-II as a result of poor sensitivity and specificity (Minnesota Department of Health, <http://www.health.state.mn.us/divs/fh/mch/devscrm/>).

The **ages and stages questionnaire** is a preferred screening tool of many pediatric clinics and public health departments for children from 4 months to 5 years old, utilizing the insight that parents and caregivers offer regarding their child's development (Thompson et al., 2010). It requires responses from parents and caregivers to answer questions regarding whether specific developmental skills are demonstrated (yes, sometimes, and not yet). Five broad developmental domains are covered: communication, gross motor, fine motor, problem solving, and personal-social. Similarly, the **parents' evaluation of developmental status** is used for children from birth to 8 years old and relies on parent report through a 10-item standardized questionnaire covering expressive and receptive language, fine motor, gross motor, behavior, socialization, self-care, and learning, which identifies risk based on parental assessment. Both the ages and stages questionnaire and the parents' evaluation of developmental status are appropriate screening tools for child development and can be completed in a busy office setting.

Often it is not development but behavior that is of concern to parents. Clarifying as much as possible the nature of the behavioral concern helps. More helpful than hearing "He's acting out" is knowing if there is a problem with attention, impulsivity, aggression, or mood swings. Is there social withdrawal? Are there compulsions? Is the maladaptive behavior triggered by something or does it occur without warning?

Assessment tools are available that can help clarify problem behavior. For young children, one of the few available standardized measures is the **infant toddler social emotional assessment** or its abbreviated version, the **brief infant toddler social emotional assessment**, both of which are designed for children from 1 to 3 years old. The Brief Infant Toddler Social Emotional Assessment includes separate forms for parents and

for childcare providers, each of which can be completed in less than 10 minutes. Two general types of behavior are assessed: 1) social emotional problems, including aggression, anxiety, dysregulation, and atypical behavior, and 2) social emotional competence such as attention, motivation, empathy, and positive peer relationships. For older children, the **child symptom inventory** provides parent and teacher checklists to help screen for a broad number of behavioral concerns in children from 5 to 18 years of age such as anxiety, attention deficit hyperactivity disorder, depression, oppositional defiant disorder, and conduct disorder. Likewise, the **Swanson, Nolan and Pelham questionnaire (SNAP)** for children from 6 to 18 years old has forms available for teachers or parents that help distinguish between attention deficit hyperactivity disorder and other childhood behavioral disorders. Other general behavior assessment tools commonly used are the **Achenbach system of empirically based assessment** for children from 6 to 18 years old (this includes the **child behavior checklist**, which is a parent-report questionnaire, and the **youth self-report** to be completed by the child), and the **behavioral assessment system for children, second edition**, for age 2 to 25 years (this also includes questionnaires for parents and teachers, as well as a self-report questionnaire). In all instances in which behavior is a concern, it is helpful to use assessment tools that characterize behavior across environments (i.e., home, school, and daycare).

A common behavioral question is whether there is attention deficit hyperactivity disorder, in which case the **revised Conners parent rating scale** (age 3 to 17 years) or the **Vanderbilt** (age 6 to 12 years) is commonly used. Another common question that arises is whether a child has autistic spectrum disorder, which can be screened for using the **modified checklist for autism in toddlers** (Fig. 1-5) completed by a caregiver or via physician interview. Screening all children for autism is now recommended by the American Academy of Pediatrics at age 18 and 24 months.

Developmental screening is an enormously important part of the neurologic evaluation, but it must be interpreted carefully. For example, language delay may be caused by a congenital brain malformation or could be entirely the result of an impoverished environment (Fernald et al., 2013). Also, a single developmental screening is not as accurate as repeated assessments over time, and any abnormal screening results should prompt an immediate referral for more complete developmental testing by an appropriate professional.

Thus, a careful and informed history is at the core of the neurologic assessment of a child. The presenting complaint is explored in detail, followed by relevant aspects of the medical history, family history, and review of prior investigations or treatments. Assessment of the developmental status of the child is an essential component of this process, which eventually guides the examination to follow.

Child neurology is a unique and inherently complex endeavor, and at times the initial history uncovers information requiring clarification through a follow-up literature search. Commonly used general medical search engines include PubMed (<http://www.ncbi.nlm.nih.gov/pubmed>) or Google Scholar (<http://scholar.google.com/>). Specific websites might be considered such as Treatable Intellectual Disorder (<http://www.treatable-id.org/>) for metabolic conditions, or the Online Mendelian Inheritance in Man (<http://www.omim.org/>) for genetic disorders. As always, a tincture of humility is helpful for even the experienced clinician, knowing that a diagnosis can be frustratingly elusive at first. But what is initially confusing may be clarified as a child is followed over time and new information obtained, and through a partnership with the family and careful attention to neurologic detail, the correct diagnosis can be identified.

## M-CHAT

Please fill out the following about how your child usually is. Please try to answer every question. If the behavior is rare (e.g., you've seen it once or twice), please answer as if the child does not do it.

- |  |     |    |
|--|-----|----|
| 1. Does your child enjoy being swung, bounced on your knee, etc.?  | Yes | No |
| 2. Does your child take an interest in other children?   | Yes | No |
| 3. Does your child like climbing on things, such as up stairs?   | Yes | No |
| 4. Does your child enjoy playing peek-a-boo/hide-and-seek?   | Yes | No |
| 5. Does your child ever pretend, for example, to talk on the phone or take care of a doll or pretend other things?       | Yes | No |
| 6. Does your child ever use his/her index finger to point, to ask for something?   | Yes | No |
| 7. Does your child ever use his/her index finger to point, to indicate interest in something?                            | Yes | No |
| 8. Can your child play properly with small toys (e.g. cars or blocks) without just mouthing, fiddling, or dropping them? | Yes | No |
| 9. Does your child ever bring objects over to you (parent) to show you something?  | Yes | No |
| 10. Does your child look you in the eye for more than a second or two?   | Yes | No |
| 11. Does your child ever seem oversensitive to noise? (e.g., plugging ears)  | Yes | No |
| 12. Does your child smile in response to your face or your smile?  | Yes | No |
| 13. Does your child imitate you? (e.g., you make a face-will your child imitate it?)                                     | Yes | No |
| 14. Does your child respond to his/her name when you call?   | Yes | No |
| 15. If you point at a toy across the room, does your child look at it?   | Yes | No |
| 16. Does your child walk?  | Yes | No |
| 17. Does your child look at things you are looking at?   | Yes | No |
| 18. Does your child make unusual finger movements near his/her face?   | Yes | No |
| 19. Does your child try to attract your attention to his/her own activity?   | Yes | No |
| 20. Have you ever wondered if your child is deaf?  | Yes | No |
| 21. Does your child understand what people say?  | Yes | No |
| 22. Does your child sometimes stare at nothing or wander with no purpose?  | Yes | No |
| 23. Does your child look at your face to check your reaction when faced with something unfamiliar?                       | Yes | No |

## Neurologic Examination of the Older Child

Kenneth F. Swaiman and John Phillips

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

The neurologic examination provides critical and unique information that cannot be acquired otherwise (Campbell, 2013). Regardless of patient age, the essence of this information is the same: mental status, cranial nerves, motor, reflexes, sensory, and coordination/cerebellar testing. How this information is obtained is very age-dependent, however (Egan, 1990).

### OBSERVATION/MENTAL STATUS

Observation during history-taking is helpful, even when a child isn't being directly questioned (Menkes et al., 2005). Abnormal movements might suggest epilepsy, motor tic disorder, or a behavioral diagnosis such as attention deficit hyperactivity disorder (Pina-Garza, 2013). Caregiver-child interactions during the interview may offer clues into what the home environment is like. During this period the examiner surreptitiously assesses mental status, making note of language, attention, affect, and general developmental status (see Table 2-1).

### SCREENING GROSS MOTOR FUNCTION

Consider beginning with a rapid screening examination in case the child later becomes uncooperative. Start with the child standing. Ask the child to hop in place on each foot, tandem-walk forward and backward, toe-walk, and heel-walk. Then, checking for Gowers' maneuver, the child is asked to rise quickly from a squatting position, followed by asking the child to stand with the feet close together, eyes closed, and arms and hands outstretched. This maneuver allows simultaneous assessment of Romberg's sign and adventitious movements. Finally, finger-nose-finger movements help assess cerebellar function.

### PHYSICAL EXAMINATION

#### Cranial Nerve Examination

Examination of the cranial nerves in infants and younger children usually requires some modification of the sequence and may need some ingenious improvisation of the procedure, according to the degree of cooperation of the child (Volpe, 2008). As is the case with all examinations of infants and young children, the less threatening portions of the examination should be performed first.

#### Olfactory Nerve: Cranial Nerve I

Cranial nerve I can be evaluated by having the child smell pleasant aromas (e.g., chocolate, vanilla, peppermint) through each nostril while the other is manually occluded. Anosmia may occur after head trauma, with a severe upper respiratory tract infection, or in the rare instance of a frontal lobe mass involving the cribriform plate region.

#### Optic Nerve: Cranial Nerve II

Begin with formal visual acuity testing using a Snellen chart or a "near card" in older children. Younger children are more difficult and many times only gross vision can be evaluated. Beyond 4 years of age, the E test is useful. The child is taught to recognize the E, and to discern the direction in which the three "arms" are pointing and point a finger accordingly.

Peripheral visual field testing is accomplished using a small (3-mm) white or red test object, a toy, or in a pinch, the examiner's fingers can be used. The test object is moved from the temporal to the nasal fields and then from the superior and inferior portions of the temporal and nasal fields while the child looks directly at the examiner's nose. Finger counting can be used if acuity is grossly distorted. In cases of extreme impairment, perception of a rapidly moving finger can be used.

The optic disc (i.e., optic nerve head) of the older child is sharply defined and often salmon-colored, which differs from the pale gray color of the disc in an infant. In the presence of a deep cup in the optic disc, the color may appear pale, but the pallor is localized to the center of the disc. The pallor of optic atrophy occurs centrally and peripherally, and is accompanied by a decreased number of arterioles in the disc margins. Most commonly, papilledema is associated with elevation of the optic disc, distended veins, and lack of venous pulsations. Hemorrhages may surround the disc. Before papilledema is obvious, there may be blurring of the nasal disc margins and hyperemia of the nerve head.

The presence or absence of the pupillary light reflex differentiates between peripheral and cortical blindness. Lesions of the anterior visual pathway (i.e., retina to lateral geniculate body) result in the interruption of the afferent limb of the pupillary light reflex, producing an absent or decreased reflex. Anterior visual pathway interruption can cause amblyopia in one eye. In this situation, the pupil fails to constrict when stimulated with direct light; however, the consensual pupillary response (i.e., response when the other eye is illuminated) is intact. The deficient pupillary reflex is revealed by alternately aiming a light source toward one eye and then the other. In the eye with decreased vision, consensual pupillary constriction is greater than the response to direct light stimulation (Marcus Gunn pupil); the pupil of the affected eye may dilate slightly during direct stimulation (Haymaker, 1969).

#### Oculomotor, Trochlear, and Abducens Nerves: Cranial Nerves III, IV, and VI

The oculomotor, trochlear, and abducens cranial nerves control extraocular motor movements; these nerves must operate synchronously or diplopia ensues. Cranial nerve III innervates the superior, inferior, and medial recti; the inferior oblique; and the eyelid elevator (levator palpebrae superioris). Cranial nerves IV and VI innervate the superior oblique muscle and the lateral rectus muscle, respectively. Unfortunately for

**TABLE 2-1** Emerging Patterns of Behavior from 1 to 5 Years of Age

15 Months	
Motor:	Walks alone; crawls up stairs
Adaptive:	Makes tower of two cubes; makes line with crayon; inserts pellet into bottle
Language:	Jargon; follows simple commands; may name familiar object (ball)
Social:	Indicates some desires or needs by pointing; hugs parents
18 Months	
Motor:	Runs stiffly; sits on small chair; walks up stairs with one hand held; explores drawers and waste baskets
Adaptive:	Piles three cubes; initiates scribbling; imitates vertical stroke; dumps pellet from bottle
Language:	Ten words (average); names pictures; identifies one or more parts of body
Social:	Feeds self; seeks help when in trouble; may complain when wet or soiled; kisses parents with pucker
24 Months	
Motor:	Runs well; walks up and down stairs one step at a time; opens doors; climbs on furniture
Adaptive:	Makes tower of six cubes; circular scribbling; imitates horizontal strokes; folds paper once imitatively
Language:	Puts three words together (subject, verb, object)
Social:	Handles spoon well; tells immediate experiences; helps to undress; listens to stories with pictures
30 Months	
Motor:	Jumps
Adaptive:	Makes tower of eight cubes; makes vertical and horizontal strokes but generally will not join them to make a cross; imitates circular stroke, forming closed figure
Language:	Refers to self by pronoun "I"; knows full name
Social:	Helps put things away; pretends in play
36 Months	
Motor:	Goes up stairs alternating feet; rides tricycle; stands momentarily on one foot
Adaptive:	Makes tower of nine cubes; imitates construction of "bridge" of three cubes; copies circle; imitates cross
Language:	Knows age and gender; counts three objects correctly; repeats three numbers or sentence of six syllables
Social:	Plays simple games (in "parallel" with other children); helps in dressing (unbuttons clothing and puts on shoes); washes hands
48 Months	
Motor:	Hops on one foot; throws ball overhand; uses scissors to cut out pictures; climbs well
Adaptive:	Copies bridge from model; imitates construction of "gate" of five cubes; copies cross and square; draws man with 2-4 parts besides head; names longer of two lines
Language:	Counts four pennies accurately; tells a story
Social:	Plays with several children with beginning of social interaction and role playing; goes to toilet alone
60 Months	
Motor:	Skips
Adaptive:	Draws triangle from copy; names heavier of two weights
Language:	Names four colors; repeats sentences of ten syllables; counts ten pennies correctly
Social:	Dresses and undresses; asks questions about meanings of words; domestic role playing

(Adapted with permission from Behrman RE, et al. *Nelson Textbook of Pediatrics*, 14th edn. Philadelphia: WB Saunders, 1992.)

purposes of understanding, the function of extraocular muscles depends somewhat on the direction of gaze. The lateral and medial recti are abductors and adductors of the globe, respectively. The superior rectus and inferior oblique are elevators, and the inferior rectus and superior oblique are depressors. The oblique muscles act in the vertical plane while an eye is adducted. The recti muscles serve this function when an eye is abducted (Figure 2-2). When directed forward (i.e., primary position), the oblique muscles effect torsion around the anteroposterior axis (rotation) of the globes.

In heterophorias, also called phorias, both globes are directed normally on near or far objects during fixation; however, one or both deviate when one eye is occluded while the other eye fixes. Forcing fixation of the uncovered eye by alternately covering each eye confirms the diagnosis of heterophorias. Exophoria is a predisposition to divergence, whereas esophoria is a predisposition to convergence.

Eye deviations detectable during binocular vision are heterotropias, also called tropias. Adduction tropias are esotropias; abduction tropias are exotropias. Tropias are most often caused by compromised extraocular muscle innervation. Extraocular palsies can frequently be detected by observation of eye movements. A red glass is placed in front of an eye, and a focused, relatively intense white light is aimed at the eyes from various visual fields while the child fixes on the light. A merged, solitary, red-white image is perceived when extraocular movements are normal; however, when muscle paresis is present, the child reports a separation of the red and white images when looking in the direction of action of the affected

**Figure 2-2.** Extraocular muscle movement. **A**, In primary position. **B**, In abduction and adduction. (Courtesy of the Division of Pediatric Neurology, University of Minnesota Medical School.)

muscle. The farthest peripheral image is the one perceived by the abnormal eye; this eye can be identified by the color of the image. Volitional turning of the head accompanies paresis of the lateral rectus muscle to forestall diplopia; the head is deviated toward the paretic muscle, and the eyes are directed ahead. In superior oblique or superior rectus muscle palsies, tilting of the head toward the shoulder opposite the side of the paretic eye muscle occurs.

Extraocular muscle dysfunction is associated with many conditions that affect the brainstem, cranial nerves, neuromuscular junction, or muscles. Cranial nerve VI function may be impaired by increased intracranial pressure, irrespective of cause. Squint, usually esotropia, often accompanies decreased visual acuity in infants and young children.

Ptosis and extraocular muscle paralysis accompany dysfunction of cranial nerve III. Ptosis resulting from oculomotor nerve compromise is usually more pronounced than is the malposition of the lid associated with Horner syndrome. Complete oculomotor nerve paralysis, although uncommon, causes the eye to position downward and outward. Poor adduction and elevation are also evident.

Eye deviation is often the harbinger of a serious neurologic problem. Destructive lesions of the brainstem nuclei cause conjugate eye deviation toward the opposite side. Destructive cerebral hemispherical lesions cause eye deviation toward the side of the lesion; conversely, an irritative cerebral hemispherical lesion (such as a seizure focus) causes the eyes to turn away from the side of the lesion. Hence for a cortical lesion, "the patient looks at their stroke but away from their seizure." Vertical gaze paresis results from dysfunction of the tectal area of the midbrain. Patients with a pineal tumor or hydrocephalus may be unable to elevate the eyes for upward gaze.

Brainstem lesions, especially those in the midbrain or pons, may disrupt the medial longitudinal fasciculus. The resultant impairment of conjugate eye movement is referred to as an internuclear ophthalmoplegia. There is weakness of medial rectus muscle contraction of the adducting eye, which is accompanied by a monocular nystagmus in the abducting eye. Occasionally, paresis of lateral rectus muscle movement in the abducting eye may occur. Medial longitudinal fasciculus involvement may be unilateral or bilateral.

Internal ophthalmoplegia consists of a fully dilated pupil that is unreactive to light or accommodation. Extraocular muscle function is normal when each muscle is tested separately. The oculomotor nerve, nucleus, or the parasympathetic ciliary ganglion may be a site of involvement.

External ophthalmoplegia results in ptosis and paralysis of all extraocular muscles. Pupillary reactivity is normal.

Opticokinetic nystagmus is a useful test in evaluating the eye movements of children. A drum or tape with stripes or figures is slowly rotated or drawn before the child's eyes in horizontal and vertical directions. With fixation, the child should visually track the object in the direction the tape is being drawn, with a rapid, rhythmic movement (refixation) of the eyes in the reverse direction to enable fixation on the next figure or stripe. Absence of such a response may result from failure of fixation, amaurosis, or disturbed saccadic eye movements.

The child who appears clinically blind because of a conversion reaction usually exhibits a normal opticokinetic nystagmus response. Children who manifest congenital nystagmus and have an opticokinetic nystagmus response in the vertical plane likely have adequate functional sight.

Spontaneous nystagmus (i.e., involuntary oscillatory movements of the eye) may be horizontal, vertical, or rotary; a patient can exhibit all three types. The movements may consist of a slow and a fast phase, giving rise to the term jerk nystag-

mus. However, the phases may be of equal duration and amplitude, appearing pendular. In general, vertical nystagmus is associated with either medication or brainstem dysfunction. While a few beats of horizontal nystagmus with extreme lateral gaze are normal, persistent horizontal nystagmus indicates dysfunction of the cerebellum or brainstem vestibular system components; the nystagmus is coarser (i.e., the amplitude of movements are greater) when the direction of gaze is toward the side of the lesion. Seesaw nystagmus is characterized by disconjugate (alternating) movement of the eyes, which move upward and downward in a seesaw motion. This type of nystagmus may accompany lesions in the region of the optic chiasm (see Chapter 6).

## Trigeminal Nerve: Cranial Nerve V

Cranial nerve V, the trigeminal nerve, has motor and sensory functions. The motor division of the trigeminal nerve innervates the masticatory muscles: masseter, pterygoid, and temporalis. Temporalis muscle atrophy manifests as scalloping of the temporal fossa. The masseter muscle bulk may be assessed by palpation while the patient firmly closes the jaw. Pterygoid muscle strength is evaluated by having the patient open the mouth and "slide" the jaw from one side to the other while the examiner resists movements with the hand to assess muscle strength. The jaw reflex is elicited when the examiner places a finger on the patient's chin while the mouth is slightly open and taps the finger to stretch the masticatory muscles. A rapid muscle contraction with closure of the mouth is the reflex response. This stretch reflex receives its afferent and efferent nerve control from cranial nerve V; the segmental level is located in the midpons. The expected reflex reaction is absent with motor nucleus and peripheral trigeminal nerve compromise. Conversely, this reflex is overactive in the presence of supranuclear lesions; rarely, jaw clonus may be evident. Because of weakness of the ipsilateral pterygoid muscles, unilateral impairment of the trigeminal nerve causes deviation of the jaw toward the side of the lesion. Cranial nerve V is also responsible for sensation involving the face, including eye and the anterior half of the scalp.

## Facial Nerve: Cranial Nerve VII

Taste sensation over the anterior two-thirds of the tongue, secretory fibers (parasympathetic) innervating the lacrimal and salivary glands, and innervation of all facial muscles are accomplished by cranial nerve VII. Complete motor dysfunction on one side of the face ensues when the cranial nerve VII pathway is disrupted in the nucleus, pons, or peripheral nerve. The patient is unable to move the forehead upward, close the eye forcefully, or elevate the corner of the mouth on the side of the affected nerve.

Central (supranuclear) facial nerve impairment produces only paresis of the muscles involving the lower face, with resultant drooping of the angle of the mouth, disappearance or diminution of the nasal labial fold, and widened palpebral fissure. The muscles of the forehead, which are innervated bilaterally, are unaffected.

Taste sensation in the anterior two-thirds of the tongue is in part provided by the chorda tympani nerve, which traverses the path of the facial nerve for a short distance. Testing of taste sensation is difficult. Evaluation of taste requires that the patient extend the tongue and that the examiner hold the tip of the tongue with a piece of gauze and place salty, sweet, acidic, and sour and bitter materials, usually represented by salt, sugar, vinegar, and quinine, on the anterior portion of the tongue. The patient's tongue must remain outside of the mouth until the test is completed. An older patient should be able to identify each substance.

## Auditory Nerve: Cranial Nerve VIII

Function and evaluation of cranial nerve VIII are discussed in detail in Chapters 7 and 8. Although cranial nerve VIII is known as the auditory nerve, it has auditory and vestibular functions.

Patients who fail to develop speech or who have slow speech development, as well as those who have difficulty with fluency and articulation, may have hearing impairment. Older children can cooperate with formal audiometric testing. Such testing may not be possible in younger infants, but brainstem auditory-evoked potentials may provide the necessary information concerning hearing impairment and the level of dysfunction within the nervous system.

Clinical evaluation and caloric testing can be used for gross assessment of vestibular function. To perform caloric testing, the patient is in the supine position, with head flexed at 30 degrees. Ice water (10 mL) is injected over 30 seconds into one external auditory canal at a time. The conscious patient develops coarse nystagmus toward the ipsilateral ear; no eye deviation occurs. If the patient has some degree of obtundation, there is a modification of the response. The eyes become tonically deviated ipsilaterally, with accompanying nystagmus occurring contralaterally. If the patient is comatose, cold water stimulation usually causes tonic deviation ipsilaterally and no nystagmus; if the coma is profound or the patient is brain-dead, no eye changes occur.

## Glossopharyngeal and Vagus Nerves: Cranial Nerves IX and X

Examination of the larynx, pharynx, and palate provides most of the desired information concerning the function of cranial nerves IX and X. Unilateral paresis of the soft palate causes an ipsilateral droop, even when the patient is expelling air through the open mouth or gagging in response to a tongue blade. Bilateral involvement causes a flaccid soft palate bilaterally.

The gag reflex is mediated through cranial nerve IX and is elicited by touching the posterior pharyngeal mucosa with a tongue blade. Normal individuals may have absence or a seemingly disproportionately violent response; assessing the importance of changes in the gag reflex is difficult in the absence of other findings. The integrity of cranial nerves IX and X is necessary for a gag response; sensation of the soft palate and uvula travels via cranial nerve IX, and motor function is carried by cranial nerve X. Thus unilateral weakness causes deviation of the uvula *away* from the weak side (unlike unilateral weakness of cranial nerve XII, discussed later, which causes deviation of the tongue *toward* the weak side).

## Spinal Accessory Nerve: Cranial Nerve XI

Cranial nerve XI provides innervation for the trapezius and sternocleidomastoid muscles. Cranial nerve XI comprises some fibers from C1 and C2, and some from the motor nucleus in the brainstem, and is unique in combining brainstem and cervical cord origins. The trapezius muscles are assessed when the patient is asked to shrug the shoulders against resistance while the sternocleidomastoid muscle is tested by asking the child to rotate their head to one side against resistance. Weakness of the sternocleidomastoid muscle results in an inability to rotate the head to the contralateral side.

## Hypoglossal Nerve: Cranial Nerve XII

The tongue muscle is the primary responsibility of cranial nerve XII. Atrophy and fasciculation of the tongue occur when

the ipsilateral hypoglossal nucleus or hypoglossal nerve is involved. The protruded tongue deviates toward the involved side because contraction of the normally innervated tongue muscle causes protrusion and is unopposed.

## Skeletal Muscles

Tone, bulk, and strength of the skeletal muscles should be determined during this portion of the examination. Motor functions of the spinal nerves are described in Table 2-3.

The strength of limb muscles is assessed, when possible, by testing the child's ability to counteract resistance imposed by the examiner on proximal and distal muscle groups or individual muscles.

## Muscle Testing

The following scoring system is useful for recording muscle power:

- 5: normal power
- 4: inability to maintain position against moderate resistance
- 3: inability to maintain position against slight resistance or gravity
- 2: active movement with gravity eliminated
- 1: trace of contraction
- 0: no contraction.

Arm and shoulder strength can also be assessed by asking the child to lean against a wall with legs placed a foot or two from the wall edge and arms outstretched with the palms against the wall. Testing lower extremity strength can be assessed by asking the child to sit on the floor then rapidly stand; the normal child will spring erect. With weakness of the hip extensors, however, Gowers' maneuver will be engaged, and the patient climbs up their own legs, pushing themselves into the erect position.

Muscle bulk is evaluated by gentle palpation and observation. Muscle tenderness, nerve tenderness, and nerve hypertrophy can also be assessed by palpation. Myotonia can be elicited by tapping over the thenar eminence and deltoid muscles.

Muscle tone is evaluated when the child is relaxed so that resistance to passive movement can be monitored. Aside from passive movement of limbs at joints, the examiner also assesses the extensibility of muscles by shaking the limbs and determining the range of motion.

Tone may be decreased in the presence of cerebellar disease and anterior horn cell disease. Tone may be increased because of the rigidity associated with basal ganglia disease and spasticity associated with corticospinal tract dysfunction.

## Deep Tendon Reflexes

Standard deep tendon reflexes (i.e., muscle stretch reflexes) are elicited: biceps, triceps, brachioradialis, patellar, and Achilles reflexes.

The response to elicitation of deep tendon reflexes can be characterized as follows:

- 0: absent
- 1: hyporeflexic (trace, or only seen with reinforcement)
- 2: normal
- 3: hyperreflexic
- 4: unsustained clonus
- 5: sustained clonus.

Enhancement of tendon reflex responses when reflexes are seemingly absent can be promoted by having the child squeeze an object such as a block or ball or perform the more

**TABLE 2-3** Extraocular Muscle Paralysis

Nerves	Muscles*	Function
<b>Cervical Plexus (C1–C4)</b>		
Cervical	Deep cervical	Flexion, extension, and rotation of neck
Phrenic	Scalene	Elevation of ribs (inspiration)
	Diaphragm	Inspiration
<b>Brachial Plexus (C5–T1)</b>		
Anterior	Pectorales major and minor	Adduction and depression of arm downward and medially
Long thoracic	Serratus anterior	Fixation of scapula on raising arm
Dorsal scapular	Levator scapulae	Elevation of scapula
	Rhomboid	Drawing scapula upward and inward
Suprascapular	Suprascapularis	Outward rotation of arm
	Infraspinatus	Elevation and outward rotation of arm
Subscapular	Latissimus dorsi	
	Teres major	Inward rotation and abduction of arm toward the back
	Subscapularis	Inward rotation of arm
Axillary	Deltoid	Raising of arm to horizontal
	Teres minor	Outward rotation of arm
Musculocutaneous	Biceps brachii	Flexion and supination of forearm
	Coracobrachialis	Elevation and adduction of arm
	Brachialis	Flexion of forearm
Median	Flexor carpi radialis	Flexion and radial deviation of hand
	Palmaris longus	Flexion of hand
	Flexor digitorum sublimis	Flexion of middle phalanges of second through fifth fingers
	Flexor pollicis longus	Flexion of distal phalanx of thumb
	Flexor digitorum profundus (radial half)	Flexion of distal phalanges of second and third fingers
	Pronator quadratus	Pronation
	Pronator teres	Pronation
	Abductor pollicis brevis	Abduction of metacarpus I at right angles to palm
	Flexor pollicis brevis	Flexion of proximal phalanx of thumb
	Lumbricals I, II, III	Flexion of proximal phalanges and extension of other phalanges of first, second, and third fingers
Ulnar	Opponens pollicis brevis	Opposition of metacarpus I
	Flexor carpi ulnaris	Flexion and ulnar deviation of hand
	Flexor digitorum profundus (ulnar half)	Flexion of distal phalanges of fourth and fifth fingers
	Adductor pollicis	Adduction of metacarpus I
	Hypothenar	Abduction, opposition, and flexion of little finger
	Lumbricals III, IV	Flexion of first phalanx and extension of other phalanges of fourth and fifth fingers
	Interossei	Same action as preceding. Also spreading apart and bringing together of fingers
Radial	Triceps brachii	Extension of forearm
	Brachioradialis	Flexion of forearm
	Extensor carpi radialis	Extension and radial flexion of hand
	Extensor digitorum communis	Extension of proximal phalanges of second through fifth fingers
	Extensor digiti quinti proprius	Extension of proximal phalanx of little finger
	Extensor carpi ulnaris	Extension and ulnar deviation of hand
	Supinator	Supination of forearm
	Abductor pollicis longus	Abduction of metacarpus I
	Extensor pollicis brevis	Extension of proximal phalanx of thumb
	Extensor pollicis longus	Abduction of metacarpus I and extension of distal phalanges of thumb
	Extensor indicis proprius	Extension of proximal phalanx of index finger
<b>Thoracic Nerves</b>		
Thoracic	Thoracic and abdominal	Elevation of ribs, expiration, abdominal compression, etc.
<b>Lumbar Plexus (T12–L4)</b>		
Femoral	Iliopsoas	Flexion of leg at hip
	Sartorius	Inward rotation of leg together with flexion of upper and lower leg
	Quadriceps femoris	Extension of lower leg
Obturator	Pectineus	Adduction of leg
	Adductor longus	
	Adductor brevis	
	Adductor magnus	
	Gracilis	Adduction and outward rotation of leg
	Obturator externus	

Continued on following page

**TABLE 2-3** Extraocular Muscle Paralysis (*Continued*)**Sacral Plexus (L5–S5)**

Superior gluteal	Gluteus medius Gluteus minimus Tensor fasciae latae Piriformis Gluteus maximus	} }	Abduction and inward rotation of leg; also, under certain circumstances, outward rotation Flexion of leg at hip Outward rotation of leg Extension of leg at hip
Inferior gluteal Sciatic	Obturator internus Gemelli Quadratus femoris Biceps femoris Semitendinosus Semimembranosus	} }	Outward rotation of leg Flexion of leg at hip
Peroneal Deep	Tibialis anterior Extensor digitorum longus Extensor hallucis brevis		Dorsiflexion and supination of foot Extension of toes Extension of great toe Pronation of foot
Superficial Tibialis	Peroneus Gastrocnemius Soleus Tibialis posterior Flexor digitorum longus Flexor hallucis longus Flexor digitorum brevis Flexor hallucis brevis Plantar	} }	Plantar flexion of foot Adduction of foot Flexion of distal phalanges II–V Flexion of distal phalanx I Flexion of middle phalanges II–V Flexion of middle phalanx I Spreading, bringing together, and flexion of proximal phalanges of toes
Pudendal	Perineal anal sphincters		Closure of sphincters of pelvic organs; participation in sexual act; contraction of pelvic floor

\*Various muscles may receive still other nerve supplies than those mentioned. The following are the principal accessory nerve supplies: the brachial muscle receives fibers from the radial nerve; the flexor digitorum sublimis, from the ulnar; the adductor pollicis, from the median; the pectineus, from the femoral; the adductor magnus, from the tibial.

(With permission from Haymaker W. *Bing's Local Diagnosis in Neurological Diseases*, 15th edn. St. Louis: Mosby, 1969.)

traditional Jendrassik maneuver (i.e., hooking the fingers together while flexed and then attempting to pull them apart). Hyperreflexia may be indicated by an abnormal “spread” of responses, which includes contraction of muscle groups that usually do not contract when a specific reflex is being elicited (i.e., crossed thigh adductor or finger flexor reflexes).

### Other Reflexes

A flexor (plantar) toe sign response is normal in children. The Babinski reflex is elicited by firm, steady, slow stroking from posterior to anterior of the lateral margin of the sole with an object such as a key or a tongue blade. The stimulus should not be painful. A positive response is a slow, tonic hyperextension of the great toe. A similar response is elicited using maneuvers such as the Chaddock (firmly stroking the lateral aspect of the foot) or Oppenheim (downward pressure on the medial aspect of the tibia).

Flicking the patient’s nail (second or third finger) downward with the examiner’s nail (i.e., the Hoffmann reflex) results in flexion of the distal phalanx of the thumb. No response or a muted response occurs in normal children; a brisk or asymmetric response occurs in the presence of corticospinal tract involvement.

Abdominal reflexes are obtained by stroking the abdomen from lateral to medial with strokes beginning just above the umbilicus, lateral to the umbilicus, and just below the umbilicus directed toward the umbilicus. Unilateral absence of the reflex can be associated with acquired corticospinal tract dysfunction.

The cremasteric reflex is elicited in males by stroking the inner aspects of the thigh in a caudal–rostral direction and observing the contraction of the scrotum. The reflex is normally present and symmetric. Absence or asymmetry may indicate corticospinal tract involvement.

### Sensory System

Cooperation is necessary for a successful sensory examination. Vibration and proprioception can be assessed in all four limbs. Touch may be assessed by a single stimulus or by double simultaneous stimulation of two skin areas, which involves touching two parts of the body simultaneously (i.e., double simultaneous stimulation test). Extinction is the term used to denote failure of the child to perceive both stimuli. The contralateral parietal lobe to the side on which the unidentified stimulus was applied is the site of dysfunction. Pain, as tested with a pinprick, must be assessed gently, rapidly, and in a nonthreatening and playful manner. Segmental sensory innervations of the arm and leg should be noted. For example, the nipples are at approximately the T5 level and the umbilicus at the T10 level.

Cortical sensory function can be tested in the older child. Stereognosis is the recognition of familiar objects by touch. After the patient closes the eyes, objects are placed by the examiner in one of the child’s hands and then the other. The patient should recognize the objects by size, texture, and form. Objects may include a button, coins, safety pin, or key. Absence of stereognosis is astereognosis. Astereognosis usually results from lesions of the parietal lobe.

Graphesthesia is the ability to recognize numbers, letters, or other readily identifiable symbols traced on the skin. This ability can be determined best by tracing the symbols in a preliminary trial while the child’s eyes are open. When the patient’s eyes are closed, the figures are traced over the palm or forearm. Failure to identify the symbols is dysgraphesthesia. By 8 years of age, most children are able to identify all single digits correctly.

The ability to distinguish between closely approximated stimulation at two points is two-point discrimination. Normal findings have been reported for children 2 to 12 years old.

Testing of this modality is frequently performed over the fingertips. Absence or impairment of two-point discrimination results from parietal lobe dysfunction.

## Cerebellar Function

Cerebellar function is assessed in a number of ways. Hand patting (i.e., alternating pronation and supination of the hand on the thigh while the other hand remains stationary on the other thigh) is a good method for assessing dysdiadochokinesis. The maneuver is repeated with each hand separately to assess the presence of mirror movements (i.e., synkinesis). Other cerebellar tests include repetitive finger tapping (thumb to forefinger), foot tapping, and finger-to-nose, finger-to-finger (examiner's)-to-nose, and heel-to-knee-to-shin stroking. Several signs of cerebellar disease include head tilt, tremor when approaching a target (intention tremor), overshooting or undershooting a target (dysmetria), speech with an unusual cadence or prosody (cerebellar speech), or gait ataxia.

## GAIT EVALUATION

The evaluation of gait is discussed in detail in Chapter 5.

## Neurologic Examination after the Newborn Period Until 2 Years of Age

*Kenneth F. Swaiman and John Phillips*

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

There is no one way to organize the examination of an infant. Experienced examiners develop individual techniques and sequences that are flexible depending on the child's level of cooperation (Jan, 2007). The technique presented here, which has worked for many clinicians, is a four-stage examination sequence, beginning with the least intrusive maneuvers. Developmental assessment is an integral part of this examination; norms are well established (Box 3-1), and when development lags, referral for more detailed testing may be considered.

The **first stage** of the examination is observation. In the **second stage**, the head, muscle tone, superficial and deep sensation, gross response to sound, and visual fields can be evaluated while the child remains on the caregiver's lap. The **third stage** becomes more invasive, and may require help from a caregiver or assistant. At this point, a general examination is performed, including measurement of the occipitofrontal circumference and optic fundi. In the **fourth stage** of the examination, the child is placed on the floor and encouraged to crawl, walk, and run, if possible.

### EVALUATION OF THE PATIENT

#### Stage 1

Because many children at this age need a few minutes to feel comfortable with a stranger, it is preferable not to rush into the examination. It is often helpful to have the child sit on the caregiver's lap facing the examiner during this history-taking session to encourage familiarity. The point is to try to help the child become comfortable with the examination room and the examiner.

The sequence of examination should be flexible and determined by the child's comfort level and temperament, although eventually a complete examination must be conducted (Campbell, 2013). Most importantly, it is imperative that the clinician comprehensively conduct that aspect of the examination related to the chief complaint.

Observations done at this stage include an assessment of the child's level of alertness, awareness of surroundings, and affect. Communication skills can be noted and compared with age-appropriate expectations (Egan, 1990). Movement should be evident as well, particularly of the face, eyes, and extremities, and the examiner should look specifically for any asymmetry or abnormalities of control or posture.

#### Head

Examination of the head is done systematically, looking for asymmetry, indentations, and protuberances. Evaluation of the fontanels and cranial sutures should be performed with gentle palpation. Hair color, distribution, texture, and pattern, including unusual whorl patterns, also should be assessed.

The occipitofrontal circumference should always be measured. If the child becomes agitated, this can be deferred until later in the examination (stage 3), but it must be taken at some

point. Change over time, rather than a single measurement, provides the most useful information. In addition, the size of the anterior fontanel, which is typically closed by 12 months of age, should be recorded, along with any tenseness when the child is sitting comfortably in an upright position. Other fontanels are usually difficult to palpate, except in pathologic states. Finally, the head should be auscultated for the presence of unusual intracranial bruits.

#### Cranial Nerves

Most of the examination of cranial nerve function of the infant and toddler can be completed by observation with minimal invasive procedures. Details concerning examination of each cranial nerve can be found in Chapter 2. Toys or colorful objects can facilitate the assessment of extraocular movements in young children. If the child appears uninterested in bright objects, the possibility of a visual defect or an underlying intellectual defect must be considered. Double simultaneous stimulation (i.e., simultaneously bringing two bright objects into both temporal fields) normally causes the child to look from one object to the other; failure to take notice of one object may indicate homonymous hemianopsia. An opticokinetic tape (with repetitive bars or objects) should be drawn horizontally and then vertically across the child's field of vision. An absent response may result from lack of visual fixation or from gross impairment of vision.

A beam from a small flashlight directed at each eye allows evaluation of pupil size, pupillary responses, and the red retinal reflex. Eye features to be noted include symmetry of the palpebral fissures, relative size of the two globes, angulation of the eyes compared with other facial components (i.e., mongoloid or antimongoloid slant) and with the ears, cataracts, conjunctival telangiectases, colobomas of the iris, ptosis, proptosis, and malformed or eccentrically placed pupils.

Observing the child's facial movements throughout the entire examination is helpful (Nelson and Eng, 1972). Widening of the ipsilateral palpebral fissure or inability to bury the limbus when crying is indicative of facial nerve weakness. In the younger infant, sucking and rooting reflexes should be obtained. Sometimes, the child can be induced to protrude the tongue if the examiner urges the child to imitate the examiner's tongue movements. Deformity, atrophy, or abnormal positioning of the tongue can be observed. Tongue fasciculations should be evaluated with the tongue in the resting position, and by gently elevating the tongue with a depressor and examining the undersurface.

Basic responses to the sound made by a tuning fork, rubbing fingers together, ringing a bell, or using a toy noise-maker that generates noise at a modest volume may provide much information. The examiner must be careful not to confuse response to a visual cue (e.g., the movement needed to elicit noise from a toy) with response to the sound.

**BOX 3-1** Child Development from 2 Months through 2 Years**2 MONTHS**

- Keeps hands predominantly fistled
- Lifts head up for several seconds while prone
- Startles in response to loud noise
- Follows with eyes and head over 90-degree arc
- Smiles responsively
- Begins to vocalize single sounds

**3 MONTHS**

- Occasionally holds hands fistled
- Lifts head up above body plane and holds position
- Holds an object briefly when placed in hand
- Turns head toward object, fixes and follows fully in all directions with eyes
- Smiles and vocalizes when talked to
- Watches own hands, stares at faces
- Laughs

**4 MONTHS**

- Holds head steady while in sitting position
- Reaches for an object, grasps it, brings it to mouth
- Turns head in direction of sound
- Smiles spontaneously

**5–6 MONTHS**

- Lifts head while supine
- Rolls from prone to supine
- Lifts head and chest up in prone position
- Exhibits no head lag
- Transfers object from hand to hand
- Babbles
- Sits with support
- Localizes direction of sound

**7–8 MONTHS**

- Sits in tripod fashion without support
- Stands briefly with support
- Bangs object on table
- Reaches out for people

- Mouths all objects
- Says “da-da,” “ba-ba”

**9–10 MONTHS**

- Sits well without support, pulls self to sit
- Stands holding on
- Waves “bye-bye”
- Drinks from cup with assistance
- Uses pincer grasp

**11–12 MONTHS**

- Walks with assistance
- Uses two to four words with meaning
- Creeps well
- Assists in dressing
- Understands a few simple commands

**13–15 MONTHS**

- Walks by self, falls easily
- Says several words, uses jargon
- Scribbles with crayon
- Points to things wanted

**18 MONTHS**

- Climbs stairs with assistance, climbs up on chair
- Throws ball
- Builds two to four-block tower
- Feeds self
- Takes off clothes
- Points to two or three body parts
- Uses many intelligible words

**24 MONTHS**

- Runs, walks up and down stairs alone (both feet per step)
- Speaks in two- to three-word sentences
- Turns single pages of book
- Builds four- to six-block tower
- Kicks ball
- Uses pronouns “you,” “me,” and “I”

(Data from Frankenburg WK, Dodds J, Archer P, et al. *Pediatrics*. 1992;89:91; Illingsworth RS. *The development of the infant and young child*. 9th ed. Baltimore: Williams & Wilkins; 1987; and Knobloch H, Stevens F, Malone A. *The revised developmental screening inventory*. Houston, Texas: Gesell Developmental Test Materials; 1980.)

## Motor Evaluation

As with all other parts of the evaluation, the motor examination begins with observation. Even before touching the child, general posture and the symmetry of movements of the arms and legs are observed, with note made of any gross discrepancies in muscle bulk or limb length. Definite hand preference (such as reaching across the midline to avoid using the contralateral hand) before 24 months is abnormal.

Decreased muscle bulk may not be appreciated because of the large amount of subcutaneous fat at this age, and muscle atrophy may be undetected. Careful palpation helps distinguish between fat and muscle.

The next step is evaluation of muscle tone, which is defined as resistance of muscle to passive stretch. This also requires palpation. Muscle tone and range of motion of the arms and legs are best assessed when the child is in the relaxed state by gently shaking and moving the hands and feet in flexion and extension. Pronation and supination of the hands and forearms provide further information about range of motion and the presence of spasticity or rigidity. Greater-than-normal resistance to passive movement indicates hypertonia, whereas

less-than-normal resistance indicates hypotonia. It is important to distinguish increased *tone* from limitation of movement due to joint *contracture*. It is also important to note when the child is actively resisting the examiner, which is a reflection of *strength*. Spontaneous muscle movements, particularly those against gravity, provide the most information concerning muscle strength. Further assessment of strength is provided by judging the degree of resistance that occurs when active movement is attempted against the examiner. Experience helps in this part of the examination, particularly in cases of mild abnormalities, but even a novice should be able to make a reasonable judgment about both tone and strength in most instances.

Upper motor neuron unit involvement may cause decreased movement of an entire extremity or more focal abnormalities, such as limited flexion of the arm at the elbow, persistent fisting, or adduction of the thumb against the palm. Erb's brachial plexus injury is a lower motor neuron disorder commonly causing internal rotation and adduction at the shoulder, often with the “waiter's tip” posture (Pina-Garza, 2013). Interacting with the infant using toys and other interesting objects may facilitate the evaluation of limb strength, range

of motion, and coordination. In the older cooperative child, individual muscle testing should be carried out when appropriate.

There is a normal developmental sequence of fine motor control as the child becomes more adept at reaching for objects. Grasping things with both hands and holding the object before the face or immediately placing it in the mouth is later superseded by transferring the object from hand to hand and manipulating the toy. The infant's grasping skills are best demonstrated in response to small objects. The 4- to 5-month-old infant is able to grasp an object with the entire hand, at 7 months the thumb and the neighboring two fingers are used, and the pincer grasp (using only the thumb and forefinger) should be present by 9 to 11 months. The palmar grasp reflex (i.e., obligate grasp reflex) should gradually diminish from 3 to 6 months of age. The persistence of the obligate grasp reflex beyond 6 months of age may signal corticospinal tract dysfunction. Observation of the child's ability to raise the arms while reaching for an object helps assess proximal muscle strength. Congenital malformations of the fingers and hands from webbing to clinodactyly can be readily determined during this portion of the examination.

Direct examination of the hips should include assessment of the range of motion; decreased excursion may signify spasticity or subluxation of the hip joints. Galeazzi's sign is performed in a supine child by flexing the hips 90 degrees with feet on the examination table, noting any asymmetry of femur length. Hip disease such as subluxation often results in a shorter leg and may exist separately or as a result of spasticity. Conversely, increased excursion may represent hypotonia or ligament laxity.

Initial examination of the legs consists of assessment of muscle symmetry and mass. Spontaneous motor movements are also evaluated, making note of the quality and symmetry of any movement. Assessment of tone is similar to that done with the arms and hands; one should gently shake the feet and passively move the joints of the lower extremities from hip to knee to ankle.

Deep tendon reflexes that are excessively brisk may indicate upper motor neuron unit disease, especially when associated with clonus. Asymmetry is particularly worrisome because of the association with pathologic conditions. Absent deep tendon reflexes are seen with anterior horn cell disease or peripheral neuropathy. The crossed adductor reflex is elicited when the patellar reflex is stimulated and resultant contraction of the adductor muscles occurs in the opposite leg. This response can be normal until approximately 1 year of age. However, persistence of the response, particularly unilaterally, suggests the presence of corticospinal tract involvement.

The plantar response can be as important in infants as in adults. There is no consensus about when an extensor response is a normal finding, although an asymmetric extensor toe sign is always abnormal, as is an extensor toe sign that persists beyond 12 months of age (Hogan and Milligan, 1971). A pathologic extensor plantar sign is indicative of upper motor neuron unit disease. Several beats of ankle clonus are often present in the neonatal period and should disappear by 2 months of age. The persistence of ankle clonus and extensor plantar responses in an older child suggests upper motor neuron unit disease even in the absence of hyperreflexia.

Cerebellar function is difficult to assess in infants; it is easiest when a cooperative child can be observed sitting, standing, walking, or reaching for objects. The examiner can also observe the child during play to see resting or intention tremor, dysmetria, titubation or truncal sway while sitting, and fine motor coordination. Decreased tone may accompany other signs of cerebellar dysfunction.

### Sensory Testing and Cutaneous Examination

Light touch can be tested by gently stroking the extremities; this should lead to a reaction, with signs of recognition ranging from eye deviation and facial response to anxious withdrawal of the limbs (Figure 3-4). Application of a tuning fork often causes arrest of motion and a wide-eyed look of wonder in the child who cannot otherwise describe the feeling.

**Figure 3-4.** Segmental distribution of the cutaneous nerves of an infant. (Modified from Fanaroff AA, Martin RJ. *Neonatal-perinatal medicine: diseases of the fetus and infant*, 5th ed. St. Louis: Mosby, 1992.)

Proprioception cannot be directly evaluated at this age, but observations of sitting positions, gait, and posture may provide some clues. Pain response from light application of a pin or gentle pinching should be reserved until late in the examination, lest causing pain confirms a child's suspicions about the examiner, and upsets an already worried parent.

During the sensory examination, careful observation of the child's skin is important to rule out a neurocutaneous disorder. Are there hypopigmented macules of tuberous sclerosis present, café au lait spots as seen in neurofibromatosis, or a port wine stain in the area of the first division of the trigeminal nerve that might suggest Sturge-Weber syndrome? Particular examination of the spine is necessary to check for scoliosis, sinus tracts, scars, dimples, and hemangiomas. Unusual skin lesions or hair growth over the spine suggest the presence of an underlying mesodermal defect, such as diastematomyelia or spina bifida occulta. The spine should be palpated along its entire course for defects.

Abdominal and cremasteric reflexes are present at birth. The abdominal reflex is elicited by stroking the skin of the upper, middle, and lower portions of the abdomen laterally from the midline. Each stroke elicits a muscle contraction mediated by a different group of thoracic nerves from T8 to T12. The response results in the retraction of the umbilicus toward the stimulated side. The cremasteric reflex is elicited by upwardly stroking the inner thigh, beginning 3 to 5 cm below the inguinal crease. The cremasteric reflex results in an elevation of the testicles due to contraction of the overlying smooth muscles. Cremasteric reflexes are mediated by spinal nerves L1 to L2.

## Stage 2

For stage 2 of the evaluation the child should be placed on an examination table with the caregiver close by to provide reassurance to the child and assistance to the examiner, if necessary. Motor evaluation of the older child can also be carried out on a larger, carpeted surface. By 3 months of age, an infant in the prone position should be able to hold the head and chest off the table. Good head control when held in the sitting position should be evident by 4 months of age. The child should be able to sit unsupported and maintain adequate balance by 8 to 9 months of age. Independent achievement of the sitting position should occur by 10 months of age. The child should crawl by 10 months, pull to a standing position by 10 months, and creep by 11 months. The child should walk with support by 12 months and without support by 13 to 14 months.

Trunk, shoulder, and pelvic girdle tone and strength are directly evaluated. The child is observed while held in vertical and horizontal suspension. A hypotonic infant often droops over the examiner's arm when held in horizontal suspension. In vertical suspension, the hypotonic child may slide through the examiner's hands (Volpe, 2008). The child may be unable to maintain a standing posture when the feet are placed on the table surface; this must be distinguished from active withdrawal of the legs that may also prevent successful standing. If spasticity is present, there may be arching of the extended head, neck, and back while in horizontal suspension. Spasticity may also cause extension of the lower extremities with "scissoring" (excessive abduction) and toe walking.

## Motor Performance Instruments

Through the years, several instruments have been devised that are useful for evaluating motor performance in relation to chronologic age. These instruments have provided norms for

evaluating the expected rate of motor development for a number of different assessments and maneuvers.

## Developmental Reflexes

Developmental reflexes represent maturational stages of the developing nervous system (Prechtl, 1997). Occasionally, developmental reflexes can have localizing value, but usually they are nonspecific. Abnormal findings include the absence or poor manifestation of the expected response, persistence of a reflex that should have disappeared, or an asymmetric response (Table 3-1).

Correctly eliciting the **Moro reflex** requires holding the infant in the supine position, lifting the head, and then allowing the head to fall approximately 30 degrees while cradling the head in the examiner's hands. The expected response is initial extension and abduction of the arms with extension of the fingers, followed by adduction of the arms at the shoulder. Asymmetry at any age, or persistence beyond 5 to 6 months, is always abnormal.

The **asymmetric tonic neck reflex (ATNR)** may be detected in the neonatal period but reaches its peak at 2 months and is absent by 6 months of age. To elicit the reflex, the head is turned to one side while the infant is lying in the supine position. There is extension of the arm and leg on the side toward which the face is turned, while the contralateral extremities flex ("fencer's posture"). A normal infant should not maintain the position beyond a few seconds (i.e., obligate ATNR).

The **palmar grasp reflex** is elicited by placing an object or the examiner's finger in the palm of the infant's hand; this leads to an involuntary flexion response. This reflex subsides by 3 to 6 months of age and is replaced by voluntary grasping, which is necessary to allow transfer of objects from hand to hand.

In slightly older infants, the **Landau reflex** can first be elicited between 5 and 10 months of age, and can usually be seen up to 2 years of age. With one hand supporting the abdomen in the prone position, the examiner flexes the infant's head with his or her other hand. The normal response is flexion of the legs and trunk.

The **placing reflex** response can be demonstrated by holding the upright infant in a manner that causes the dorsal surface of the infant's feet to touch the underside of a tabletop. The infant flexes the legs at the hips and knees so that contact with the underside of the surface ceases.

One of the most useful maneuvers is the **traction response (Zafeiriou, 2004)**. This is elicited with the infant in the supine position; the examiner grasps both hands and pulls the infant gently and slowly upward, to a sitting position. Marked head lag with little resistance to the examiner's pulling efforts characterizes the newborn response. By 1 month, the infant's head shows transient neck flexion followed by extension as the infant is pulled forward. Usually, by 3 to 5 months of age at the latest, the infant is able to participate actively with arm flexion at the elbow, and by holding the head and trunk in a straight line as the examiner pulls the child to the upright position. At this point there should be no head lag, and little or no forward motion of the head as the child reaches the upright position.

A valuable measure of vestibular function in the newborn can be obtained by holding the infant in a supine position with the feet closest to the examiner. As the examiner rotates the infant laterally in each direction, the eyes of the infant deviate in the direction of rotation, accompanied by intermittent nystagmus to the opposite side. This maneuver also allows extraocular movements to be assessed.

**TABLE 3-1** Eliciting Primitive Reflexes

Reflex	Position	Method	Response	Age at Disappearance
Palmar grip	Supine	Placing the index finger in the palm of the infant	Flexion of fingers, fist making	6 months
Plantar grip	Supine	Pressing a thumb against the sole just behind the toes	Flexion of toes	15 months
Galant	Prone	Scratching the skin of the infant's back from the shoulder downward, 2–3 cm lateral to the spinous processes	Incurvation of the trunk, with the concavity on the stimulated side	4 months
Asymmetric tonic neck	Supine	Rotation of the infant's head to one side for 15 seconds	Extension of the extremities on the chin side and flexion of those on the occipital side	3 months
Suprapubic extensor	Supine	Pressing the skin over the pubic bone with the fingers	Reflex extension of both lower extremities, with adduction and internal rotation into talipes equinus	4 weeks
Crossed extensor	Supine	Passive total flexion of one lower extremity	Extension of the other lower limb, with adduction and internal rotation into talipes equinus	6 weeks
Rossolimo	Supine	Light tapping of toes 2–4 at their plantar surfaces	Tonic flexion of the toes at the first metacarpophalangeal joint	4 weeks
Heel	Supine	Tapping on the heel with a hammer, with the infant's hip and knee joints flexed and the ankle joint in neutral position	Rapid reflex extension of the lower extremity in question	3 weeks
Moro	Supine	Sudden head extension produced by a light drop of the head	Abduction followed by adduction and flexion of upper extremities	6 months
Babinski	Supine	Striking along the lateral aspect of the sole, extending from the heel to the head of the fifth metatarsal	Combined extensor response: simultaneous dorsiflexion of the great toe and fanning of the remaining toes	Presence always abnormal

(Data from multiple sources: Futagi Y, Tagawa T, Otani K. *Brain Dev.* 1992;14:294; Vojta V. *Die cerebralen Bewegungsstörungen im Kindesalter*, 4te Auflage. Stuttgart: Ferdinand Enke Verlag; 1988; Zafeiriou DI, Tsikoulas IG, Kremenopoulos GM. *Pediatr Neurol.* 1995;13:148; Zafeiriou DI, Tsikoulas I, Kremenopoulos G, et al. *Brain Dev.* 1999a;21:216; Zafeiriou DI, Tsikoulas I, Kremenopoulos G, et al. *J Child Neurol.* 1999b;14:514; Zafeiriou DI, Tsikoulas I, Kremenopoulos G, et al. *Brain and Development.* 1998;20:307; and Zafeiriou DI. *Pediatr Neurol.* 2000;22:75.)

There are other developmental reflexes, but those discussed here appear to be the most often evaluated and the most useful.

### Stage 3

Examination of the optic fundi should be performed with the infant supine, possibly lying in the caregiver's lap or held over the caregiver's shoulder with the infant's head held tightly against the caregiver's head. Abnormalities of the fundi, including vascular changes, elevation of the optic disc, and retinal changes, along with abnormalities of the lens and media, should be assessed. Mydriatic agents and sedation are rarely employed in the office evaluation, although they are both occasionally necessary. During the first few months of life, the optic discs may be somewhat gray. This normal finding should not be confused with optic atrophy.

The general portion of the examination follows. A heart murmur may signify congenital structural anomalies more widespread than just in the heart. Stridor heard on auscultation may accompany weakness of the upper respiratory musculature. The presence of hepatosplenomegaly should be determined because many storage diseases, which also affect the brain, may be the cause of organ enlargement. When spinal lesions are suspected, the anal sphincter should be examined for tone and the presence of an anal cutaneous

reflex (the so-called "anal wink"). Congenital anomalies of the genitalia should be noted. The remainder of the general examination, particularly the intrusive aspects, such as evaluation of the auditory meati, tympanic membranes, mouth, and teeth, can be done at this time.

### Stage 4

Spontaneous motor abilities are assessed in this stage of the examination. The crawling child can be put on a carpeted floor or a suitable pad; if the child stands, or walks, he or she should be placed on the floor. The child should be allowed to ambulate or encouraged by rolling a ball across the room or having the child follow a parent across the room. Spastic diparesis, hemiplegia, waddling, footdrop, limp, or ataxia may be evident. The manner in which the child stoops and bends to retrieve a ball or block may show premature hand dominance, athetosis, tremor, or weakness of the legs. Whenever there is a question of proximal weakness, the child should be observed when arising from the floor to a standing position to determine the presence of Gowers' maneuver.

Unlike in the examination of older children, the testing of individual muscle groups in infants is usually impracticable. Nevertheless, evaluation of spontaneous movements and use of some specific maneuvers (e.g., traction response, wheelbarrow maneuver, standing from the floor or a seated position)

can provide information about spasticity, weakness, and incoordination. As always, a comparison of the examination findings must be made with expected age-related norms.

Further examination of muscle strength can be accomplished by using the parachute response; the examiner holds the child in the prone position over an examination table and gently thrusts the patient toward the table surface. A fully developed response (expected at 8 months) consists of arm and wrist extension, allowing the outstretched palms to make contact with the table as the infant supports his or her body weight with the arms and shoulders. Formal individual muscle testing can be used in the older child whenever necessary.

The sensory examination can be difficult. Begin with examination of touch, position sense, and vibration sense. A tuning fork placed on the appropriate bony prominence may elicit a look of surprise or bemusement. Evaluation of pain should be done last and only after the examiner demonstrates to the child the method that will be used.

During this phase of the examination, the Romberg maneuver can be performed. The older child is asked to stand in one place with the feet together and close the eyes; a positive Romberg's sign occurs when the child sways or falls with the eyes closed. The examiner should also observe the child for titubation, nystagmus, and dysmetria while reaching for objects. Cooperative children older than 3 years should be able to perform finger-to-nose testing with the eyes closed. The heel-shin test is frequently not possible in children younger than 4 years.

Assessment of the deep tendon reflexes is best carried out with the infant or toddler in the caregiver's lap. The biceps response in most infants can be difficult to elicit, but the triceps and brachioradialis reflexes are usually readily detected. The patellar and Achilles responses are typically present and easy to elicit. Toe signs can be evaluated as in older children.

## GENERAL CONSIDERATIONS

Throughout the examination, the clinician should evaluate the child's alertness, interest in the surroundings, and ability to learn during the examination. The child's speech pattern should also be assessed. By 15 months of age, the child should have a consistent vocabulary of 2 to 6 words, and by 18 months, up to 20 words. Short phrases consisting of two or three words are usually part of the child's repertoire by 21 to 24 months. By 2 years of age, most children have a vocabulary of up to 50 words. Using specific scales to evaluate intelligence and development levels is of some help, but a single office assessment may not be reliable. It is therefore important that the examiner become proficient in informal means of evaluating these characteristics (Maria and English, 1993).

Young children are not always easy to examine. However, taking a staged approach as suggested here, and being sensitive to the child's temperament, often results in a successful examination.

## Neurologic Examination of the Term and Preterm Infant

Kenneth F. Swaiman and John Phillips

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

### THE TERM INFANT

The essence of the newborn neurologic examination, whether for a premature or a term-born child, remains exactly the same as with older children. It begins with observation, followed by an examination that may need to be done “out of order” depending on circumstances. Several examinations done over time may be required to most accurately characterize an infant’s neurologic status.

### Observation

Careful observation begins the examination, noting any congenital abnormalities that are present and the general level of alertness. Cranial nerve assessment can be largely obtained via observation, making note of spontaneous eye movement, facial symmetry, and response to sounds and light. Observation also provides much information regarding the motor system. For example, term infants have predominantly flexor tone with frequent flexion at the knees and elbows. Intermittent fisting of the hands, including adduction and infolding of the thumbs (i.e., cortical thumbs), is often present. Limb position and posturing should be roughly symmetric. While supine, a healthy infant may have spontaneous limb movements that are asymmetric with a jerking quality—this is normal. Excessive jitteriness or tremulousness, however, particularly of the hands or jaw may suggest hyperexcitability of the central nervous system (CNS).

### Cranial Vault Evaluation

The occipitofrontal circumference should be plotted on a graph standardized for gender, race, and gestational age to determine whether the measurement falls within the normal range (i.e., two standard deviations above or below the mean). Variances within two standard deviations may be due in part to head shape; for example, the same volume will require a larger circumference in an oblong head compared with a round head. Significant deviation from normal always requires further evaluation.

Some deformities of the cranium are related to the birthing process. Vaginal deliveries may be associated with scalp and subcutaneous edema causing *caput succedaneum*, particularly if vacuum extraction is used. *Cephalohematomas* are hemorrhages within the periosteum of individual cranial bones and therefore do not cross suture lines. *Subgaleal hematomas* result from bleeding under the scalp aponeurosis and are often preceded by forceps or vacuum-assisted delivery space. The scalp may be edematous and boggy because of underlying blood. Although most subgaleal hematomas are benign, if large enough they can cause hypovolemic shock. Infants delivered by cesarean section usually have relatively round heads.

The anterior fontanel, readily palpable at birth and often pulsating with the infant’s heart rate, is concave or flat in relation to the surrounding cranium. The fontanel should be assessed with the child held in the sitting position if there is

any question of increased pressure. A bulging fontanel without the child crying raises a concern regarding increased intracranial pressure. The anterior fontanel varies in size but usually ranges from 1 to 3 cm in its longest dimension (Popich and Smith, 1972). The posterior fontanel in the neonate usually is open but admits only a fingertip.

Cranial sutures (e.g., sagittal, metopic, lambdoidal, and squamosal) are readily palpable in the newborn. Overriding sutures, often the sagittal and lambdoidal, are sometimes seen in the first week of life. Gentle palpation should demonstrate that sutures readily separate from one another unless premature closure has occurred, which may cause asymmetric skull growth.

Auscultation over the infant skull, particularly the anterior fontanel and neck vessels, usually reveals a venous hum in a number of locations. Rarely, systolic-diastolic bruits, particularly those that are focal and asymmetric, indicate the presence of an arteriovenous malformation; however, at times these bruits may be heard in normal infants.

### Developmental Reflexes

Developmental reflexes are primitive reflexes with complex responses, and largely reflect the integrity of the brainstem and spinal cord; the role of higher centers, although of importance, is not fully known. This includes the Moro, rooting, grasping, tonic neck, stepping, and placing reflexes. Many of these reflexes are present at birth and undergo modification during the first 6 months of life. Detailed discussion of these reflexes is presented in Chapter 3.

### Motor Function

Gentle manipulation of the infant’s limbs allows for assessment of muscle tone and strength. *Tone* is resistance to passive movement and should be evaluated while the infant is awake but at rest. *Strength* is resistance to active movement, which can be assessed in an infant by noting resistance to spontaneous movements. The optimal position to assess tone and strength is supine with the head in the midposition so that the tonic neck reflex does not augment tone unilaterally.

Horizontal and vertical suspensions are helpful maneuvers when assessing infant motor function. When held in the vertical position, the hypotonic and weak infant tends to slide through the examiner’s hands. In the horizontal position, the hypotonic infant droops over the examiner’s arms without raising head or legs. Conversely, increased tone may cause opisthotonus, with persistent extension in both vertical and horizontal positions. Scissoring (i.e., crossing of the legs because of excessive, involuntary adductor magnus contraction) may also be evident with increased tone, but usually does not occur until after the neonatal period. The most common cause of generalized decreased tone is depression of CNS function, congenital malformations, or neuromuscular disorders. Increased muscle tone may be seen in a variety of conditions that cause neonatal encephalopathy. Indeed, there

are myriad causes of abnormalities of tone and strength, and careful serial examinations over time are often required to arrive at the correct diagnosis.

While the infant is being handled, stimulation may cause jittery or tremulous movements of the jaw or limbs. The movements usually terminate when stimulation ends, although noises or abrupt changes in light may trigger them. Brief and mild tremulousness can be normal; however, when increased, these movements may indicate metabolic abnormalities (e.g., electrolyte imbalance), bleeding, congenital CNS defects (structural or functional), infections, or drug withdrawal syndromes.

Deep tendon reflexes are assessed just as with older children. Although they may be brisk or absent in the newborn (Critchley, 1968), asymmetry is always abnormal.

Typically, the plantar response is extensor for at least the first month of life and usually through the first year of life. Persistence of extensor toe-sign responses beyond infancy or any asymmetry suggests corticospinal tract impairment and may be associated with alterations in tone and other deep tendon reflex abnormalities.

Several beats of ankle clonus are frequently elicited in the newborn, often enhanced by crying. Increased clonus, however, often with other examination abnormalities, may be the harbinger of serious CNS disease.

## Cranial Nerve Examination

A more detailed discussion of the cranial nerve examination is found in Chapter 2. Cranial nerve I, the olfactory nerve, is infrequently tested but may be evaluated by the use of pleasant but definitive aromatic substances; virtually, all neonates born after 32 weeks' gestation respond.

Evaluation of cranial nerves II, III, IV, and VI involves assessment of the eyes. Pupils should be symmetric, with equal response to light. A bright light causes the infant to blink or hold the lids closed. The presence of ptosis or increased height of the palpebral fissure should be evaluated.

Examination of the optic fundi may be difficult but is necessary. Numerous changes, including chorioretinitis (i.e., salt-and-pepper pigmentary changes), may be observed. Hemorrhages are commonly detected after vaginal delivery, even in the absence of traumatic delivery. The optic nerve may be hypoplastic, as manifested by a small, pearl-colored optic disc. The color of the optic disc in the newborn infant is grayish white. Retinal hemorrhages may be found in a large percentage of otherwise normal infants who have no history of abnormal delivery and who later prove to be neurologically normal.

The newborn infant turns toward a light of moderate intensity and fixes on a bright object or the examiner's face. Most often, the newborn's eyes are symmetrically open or closed. If one eye is open and the other closed, there should be a shifting from one side to the other. Width of palpebral fissures should be equal; if not, the presence of ptosis may suggest an abnormality of cranial nerve III function, sympathetic innervation dysfunction, neuromuscular junction difficulty, weakness of the levator muscle of the lid, or abnormality of the lid connective tissue. Occasionally, central or peripheral seventh nerve paresis may result in asymmetry of the palpebral fissure.

Extraocular movements are monitored while a child is lying quietly. Slight lapses of conjugate gaze are common in the newborn period. Newborn visual acuity is difficult to assess, but black and white-patterned objects can be used. The examiner's face is often the best "target." The intended object of focus is moved slowly in the infant's field of vision, less than a foot from the infant's eyes. The infant slowly follows

with eye movement, particularly in lateral directions. Prolonged gaze may occur in the newborn period (Brazelton et al., 1976). Opticokinetic nystagmus may be elicited by using a striped, rotating drum or striped cloth strip, which is slowly pulled across the infant's visual field in the vertical and horizontal directions. The response is the same as in older children (Chapter 2).

Although small-excursion, lateral-gaze nystagmus may be present in the newborn, the coarser to-and-fro pattern of congenital nystagmus, which is oscillatory in nature, is usually unmistakable. Although unusual, nystagmus associated with mild esotropia or exotropia may be evident in the newborn. Wild, jerky nystagmus of congenital opsoclonus is a startling and readily discernible finding suggesting midbrain involvement.

Doll's-eye movement is elicited by the examiner by gently rotating the infant's head from one side to the other. The eyes move conjugately in the direction opposite to the rotation of the head. Movement of the head in the vertical position (upward and downward) causes similar movements in the vertical plane. Failure of the eyes to move in the expected manner may suggest abnormalities of cranial nerves or brainstem nuclei.

To gain further information, the infant may be held supine on the examiner's arm as the examiner rotates and watches the infant's eyes. This oculovestibular maneuver causes movement so that there is lateral conjugate deviation in the direction of the rotation. When the rotational movement is terminated abruptly, the eye movements reverse. It is possible to assess the integrity of cranial nerves III and VI with this maneuver.

Facial movements are readily observed during crying. Asymmetry should be carefully assessed to determine whether it is related to an upper motor neuron lesion (such as the so-called central seventh nerve palsy causing contralateral lower face weakness), a peripheral nerve lesion (causing unilateral weakness of both the upper and lower face), or a muscle problem such as hypoplasia of the depressor anguli oris that causes weakness of a lower lip and is also referred to as asymmetric crying facies (Nelson and Eng, 1972). This syndrome is a congenital abnormality that does not involve cranial nerve VII, but may be associated with somatic atrophy, vertebral and rib abnormalities, renal dysgenesis, or cardiac defects. Thus, careful observation makes an enormous difference in helping localize abnormalities of facial movement.

Meaningful hearing evaluation during routine neurologic examination is difficult because of simultaneous visual cues and variable responses.

Crying should not be intentionally elicited by the examiner; however, when it does occur, as it often the case, there is an opportunity to assess cranial nerves IX, X, and XII. During the lusty segments of crying, the infant's tongue and palate may be readily inspected. Asymmetry or loss of tongue bulk may indicate abnormalities of cranial nerve XII or its nucleus. Tongue fasciculations are best identified when the child is quiet and not crying and often occur along the lateral margins and underside of the tongue.

Furthermore, the quality of crying may reflect general neurologic status. An infant with generally depressed CNS function often cries infrequently, and the cry is weak and may be high-pitched. An irritable child with a hyperexcitable nervous system may have a high-pitched shriek.

Cranial nerves V, VII, IX, X, and XII are involved in sucking and swallowing. Swallowing dysfunction requires close scrutiny to determine which cranial nerve or nerves are involved. The gag reflex is present in term newborns and requires normal function of cranial nerves IX and X.

Tests for pain and sensation are imprecise at this age, and the gross response of infants to stroking and pinprick with

withdrawal, crying, and change in sucking rates may be the only information possible. More sophisticated testing can be devised during which heart and respiratory rates are monitored.

If necessary, in the presence of olfactory, gustatory, visual, tactile, or auditory stimuli, sophisticated monitoring and scoring of body activity may be performed. All such sensory stimuli produce habituation in the newborn.

## THE PRETERM INFANT

The designation of an infant as preterm is related primarily to length of gestation. Term gestation is 38 to 42 weeks from conception. Late prematurity is used to describe infants born between 34 and 37 weeks' gestation. Gestational age must be estimated to appropriately interpret the neurologic examination (Mercuri et al., 2003). Normally, birth weight reflects gestational age; infants born before 28 weeks' gestation usually weigh less than 1000 g (so-called *extremely low birth weight*), and infants born after 31 to 32 weeks' gestation often weigh between 1000 and 1500 g (*low birth weight*).

### General Examination

It is sometimes difficult (as well as inaccurate) to estimate gestational age from the date of the first day of the mother's last menstrual period. Examination findings can be helpful when determining gestational age such as skin texture and color, quantity of breast tissue and ear cartilage, and the stage of development of the external genitalia (Table 4-3) (Dubowitz et al., 1970).

### Neurologic Examination

Although estimation of gestational age should be made as soon after birth as possible, the neurologic examination may be postponed for 1 to 2 days, depending on the condition of the infant and the need for physiologic support. The examination should be performed while the infant is awake and approximately 1 hour before the next scheduled feeding. Otherwise the child may seem fussy if examined when hungry, or hypotonic and lethargic if examined shortly after a feeding.

### Environmental Interaction

Responsiveness increases with CNS maturation. Periods of apparent wakefulness are rare before 28 weeks' gestation. By 31 weeks' gestation, a readily recognizable level of alertness during wakeful stages occurs and by 32 weeks, external

stimulation is usually unnecessary to provoke wakefulness. In those born after 37 weeks' gestation, crying is commonly present during wakefulness. By 40 weeks' gestational age, the preterm infant continues to be alert for reasonable periods and responds to visual, auditory, and tactile stimulation. Sleep and wakeful periods are easily identified.

### Formal Scale of Gestational Assessment

Using a systematic evaluation of body and neurologic characteristics, Dubowitz et al. (1970) were able to achieve a high correlation with gestational age (Fig. 4-3).

### Deep Tendon Reflex Assessment

Deep tendon reflexes vary with maturity (Kuban et al., 1986). In a study of preterm infants of more than 27 weeks' postconceptional age, the pectoralis major reflex was elicited in all, and by 33 weeks' gestation, essentially all demonstrated the Achilles, patellar, biceps, thigh adductor, and brachioradialis reflexes. Infants of less than 33 weeks' gestation had decreased elicitation rates for patellar and biceps reflexes and had overall decreases in reflex intensity compared with their older counterparts. Contrary to conventional wisdom, head position had no effect on the reflexes.

### Body Attitude

During maturation, preterm infants adopt typical postures that correspond to gestational age. These postures have been charted and are useful for evaluation of gestational age (Dubowitz et al., 1970).

### Muscle Tone

At 26 to 28 weeks' gestation, the infant is extremely hypotonic. When held by the examiner in vertical suspension, the infant does not extend the head, limbs, or trunk. The change from the hypotonia of the preterm infant to the flexion posture of the term infant manifests first in the legs and then in the arms and head. At 34 weeks' gestation, the infant lies in the frogleg position while supine; the legs are flexed at the hip and knee, but the arms remain extended and relatively hypotonic.

Measurement of various limb angles offers some objective evidence for the degree of tone. The popliteal angle, measured by maximum extension of the leg at the knee with the hip fully flexed, decreases from 180 degrees at 28 weeks' gestation to less than 90 degrees at term, and further decreases through the first year of life.

During the traction maneuver, the head lags considerably, with little resistance until after 30 weeks' gestation. The head

**TABLE 4-3** External Characteristics Useful for Estimation of Gestational Age

External Characteristics	Gestational Age			
	28 Weeks	32 Weeks	36 Weeks	40 Weeks
Ear cartilage	Pinna soft, remains folded	Pinna slightly harder but remains folded	Pinna harder, springs back	Pinna firm, stands erect from head
Breast tissue	None	None	1- to 2-mm nodule	6- to 7-mm nodule
Male external genitalia	Testes undescended; smooth scrotum	Testes in inguinal canal; few scrotal rugae	Testes high in scrotum; more scrotal rugae	Testes descended; pendulous scrotum covered with rugae
Female external genitalia	Prominent clitoris; small, widely separated labia	Prominent clitoris; larger separated labia	Clitoris less prominent; labia majora cover labia minora	Clitoris covered by labia majora
Plantar surface	Smooth	1-2 anterior creases	2-3 anterior creases	Creases cover sole

(With permission from Volpe JJ. *Neurology of the newborn*, 4th edn. Philadelphia: WB Saunders, 2001.)

extensors develop gradually, followed by the flexors. By 38 weeks, the head follows the trunk, is maintained briefly, and then falls forward when the infant is pulled from a supine to a sitting position during the traction maneuver.

In small preterm infants, the scarf sign, which is elicited by folding the arm across the chest toward the opposite shoulder, is present if the elbow reaches the opposite shoulder. In term infants, the elbow cannot be brought beyond the midline.

The extreme hypotonia of preterm infants permits the legs to be flexed at the hip so that the heel can be passively brought to the side of the face (i.e., heel-to-ear maneuver). Understandably, this positioning is restricted in the older infant because of increasing tone.

Tone may also be monitored while postural and righting reflexes are assessed. During the stepping maneuver, the 28-week preterm infant will not support weight. However,

over the next few weeks, there is gradual support of weight, and by 34 weeks, a good supporting response is present. Tremors and even clonic movements may occur in the small preterm infant but are not normally present after 32 weeks' gestation. Stretching movements of the limbs are common in small preterm infants while they are awake but somewhat less common during sleep. These movements may spread to include the trunk and head.

**Cranial Nerves**

Some features of the preterm infant examination are different from features of the older infant's examination. Head position is unpredictable in the small preterm infant, but by 35 weeks' gestation, there is a preference for the head to be held to the right, which is normal.

**Neuromuscular Maturity**

	-1	0	1	2	3	4	5

Continued

## SOME NOTES ON TECHNIQUES OF ASSESSMENT OF NEUROLOGIC CRITERIA

**POSTURE:** Observed with infant quiet and in supine position. Score 0: Arms and legs extended; 1: Beginning of flexion of hips and knees, arms extended; 2: Stronger flexion of legs, arms extended; 3: Arms slightly flexed, legs flexed and abducted; 4: Full flexion of arms and legs.

**SQUARE WINDOW:** The hand is flexed on the forearm between the thumb and index finger of the examiner. Enough pressure is applied to get as full a flexion as possible, and the angle between the hypothenar eminence and the ventral aspect of the forearm is measured and graded according to diagram. (Care is taken not to rotate the infant's wrist while doing this maneuver.)

**ARM RECOIL:** With the infant in the supine position the forearms are first flexed for 5 seconds, then fully extended by pulling on the hands, and then released. The sign is fully positive if the arms return briskly to full flexion (Score 2). If the arms return to incomplete flexion or the response is sluggish it is graded as Score 1. If they remain extended or are only followed by random movements the score is 0.

**LEG RECOIL:** With the infant supine, the hips and knees are fully flexed for 5 seconds, then extended by traction on the feet, and released. A maximal response is one of full flexion of the hips and knees (Score 2). A partial flexion scores 1, and minimal or no movement scores 0.

**POPLITEAL ANGLE:** With the infant supine and the pelvis flat on the examining couch, the thigh is held in the knee–chest position by the examiner's left index finger and thumb supporting the knee. The leg is then extended by gentle pressure from the examiner's right index finger behind the ankle and the popliteal angle is measured.

**SCARF SIGN:** With the infant supine, take the infant's hand and try to put it around the neck and as far posteriorly as possible around the opposite shoulder. Assist this maneuver by lifting the elbow across the body. See how far the elbow will go across and grade according to illustrations. Score 0: Elbow reaches opposite axillary line; 1: Elbow between midline and opposite axillary line; 2: Elbow reaches midline; 3: Elbow will not reach midline.

**HEEL TO EAR MANEUVER:** With the infant supine, draw the infant's foot as near to the head as it will go without forcing it. Observe the distance between the foot and the head as well as the degree of extension at the knee. Grade according to diagram. Note that the knee is left free and may draw down alongside the abdomen.

B

Figure 4-3, cont'd B, Description of techniques used to assess neurologic signs.

The small preterm infant may cry in response to provocation (Fenichel, 1978), but crying often occurs when the infant is unprovoked. By 36 to 37 weeks' gestation, the cry is more vigorous, frequent, and persistent, and it is easily elicited by noxious stimuli.

The pupillary light reflex is not fully mature before 29 to 30 weeks' gestation, and in the resting state, the infant's pupils are usually miotic. The reflex becomes progressively evident and is mature by 32 weeks.

Although they may forcefully close their eyes when a bright light is directed toward them, infants of 28 weeks' gestation or less do not turn in the direction of the light. By using a large target (e.g., large, red ball; hoop; and handful of yarn), visual fixation and even rudimentary scanning and tracking may be evident in infants of 31 to 32 weeks' gestation (Hack et al., 1976). Associated with this response, there may be widening of the palpebral fissure. By 36 to 38 weeks' gestation, the infant rotates the head toward a light and closes the eyes forcefully when a strong light stimulus is presented.

The doll's-eye reflex is elicited in the 28- to 32-week preterm infant who has no compromise of consciousness. The ease of eliciting a response is enhanced because infants do not visually fixate. By 36 weeks' gestation, this response is not elicited in the normal infant.

## Developmental Reflexes

Observation and description of the major reflex changes peculiar to the preterm infant have been undertaken by many investigators (Table 4-7).

The *rooting and sucking reflexes* in small preterm infants are perfunctory but become vigorous in infants of 34 weeks' gestation. The Moro reflex, first present in fragmentary form at 24 weeks, is well developed by 28 weeks, although it fatigues easily and lacks a complete adduction phase. Not until 38 weeks' gestation is the entire response characteristic of the term infant observed.

At 28 weeks' gestation, the *grasp reflex* is evident just in the fingers, and by 32 weeks, the palm and fingers participate. Slightly later, contraction of the muscles of the shoulder girdle and elbows occurs during the traction maneuver when the infant is pulled from a supine to a sitting position.

The *tonic reflex* is elicited by turning of the head to one side. The arm on the side to which the head is turned extends, and the other arm flexes. The legs may follow suit, but the response is often absent or subtle. This "fencing" position often can be elicited in the 35-week preterm infant.

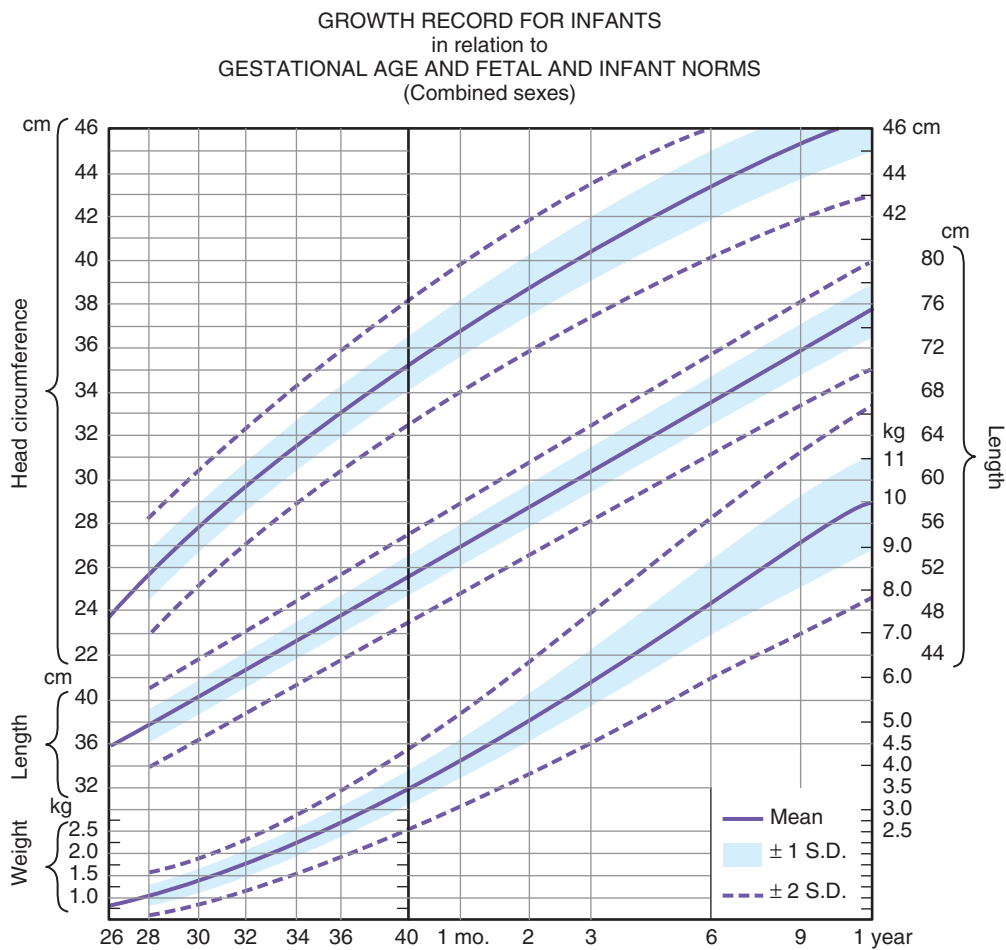

The *crossed-extensor reflex* is obtained by stroking the sole of one foot while holding the leg firmly in extension. The response occurs in the opposite leg and comprises rapid flexion at the hips and knees with attendant withdrawal, followed by extension, adduction, and fanning of the toes. The complete response, elicited in infants of about 36 weeks' gestation, is informative when asymmetric. Otherwise, it only establishes that some degree of primitive function is present.

The *stepping response* (i.e., automatic walking) is usually present by 37 weeks' gestation and can be induced by resting the infant's soles on a mattress and rocking the infant gently from one foot to the other. This procedure usually initiates

**TABLE 4-7** Neurologic Maturation

Function	26 Weeks	30 Weeks	34 Weeks	38 Weeks
Resting posture	Flexion of arms Flexion or extension of legs	Flexion of arms Flexion or extension of legs	Flexion of all limbs	Flexion of all limbs
Arousal	Unable to maintain	Maintain briefly	Remain awake	Remain awake
Rooting	Absent	Long latency	Present	Present
Sucking	Absent	Long latency	Weak	Vigorous
Pupillary reflex	Absent	Variable	Present	Present

**Figure 4-15.** A fetal-infant growth graph for infants of various gestational ages. This can be used for plotting growth from birth until 1 year of age after term status has been reached. *(With permission from Babson SG, Benda GI. Growth graphs for the clinical assessment of infants of varying gestational age. J Pediatr 1976;89:814.)*

a walking sequence, which is facilitated by the examiner supporting the infant’s weight and tilting the infant forward and begins at approximately 32 to 34 weeks’ gestation. The preterm infant usually walks on the toes, whereas a term infant typically uses a heel-to-toe gait pattern.

Ongoing neurologic examinations of the preterm infant are most important for the assessment of development and neurologic status. When the preterm infant reaches the equivalent

of 40 weeks’ gestation, the neurologic examination results are not the same as those of a term newborn. After reaching 40 weeks’ gestation the preterm infant lies with relatively less elevation of the pelvis, and so the prone body profile is flatter than that of the term newborn. The preterm infant continues toe-walking and, even at 40 weeks, often has hypotonia, incomplete dorsiflexion of the foot, and a greater popliteal angle compared with the term newborn.

## Assessment of Head Growth Patterns

There are expected changes in head growth. Naturally, size should increase with age, but the shape also changes, becoming more elongated during the first few months of life. Abnormalities of head growth such as microcephaly or hydrocephalus often develop over time, and therefore serial measurements are required to make such diagnoses. A standard plotting curve is necessary to monitor head growth in the preterm infant such as depicted in [Fig. 4-15 \(Babson and Benda, 1976\)](#).

Thus with flexibility and persistence, a newborn neurologic examination is accomplished. As always, it is helpful to be aware of the range of normal variation among children, and any abnormal findings need to be carefully replicated. Involving the family when possible during the examination provides an opportunity to build trust and establish rapport. This is essential to the job of the child neurologist, who not only characterizes the neurologic status and helps guide a diagnostic and therapeutic plan, but must also engage in that most human of endeavors, providing support and empathy to a family facing an unexpected and often frightening future.

## Muscular Tone and Gait Disturbances

Kenneth F. Swaiman and John Phillips

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

### TONE

Muscle tone is defined as resistance to passive stretch (Sanger et al., 2003). It is conventionally separated into postural and phasic types. **Postural tone** is the result of a steady, restrained stretch on tendons and attached muscles, resulting in protracted muscle contraction. Gravity is the most common stimulus for this response. The axial muscles are primarily involved with postural tone. **Phasic tone** is the result of rapid stretching of a tendon, attached muscle, and most importantly, the muscle spindle. Muscles of the extremities are primarily involved in phasic tone. The response is rapid and short-lived. Phasic tone is the topic primarily discussed in this chapter, and it is referred to simply as tone.

Abnormalities of tone can be broadly defined as hypertonia (increased tone) or hypotonia (decreased tone). Common forms of hypertonia are spasticity, dystonia, and rigidity. **Spasticity** is velocity-dependent resistance to passive stretch. **Dystonia** includes velocity-independent resistance to passive stretch, often with simultaneous contraction of agonist and antagonistic muscles and fluctuating involuntary extremity movement or postures. With dystonia, tone may increase if another body part is moved or touched. **Rigidity** is also velocity-independent resistance to passive stretch in all directions of joint movement, but unlike dystonia there is no involuntary movement or extremity postures (Sanger et al., 2003).

### PATHOLOGY

The final common pathway of upper or lower motor unit modification of tone is through the gamma loop (fusimotor) system. Intimately involved with monitoring and effecting tone are the two stretch-sensitive muscle receptors—the muscle spindles and the Golgi tendon organs (Figure 5-1). Spinal cord reflex responses depend on ongoing activity in interneurons.

Stationed in all areas of the skeletal muscle is the muscle spindle, a fusiform-shaped receptor structure. Sensory endings wrap around the central sections of the intrafusal fibers and monitor the stretch of these fibers. Through efferent axons, gamma neurons within the anterior horn of the spinal cord innervate the contractile muscle portions on each end of the intrafusal fiber and enhance the sensitivity of the sensory endings to stretch.

The intrafusal muscle fibers are divided into three types: nuclear chain fibers, dynamic nuclear bag fibers, and static nuclear bag fibers. A solitary Ia afferent fiber provides primary sensory innervation for all three types of intrafusal fibers. A group II afferent fiber innervates chain and static bag fibers, providing secondary sensory endings. The various sensory endings on the different types of intrafusal fibers have different sensitivities to the rate of the change of length. This intricate system of muscle spindle innervation allows the muscle stretch receptors to monitor muscle tension, length, and velocity of stretch, and provide input for maintenance of tone.

It is through their effect on the gamma motor neuron that portions of the central nervous system (CNS) (i.e., motor cortex, thalamus, basal ganglia, vestibular nuclei, reticular formation, and cerebellum) modify tone, with ensuing hypotonia or hypertonia (i.e., spasticity).

The Golgi tendon organs, unlike the muscle spindles, are found in series with the skeletal muscle fibers and are attached at one end to the muscle and at the other to the tendon. Tendon organs are much more sensitive to muscle contraction than muscle spindles. Conversely, tendon organs are much less sensitive to stretch than muscle spindles. Each of these relative sensitivities plays a specific role during the performance of various motor tasks.

### EVALUATION OF THE PATIENT

#### History

It is critical to establish when an abnormality first became evident, and what changes, if any, have occurred over time.

#### Examination

Preterm infants, even when healthy, are normally hypotonic relative to a term newborn; therefore, corrected ages must be considered when assessing preterm infants during the first months of life.

The infant's tendency to assume unusual postures may indicate the presence of hypotonia—especially the “frogleg” position, in which the supine infant lies with the lower limbs externally rotated and abducted. Hypotonia is often associated with generalized weakness, with resultant poor suck, cry, and respiratory effort in addition to a paucity of spontaneous limb movements. Observation of the chest may disclose pectus excavatum and a bell-shaped chest, indicating relative weakness of intercostal muscles compared with the better-preserved strength of the diaphragm during respiratory efforts.

Tone should be assessed both when the neonate is active and also when at rest. Passive pronation, supination, flexion, and extension of the limbs and gently shaking the hands and feet is required. The scarf sign (wrapping the infant's arm across the chest) and the traction can be helpful as well.

The hypotonic infant will slip through the hands of the examiner when held under the axillae (i.e., vertical suspension maneuver). If the hypotonic infant is supported by the trunk in an outstretched prone position (i.e., horizontal suspension maneuver), gravity causes flexion, or droop of the head and extremities (“inverted comma”). The infant with *hypertonia* responds differently to these maneuvers. In vertical suspension the infant with spasticity may demonstrate extension and scissoring of the legs with fisting, and in horizontal suspension there can be persistent hyperextension of the legs and neck.

Weakness is often readily diagnosed in the infant and younger child by observation; in the older child, more formal

**Figure 5-1. Muscle spindles and Golgi tendon organs are encapsulated structures found in skeletal muscle.** The main skeletal muscle fibers, or extrafusal fibers, are innervated by large-diameter alpha motor axons. The muscle spindle has a fusiform shape and is arranged in parallel with extrafusal fibers. It is innervated by afferent and efferent fibers. The Golgi tendon organ is found at the junction between a group of extrafusal fibers and the tendon; it is therefore in series with extrafusal fibers. Each tendon organ is innervated by a single afferent axon. (Adapted from Granit R., 1975. *The functional role of the muscle spindles—facts and hypotheses. Brain* 98, 531.)

and discrete muscle testing is possible, as described in Chapter 2.

Deep tendon reflexes should always be elicited. When the lower motor unit is involved, the deep tendon reflexes range from hypoactive to absent.

Whereas hypotonia may occur due to pathology in either the peripheral or CNS, increased tone always involves the CNS. In general terms, dystonia and rigidity are usually related to involvement of the basal ganglia or their output tracts and are associated with normal or decreased deep tendon reflexes. Spasticity can be conceptualized as involving the pyramidal tract system and is associated with hyperreflexia, the sometimes abnormal spread of the reflex (crossed adductor response or Hoffman sign) and extensor plantar responses. An exception is in the acute phase of traumatic injury when transient hypotonia and decreased reflexes can occur (for example, as seen in the so-called “spinal shock”).

Specific laboratory studies may be essential in establishing the diagnosis. There is increasing reliance for specific diagnosis on genetic analysis, which has been replacing the need for biopsy in most cases. When upper motor unit diseases are involved, a careful history, electroencephalography, evoked potentials, brain imaging, specific endocrine evaluations, and specific enzyme determinations may be required.

## DIAGNOSIS

For didactic purposes and simplification, the motor pathway from the motor neuron in the motor strip to the skeletal muscle fiber can be divided into upper and lower motor neuron units. The upper motor neuron (unit) includes the pyramidal neuron in the motor cortex and the myelinated nerve fiber, which traverses the corticospinal tract and eventually terminates in the internuncial pool in the spinal cord adjacent to the anterior horn cell. The lower motor neuron (unit) consists of the anterior horn cell, peripheral nerve, neuromuscular junction, and muscle. Upper motor unit disease may result in increased or diminished muscle tone in infants and young children, whereas lower motor unit disease generally results in decreased tone.

When assessing a child with hypotonia, it is important to distinguish whether there is a central or peripheral etiology. Impairment of the lower motor unit causes hypotonia and weakness. Hyporeflexia, fasciculations, and muscle atrophy also result.

Inadequate brain control of the motor pathways, or central hypotonia, is the most common cause of decreased tone. The presence of normoactive or brisk deep tendon reflexes suggests that the child is probably not suffering from lower motor unit impairment. The examiner should be alert for other signs of brain dysfunction, such as lethargy, unresponsiveness to the environment (i.e., visual and auditory stimuli), lack of development of social skills in the early months of life, and delayed development of language and reasoning skills in older children.

Diseases of the upper motor unit may be classified according to pathophysiologic causes (i.e., metabolic, degenerative, traumatic, congenital–structural, infectious, or toxic). A similar classification may be used for lower motor unit diseases; such diseases also may be categorized by the anatomic site of involvement.

Increased muscle tone needs to be characterized as spasticity, dystonia, or rigidity. The Hypertonia Assessment Tool provides a convenient approach to patient evaluation, particularly when mixed tone exists (Figure 5-4) (Jethwa et al., 2010). More detailed evaluation of spasticity is possible using the Modified Ashworth Scale (Bohannon and Smith, 1987) and the Tardieu assessment (Patrick and Ada, 2006).

## CLINICAL LABORATORY STUDIES

Conventional laboratory studies are rarely helpful, although creatine kinase and thyroid studies should be performed in the presence of hypotonia. Abnormalities of increased or decreased tone may require specific enzyme testing or genetic analysis.

Magnetic resonance imaging (MRI) is the standard imaging modality for the diagnosis of structural CNS abnormalities. Cerebrospinal fluid studies may demonstrate pleocytosis, increased levels of protein, or abnormal proteins, and specific patterns may point to demyelinating conditions or peripheral neuropathy. Spinal fluid neurotransmitter metabolite assessment may be helpful in the evaluation of dystonia. Assessment for leukocyte enzyme activities associated with certain lipid storage diseases may provide definitive diagnoses for conditions that affect the brain alone, the brain and anterior horn cells, or the brain and peripheral nerves.

Some neuromuscular and mitochondrial diseases are associated with cardiomyopathies, and electrocardiography or echocardiography may be of assistance in establishing a diagnosis. Electromyography differentiates neurogenic from myopathic conditions.

The diagnosis of peripheral neuropathy, particularly in conditions that involve the central and peripheral nervous systems, may be readily overlooked without the determination of nerve conduction velocities. Normative data are available for all age groups.

## GAIT IMPAIRMENT

### Physiologic Considerations

Conventionally, the period from one heel–ground contact to the next heel–ground contact of one foot is one gait cycle; walking can be divided into stance and swing phases. The instant from which heel–ground contact occurs until the instant when contact terminates is the stance phase. The period beginning immediately after the toe leaves the ground

until the heel contacts the ground is the swing phase. Normally, the stance phase occupies 60% of the duration of the cycle, and the swing phase occupies 40%.

## Evaluation of the Patient

Specific aspects of the neurologic examination are particularly relevant to gait. It is important to determine whether abnormalities are focal or diffuse and to note whether there is abnormal muscle tone, weakness, extrapyramidal movements, extensor toe signs, or abnormalities of deep tendon reflexes.

To evaluate gait fully, it is important that the examiner be able to see the entire picture, so the patient should be unencumbered by clothing and is best tested wearing only underwear (or, for more modest older children, short pants and an undershirt). The child's back should be carefully examined with special attention to the lower spine, looking for cutaneous lesions or scoliosis.

The hip, knee, and ankle joints should be moved through their entire range of motion, and the presence of contractures determined. Any pain associated with joint movement should be evaluated. In infants, congenital dislocation or subluxation of the hip is often associated with skin fold asymmetry along the medial thigh. Before the patient's walk is observed, the Romberg test should be performed. Walking should be assessed while the patient is barefoot and also while the patient is wearing shoes. Patients who wear braces should be examined both with and without braces. Among the important characteristics are symmetry of gait from leg to leg; whether walking occurs on the balls of the feet, flat-footed, or on the heels; and the relative stability of the pelvis.

Fluctuating upper extremity postures triggered by walking may suggest a dystonic component. Reduced arm swing is often seen in hemiparesis. The arms should move so that the contralateral arm swings forward synchronously with the swing phase of each leg (see [Figure 5-5](#)). When the child runs, abnormal arm and hand postures and movements are frequently accentuated.

An older child should be asked to tandem-walk forward and backward (heel-to-toe); the examiner can facilitate compliance by demonstration. The child should be asked to pivot quickly when changing direction. The backward heel-to-toe walk should also be executed. The child should walk on the toes and reverse direction, remaining on the toes. This process needs to be repeated on the heels.

The clinician should ask the child to circle the examiner, first in one direction and then in the other. If the child has hemispheric cerebellar disease, the child will tend to depart from the circular path toward the examiner or away from the examiner, depending on the side of the lesion.

It is advantageous to have the child climb steps to observe pelvic strength and stamina. Hip girdle strength can be

assessed when the child is asked to squat and then stand rapidly. Evidence of hip girdle weakness may also be gained by asking the child to lie down in the supine position and sit up by flexing at the hip. Gowers' maneuver can help identify proximal leg weakness.

While the child walks and runs with shoes on, the examiner should listen and observe for evidence of scraping, scuffing, and slapping sounds. Formal gait analysis may be obtained, which assesses various facets of gait in children.

## DIFFERENTIAL DIAGNOSIS

### Spastic Hemiplegic Gait

Hemiplegia typically results from disruption of the corticospinal tract above the medulla. Tone is often increased, and posture is characterized by leg extension or slight knee flexion. Hemiplegic gait includes impaired natural swing at the hip and knee with leg circumduction. The pelvis is often tilted upward on the involved side to permit adequate circumduction. With ambulation, the leg moves forward and then swings back toward the midline in a circular movement. The heel-walking exercise is impaired as the patient scuffs the lateral sole and the toe of the shoe while dragging the foot.

The affected leg bears weight for less time than the normal leg during ambulation. The expected rhythmic reciprocal swing of the arm with the stance phase of the opposite leg is absent. Dystonia rather than spasticity should be considered if the arm is held behind the plane of the body on a routine basis.

The etiology of hemiplegic gait cannot always be determined, but one should look for focal brain lesions such as porencephalic cysts, subdural hematomas, cerebral masses, and cerebrovascular accidents.

### Spastic Diplegic Gait

Spastic diplegia implies bilateral corticospinal tract dysfunction involving both legs out of proportion to arms. [Sutherland and Davids \(1993\)](#) provided the classic description of four types of pathologic gait patterns seen with spastic diplegia.

**Jump gait** is characterized by excessive flexion throughout the gait cycle of the hip and knee with plantar flexion of the ankle, resulting in a jumping quality to each step. **Crouch gait** has excessive hip and knee flexion with the ankle in excessive dorsiflexion through the gait cycle and is often seen in patients with severe spastic diplegia or quadriplegia. In the **stiff knee gait** pattern, the knee is stiff with insufficient flexion in the swing phase, causing difficulty with foot clearance, resulting in compensatory hip circumduction and external rotation of the affected leg and a vaulting quality to the contralateral leg during stance. **Recurvatum gait** is less common and occurs

**Figure 5-5.** Schematic representation of various phases of a child walking. (Adapted from Öunpuu, S., Gage, J.R., Davis, R.B., 1991. Three-dimensional lower extremity joint kinetics in normal pediatric gait. *J Pediatr Orthop.* 11, 341.)

with excessive knee extension in the stance phase of the gait cycle with or without an equinus ankle contracture.

## Cerebellar Gait

An unsteady, wide-based, often lurching gait signifies cerebellar pathway dysfunction. Cerebellar hemispheric lesions result in veering to the ipsilateral side. For example, if a child with a right cerebellar lesion is asked to circle the examiner in a clockwise direction, he or she will collide with the examiner within a few circles.

In order for cerebellar impairment to be better observed, the child should be asked to rise from a chair, walk a straight line, and suddenly reverse direction while walking in a tight circle. The child should be asked to tandem-walk along a straight line to facilitate observation of ataxia. The child should be asked to stand with feet close together, first with eyes open and then with eyes closed. This is the Romberg test, and the child with cerebellar difficulties will maintain a stable or mildly unsteady stance with eyes open, but sway or fall toward the involved cerebellar hemisphere with eyes closed.

Compromise of the cerebellar hemisphere is associated with abnormal movement of the ipsilateral limbs. If the anterior lobe of the cerebellum or midline cerebellar structures are compromised, only gait may be involved, without abnormalities of the upper extremities.

The clinical presentation of **sensory ataxia** can be similar to ataxia due to a midline cerebellar lesion. With sensory ataxia, the cerebellum lacks normal sensory input from various portions of the sensory system, including peripheral nerves, posterior roots, posterior columns, or connections leading from the posterior columns to the parietal lobes through the medial lemnisci. This results in marked instability during standing, and when walking there is a wide-based gait. Muscle power remains unaffected.

The patient with sensory ataxia lacks position sense and avoids obstacles by raising the legs inordinately and stepping sharply downward, the heel striking the ground first ("step-page gait"). A fraction of a second later the toe makes contact and produces the second part of a split sound. The child often compensates for loss of sensory awareness by looking at the ground during walking. The child usually has no complaint of sensory abnormality unless ataxia is caused by a global peripheral neuropathy (i.e., one severely affecting all sensory modalities). However, examination will reveal abnormal position and vibratory sense primarily in the lower extremities. The Romberg test is positive as well, just as it is with lesions of the cerebellum.

The **differential diagnosis** of a cerebellar gait depends on time course. Chronic or slowly progressive ataxia may be caused by congenital malformations, inherited cerebellar atrophies, aminoacidurias, mitochondrial diseases, lipid storage diseases, anoxic encephalopathy, demyelinating diseases, posterior fossa tumors, or hydrocephalus. Whole exome sequencing may provide a diagnosis in more than half of patients without a clear etiology for their ataxia (Pyle et al., 2015). Some causes of sensory ataxia include subacute combined degeneration, polyneuritis, demyelinating disease, and Friedreich's ataxia.

**Acute onset** of ataxia can be frightening for parents as well as clinicians. Although the process is most often benign and self-limited, the differential diagnosis is broad and includes a number of serious conditions. A careful, systematic, neurologic evaluation helps ensure dangerous processes are not missed.

Evaluation of acute ataxia requires neuroimaging to rule out a growing structural lesion such as a posterior fossa tumor. MRI is required for best visualization of the posterior fossa

structures. Obtaining urine for catecholamine metabolites might be considered to rule out neuroblastoma, which can present with opsoclonus and myoclonus or "dancing eyes, dancing feet." Urine should also be obtained for toxicology screening (Onders et al., 2015; Monte et al., 2015).

Episodic ataxia might be seen with inborn errors of metabolism such as Hartnup disease or maple syrup urine disease; therefore, serum amino acid testing might be considered in the appropriate setting. Epileptic seizures may also appear as episodic clumsiness or ataxia, therefore an electroencephalogram (EEG) might be considered as part of the workup. The extensive differential diagnosis of ataxia is found in Chapter 67.

**Acute cerebellar ataxia of childhood** is a diagnosis of exclusion, generally felt to be an autoimmune disorder involving the cerebellum. The patient is usually between 1 and 4 years old with a peak in the second year of life (Connolly et al., 1994). The attacks may be so severe that the patient is bedridden, but more often present with unsteadiness and truncal ataxia.

Lumbar puncture usually includes normal opening pressure, mild pleocytosis, and normal glucose and protein, although a slight increase in protein content may be evident after several weeks.

There is no standard therapy for acute cerebellar ataxia of childhood. Full recovery without treatment typically occurs within several weeks. Acyclovir does not appear beneficial; although, there are several case reports of using steroids and intravenous immunoglobulin. Long-term neurologic sequelae can occur.

## Extrapyramidal Gait

Extrapyramidal gait disturbance is identified by decreased automatic movements, rigidity, and bradykinesia. The patient often leans forward, with a subsequent anterior shift of the center of gravity; this results in propulsion or festinating gait. The child may lose control and fall if the steps become more rapid and the center of gravity shifts unduly forward.

Characteristically, the affected child may have difficulty with the initial step and may take a few short steps or actually hop and shuffle forward before the walking sequence is established. In addition to the gait difficulties, children with extrapyramidal involvement may have reduced blinking, be devoid of normal facial expression ("mask facies"), and seldom fold their arms or cross their legs.

## Other Dyskinetic Gaits

A number of other movement disorders cause unusual gait patterns. Athetosis, when profound, may be associated with overall stiffness and bizarre body postures. The walk may have an associated dance-like or prancing appearance and may be incorrectly diagnosed as a form of conversion reaction. Arms, hands, wrists, and fingers frequently move in deliberate, writhing movements about the long axis of the limb and then slowly reverse the rotational movement with irregular pace.

Other uncommon gait manifestations may accompany torsion dystonia. The foot may be held in plantar flexion or inversion. Manifestations may fluctuate in intensity; therefore, the clinician should be careful not to diagnose a conversion reaction. Children with this condition walk better backward than forward, including during the tandem-walk examination. This pattern of walking better backward than forward also may be found in patients who have quadriceps muscle weakness.

Chorea may also impair proximal hip muscle and trunk muscle action. The result is a rapidly shifting positioning of

the trunk and body. The head may also move quickly along, with associated grimacing of the facial muscles, choreiform movements of the trunk and limbs, and irregular breathing patterns and sounds.

### Steppage Gait

Weakness of dorsiflexion of the feet and toes and fixed contracture in plantar flexion result in a steppage gait. The contracture most often accompanies weakness of the peroneal and anterior tibial muscles. To avoid stumbling, the child lifts the foot disproportionately high at the start of each stride. Flexion at the hip and knee is exaggerated, followed by a forward flinging of the foot. The toe precedes the heel or ball of the foot in hitting the ground, emitting the first portion of a split sound.

### Hip Weakness Gait

Severe weakness of the abductors and extensors of the hip leads to a pathologic “waddling” gait caused when the child walks with a marked lordosis of the thoracolumbar spine with a forward center of gravity to compensate for pelvic instability and a wide-based gait. The pelvis markedly pivots and rotates sharply from side to side as weight shifts. This unusual movement pattern allows balance to be maintained despite hip muscle weakness.

### Gait Apraxia

Severe frontal lobe disease can result in gait disturbance despite absence of any direct motor or sensory impairment. Although the child may successfully complete certain simple and automatic movements with the legs, he or she is unable to implement more complex activities, such as tracing a circle with the feet, kicking an object, or attempting to walk in a prescribed pattern. The patient may have difficulty initiating the walking process when already standing and have further problems with execution of the serial acts of rising, standing, or walking. Other frontal lobe manifestations, such as dementia and reappearance of primitive grasp reflexes, rooting, and palmomental reflexes, may be present.

### Antalgic Gait (Painful Gait)

Pain can arise from any leg and foot structure, including nails, skin, joints, bone, and muscles. The associated limp is caused by a decreased weight support on the painful leg and increased duration of weight support on the unaffected leg.

### Conversion Disorder

Various terms have been used for nonneurologic gait abnormalities such as psychogenic gait disorder, functional gait disorder, hysterical paralysis, and conversion disorder. Presentations are diverse. Characteristic of the gait pattern with conversion disorder is that it may vary from one moment to the next, and there is often a distractible component to the movement disorder. Usually the clinician will find no associated abnormalities of coordination, tone, or strength when the patient is sitting or lying down.

Pediatric patients with conversion reaction gait difficulties are almost never malingerers. Rather, they have physical manifestations of underlying psychological disorders and require supportive and empathetic intervention. Confronting the patient and family with a diagnosis that appears to trivialize

their pain and fear is never helpful. Accurate, prompt diagnosis leading to early treatment in a multidisciplinary setting offers the best chance of a successful outcome in pediatric conversion disorders (Schwingschuh et al., 2008).

It is therefore with careful observation and a systematic approach that abnormalities of tone and gait are appropriately addressed. A thoughtful examination can often avoid the need for extensive diagnostic testing, or can identify patients in whom an expedient workup is required because of serious pathology. Addressing such problems requires an understanding of basic neuroanatomy and neurophysiology, as well as possessing the compassion required to calm a nervous child or listen carefully to a worried parent. This is indeed part of the challenge and satisfaction that comes from the practice of child neurology.

## Vision Loss

Douglas R. Fredrick

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

In children, the complaint of blurred vision or vision loss is often nonspecific and may be difficult to elicit. Although most causes of vision loss in children result from ocular problems, neurologic disorders may have vision loss as a characteristic and early manifesting feature. The ability to determine the cause of vision loss frequently aids in the diagnosis of the underlying neurologic disorder, may help determine prognosis, and can be used to monitor treatment efficacy.

### VISUAL DEVELOPMENT

Of all the sensory systems, the visual system is perhaps the most immature at birth. Postnatal developmental reorganization of the retina takes place during the first several months of life, with intercellular connections forming between the photoreceptors and inner retinal cells. Myelination of the optic radiations through the temporal, parietal, and occipital lobes occurs in the first year of life. The most dramatic structural reorganization occurs in the striate cortex, where cortical cells responsible for the first stages of visual processing require normal focused visual input to develop in the correct orientation and to achieve maximum visual acuity. As described by Hubel and Wiesel in 1962, visual deprivation occurring in an immature brain causes abnormal formation of the striate cortical cells and decreased synaptic connections and leads to amblyopia. For vision to develop normally, all of the anatomic components of the visual system must be properly formed during development. A structurally intact neurologic substrate must receive properly focused visual information consistently over the first several years of life if normal, maximal visual acuity is to be achieved.

### ASSESSMENT AND QUANTIFICATION OF VISUAL ACUITY

#### Vision Assessment in Infancy

At term, healthy infants display a wide range of visual behaviors, with some infants lying awake and alert and tracking faces from the first day of life, whereas others are seemingly disinterested in their visual world for the first several weeks. Most infants can visually fix on a face and follow by 2 months of age. It is possible to assess vision before this time in the office with no special tools or techniques. The most important requisite for assessing visual acuity is that the infant is fully awake (Huo et al., 1999).

For infants, light is usually an aversive stimulus, and turning on the lights or shining a light in the eye causes the infant to wince. This response is an indication that the child is experiencing some light stimuli. The best stimulus to elicit visual behavior is the face of a parent or caretaker. Positional changes can also be used to the examiner's advantage, because an infant who keeps his or her eyes closed often opens the eyes when held in the supine position and rotated gently about the observer. Another method is to grasp the infant under the arms and lift her or him above the observer's head. The infant

reflexively opens the eyes, allowing the observer to attract the infant's attention. As most infants fix and follow by 2 months of age, those who do not should be referred to an ophthalmologist.

Although fixation behavior allows the clinician to determine whether the infant can see, it does not quantify visual acuity. Two techniques have been devised for this purpose. The visual evoked potential is an electrophysiologic test in which visual stimuli are presented to an alert and focused infant, and the cortical response to the visual stimulus is measured in a repeatable and quantifiable fashion (see Chapter 12) (Fulton et al., 1981). The pattern may be an alternating checkerboard, or horizontally or vertically aligned black-and-white stripes. The size of the stripes or checkerboard is described as cycles per degree or cycles per centimeter, which can be correlated to standard methods of visual or decimal visual acuity. Large targets are initially used to confirm that a cortical signal is recorded by occipitally placed scalp electrodes. The stimulus pattern is then slowly decreased in size until a recordable response can no longer be elicited.

A second test used to quantify visual acuity is the forced-choice preferential looking test (PLT) (see Figure 6-1). Instead of using a cortically recorded electrical response, visual stimuli are presented and the child's ability to see is determined by the ability to move the eyes toward the visual stimulus. Vertically or horizontally aligned black-and-white stripes are presented to the child on a test card. When given a choice between a pattern background and a homogeneous background, infants instinctively are interested in the pattern background and make an eye movement or saccade toward the black and white stripes. An observer who is watching through a peephole in the middle of the card records in a masked fashion whether he or she sees the infant make the saccade. Limitations of this test include the need for an infant who is not irritable and a trained observer.

Both techniques have been validated in older children and are reliable and accurate methods to assess visual acuity. Using these techniques, it can be estimated that a neonate's visual acuity is approximately 20/2000. By 2 months of age, acuity has improved to 20/200, and by 1 year of age, it is approximately 20/60. By 4 years of age, infants should see 20/25. At this age, more reliable tests of visual acuity can be used.

#### Vision Assessment in Children

Once a child becomes verbal but is still preliterate, matching tests can be used to quantify visual acuity (Figure 6-2). In the past, the tumbling E has been used; the examiner asks the child to show the direction of the letter E as it is presented in numerous different positions. These tests have been replaced by matching games such as HOTV cards and child recognition symbols or Lea symbols that ask a child to match test optotypes that are presented in progressively smaller sizes (Figure 6-2). These tests have been validated and are consistent with Snellen visual acuity, which is the gold standard for measurement of visual acuity in children and adults. Snellen visual

acuity can be recorded in numerous forms using notations such as 20/20, decimal notation, or *logmar* notation, a method of quantification that allows more useful statistical analysis when conducting studies of visual acuity in children and adults.

## ASSESSMENT OF COLOR VISION

Assessment of color vision can be useful in determining the cause of vision loss. Optic nerve injury often causes decreased color vision as its first presenting sign, even before distance visual acuity or the size of the visual field has been affected. The most useful tests for this purpose are the Hardy-Rand-Rittler (HRR) test plates and the Ishihara color plates. The combination of these techniques can separate those children who simply have red–green color deficiency from those with impaired color vision caused by optic nerve injury.

## ASSESSMENT OF VISUAL FIELDS

It is not possible to quantify small visual-field deficits in young children. It is possible to diagnose significant hemianopias in small infants using a two-person examination technique. With this technique, one examiner sits in front of the child, maintaining fixation through use of a toy or verbal stimulus. A second tester stands behind the child and introduces a toy or colored object silently in the periphery of the child's vision. When the child sees the toy, he or she generates a saccade or a head movement toward the toy. In this fashion, hemianopias can be detected, aiding in the diagnosis of underlying neurologic problems and determining rehabilitation strategies for children with vision impairment associated with neurologic disease. Older patients can be tested with kinetic perimetry using the Goldmann perimeter or automated visual fields. These tests are particularly useful for patients who are being monitored for visual-field changes associated with benign intracranial hypertension, low-grade gliomas, or midline tumors that, before treatment, may induce ocular or central nervous system (CNS) injury.

## ASSESSMENT OF OCULAR MOTILITY

Assessment of ocular motility allows the examiner to assess function of cranial nerves III, IV, and VI (see Chapters 2–4). Ductions and versions can be tested using brightly colored toys and objects. It is important to check the child binocularly first before patching the infant's eye because patching may be distracting and preclude acquiring useful information. Alignment should be checked using the alternate cover test where fixation is maintained and the visual axis of each eye is occluded alternately. Refixation of the eyes during alternate occlusion may indicate the presence of strabismus such as esotropia, exotropia, or hypertropia (Figure 6-3).

### Assessment of Optic Nerve and Retinal Nerve Fiber Layer Integrity

Assessment of the health of the optic nerve is an essential task when evaluating a child with vision loss. Either the direct ophthalmoscope or the indirect ophthalmoscope can be used, and when examining a cooperative child through a dilated pupil, this can be simple. However, when examining an unhappy infant with nystagmus and an undilated pupil, this can be a challenge even for experienced ophthalmologists, let alone the pediatric neurologist. The color, contour, and clarity of the peripapillary vessels should be evaluated. If the nerve is pale and flat, that may indicate optic atrophy; if the optic

cup is enlarged, that may indicate glaucoma or transsynaptic degeneration; if the nerve is elevated and disc margins are blurred, that may indicate papilledema or nerve head drusen. In the past, the description of the nerve was qualitative, or could be documented by photographs, which could be compared in a longitudinal serial fashion. In recent years, spectral domain ocular coherence tomography (sd-OCT) has been used to objectively quantify the contour of the optic nerve and the thickness of the retinal nerve fiber layer (Avery et al., 2015). This technology will be standard of care for following children with demyelinating disorders and children with compressive optic neuropathy and degenerative neurometabolic disorders.

## CLINICAL FEATURES ASSOCIATED WITH VISION LOSS

The three features that must be characterized in assessing vision loss are laterality of vision impairment, temporal nature of vision loss, and associated ocular and neurologic abnormalities. Children with unilateral vision loss are frequently asymptomatic. When a child does realize that there is unilateral decreased visual acuity, it is usually because of the sudden discovery of this problem rather than its sudden onset. Mild degrees of vision loss are not usually recognized by the child but are detected by a teacher or healthcare provider at the time of a vision-screening examination. The rapidity of onset of the vision loss also depends on whether the loss is unilateral or bilateral; long-standing unilateral vision loss may not be noticed until the unaffected eye is covered. In contrast, bilateral sudden vision impairment, as can occur with compressive or rapidly demyelinating lesions, may be noticed by the child or caretaker immediately. Associated neurologic signs and symptoms often allow the clinician to localize the disease process before neuroimaging and help the neuroradiologist determine the best type of study to perform.

Because symptoms are inconsistently reported, clinicians must be familiar with the physical signs of unilateral vision loss. During the newborn's physical examination, pediatricians must look for the presence of a red pupillary reflex in each eye. The presence of a white pupil is called leukocoria, and it is associated with poorly developed vision in one or both affected eyes in the infant (Figure 6-4). The causes of leukocoria are variable, and at a minimum, the condition can cause loss of vision; in more serious situations, leukocoria can be associated with life-threatening conditions such as retinoblastoma. Poor vision in one eye from birth often leads to strabismus that is noticed by the caretaker. Nystagmus is common when there is decreased visual acuity in one or both eyes resulting from a structural anomaly or to a functional deficit preventing visual information from being transmitted from the eye to the cortex. In an infant, bilateral vision loss is manifested by strabismus or nystagmus and visual inattention with poor fixation after 2 months of age. Older children with mild vision loss are usually asymptomatic and their problems are not detected until vision is screened by their pediatrician or family practitioner. Children who have progressive loss of visual acuity exhibit behaviors such as sitting extremely close to the television, being disinterested in distant objects or activities, and having difficulty with tasks that require fine visual acuity.

Associated ocular features of vision loss are important to confirm. Infants with poor vision often develop nystagmus by 2 months of age. They are visually inattentive and do not fix and follow well by this age, and they frequently manifest strabismus or a "wandering eye." Older children usually do not complain of vision problems but have strabismus. They

often close one eye or squint the eye in different lighting conditions, rub their eyes frequently, and occasionally complain of double vision when strabismus occurs suddenly. Children with significant vision loss have disrupted circadian rhythms and disturbed sleep–wake cycles. Other associated neurologic symptoms include headache, nausea, and vomiting.

## EXAMINATION OF CHILDREN WITH VISION LOSS

It is the role of the neurologist or the primary care physician to document decreased visual acuity in children who are suspected of having vision loss or found to have vision loss during a screening examination. Infants should have their visual acuity assessed by their fixation behavior. Extraocular movements should be tested to evaluate cranial nerve function, and pupils should be tested to determine the response to light and presence or absence of an afferent pupillary defect. A direct ophthalmoscope should be used to check for a red reflex, because absence of the red reflex indicates a corneal or lenticular opacity or an intraocular tumor such as retinoblastoma. If the patient has any of these abnormalities, she or he should be seen by an ophthalmologist to assess for structural abnormalities and to recommend additional diagnostic tests. Older children can have their acuity assessed as described earlier. They should have a full motility examination, and an attempt should be made to examine the fundus. The neurologist should feel comfortable using dilating eye drops such as tropicamide. This procedure facilitates examination of the optic nerve head and macula. Any child with abnormal visual acuity, motility, pupillary reflexes, or retinal examination should be referred to an ophthalmologist for further examination.

## VISION LOSS IN INFANTS

### Clinical Manifestations

Whereas most adults and older children with neurologic disease involving the visual pathways have alterations in visual acuity or visual function, infants usually have problems resulting from failure of vision to develop normally after birth. Parents are concerned that their children fail to use their vision appropriately or never develop normal visual fixation behaviors. These children have no symptoms because they cannot articulate their complaints, but they manifest many signs that can be useful in diagnosing and localizing the cause of the decreased visual acuity. Signs of decreased visual acuity in an infant include failure to fix and follow an object by 2 months of age or visual inattention manifested by the complaint that the infant looks through the caretaker or indirectly at the caretaker's face.

Strabismus is another common complaint in children and infants who have poor visual acuity. Strabismus early in life is not rare. Up to 30% of infants manifest intermittent deviations in the first 2 months of life, with exotropia occurring more commonly than esotropia. The deviation is usually intermittent and decreases in frequency over the first few months of life. Any child who has a strabismus lasting longer than a few months should be assessed for an underlying ocular anomaly.

Nystagmus is commonly seen in children who have bilateral structural anomalies, leading to abnormal visual development. Nystagmus rarely exists at birth. At birth, there may be other movements such as ocular flutter, square wave jerks, or saccadic intrusions that are short-lived and become infrequent over time. In contrast, when a child has a structural anomaly such as bilateral optic nerve hypoplasia, lack of visual stimulation of the striate cortex leads to a sensory nystagmus. The

amplitude of the nystagmus can be quite large between the ages of 2 and 6 months, with the amplitude decreasing and the frequency increasing with time.

Infants with visual problems also often demonstrate behavioral mannerisms that help suggest the cause of the vision loss. Children with retinal dysfunction from congenital dysfunction of the photoreceptors or from retinopathy of prematurity often press their eyes to generate some sort of photic stimulation. Children with cortical visual impairment may demonstrate overlooking behavior, an eccentric fixation, to maximize visual function in the visual fields that are least damaged from the underlying cortical injury. Patients with achromatopsia or congenital glaucoma may be quite photosensitive and demonstrate behaviors to shield their eyes from the light to minimize the dysphoric sensation they receive from visual stimulation.

## Differential Diagnosis of Vision Loss in Infants

As with every physical sign and symptom, the history and general physical examination often determine the diagnosis, even before ophthalmologic and neurologic examination. If vision loss is suspected by the pediatrician or family practitioner, the child should be seen by an ophthalmologist before being referred to a neurologist. Most infants with vision loss have underlying ocular anomalies that can be diagnosed and obviate the need for expensive neuroimaging or genetic and metabolic testing. The ophthalmologist can direct the neurologist and geneticist toward the most likely diagnosis to minimize the inconvenience, cost, and morbidity associated with diagnostic evaluation in children with vision loss resulting from neurologic disease.

### Structural Anomalies

**Retinopathy of Prematurity.** Retinopathy of prematurity remains a common cause of vision impairment in infants, causing blindness in more than 500 infants each year in the United States. These patients develop cicatricial changes in the retina leading to vision impairment. Premature infants who do not develop retinopathy of prematurity are still at risk for cerebral vision impairment because of periventricular leukomalacia. Prematurity is the most common cause of pediatric vision impairment in developed countries and the vision loss can be caused by damage to the retina or injury to gray or white matter involving the visual pathways (Dutton and Jacobson, 2001). Children with periventricular leukomalacia can sometimes have enlargement of the optic cup, mimicking glaucoma, but representing loss of nerve fiber layer because of transsynaptic degeneration.

**Congenital Cataracts.** All infants should be screened for cataracts at birth by their pediatrician or family practitioner. The presence of a clear red reflex makes it unlikely that cataracts are present. An abnormal red reflex should prompt ophthalmologic evaluation to determine the location of the optical opacity.

Treatment involves prompt recognition, removal of visually significant cataracts, and visual rehabilitation with intraocular lens implantation, extended-wear soft contact lenses, or aphakic spectacles.

**Corneal Opacity.** Corneal opacities usually are easily detected by pediatricians or parents at birth when a white spot, or leukoma, is detected within the cornea (see Figure 6-5). These opacities are associated with other structural anomalies, such as microphthalmos, or small eye, and anterior segment dysgenesis, which may also be associated with glaucoma or birth trauma. These corneal opacities can cause significant vision

impairment and are difficult to correct, because the success rate of corneal transplantation is poor in infants.

**Ocular Coloboma.** Coloboma, or absence of tissue, can affect vision profoundly. If the coloboma involves the iris but not deeper tissues, visual acuity can be normal (Figure 6-6). However, when the coloboma involves the central retina, macula, or the optic nerve, vision can be severely impaired. Children with bilateral colobomata are at high risk for underlying neurologic problems. Any child with bilateral colobomata should be evaluated for chromosomal trisomies and the CHARGE association (i.e., coloboma, heart defects, atresia choanae, retardation of growth and development, genitourinary problems, and ear anomalies). Aicardi syndrome should be considered in any female with a seizure disorder and ocular colobomata (Figure 6-7). Patients with Aicardi syndrome have ectopic gray matter and other CNS malformations; the disorder is X-linked and lethal for males. Coloboma of the optic nerve can also be associated with underlying renal disease, known as the papillorenal syndrome; this diagnosis is made by genetic testing for mutations in the *PAX6* gene.

**Retinal Dysplasia.** Structural anomalies of the retina not associated with retinopathy of prematurity can lead to significant vision impairment. These forms of retinal dysplasia are frequently associated with a variety of neurologic malformations. An example is Walker-Warburg syndrome, in which congenital retinal dysplasia is associated with cerebral structural abnormalities such as hydrocephalus, agyria, and occasionally encephalocele (see Chapters 25–30) (Liu, 2001). Muscle-eye-brain disease is another example of neurologic and retinal dysplasia resulting from abnormal glial development caused by defective glycosylation of  $\alpha$ -dystroglycan. This results in profound CNS involvement and significant vision loss. Norrie disease is an X-linked condition in which retinal dysplasia is associated with mental retardation and deafness.

**Optic Nerve Hypoplasia.** Failure of the optic nerves to form properly leads to a small dysfunctional optic nerve. In optic nerve hypoplasia, the nerve is small and its morphology abnormal (Figure 6-8). Frequently, there is a double-ring sign; the scleral canal of the optic nerve is present, but the optic nerve tissues comprise only a small portion of the canal, leading to two distinct rings. Children with optic nerve hypoplasia frequently have nystagmus. Children with optic nerve hypoplasia may have de Morsier syndrome, or septo-optic dysplasia, characterized by midline structural defects of the CNS (e.g., absence of the septum pellucidum and agenesis of the corpus callosum) in addition to neuroendocrine dysfunction (see Chapter 97). All children with optic nerve hypoplasia should undergo neuroimaging, with particular attention to the septum pellucidum, corpus callosum, and pituitary body. The presence of an ectopic bright spot places the child at higher risk for neuroendocrine dysfunction. The absence of cerebral developmental anomalies does not mean that endocrine abnormalities will not occur, and children require continued endocrinologic follow-up. There have been numerous cases of sudden death associated with septo-optic dysplasia, in which affected children develop a febrile illness that leads to rapid decompensation and death as a result of adrenal insufficiency. Parents should be advised concerning these potential risks and treat all illnesses seriously.

**Ocular or Oculocutaneous Albinism.** Normal pigment formation is essential for normal ocular development and normal function of the retinal pigment epithelium. Albinism may involve the eye and skin (oculocutaneous albinism), or only the eye (ocular albinism); both forms are associated with decreased visual acuity. Patients with oculocutaneous albinism are more severely affected, with visual acuity in the

20/200 range, whereas those with ocular albinism have acuity in the range of 20/60 to 20/80. Both conditions manifest with nystagmus early in life. The diagnosis of ocular albinism is made by documenting transillumination defects in the iris during slit-lamp examination. This test can be performed in infants, and it obviates the need for further evaluation.

**Leber Congenital Amaurosis.** Leber congenital amaurosis is a disorder of the photoreceptors and the retinal pigment epithelium in which photoreceptor function is extinguished. Infants have large-amplitude, slow-frequency, roving nystagmus. They frequently begin to press on their eyes by 2 to 3 months of age, and they may have a completely normal ophthalmoscopic examination with normal-appearing optic nerve and retina. The diagnosis is established by electroretinography. In this test, the electrical amplitude of the retina is measured using a contact lens placed on the eye that is stimulated by bright lights to elicit a cone response and dim lights to stimulate a rod response (Figure 6-9). In congenital amaurosis, both rod and cone responses are extinguished.

### Vision Loss Caused by Cortical Visual Impairment

In developed countries, decreased vision caused by cortical or cerebral visual impairment is the leading cause of vision impairment in infants. Damage to the visually immature brain impedes normal visual development and leads to lifelong subnormal vision. The most common causes of cortical visual impairment in developed countries are neonatal encephalopathies (see Chapter 17). The second most common cause of cortical visual impairment is periventricular leukomalacia (see Chapter 19). Injury and ischemia lead to damage in the periventricular white matter and frequently affect visual development.

Clinical features of cortical visual impairment are those of an infant who fails to develop visual fixation behavior after 2 to 3 months of age. These children are often neurologically impaired and have delayed motor milestones and abnormal findings for the neurologic examination. Magnetic resonance imaging (MRI) in affected children usually provides evidence of leukoencephalopathy. Infants with cortical visual impairment do not fix or follow, and appear to be visually disinterested in the environment. Infants commonly demonstrate off and on visual behavior, during which there are moments of what appears to be normal visual fixation interspersed with longer periods of visual inattention. Infants respond well to high-contrast targets such as black-and-white toys and large pattern images. Children with profound cortical visual impairment early in infancy can demonstrate a progressive increase in visual function over several years and may become quite visually proficient. It is important to refer children with cortical visual impairment for low-vision services that can provide sensory stimulation exercises, which improve the visual performance of infants and provide emotional, social, and educational support for parents.

### Structural Cerebral Anomalies Causing Cortical Visual Impairment

**Hydrocephalus.** Ophthalmic signs of hydrocephalus and increased intracranial pressure include the setting sun sign, which describes the infant's gaze held in a downward fixed position, with the eyelids retracted and the infant unable to elevate the eyes willfully. Because the cranial sutures are not closed, papilledema usually does not occur early in infancy. After the cranial vault is closed, papilledema can occur as with any child with increased intracranial pressure (see Chapter 77). Children with hydrocephalus require surgical relief of their obstruction by ventriculostomy or ventriculoperitoneal

shunt placement. An ophthalmologic examination should be obtained to document the presence of normal optic nerves or the absence of optic atrophy. Many older children with chronic hydrocephalus have optic atrophy that precludes future useful information about the presence of intracranial pressure because atrophic optic nerves do not swell and cannot reflect increased intracranial pressure. Other ocular signs of increased intracranial pressure include cranial nerve VI paresis, often manifesting as new-onset esotropia.

**Structural Brain Anomalies.** Children with schizencephaly frequently have decreased visual acuity as a result of damage to the optic radiations and pathways. Contralateral hemianopias and epilepsy are common clinical manifestations. Visual function in children with large schizencephalic clefts, as well as those with porencephaly or hydrocephalus, may improve despite a very abnormal appearance on neuroimaging once the patient is shunted and the cortex re-expands.

There are numerous congenital disorders associated with brain malformations, such as the Walker-Warburg syndrome, Dandy-Walker syndrome, and muscle-eye-brain disease, in which structural brain anomalies (see Chapters 22–27) are accompanied by decreased visual function because of striate cortex involvement or associated ocular anomalies such as retinal dysplasia.

**Vision Loss Caused by Epilepsy.** Children with epilepsy frequently have poor visual function. When the seizure disorder results from a structural abnormality, there is often concomitant strabismus, nystagmus, and developmental delay. Patients with seizures may develop visual auras before the seizure (see Chapter 54), and functional blindness during the postictal period. Children with frequent seizures throughout the day often have poor visual fixation development. The use of antiepileptic drugs may sedate the child to the point where general development is delayed, and this can affect development of visual acuity. Optimizing antiepileptic drug therapy should be encouraged, because visual acuity can markedly improve when seizures are well controlled. Certain antiepileptic drugs such as vigabatrin may be associated with specific retinal or ophthalmic abnormalities (see Chapter 59).

**Delayed Visual Maturation.** Occasionally, a healthy infant older than 2 months is referred because of failure of development of visual fixation behaviors. Results of ophthalmologic and neurologic examinations may be completely normal. Such infants may have the condition of delayed visual maturation, a diagnosis of exclusion in which visual development is delayed but eventually becomes normal. Often, the onset of visual fixation is dramatic and usually occurs by 6 months of age.

## Diagnostic Evaluation of Infants with Poor Vision

An infant who fails to develop visual fixation should first be referred to an ophthalmologist. Examination by an ophthalmologist most often uncovers the causes of decreased vision, which may be caused by any of the congenital structural anomalies described previously. If examination findings are completely normal, the next considerations are a neurologic examination and possibly neuroimaging. Neurometabolic testing should be performed to exclude reversible and potentially treatable inborn errors of metabolism involving carbohydrate or urea cycle metabolism or mitochondrial disorders. These conditions are described in detail in various chapters in this textbook.

In an infant with poor visual function but normal neurologic examination results and normal neuroimaging findings,

electroretinography may be used to determine the presence of photoreceptor dysfunction. Such patients usually demonstrate signs of retinal disease, including nystagmus and eye-pressing behavior. Depending on the response to different light stimuli, determination can be made whether there is rod-related (affecting night vision) or cone-related dysfunction that affects central vision or color, or both (Figure 6-9).

## VISION LOSS IN CHILDREN

The disease processes leading to vision loss in children are quite different from those affecting infants. Children often demonstrate different signs of vision loss and are frequently able to complain of symptoms associated with vision loss, thus aiding in the evaluation and guiding diagnostic strategies.

### Symptoms and Signs of Vision Loss

Children with vision loss frequently do not complain about vision loss unless it is bilateral. Children often do not use the term *blurred vision*, but may say, “I can’t see,” “things are fuzzy,” or “things are double.” Signs of vision loss are much more helpful. When the child squints and closes the eyelids, the pinhole effect helps focus out-of-focus light. This behavior is common in children with refractive errors. Those with acute bilateral loss of vision will sit close to the television or become disinterested in activities occurring at a distance. They may hold objects very close to their faces to see them clearly. Children with new-onset strabismus associated with vision loss frequently close one eye to avoid diplopia. They may be sensitive to sunlight and shield their eyes because bright light may markedly decrease their visual acuity, especially when there is associated retinal dysfunction. Children may also tilt their heads when vision is reduced in one eye.

### Differential Diagnosis of Vision Loss in Children

Refractive errors are the most common cause of vision loss in children. This form of vision loss is usually detected by a pediatrician, who does a vision screening examination in the office, or by the school district that mandates vision checks in kindergarten or first grade. Vision loss may be unilateral or bilateral. When vision loss is caused by refractive error, correcting the refractive error yields 20/20 vision in each eye.

### Amblyopia

Amblyopia is a functional and structural condition wherein an abnormal visual stimulus leads to abnormal development of cortical visual processing cells with smaller cell size and abnormal intercellular connections. Amblyopia results from early visual deprivation, strabismus, or unequal refractive errors. These structural changes are reversible if detected early in life and treated with occlusion therapy. By removing the visual impairment, straightening the eye, or focusing the vision through spectacles, and then patching the unaffected eye to stimulate the immature visual system, amblyopia can be reversed. Whether or not vision can be restored depends on the age of detection. As a rule, most children with amblyopia should be detected and treated by the age of 6 months for the best visual prognosis.

### Ocular Anomalies Causing Vision Loss

In an infant with vision loss, it is helpful to approach the eye systematically from an external to an internal point to evaluate for causes of vision impairment.

**Eyelid Abnormalities: Ptosis.** Ptosis can be a cause of vision loss and a localizing sign of underlying impairment. It may be so profound that it occludes the visual axis, leading to deprivation amblyopia. The eyelid may rest over the cornea and be associated with significant astigmatism that can lead to anisometropic amblyopia. Other forms of congenital ptosis include congenital third nerve palsy and the congenital fibrosis syndrome, which are associated with abnormalities of all extraocular muscles with very abnormal eye movements. Neurologic causes of ptosis in children include infant botulism, congenital Horner syndrome (associated with congenital neuroblastoma), or Marcus Gunn jaw wink syndrome, a synkinesis with eyelid bobbing occurring during masseter muscle function and chewing as a result of synkinesis of cranial nerves V and III.

**Corneal Anomalies.** Although most corneal anomalies are structural anomalies seen in infants, such as Peters syndrome or scleralization of the cornea, acquired corneal dystrophies and degenerations can lead to vision loss. Some metabolic diseases manifest with corneal changes leading to vision loss. These include the mucopolysaccharidoses such as Hurler syndrome, which is associated with corneal clouding, and Fabry disease, which can lead to deposition of material in the cornea, decreasing visual acuity.

**Anomalies of the Retina.** Degenerative diseases of the retina can cause gradual loss of visual acuity and may be extremely difficult to diagnose in young children (Table 6-1).

Unlike congenital retinal dysfunction that leads to large-amplitude nystagmus, marked vision impairment, and clear-cut electroretinographic findings, retinal degeneration in older children may be insidious in onset, unaccompanied by significant visual symptoms and with equivocal findings on electroretinography.

One of the most common causes of visual dysfunction resulting from retinal dysfunction is Stargardt disease, also known as fundus flavimaculatus. This disease is a degenerative condition of the retinal pigment epithelium leading to photoreceptor dysfunction. Children have slowly decreasing visual acuity. There are characteristic changes on funduscopic examination, and diagnostic tests such as fluorescein angiography, visual-field testing, and electroretinography can help confirm the diagnosis (Figure 6-10).

**Retinitis Pigmentosa.** In retinitis pigmentosa, abnormalities of the retinal pigment epithelium can lead to photoreceptor dysfunction and death. Retinitis pigmentosa typically affects rods before affecting cones. This process leads to initial symptoms of night blindness and constriction of the peripheral visual field, eventually affecting cones and central visual acuity. A typical *bone spicule* pattern of the retinal pigment epithelium is diagnostic. Electrodiagnostic tests, such as electroretinography, may be helpful. Retinitis pigmentosa has been characterized as involving rods or cones, or both. All modes of inheritance patterns have been described, and there may be variations of phenotypic expression within families.

**Neurometabolic Retinal Dysfunction.** Several neurometabolic disorders have been associated with retinal dysfunction and secondary vision loss. In neuronal ceroid lipofuscinosis, abnormal accumulation of neurotoxic products within the retina leads to cell dysfunction and death (see Chapter 41). There are multiple forms of neuronal ceroid lipofuscinosis occurring in different age groups. Characteristic of all forms of neuronal ceroid lipofuscinosis is the development of decreased visual acuity resulting from poor retinal function. Degeneration of the ganglion cell layer results in a typical fundoscopic appearance, and ophthalmoscopic examination coupled with electrophysiologic testing can help diagnose these children who have seizures and progressive loss of milestones (Figure 6-10). Retinal dysfunction occurs in inherited mitochondrial cytopathies such as Kearns–Sayre syndrome, in which a pigmentary retinopathy is associated with decreased visual acuity, external ophthalmoplegia, and cardiac conduction defects.

## Optic Nerve Disorders

**Papilledema.** The presence of increased intracranial pressure leads to edema of the optic nerve (i.e., papilledema). The borders of the optic nerve are indistinct and the vessels are swollen; the nerve itself is elevated, with surrounding hemorrhage or exudates (Figure 6-11). Papilledema in children can be caused by obstruction of the ventricular system, craniosynostosis, or communicating hydrocephalus. Whereas early papilledema in adults rarely causes visual symptoms, papilledema can be chronic in children, with slow onset and relatively late discovery of disease, and decreased visual acuity can be a presenting complaint. Usually, this does not occur unless the increase in intracranial pressure is rapid and significant in onset or has been of long duration, leading to chronic axonal compression and edema formation in the retina and causing decreased visual acuity or cell death and incipient optic atrophy. For papilledema in children, mandatory neuroimaging should be followed by lumbar puncture. Pseudotumor cerebri or benign intracranial hypertension is not an infrequent cause of papilledema in overweight children. The diagnosis is made after neuroimaging excludes an obstructive lesion and lumbar puncture reveals increased intracranial pressure and no abnormal cytology. Occasionally, pseudotumor cerebri may be associated with sinovenous thrombosis that can be detected with magnetic resonance venography (MRV). Because many drugs can cause benign intracranial hypertension, the treatment is withdrawal of inciting agents such as tetracycline and its derivatives, and vitamin A analogs. Visual dysfunction associated with possible secondary ischemic optic neuropathic changes should prompt consideration for optic nerve sheath fenestration or lumbar or ventriculoperitoneal shunting to relieve pressure to prevent permanent loss of visual acuity.

**Pseudopapilledema.** In pseudopapilledema, the optic nerve appears to be elevated, but there is a lack of edema surrounding the nerve, which is seen with true papilledema (Figure 6-12). Pseudopapilledema can be seen with optic nerve head drusen. Optic nerve drusen are extracellular deposits of material within the nerve fiber layer that cause a lumpy elevation of the optic nerve. Later in childhood, the material develops a glistening calcific appearance and can be easily detected by autofluorescence angiography or by ultrasonography. In earlier stages of the disease, the bright signal intensity and reflective characteristics are not as evident, making the diagnosis one of exclusion considered only after lumbar puncture and neuroimaging have eliminated more dangerous conditions. The absence of hemorrhages and of blurred

disc margins suggests that pseudopapilledema is more likely to be present. Serial examinations and documentation by photography can help differentiate true papilledema from pseudopapilledema.

**Optic Neuritis.** Whereas adults with optic neuritis usually have unilateral disease, bilateral presentation is more common in children. Children rarely complain of decreased vision in one eye. Optic neuritis in children frequently follows viral illnesses; it is most commonly associated with inflammation and swelling of the optic nerve head, and may be accompanied by vasculitis (Figure 6-13). In children, there is usually edema of the optic nerve associated with loss of vision and an afferent pupillary defect, whereas in adults, most cases of optic neuropathy are retrobulbar with no visible changes on ophthalmoscopy. Any demyelinating episode may be the first sign of multiple sclerosis, and the risk of a pediatric patient eventually developing multiple sclerosis varies from 7% to 56% (Waldman et al., 2011). Children who have white matter changes on neuroimaging have a higher risk of developing multiple sclerosis and require close observation so that use of interferons may be considered. A particular form of optic neuritis that occurs more frequently in children than in adults is acute disseminated encephalomyelitis (ADEM), as described in Chapter 72. Neuromyelitis optica, or Devic disease, is a rare but debilitating form of optic neuritis that occurs in association with transverse myelitis; diagnosis is made by serologic detection of aquaporin-4 autoimmunity (NMO-IgG), a test that should be performed on all children with optic neuritis.

**Optic Atrophy.** In children, optic atrophy is often not diagnosed until both eyes are affected (Table 6-2). The most worrisome cause of optic atrophy is compressive disease of the optic nerve. Atrophy may occur from increased intracranial pressure caused by obstructive intracranial lesions, or from compression of the optic nerve from orbital processes or intrinsic tumors of the optic nerve (e.g., optic nerve gliomas). Children with optic atrophy should undergo neuroimaging to establish a specific diagnosis. Children with neurofibromatosis type 1 and optic gliomas require close ophthalmic monitoring, as these tumors may demonstrate spontaneous regression, and treatment should be considered only if there is documented progressive loss of visual acuity or peripheral visual field.

When neuroimaging fails to demonstrate compressive lesions, hereditary optic atrophy should be considered. Kjer optic atrophy is transmitted in an autosomal-dominant pattern; it presents with slow onset of visual acuity loss, first in a 20/80 to 20/100 range and then stabilizing in the 20/400 range. Wolfram syndrome includes optic atrophy as one of its clinical features (i.e., diabetes insipidus, diabetes mellitus, optic atrophy deafness [DIDMOAD]), and this autosomal-recessive condition maps to *WFS1* on chromosome 4p. Neurometabolic diseases may cause optic atrophy and are usually diagnosed by the constellation of neurologic and physical findings associated with the disease. Ischemic optic neuropathy has been described in children with underlying renal insufficiency in which the patient develops sudden changes in blood pressure because of illness or blood loss.

Other disorders that can lead to optic atrophy are the mitochondrial encephalopathies (see Chapter 37). Patients with maternally transmitted Leber hereditary optic neuropathy have loss of visual acuity in the second decade of life. This is associated with characteristic unilateral changes in the optic nerve head and telangiectatic changes in the optic nerve head vessels. There have been numerous genetic polymorphisms described in patients with Leber optic atrophy, and molecular DNA testing is available. Included in this group of

disorders is Kearns–Sayre syndrome, mitochondrial encephalomyopathy with lactic acidosis and stroke-like syndrome (MELAS), and myoclonic epilepsy with ragged red fiber disease (MERRF) (see Chapter 37).

### Cerebral Vision Impairment

Whereas cerebral vision impairment in infants results from ischemic encephalopathy or white matter disease, impairment in older children usually is traumatic in nature. An ischemic episode such as a near-drowning, meningitis, or stroke can also cause cortical vision impairment. Toxic cortical blindness can be caused by vincristine, cyclosporine, and tacrolimus. Visual acuity can be profoundly affected and show slow, progressive improvement over 1 to 2 years. The diagnosis is made by a combination of history, neuroimaging, and normal ocular examination findings.

### NYSTAGMUS IN INFANCY

Like the visual system, the ocular motor system is immature at birth. Abnormal eye movement such as ocular flutter, bobbing, saccadic intrusions, or saccadic paresis may be

transient in the first few weeks of life, but they usually resolve completely. Nystagmus, or oscillation of the eyes in a stereotypical fashion, is rarely seen at birth but usually develops by 2 months of age. There are three primary causes of nystagmus in infancy—problem with the eyes, problem with the brain, or infantile nystagmus—each having different visual consequences and health considerations (Papageorgiou et al., 2014). The presence of nystagmus can make assessment of visual function difficult, as normal fixation responses will be abnormal. All infants and children with nystagmus without a previous neurologic diagnosis should be seen by an ophthalmologist to determine whether there is an ocular cause for the abnormal eye movements (Table 6-3).

### TRANSIENT EPISODIC VISION LOSS IN CHILDREN

To hear a child complain about occasional abnormal vision is not a rare phenomenon. School-aged children frequently complain about blurred vision after prolonged distance or near-visual tasks such as reading, taking tests, or taking notes from the white board. These symptoms are usually brief and

**TABLE 6-3** Causes of Bilateral Infantile Vision Impairment Manifesting with Nystagmus by Age 2 Months

Category	Cause of Impairment
Disorders of corneal clarity	Developmental anomalies Peters syndrome Rieger syndrome Sclerocornea Congenital glaucoma Forceps birth trauma
Crystalline lens opacity	Congenital cataract
Uveal anomalies	Aniridia Oculocutaneous or ocular albinism
Vitreous anomalies	Vitreous hemorrhage Persistent hyperplastic primary vitreous
Retinal anomalies	Leber congenital amaurosis Achromatopsia or monochromatopsia Retinopathy of prematurity Retinal dysplasia Chorioretinal scarring Congenital toxoplasmosis Chorioretinal coloboma
Optic nerve anomalies	Optic nerve hypoplasia Optic nerve atrophy Optic nerve coloboma Morning glory disc

resolve after a short period of rest. Complaints of more profound transient and episodic visual loss or blindness should make the clinician consider three causes: intracranial hypertension, migraine, and functional vision loss. Increased intracranial pressure can cause transient obscuration of vision, especially when children change position from supine to standing. They may also complain of positive scotoma and "black-out spells." Migraines in children do not usually manifest as classic migraines but frequently have an atypical presentation with vision loss, frequent episodes of abdominal pain, and absence of headache. A child may complain about decreased visual acuity but have normal vision without ocular pathology. This form of functional visual loss has a variety of causes and may be difficult to diagnose and detect. Children most often complain about bilateral vision loss and initially report visual acuity in the 20/400 range. Their symptoms may be exaggerated, but the children rarely bump into objects when entering a room despite reports of markedly diminished visual acuity. This is a diagnosis of exclusion, and children should be carefully examined, perhaps on repeated occasions, before the diagnosis is made (Table 6-4).

**TABLE 6-4** Causes of Vision Loss, Associated Findings, and Diagnostic Recommendations

Cause of Vision Loss	Associated Findings/Syndrome	Diagnostic Evaluation
Leber congenital amaurosis	Large-amplitude, slow-frequency, roving nystagmus at 2 months of age; eye pressing (oculodigital sign)	Electroretinogram for photoreceptor function; renal consultation to rule out Senior syndrome
Ocular albinism/ oculocutaneous albinism	Moderate-amplitude nystagmus by 2 months, fair skin, X-linked inheritance; rule out Chediak-Higashi and Hermansky-Pudlak syndromes	Slit-lamp examination for iris transillumination defects; examine mother for signs of retinal hypopigmentation
Aniridia	Nystagmus at 2 months; consider WAGR syndrome	Slit-lamp examination shows lack of iris development; obtain genetic consult and urologic consultation to rule out and follow for Wilms tumor
Achromatopsia	High-frequency, low-amplitude nystagmus caused by lack of cone photoreceptor development; photophobia	Electroretinogram for photoreceptor function
Optic nerve coloboma	Nystagmus if severe and bilateral, strabismus if unilateral; CHARGE sequence, papillorenal syndrome	MRI of brain to rule out encephalocele and other structural anomalies; genetic and renal consultation to rule out other syndromes
Optic nerve hypoplasia	Nystagmus by 2 months if bilateral, strabismus if unilateral; septo-optic dysplasia/Aicardi syndrome; hypoglycemic at birth, signs of panhypopituitarism	MRI of brain—look for agenesis of corpus callosum, absence of septum pellucidum, absence or ectopy of pituitary bright spot, gray matter heterotopia in Aicardi syndrome
Retinopathy of prematurity	History of prematurity, oculodigital sign	Ophthalmic examination
Norrie disease	Nystagmus at 2 months, X-linked, bilateral retinal detachment with cataract	Ophthalmic examination; genetic consultation
Congenital cataract	Nystagmus at 2 months if complete cataract, strabismus if unilateral; stigmata of trisomies; metabolic signs if enzymatic or mitochondrial	Ophthalmic examination; if bilateral, consider galactosemia screen, urine amino acids (Lowe syndrome), urine for reducing substances, genetic consultation; examine parents to rule out autosomal-dominant cataract; TORCH evaluation

*Continued on following page*

**TABLE 6-4** Causes of Vision Loss, Associated Findings, and Diagnostic Recommendations (*Continued*)

Cause of Vision Loss	Associated Findings/Syndrome	Diagnostic Evaluation
Optic neuritis	Vision loss, possible pain with eye movements, afferent pupil defect, focal neurologic findings; ADEM, neuromyelitis optica (Devic disease), multiple sclerosis, syphilis, Lyme disease, cat-scratch disease, toxin (nutritional, ethambutol, methanol), Leber hereditary optic neuropathy	Ophthalmic examination, MRI, lumbar puncture with opening pressure, serology and monoclonal bands, infectious disease consultation, genetic evaluation if positive family history; test for Leber hereditary optic neuropathy
Optic atrophy	Vision loss, strabismus, associated focal neurologic findings, endocrine signs/symptoms, deafness, loss of milestones in NCL/neurometabolic disorders/Leigh disease; family history	Attention to pre- and perinatal history, neuroimaging, genetic consultation, endocrinologic consultation, assess for mitochondrial dysfunction
Cerebral visual impairment	Vision loss, stereotypic features: off/on, saccadic paresis; history of pre-/perinatal ischemia, intraventricular hemorrhage/prematurity, meningitis, cerebral developmental anomaly, cerebral palsy, seizure disorder	Neuroimaging; genetics if no known etiology
Refractive errors/amblyopia	Often sudden discovery or during screening examination; family history common; nonfocal neurologic examination; refractive errors correct with pinhole	Ophthalmic examination
Papilledema	Vision loss only if chronic or rapid onset, scotoma on change in position, constricted fields, esotropia with abducens paresis, headache, nausea; risk factors for idiopathic intracranial hypertension—obese, female, estrogen use, tetracycline, vitamin A, steroids, growth hormone, cerebral venous thrombosis	Ophthalmic examination—loss of spontaneous venous pulsations and edema of optic nerve, MRI and MRV, lumbar puncture with opening pressure

ADEM, acute disseminated encephalomyelitis; CHARGE, coloboma, heart defects, atresia choanae, retardation of growth and development, genitourinary problems, and ear anomalies; MRI, magnetic resonance imaging; MRV, magnetic resonance venography; NCL, neuronal ceroid lipofuscinosis; TORCH, toxoplasmosis, rubella, cytomegalovirus, herpes simplex virus; WAGR, Wilms tumor, genitourinary abnormalities, and mental retardation.

## Hearing Impairment

Lionel Van Maldergem, Guy Van Camp, and Paul Deltenre

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

### INTRODUCTION

The terms “hearing loss” (HL) and “hearing impairment” designate an abnormal auditory function whatever its type, localization, or the mechanism underlying it. In most circumstances the term “hearing loss” is used after a standard clinical audiogram has indicated elevated thresholds for detection of sound waves. But the hearing process cannot be reduced to this quantitative assessment. To fulfill its two main ecological functions, namely, keeping us aware of what is happening in our surroundings and sound-based communication, a normal auditory function must be able to influence behavior in a way appropriate to the meaning of the physical event having produced the detected sound. In real life, we do not perceive sound waves; we perceive mental images of their sources. Not only do we identify the sources around us, but also we are able to localize them in space. In case they are moving, we perceive whether they are approaching us or moving away. In most real-life situations there are several simultaneously active sound sources. The ears receive a mixture of sound waves, which our auditory system interprets to reconstruct the mental images of their respective sources. Our peripheral sensory organ named the cochlea provides the brain with a neural representation of sounds through the cochlear nerve. The cochlea does not perform source reconstruction: it has an analytic role based on filtering of complex multisource environmental sound waves, parsing them into an array of narrow frequency bands. The neural code conveyed by each afferent fiber of the cochlear nerve represents fluctuations in time of environmental sound intensities within a specific tonotopic frequency channel. As shown in [Figure 7-1](#), the output of each cochlear filter comprises two components: the temporal fine structure that represents the instantaneous acoustic pressure variations and the envelope describing the overall amplitude variations over time.

The central auditory nervous system (CANS) is faced with the enormous neurocomputing challenge of reconstructing sound sources from these individual spectro-temporal profiles. Processes by which the brain reconstructs our auditory environment from cochlear output have been named auditory scene analysis (ASA). These processes allow us to selectively attend to one among several speakers, a situation described as the cocktail party problem ([McDermott, 2009](#)). Deterioration of ASA mechanisms can occur in the absence of measurable threshold elevation and lead to auditory complaints taking the general form of poor understanding in noise despite normal thresholds, a combination recognized as obscure auditory dysfunction, King-Kopetzky syndrome, or central auditory processing disorder (CAPD). Efficiency of ASA processes can also be reduced as a consequence of peripheral sensory defects that not only cause a threshold elevation but also distort the primary neural code conveying the details of suprathreshold sound components.

### ANATOMY AND PHYSIOLOGY OF THE EAR AND AUDITORY SYSTEM

Interested readers will find information on the anatomy and physiology of the auditory system in the online version of this chapter as well as in recent books (e.g., [Pickles, 2012](#)) or on the Cochlea and Neuroreille websites (<http://www.cochlea.eu/en>; [http://www.neuroreille.com/promenade/english/start\\_gb.htm](http://www.neuroreille.com/promenade/english/start_gb.htm)).

### HEARING LOSS HL Classification

Multiple descriptive dimensions of HL are used to provide a comprehensive evaluation in a given patient:

#### Classification by Definition of Impairment Site

Current clinical and electrophysiological tools allow delineating four main categories:

- 1. Conductive HL.** This type of impairment is caused by defective transmission of sound to the cochlea. It can occur because of an external ear or middle ear defect. By definition, the inner ear remains normal. Owing to bone conduction, conductive HL never exceeds 60 dB.
- 2. Sensorineural HL.** This term points to a defect anywhere along the auditory pathway between the cochlea and the cerebral cortex. The vast majority are of endocochlear origin, a term referring to nonconductive HL secondary to cochlear defects, including the cochlear nerve in its intracochlear segment. Clinical and electrophysiological tools often do not allow precise identification of the defective structure involved in endocochlear deafness in contrast with major genetic advances made in recent years. Improved imaging and electrophysiological tools allow proper detection of many of the central defects.
- 3. Auditory Neuropathy Spectrum Disorder.** Preserved outer hair cell (OHC) responses (cochlear microphonic and/or otoacoustic emissions [OAEs]) and absent or severely disrupted auditory brainstem responses (ABR) including wave I are mandatory to make a diagnosis of auditory neuropathy spectrum disorder (ANSD). Many mechanisms interfering with the normal synchrony of the primary neural code sent to the brain by the cochlear nerves can lead to an ANSD profile ([Starr et al., 2008](#)). These include inner hair cell defects, ribbon synapse defects, or a defect of the cochlear nerve itself. Clinical manifestations are dominated by speech misunderstanding, usually worse than that which could be anticipated from the audiogram. Whenever the cochlear nerve alone is involved, a diagnosis of true neuropathy can be made.

**Figure 7-1.** Original acoustic waveform of the French synthetic syllable /ba/ (courtesy W. Serniclaes, ULB, Brussels) (A) compared with simulation of the output of three normal cochlear filters, respectively, centered on 0.5, 1, and 2 kHz (B), fed with the /ba/ waveform. Each cochlear filter extracts a spectral portion of the syllable and yields a composite signal describing variations of the temporal fine structure (red) and envelope (blue) components over time. CF, central frequency; ENV, envelope; TFS, temporal fine structure.

**TABLE 7-1** Hearing Loss Classification by Degree: ASHA and BIAP Schemes

Hearing Loss Classification by Degree			
Degree of HL	ASHA	BIAP	Speech Perception
	Average Loss (dB HL)		
Normal to <i>normal-subnormal</i>	-10 to 15	<20	
Slight	16 to 25	21 to 40	Normally voiced speech perceived; whispered/distant speech missed
Mild	26 to 40	—	
Moderate to <i>moderate 1st degree</i>	41 to 55	41 to 55	Voice level must be raised above normal to be perceived. Lip reading may be used to compensate.
Moderately severe to <i>moderate 2nd degree</i>	56 to 70	56 to 70	
Severe	71 to 90	70 to 90	Voice level must be raised and delivered close to the ear.
Profound	>90	>90	No speech perception

ASHA, American Speech-Language-Hearing Association; BIAP, European Bureau International d'Audio-Phonologie; HL, hearing loss.

**4. Central HL.** Compression of brainstem auditory pathways by neighboring tumors is rare in children. Intrinsic tumors such as brainstem gliomas may interfere with auditory function. Hypomyelinating and demyelinating diseases may occasionally cause central HL (Pelizaeus–Merzbacher disease, adrenoleukodystrophy, multiple sclerosis, acute disseminated encephalomyelitis). Cortical deafness describes very rare instances of abnormal auditory reactivity caused by extensive bilateral auditory cortex destruction or deafferentation. Electrophysiological recordings exclude a cochlear origin, whereas behavioral testing is indicative of auditory agnosia. Most cases are attributable to cerebrovascular diseases and usually occur in adults. Landau–Kleffner syndrome produces similar central disturbances, affecting children who often appear to have HL of various severities related to auditory agnosia. Classical kernicterus and mild forms often called bilirubin-induced neurologic dysfunction spare the cochlea but affect the auditory nerve and central auditory pathways depending on the degree of hyperbilirubinemia. Resulting hearing deficits may range from normal thresholds with defective central processing to profound deafness.

### Classification by Severity and Profile of Thresholds Elevation

Most severity scales categorize HL severity on the basis of average audiometric pure-tones thresholds obtained at three to four frequencies: 0.5, 1, 2, and 4 kHz. Thresholds are

expressed in dB on the hearing level scale used in clinical audiometry, and so 0 dB represents the average threshold of normal subjects whatever the frequency. Most systems share four main descriptive categories: mild, moderate, severe, and profound, but may vary in their details. Table 7-1 illustrates a simplified version of the classifications recommended by the American Speech-Language-Hearing Association (ASHA; <http://www.asha.org/public/hearing/Degree-of-Hearing-Loss/>) and the European Bureau International d'Audio-Phonologie (BIAP; <http://www.biap.org/index.php>).

### EVALUATION OF AUDITORY FUNCTION

Hearing tests are either behavioral (i.e., they seek a behavioral reaction to stimulus) or objective (i.e., independent from the subject's willingness and cognitive state), being based on stimulus-induced physiological responses.

#### The Cross-Check Principle

The cross-check principle, a cornerstone of pediatric audiology, states that a battery of independent tests is needed to provide an accurate description of hearing problems.

#### Behavioral Methods

Behavioral methods depend on the developmental age and neurologic status, and reliable thresholds are often impossible to obtain in pediatric patients with moderate to profound

intellectual disability. Even in normally developing children, one must wait until 36 months of age before reliable thresholds can be obtained across the entire population.

## Objective Methods

### Tympanometry

Acoustic immittance measurements by tympanometry yield a series of objective parameters: tympanic admittance or compliance, related to tympanic membrane mobility, Eustachian tube function, and external auditory ear canal volume, which is increased in case of perforated eardrum or permeable trans-tympanic ventilating tubes.

### Objective Audiometry

**Otoacoustic emissions.** OAEs are byproducts of sound processing by OHCs that lose control of a small fraction of incident energy and send it back to middle ear. OAEs are rapidly abolished with threshold elevation ( $\geq 35$  dB) in sensorineural HL (SNHL) involving OHCs, which is the case of most endocochlear HLs, but not of retrocochlear HLs and ANSD.

**Auditory evoked potentials.** They are classified according to three main characteristics: their latency range, time course, and dependency on cognitive processing. Early auditory evoked potentials (AEPs) represent the cornerstone of pediatric objective audiometry. Click-evoked ABRs are the centerpiece of electrophysiological evaluation of children at risk for hearing and complex neurologic disorders. Figure 7-6 illustrates how ABR morphology, amplitude, and latency evolve according to click level in a normal subject.

## IMAGING

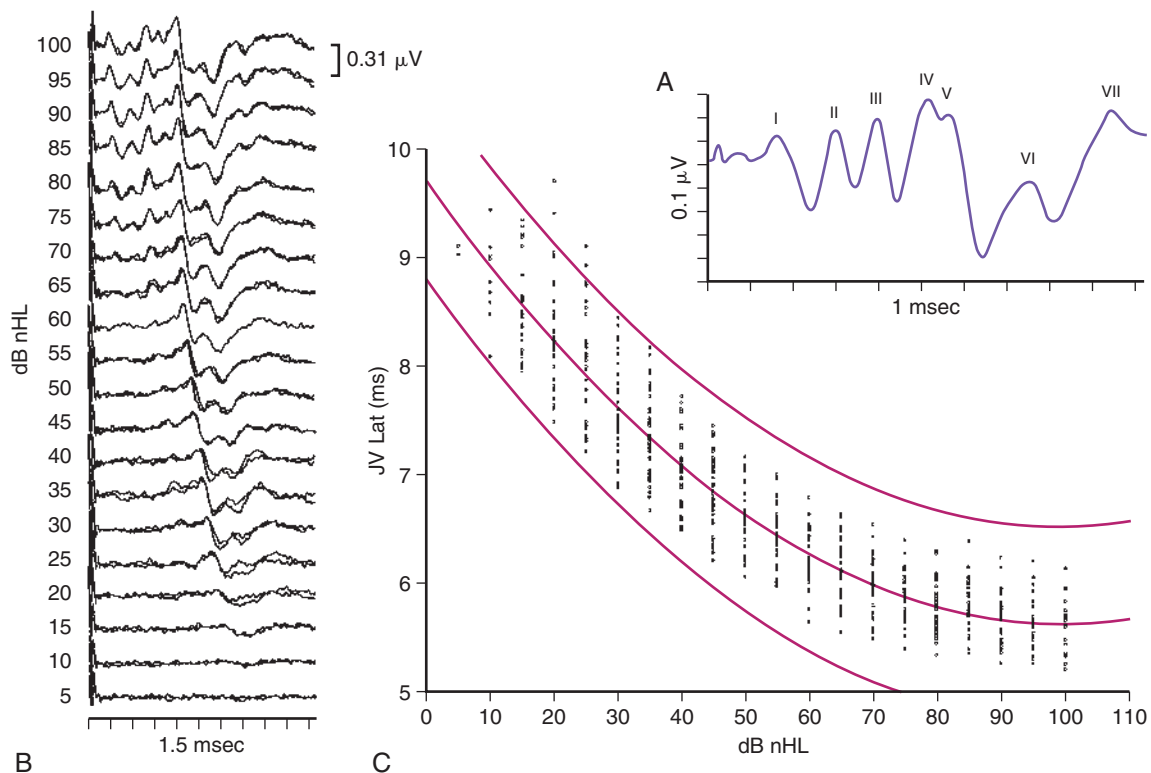

Magnetic resonance imaging (MRI) is the main technique used for patients with SNHL for defining intralabyrinthine and intracranial anomalies. Computed tomography (CT) is more useful for middle ear and temporal bone assessment.

## HEARING PROBLEMS IN THE PEDIATRIC POPULATION

### Conductive HL and External Ear Malformations

Conductive HL is the most common cause of HL in children. Eighty percent of all children have had at least one episode of otitis media with effusion by age 10 years. Reversible conductive HL often coexists with cochlear HL, the combination being designated as mixed HL. An additional conductive loss may severely reduce auditory performances in the case of cochlear HL.

Congenital malformations of the external or middle ear are often unilateral. Congenital anomalies of the external ear have an incidence of about 1:6000. Inner ear malformations are present in 11% to 30% of individuals with outer and middle ear malformations. External and inner ear malformations frequently have a genetic basis and are rarely acquired. Syndromes associated with pinnae malformation include the branchio-oto-renal syndrome (OMIM 113650); auriculo-facio-vertebral syndrome or Goldenhar syndrome (OMIM 164210); coloboma, heart defect, atresia choanae, retarded growth, genital and ear anomalies (CHARGE) syndrome (OMIM 214800); Treacher-Collins syndrome (OMIM

**Figure 7-6.** **A**, A normal click-evoked ABR waveform as it can be obtained from a normally hearing young subject. Stimulus level is 75 dB nHL. For brief stimuli such as clicks and tone-bursts, the nHL scale refers to the average threshold of a small group of normal subjects for a given stimulus. **B**, Effect of click intensity on ABR parameters: rise in latencies, drop in amplitudes, and progressive disappearance of early waves with reduction of intensity toward threshold. **C**, ABR wave V correlation between latency and intensity: individual data from 32 normal young subjects fitted by a quadratic function and 99% upper and lower confidence limits. Wave V is sometimes referred to as JV after D.L. Jewett, one of the ABR discoverers. ABR, auditory brainstem responses.

154500); and Townes–Brocks syndrome (OMIM 107480). The size and morphological alterations in these conditions are more frequently bilateral and rather symmetric. Chromosomal anomalies are also associated with external ear malformations as seen with autosomal aneuploidies, namely, Down syndrome, Patau syndrome (trisomy 13), and Edwards syndrome (trisomy 18), but also for more complex chromosomal rearrangements.

## Sensorineural HL

Permanent SNHL is the most prevalent sensory impairment in childhood, affecting 1/700 infants. SNHL may result from genetic or environmental factors and can be syndromic or nonsyndromic.

An enlarged vestibular aqueduct (EVA) is the most common inner ear malformation found in children with cochlear HL. The associated HL is variable in severity, may be asymmetric or unilateral, may be pre- or postlingual, and can fluctuate over time or suddenly progress.

It is frequently observed in *SLC26A4*-related autosomal recessive nonsyndromic hearing loss (ARNSHL) and Pendred syndrome, and rarely in CHARGE syndrome, Waardenburg syndrome (WS), or Branchio-Oto-Renal syndrome.

Toxoplasmosis, other (viruses), rubella, cytomegalovirus, herpes simplex (infection) (TORCH) infections may cause HL, often not isolated but associated with CNS involvement, including intracranial calcifications and destructive lesions seen on MRI and CT. CMV infection remains a frequent cause of acquired SNHL in neonates worldwide. Its prevalence is 0.58% in developed countries. CMV explains up to 21% of acquired HL at birth and up to 25% at the age of 4 years. Congenital toxoplasmosis and bacterial meningitis remain a concern, as up to 5% to 35% of survivors experience bilateral SNHL when infection occurs before the age of 2 years.

## Ototoxicity

Aminoglycosides antibiotics, mainly gentamycin, streptomycin, and vancomycin, are major ototoxic drugs, their deleterious role being modulated by the presence of m.1555A>G mutation. Macrolides may also be associated with some drug-induced deafness, as are antineoplastic cis- and carboplatin agents, rarely used in infancy and childhood. Nonsteroidal antiinflammatory drugs and antimalarial medications may also cause a reversible ototoxicity. High doses of ionizing radiation used in cranial radiotherapy have been reported to cause HL, as can excessive noise exposure.

## Auditory Neuropathy Spectrum Disorder

ANSD is not a rare entity: it is associated with 8% of newly diagnosed pediatric cases of HL and 10% of children with permanent HL. Both genetic and nongenetic causes have been established.

## GENETIC HEARING LOSS

Genetic HL can be divided into syndromic (SHL) and nonsyndromic forms (NSHL). Both have a monogenic cause in many cases, and all major types of inheritance patterns are observed. The most frequent type is autosomal recessive HL (ARNSHL) that accounts for almost 80% of cases. ARNSHL is typically congenital and severe to profound in nature, although at a later age at onset, milder forms or a progressive character is described in a minority of cases. Approximately 20% of cases are dominantly inherited, mostly of later onset and usually progressive (autosomal dominant nonsyndromic hearing loss;

ADNSHL). Infrequently, HL follows the rules of X-linked or mitochondrial inheritance. NSHL is a highly heterogeneous trait, with more than 80 genes identified. It is likely that many more gene abnormalities remain to be identified. A continuously updated overview of genes associated with hereditary HL is available online at the Hereditary Hearing Loss Homepage (HHLH; <http://www.hereditaryhearingloss.org>).

## Nonsyndromic Hearing Loss

Genes that have been associated with NSHL fall into different categories. Most show an expression pattern largely restricted to the inner ear, as they encode proteins involved in cochlea development or function. Others have a broad expression pattern, encoding proteins present in other organs. The frequency of HL mutation carriage in unaffected individuals varies across populations and ethnicities. Data are only available for a small number of genes.

### Autosomal Recessive Inheritance

ARNSHL is caused by mutations in a limited set of genes, including *GJB2*, *SLC26A4*, *MYO15A*, *OTOF*, *CDH23*, and *TMC1*. *GJB2* mutations represent the most frequently reported cause of ARNSHL. Over 100 different mutations have been reported in this gene (<http://davinci.org.es/deafness/index.php>). It is frequent in European countries close to the Mediterranean (up to 50% of ARNSHL cases). One is particularly prevalent in European populations because of a founder effect: 35delG.

Another common mutation is *SLC26A4*, which also is involved in a syndromic form of ARNSHL, Pendred syndrome, in which HL is accompanied by a thyroid goiter. However, as goiter usually appears later in life, or in some cases never appears, it is also considered an NSHL gene. An ARNSHL gene in which mutations are associated with a recognizable audiological phenotype is that encoding otoferlin (*OTOF*). Mutations in this audiological gene often result in prelingual, profound ARNSHL associated with an ANSD electrophysiological profile.

### Autosomal Dominant Inheritance

In contrast to ARNSHL where *GJB2*-related and *SLC26A4*-related HL are overrepresented, none of the ADNSHL genes is particularly frequent. Dominant mutations in *WFS1* encoding wolframin and those in *COCH* encoding cochlin are associated with a recognizable phenotype.

### X-Linked and Mitochondrial Inheritance

Although X-linked and mitochondrial inherited HL are not frequent, representing together less than 3% of cases, a couple of mutations are often included in diagnostic panels because of their nature (point mutations) or their associated anomalies (see syndromic HL section). Mutations in *POU3F4* cause an X-linked form of HL characterized by a mixed or purely sensorineural HL and temporal bone malformation on MRI. Its diagnosis has therapeutic consequences because the presence of a *POU3F4* mutation can represent a contraindication for stapes surgery, hence the importance of temporal bone imaging in any basic workup of congenital HL. One mitochondrial gene is especially noteworthy. This is *MT-RNR1*, encoding the mitochondrial small subunit ribosomal RNA. The 1555A>G substitution causes HL induced by administration of clinically appropriate doses of aminoglycosides. In some individuals, HL can be present without exposure to aminoglycosides, suggesting involvement of modifier genes.

## Genetic Diagnostics for Nonsyndromic Hearing Loss

For more than two decades, attempts at establishing the molecular basis of HL have been made by Sanger sequencing. Although genes routinely analyzed for NSHL may differ between countries and labs, some are more common (e.g., *GJB2*, *GJB6*, and *SLC26A4*), or those giving rise to a recognizable audiological or clinical phenotype when mutated (Table 7-2).

Traditional DNA diagnostic strategies usually deal with a small number of genes and a one-by-one sequential basis, meaning that the vast majority of HL genes remain unexplored outside a research setting. However, as next-generation sequencing (NGS) is becoming more available, it is now possible to sequence a large number of genes. Universities and private labs are able to offer testing for up to 125 HL genes, including both syndromic and nonsyndromic forms. In addition, multiple family members can be analyzed by NGS, allowing segregation studies, that is, characterization of those individuals from the family that inherited different genetic markers. This approach allows diagnosis of a specific HL type in a family, but also in up to 15% of families establishing a digenic inheritance by diagnosing a combination of two different types of deafness within the same family. However, although Sanger sequencing has a claimed sensitivity of 99%, the sensitivity of NGS-related techniques remains dependent on the number of reads, and a small percentage of mutations will be missed.

## Syndromic Hearing Loss

Syndromes in which deafness is not isolated but associated with other anomalies or involving other systems represent a

significant part (about one third) of the so-called genetic deafness. Two points deserve consideration (Toriello and Smith, 2013). The first is that of an enhanced interest in nonsyndromic deafness through availability of gene panels has rendered more frequent extensive audiological and imaging work-ups in previously unexplored children, thus dramatically increasing our knowledge of previously obscure rare conditions and drawing attention to new entities. This extended workup also led to reassignment of a number of nonsyndromic cases to the syndromic group by recognition of new entities and recognition of unsuspected known syndromes and subtle unreported clinical signs by reverse phenotyping. The other point pertains to the dramatic increase in the number of HL syndromes that has to be considered, and it is beyond the scope of this chapter to provide a detailed description of the clinical features of these syndromes (Hennekam et al., 2010).

Because of the large number of conditions causing HL, there is a need for differentiating the vast majority of conditions in which deafness is an occasional finding, entities remaining private by the small number of families described so far from *bona fide* regular and frequent HL syndromes. These, less than two dozen major deafness syndromes, most, if not all, following the rules of mendelian inheritance, will be the subject of this section (Table 7-3).

**Waardenburg syndrome.** WS is a clinically and genetically heterogeneous condition that manifests with HSNHL and abnormal pigmentation of the hair, skin, and iris. Four subtypes have been described. A neurologic variant (peripheral demyelinating neuropathy, central dysmyelinating leukodystrophy, Waardenburg syndrome, Hirschsprung disease, PCWH) has also been delineated. Its classical phenotype includes WS type 1 with telecanthus and *PAX3* mutations, WS type 2 without telecanthus and *MITF* or *SOX10* mutations, and

**TABLE 7-2** Frequently Analyzed NSHL Genes in Routine Genetic Diagnostics

Gene	Inheritance Pattern	Phenotype
<i>GJB2</i>	AR	Most frequent gene associated with ARNSHL in many populations. Its mutations in <i>GJB2</i> give rise to severe to profound HL in most cases, although rarely mild to moderate HL is observed. It may be combined with <i>GJB6</i> deletion.
<i>SLC26A4</i>	AR	Both a frequent gene and a recognizable phenotype. Enlargement of vestibular aqueduct or Mondini dysplasia is seen on inner ear imaging. Mutations in this gene are also determining Pendred syndrome.
<i>OTOF</i>	AR	Congenital severe hearing loss caused by auditory synaptopathy, characterized by initially normal otoacoustic emission responses and preserved cochlear microphonic, whereas auditory brainstem responses are absent.
<i>TECTA</i>	AR/AD	By contrast to most cases of ARNSHL, which are severe to profound in nature, a milder phenotype is observed in <i>TECTA</i> -related ARNSHL (OMIM 603629). HL is typically moderate to severe, mainly affecting the midfrequencies. There is heterogeneity of mode of inheritance for <i>TECTA</i> -related HL, because some mutations give rise to an autosomal dominant transmission (ADNSHL; OMIM 601543).
<i>WFS1</i>	AD	Mild or moderate nonprogressive HL, only affecting the low frequencies. An autosomal recessive syndrome with multisystemic involvement is observed in case of homozygosity or compound heterozygosity (Wolfram Syndrome; OMIM 222300).
<i>COCH</i>	AD	Usually onset in the third decade with progressive hearing loss, accompanied by vestibular dysfunction, leading to absence of cochlear and vestibular function after during the fourth decade. The condition is particularly frequent in Belgium and the Netherlands because of a founder effect of P51S mutation (OMIM 603196).
<i>POU3F4</i>	XL	Sensorineural or mixed hearing loss associated with defects in bony labyrinth, including enlargement of the auditory canal, Mondini dysplasia, and/or stapes fixation (OMIM 300039).
<i>MT-RNR1</i>	Mitochondrial	m.1555A>G mutation in this gene is a relatively frequent cause of an aminoglycoside-induced HL, although in some cases it causes HL without aminoglycoside exposure.

This table contains a list of frequently analyzed NSHL genes in routine genetic diagnostics because of their high prevalence like *GJB2* and *SLC26A4* or as a result of the distinctive recognizable pattern of the HL they are associated with, differing from the severe to profound sensorineural HL caused by most genes. ADNSHL, autosomal dominant nonsyndromic hearing loss; ARNSHL, autosomal recessive nonsyndromic hearing loss; CM, cochlear microphonic; HL, hearing loss; NSHL, nonsyndromic hearing loss.

**TABLE 7-3** Examples of Syndromes Involving Hearing Loss

Syndrome	Syndromic Features
Alport syndrome (OMIM 301050, 203780, 104200)	Kidney
Branchio-oto-renal syndrome (OMIM 113650)	Kidney, external ear
Treacher–Collins syndrome (OMIM 154500)	Craniofacial
Pendred syndrome (OMIM 274600)	Endocrine
Waardenburg syndrome (OMIM 193500, 193510, 148820, 277580)	Integuments, eye
Jervell–Lange–Nielsen syndrome (OMIM 220400)	Heart
Usher syndrome (OMIM 276900, 276901, 276902)	Eye

This table contains a list of syndromes associated with hearing loss and their syndromic feature. For additional information, please refer to the following section and/or to specific (<http://www.ncbi.nlm.nih.gov/omim>) and (<http://www.ncbi.nlm.nih.gov/books/NBK1434/>).

type 4, sometimes called WS, recessive phenotype, which is a severe, early-onset subtype often associated to Hirschsprung syndrome. There is genetic heterogeneity of this subtype, with mutations in genes encoding endothelin 3, its receptor, and mutations in *SOX10*, encoding a transcription factor being also at cause in recessive forms. In *SOX10*-related type 4 WS, temporal bone imaging studies frequently show an enlarged vestibular aqueduct that could point to the diagnosis. Interestingly, some *SOX10*-mutated patients have instead of WS, a Kallmann disease phenotype, and some others have a sporadic deafness-only phenotype, without any pigmentary, olfactive, or dysmorphic features, that can be diagnosed by appropriate interpretation of temporal bone MRI. Since 1998, approximately 100 heterozygous point mutations or deletions of *SOX10* have been reported, first in WS4 (WS with Hirschsprung disease), then in its neurologic variant, and recently in WS2. Although very rare, mutations in genes encoding endothelin 3 or receptor (*EDN3*-related, *EDNRB*-related) are also described. The common features of WS syndrome are SNHL and depigmentation of scalp, skin, and irides. A white forelock is the most remarkable sign, but premature, widespread graying of hair or depigmented skin macules are seen. Because of variable expressivity common to AD disorders, asking for the presence of this type of anomalies in relatives during the taking of a patient's history is of value in cases of apparently sporadic deafness: it is not uncommon to have a hearing relative with one or several of these signs. Type 3 WS is an exceedingly rare occurrence of homozygosity for *PAX3* mutations determining a more severe phenotype that includes short stature and bone deformity.

**Usher syndrome.** US is another instance in which the differential timing at onset of different components of the syndrome may critically delay diagnosis. US comprises three main phenotypes. US type I combines congenital profound HL with vestibular areflexia, followed by delayed progressive retinitis pigmentosa (RP). Vestibular function is preserved in types II and III. Because vision is doomed to extinction in US, it is particularly important to perform cochlear implantation at an early age in order to optimize speech development before the visual channel is lost. Visual impairment can be diagnosed by fundoscopy and by electroretinography (ERG), the latter allowing a more reliable and earlier detection of RP. In US type I, the earliest clinical signs are delayed walking and hypotonia because of the vestibular deficit, and so these

findings in a congenitally profoundly deaf child should prompt ERG investigations. US is the principal cause of deaf-blindness.

**Treacher–Collins syndrome.** Also known as Franceschetti–Klein syndrome, Treacher–Collins syndrome is the most frequent mandibulofacial dysostosis. It has a very characteristic facial dysmorphism that combines hypoplasia of zygomatic bones and mandible, external ear abnormalities, notching of lower eyelid, malar hypoplasia, downward slant of palpebral fissures, and microretrognathia. It is often associated with medial cleft palate. HL is present in nearly 50% affected individuals. It is of the conductive type, with fusion or undermodeling of the ossicles being at cause. Although dysmorphic features of variable severity are present at birth, conductive deafness may become obvious only later in life. Besides a prevalent autosomal dominant form caused by heterozygous mutations in *TCOF*, autosomal recessive forms have been demonstrated to be caused by mutations in genes encoding subunits of the polymerase complex *POLR1D* and *POLR1C*.

**Refsum disease and infantile Refsum disease.** Although very rare, Refsum disease deserves mention because early diagnosis, often based on detection of visual impairment associated with anosmia and neurologic features, can lead to specific treatment and prevent otherwise irreversible complications. This is a singular inborn error of metabolism linked to a single peroxisomal enzyme deficiency, either the one encoding phytanoyl-CoA hydroxylase or *PEX7*. It induces signs and symptoms that include peripheral neuropathy, ichthyosis, visual impairment due to retinitis pigmentosa and, lately, hearing loss. Dietary lowering plasma concentration of phytanic acid or iterative plasmapheresis allows a partial control of progression of ichthyosis, peripheral neuropathy, and/or RP.

There are other inborn errors of metabolism in which progressive HL has been linked to accumulation of toxic metabolites. Very-long-chain fatty acids, biliary acids, and phytanic acid are such metabolites thought to play such a role in much more severe conditions belonging to the group of generalized peroxisomal disorders or peroxisome biogenesis defects. For historical reasons, one of these severe diseases has been unfortunately given the name infantile Refsum disease, resembling too closely to the completely different adult Refsum disease and a source of confusion, as the neurodevelopmental outcome of the former is much more severe than that of the latter. More than 40 different enzyme deficiencies versus a single enzyme deficiency explain this discrepancy. Stabilization or even regression of HL has been achieved after orthotopic liver or hepatocyte transplantation in infantile Refsum disease.

**SLC26A4-related deafness, Pendred syndrome.** This mixed type of autosomal recessive deafness is usually nonsyndromal, accounting for about 12% of AR cases and is the second cause after connexin 26-related deafness. However, a small percentage of mutated patients have thyroid gland dysfunction and goiter, usually manifest during the second decade of life, defining one of the first deafness syndromes described by Pendred in 1896.

**CHARGE syndrome.** Elucidation of the molecular basis of what has been called CHARGE association (and not syndrome) for decades, an acronym for *coloboma*, *heart* defects, *atresia choanae*, *retardation* of growth and development, *genitourinary* problems, and *ear* malformation by a Dutch group in 2004, resulted in considerable expansion of its clinical phenotype, *CHD7* heterozygous mutation, now being observed not only in a number of incomplete phenotypes, but also in case of sporadic deafness observed in association with isolated or multiple cranial nerve palsies.

Also, it does not occur as a *de novo* mutation, but as a mutation inherited from an asymptomatic parent in up to 10% of

the cases. In terms of genetic counseling, to differentiate between these distinct situations is of importance (<1% vs. 50% recurrence risk). Deafness in this syndrome can be caused by a cochlear malformation or auditory nerve absence. In contrast to other causes of deafness, moderate to severe intellectual disability is very common and makes prenatal diagnosis and early family counseling concerning quality of life issues an option.

**Mitochondrial deafness.** Maternal inheritance occurs commonly but not universally in mitochondrial disorders, partly due to the fact that genotype does not predict phenotype, by contrast to disorders resulting from mutations in nuclear-encoded genes. It is worth noting that an important part of mitochondrial disorders are due to mutations in these nuclear-encoded genes. From a clinical point of view, mt.3243G>A mutation is important as it may induce deafness in association with a wide spectrum of other symptoms. In intermediate situations, deafness is found in association with insulin-dependent diabetes mellitus, or more complex phenotypes with either ataxia or stroke-like episodes, in the context of lactic acidosis.

Another interesting deafness/mitochondrial mutation is the m.1555A>G mutation, for its double-sided expression: on the one hand, it may give rise to a classical postlingual deafness in the absence of any triggering factor; on the other hand, it is associated with deafness related to aminoglycoside exposure. There are many other mitochondrial DNA mutations that are associated with deafness (OMIM). Co-occurrence of an associated movement disorder, cardiomyopathy, and elevated creatinine kinase level, presence of a tubulopathy, or lactic acidosis should prompt consideration of this possibility.

**Alport syndrome.** In this condition, postlingual HL is associated with kidney disease detected by hematuria prior to end-stage renal insufficiency. It is important to recognize because it is inherited in most cases as an X-linked recessive condition, with up to 15% of carrier females eventually becoming symptomatic. Its cardinal features are hematuria with subsequent renal insufficiency leading to dialysis and renal transplantation in a majority of patients. SNHL deafness generally occurs after the onset of renal disease. Carrier females are at risk of giving birth to affected male offspring, and in addition to determination of whether or not they have deafness, a urinalysis to screen for hematuria is indicated. Additional genetic studies of the family may be helpful as the mutation may not occur *de novo*. The alpha 5 chains of type 4 collagen are deficient, because of mutations in the corresponding gene *COL4A5*. Rarely, the disease is transmitted in an autosomal recessive manner, with an increased severity and mutations affecting *COL4A3* and *COL4A4*.

**Marshall–Stickler spectrum.** This syndromic autosomal dominant condition, also because of a collagen deficiency, is remarkable by its distinctive dysmorphic features that include flattening of the face, nasal hypoplasia and upturned nares, eye involvement (high myopia, retinal detachment), high arched palate and/or cleft palate, micrognathia, and short stature. Mutations are usually identified in the gene encoding the alpha 1 chain of type 2 collagen (*COL2A1*), but have also been described in association to involvement of type 9 collagens.

**Jervell–Lange–Nielsen syndrome.** Autosomal dominant and recessive forms of a similar condition coexist and are characterized by the long QT syndrome, which is inconstantly associated with HSNHL in the context of the presence of voltage-gated potassium channelopathies (KCNQ1 and KCNE1). Because profound to moderate deafness is the clinical presentation and prolonged QT interval can only be diagnosed after recording an electrocardiogram (ECG), it is of paramount importance to include this test in the evaluation of a congenitally deaf patient or even in children or older

patients with postlingual deafness. In patients with Jervell–Lange–Nielsen Syndrome, appropriate treatment (beta-blockers) and surveillance could be initiated, keeping in mind that sudden death because of ventricular fibrillation is the most severe complication. In some families, there is a history of intrauterine fetal death.

## CONSEQUENCES OF HEARING IMPAIRMENT

Consequences of HL are to be understood in the context of speech development during critical maturational periods (Kral, 2013). Lack of auditory reference to real words, objects, and events leads to adverse cognitive effects. Uncorrected congenital or early acquired profound HL has far reaching consequences impinging on literacy development and cognitive abilities. There is accumulating evidence that this is also true for mild losses and even unilateral ones. Intervention programs recommend screening before 1 month, definite diagnosis no later than 3 months, and intervention by 6 months (Joint Committee on Infant Hearing). Any provider of pediatric healthcare involved with a child whose diagnosis or intervention program is not secured could play a major role in this respect. It cannot be overemphasized that in caring for a child with suspected HL or who has known risk factors (e.g., congenital CMV infection, positive family history), passed neonatal screening does not exclude significant HL as it may be delayed in onset or progressive in nature (Kral and O'Donoghue, 2010).

## CLINICAL EVALUATION AND SPECIALIZED TESTING OF SUSPECTED HL

### Patient and Family Histories

A detailed family history and pedigree are an integral part of the evaluation of every newly identified hearing-impaired child. Of importance is the pedigree reconstruction. Each parent should be questioned on his/her sibship with first name, maiden name, year of birth, number of offspring, and miscarriage(s). Special attention should be paid to grandparents, the place where they were born, and any history of hearing impairment, keeping in mind that presbycusis is physiological after age 50. Of significance is any kind of relationship between the parents, pointing to autosomal recessive inheritance.

### Clinical Evaluation and Specialized Testing

Once the pedigree and a detailed clinical history have been completed, a suspected mode of inheritance can usually be ascertained. If HL is thought to be of sporadic occurrence, one must still consider that autosomal recessive inheritance is possible as is autosomal dominant inheritance as a *de novo* mutation, or when a parent is mildly affected (variable expressivity). In addition, nonpenetrance, as well as mitochondrial inheritance or X-linked inheritance remains to be considered. Likewise, the absence of family history does not preclude a genetic basis and the possibility of an environmental etiology must also be looked for.

The clinical examination is of great importance and may yield diagnostic clues. In addition to growth parameters, attention should be paid to whether there are facial dysmorphic features, abnormal pinnae, branchial cleft pits, cysts or fistulae, preauricular pits or nodules, telecanthus, heterochromia iridis and pigmentary anomalies, high myopia, pigmentary retinopathy, increased or decreased occipitofrontal head circumference, nasolabial folds, submucous cleft palate, goiter, limb anomalies, organomegaly, disproportionate short or

tall stature, muscle wasting, ataxia, and so on. Neurologic examination should determine the presence or absence of pyramidal signs, cranial nerve involvement, a movement disorder, and abnormal deep tendon reflexes. In autosomal dominant forms of syndromic HL that tend to have a variable expression, a key diagnostic feature may be found in a relative rather than in the proband. A complete blood count is important, including platelets size, as megathrombocytopenia is a good marker of *MYH9*-related deafness (OMIM 153650). The presence of hematuria on a urinalysis may suggest Alport syndrome (OMIM 301050, 203780, 104200) and Fanconi syndrome.

Screening for inborn errors of metabolism, especially mitochondrial when diabetes mellitus, ptosis, cardiomyopathy, failure to thrive, or seizures are present. Screening for disorders of amino acid and organic acid metabolism, obtaining plasma lactate and pyruvate levels, and chemistry profiles, including liver enzymes, are all helpful.

A muscle biopsy with biochemical and immunological study of the respiratory chain can be instrumental if additional clinical signs and symptoms are compatible with a mitochondrial cytopathy. Elevation of liver enzymes, associated with a visual deficiency or the presence of retinitis pigmentosa in an infant or toddler, should elicit a search for a peroxisomal biogenesis defect, including assessment of very-long-chain fatty acids, bile acids, and phytanic acid followed by a skin/liver biopsy in case of positive findings. A lysosomal storage disorder must be considered if the liver or spleen is enlarged, and if there are coarse facial features or stiff joints, distended abdomen, or a history of chronic otitis media assessment for a storage disorder should be considered. A search for vacuolized lymphocytes is a basic test, as is the search for an accumulation of urinary glycosaminoglycans. However, the first one requires expertise and the latter has a low specificity. Hence, asking for direct assessment of suspected enzyme deficiency in fresh leukocytes may accelerate the diagnostic process. For example, detection of iduronate-sulfatase is indicative of Hunter disease and alpha-iduronidase is indicative of Hurler syndrome. In a different set of conditions, skin lesions may provide diagnostic clues. Examples include the presence of angiokeratoma in patients with Fabry disease or an oligosaccharidosis like beta-mannosidosis and H syndrome, a recently described histiocytosis with cutaneous rash and frequently associated HL. It introduces a new class of genetic deafness where inflammatory cutaneous lesions can give suggest a different category of diagnostic entities. A second example includes the pigmentary anomalies seen in patients with WS.

## Audiological Evaluation

Recommendations on techniques that should be applied and information that should be gathered have been issued for the audiological assessment of infants between birth and 6 months. Recommendations to fit the needs of older subjects with delayed development, multiple handicaps, or increased risk of auditory nervous system anomalies may be summarized and commented on as follows:

1. External and middle ears assessment by otoscopy and tympanometry, including acoustic reflexes and appropriate selection of probe frequency according to age
2. Evoked potentials recording to define type, degree, and configuration of HL and detect abnormal neural conduction along the cochlear nerve and/or brainstem pathways
3. Otoacoustic emissions
4. Behavioral audiometry
5. Speech detection and recognition

6. Follow up and monitoring of the infant's communication skills. Several forms of HL are delayed or progressive. It has been estimated that 1/56 children with permanent HL at 1 year had delayed-onset HL.

## MANAGEMENT OF HEARING LOSS

A primary aim of rehabilitation efforts is promoting or restoring an infant's or child's communication skills and optimizing the level of language development on which cognitive and socioemotional behavior is contingent. A secondary aim is to provide environmental auditory object identification and localization. Efficient management often requires the combined expertise of otologists, audiologists, speech and language therapists, psychologists, special educators, and social workers. Currently available assistive devices (conventional hearing aids, cochlear implants, frequency modulation systems) allow many severe to profound HL children to be to a regular classroom setting.

### Reconstructive Surgery for External and Middle Ears Malformation

Surgery is usually performed after the age of 8 years. Meanwhile, at least in children with HL, bone conduction hearing aids must be fitted early to avoid hearing deprivation during critical developmental periods.

### Choice of Communication Mode for Severe to Profound HL

Among the two main communication strategies, namely, speech-based (oralism) and sign-based (sign language), the oral mode is usually preferred to sign communication to promote integration in the hearing population. In some individuals, parents will make the choice of acculturation of their child to the deaf signing world rather than to the hearing, speaking one, because, being profoundly deaf themselves, they use sign language in daily life or because they wish to respect and protect the communicative and social modes developed by their child. Choosing between these options is not a simple matter and has to be thoroughly discussed with the parents and the multidisciplinary rehabilitation team, before selecting what appears most appropriate for an individual child and his/her family.

### Assistive Devices

Two main types of assistive devices are used to restore or improve auditory perception: conventional hearing aids (amplification devices) and cochlear implants. Frequency modulation systems are of great help: acquiring the teacher's speech by a collar-worn directional microphone, the system sends the target signal to the child's hearing aid by radio waves, and so ambient noise surrounding the subject is not amplified as it would have been with a child-worn microphone. Binaural amplification is recommended because it improves sound source localization and hearing in noise performances.

### Cochlear Implants

Cochlear implants are now well established as the gold standard for restoring useful hearing in bilateral severe-to-profound HL for which amplification fails to allow satisfactory progress. The best results are obtained in two situations: cases of postlingually acquired deafness and early implantation of congenital cases. The optimal age for implanting congenital cases is between 6 months and 2 years.

## Brainstem Implants

An auditory brainstem implant stimulating the surface of cochlear nucleus can be indicated when cochlear implantation is impossible. The main indication for auditory brainstem implantation is type 2 neurofibromatosis.

## FUTURE DEVELOPMENTS

Advances in HL research over the next decade will focus on electrophysiological applications to better understand the mechanisms of speech development, use of newer imaging technologies, improvement of conventional hearing aid functionality, and in the implementation of hearing restoration therapies. Measurement of the quality of neural coding within the CANS using digital signal processing techniques and perceptual training will possibly improve central representation of speech items. Functional imaging and diffusion tensor imaging are likely to be useful in the study of functionally or structurally abnormal CANS pathways. Digital signal processing techniques that can now be implemented in conventional hearing aids should contribute to alleviate the consequences of at least some forms of neural code distortion. Gene, stem cells, and molecular therapies are beginning to show efficiency in animal models, and it is hoped that they will be applied to use in humans in the forthcoming decades.

## Vertigo

Joseph M. Furman and Amy Goldstein

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

### INTRODUCTION

Vertigo in children may escape recognition because of the child's inability to describe the symptoms, the short duration of most vertiginous episodes, the presence of overwhelming autonomic symptoms, or the mistaken idea that an episode of vertigo may be a manifestation of a behavioral disorder.

Vertigo is defined in clinical practice as a subjective sensation of movement, such as spinning, turning, tilting, or whirling, of the patient or the surroundings. Dizziness is a nonspecific term used by patients to describe sensations of altered orientation to the environment that may or may not include vertigo, and often is used to describe lightheadedness or presyncopal symptoms.

Although vertigo may be a symptom of a vestibular disorder in the pediatric population, patients react to and describe dizziness in different ways in relation to their age. For instance, young children cannot accurately relate symptoms of dizziness. Preschool children rarely complain of vertigo or dizziness but may feel clumsy or be perceived as such by family or teachers. Older children and adolescents are usually able to explain their symptoms well, with their explanations differing little from the explanations of adults.

In any case, a vestibular abnormality should be suspected in a child who is observed to be clumsy or displays unprovoked fright, or who spontaneously clings to a parent. Sudden and recurrent bouts of unexplained nausea and vomiting also are suggestive of a vestibular abnormality.

In children, as well as in adults, a careful history, physical examination, and laboratory testing can establish the cause of dizziness in most patients.

### PHYSIOLOGIC BASIS OF BALANCE

When a hair cell is stimulated by rotation, translation, or change in orientation with respect to gravity, the firing rate in the eighth nerve fiber innervating that particular hair cell either increases or decreases. Movements that cause the stereocilia to bend toward the kinocilium result in a depolarization of the hair cell and cause the eighth nerve fiber to increase its firing rate, whereas movements that bend the stereocilia away from the kinocilium decrease the neural firing in the eighth nerve. The eighth nerve synapses in the vestibular nuclei, which consist of superior, medial, lateral, and inferior divisions. In addition to the input from the labyrinth, the vestibular nuclei receive input from other sensory systems, such as vision, somatic sensation, and hearing. The sensory information is integrated and the output from the vestibular nuclei influences eye movements, truncal stability, and spatial orientation.

The oculovestibular reflex is a mechanism by which a head movement automatically results in an eye movement that is equal to and opposite of the head movement so that the visual axis of the eye stays on target: that is, a leftward head movement is associated with a rightward eye movement and vice versa. Another feature of the oculovestibular reflex is that the two vestibular nuclear complexes on either side of the

brainstem cooperate with one another in such a way that, for the horizontal system, when one nucleus is excited, the other is inhibited. The central nervous system (CNS) responds to differences in neural activity between the two vestibular complexes. When there is no head movement, the neural activity, i.e., the resting discharge, is symmetrical in the two vestibular nuclei. The brain detects no differences in neural activity and concludes that the head is not moving (Fig. 8-1A). When the head moves, e.g., to the left, endolymph flow produces an excitatory response in the labyrinth on the side toward which the head moves, e.g., on the left, and an inhibitory response on the opposite side, e.g., on the right. Thus neural activity in the vestibular nerve and nuclei, e.g., on the left and right, increases and decreases respectively (Fig. 8-1B). The brain interprets this difference in neural activity between the two vestibular complexes as a head movement and generates appropriate oculovestibular and postural responses. This reciprocal push-pull balance between the two labyrinths is disrupted as a result of labyrinthine injury.

An acute loss of peripheral vestibular function unilaterally, e.g., on the right, causes a loss of resting neural discharge activity in that vestibular nerve and the ipsilateral nucleus (Fig. 8-1C). Because the brain responds to differences between the two labyrinths, this will be interpreted by the brain as a rapid head movement toward the healthy labyrinth, i.e. vertigo. "Corrective" eye movements are produced toward the opposite side, resulting in nystagmus, with the slow component moving toward the abnormal side, e.g., the right, and the quick components of nystagmus moving toward the healthy labyrinth, e.g., the left.

### EVALUATION OF PATIENTS WITH DIZZINESS

At the initial visit, in addition to the chief complaint, a complete medical history that includes associated symptoms, medical history, family history, and medication use is mandatory.

After the interview, a complete physical examination should be performed, with particular emphasis on the cranial nerves, including an examination of eye movements.

In some patients, further testing may be medically necessary if the diagnosis is not clear, including the use of vestibular testing in a specialized laboratory.

### History

#### Chief Complaint

It is important that the child explain the symptoms in his or her own vocabulary and describe associated sensations, such as headache, nausea, vomiting, or motion sickness. It might be helpful to relate the patient's symptoms to experiences, such as being on a merry-go-round or a boat. It is important to establish the onset, duration, and frequency of dizziness episodes and to associate the episodes with certain activities. Triggering factors include change in position, coughing or sneezing, sleep deprivation, and psychological stressors.

**Figure 8-1.** Schematic illustrations of the “push-pull” effect of the oculovestibular reflex. **A**, No head movement in healthy subject. **B**, Head movement to the left in healthy subject. **C**, Right acute peripheral vestibular injury.

The clinician should inquire about the presence of hearing loss, its onset, evolution or progression, fluctuation and worsening, and improving or stable status. Does the patient have tinnitus or a feeling of fullness? Is the hearing loss bilateral or unilateral? To establish the presence of neurologic symptoms, the clinician should determine whether there have been instances of seizure activity, altered mental status, ataxia, weakness, numbness, disturbances of swallowing or taste, coughing, facial paralysis, or blurring and loss of vision.

## Physical Examination

In addition to a complete neurologic examination, the child should also be observed when walking or running for incoordination of movements, i.e., ataxia. Also, an assessment of nystagmus is especially important. Spontaneous nystagmus is an involuntary, rhythmic movement of the eyes not induced by any external stimulation. Spontaneous nystagmus has two components: slow and fast. Nystagmus is named by the fast component, which is easily identified. Spontaneous nystag-

mus is tested by having the patient look straight ahead with and without fixation (i.e., in primary gaze). Gaze-evoked nystagmus is assessed by having the patient deviate the eyes laterally (no greater than 30 degrees) with fixation. End-gaze nystagmus with eyes fully deviated laterally is a normal finding. Positional testing is performed with the use of maneuvers that may produce nystagmus or vertigo. Static positional nystagmus is assessed by placing the patient in each of these six positions: sitting, supine, supine with the head turned to the right, supine with the head turned to the left, and right and left lateral positions. Positional nystagmus presents as soon as the patient assumes the position and persists for as long as the patient remains in the provocative position. Assessment of vestibulospinal function with a foam pad should be performed with or without a visual conflict dome.

In addition to a history and physical examination, an assessment may include vestibular testing. Vestibular laboratory testing is recommended in any child with a history of vertigo in whom a thorough history and physical examination have not established a diagnosis, in order to differentiate between a peripheral or central vestibular lesion, and to identify the side of the lesion in a peripheral abnormality. In addition, vestibular laboratory testing provides permanent documentation, and changes can be followed by repeat testing. Vestibular laboratory testing includes oculovestibular and vestibulospinal tests. Both types of tests provide only an indirect measure of the function of the vestibular end organs, in that they rely on measures of motor response, e.g. eye movements or postural sway, resulting from vestibular sensory input.

## Videonystagmography

Videonystagmography is currently the most widely used method of recording eye movements; it uses infrared light. Ocular motor testing, positional testing, and caloric testing constitute a common test battery that requires about 1 hour. Sedatives and vestibular suppressant medications should be discontinued for 2 days before testing. Ocular motor testing evaluates neural motor output independent of the vestibular system. Abnormalities in the ocular motor system may cause misleading conclusions from vestibular testing that relies on eye movements. Testing saccades uses a computer-controlled sequence of target jumps. Saccade abnormalities are defined as overshooting the target (hypermetric saccades) and undershooting the target (hypometric saccades). Disorders in the saccadic system suggest a CNS abnormality. Spontaneous nystagmus and gaze-evoked nystagmus are recorded with and without fixation (closing the eyes or darkness), and by asking the patient to look 30 degrees to the right and left. Spontaneous nystagmus present in darkness without fixation, which decreases or resolves with visual fixation, suggests a peripheral vestibular disorder. However, spontaneous nystagmus that is present with fixation and does not significantly decrease with loss of fixation is most likely a CNS abnormality. Ocular pursuit involves asking the patient to follow a moving target back and forth along a slow, pendular path. Normal subjects can follow a target smoothly without interruption. Abnormalities of pursuit tracking are caused by lesions in the CNS. Laboratory testing of optokinetic nystagmus uses black-and-white stripes moving left and right. Abnormalities include asymmetries or absence of responses, which suggest a CNS abnormality.

Positional testing includes both static and paroxysmal (dynamic) testing. As in the clinical assessment, during static positional testing, the patient is placed in the sitting, supine, head left, head right, left lateral, and right lateral positions in darkness. Static positional nystagmus, contrary to paroxysmal nystagmus, presents as soon as the patient assumes the

provocative position and persists for as long as the patient stays in that position. Static positional nystagmus is a nonspecific, nonlocalizing vestibular sign. Paroxysmal positional testing employs the Dix–Hallpike maneuver, a maneuver that involves bringing the patient from sitting with the head straight to sitting with the head turned 45 degrees to one side to lying down with the head still turned and the neck extended 20 degrees below the horizontal. The patient is then seated upright again, and the maneuver is repeated with the head turning to the opposite side. Upon attainment and maintenance of each head-back stance, the eye movements are noted. Latency to onset of nystagmus, a rotational component to the nystagmus, and attenuation of the nystagmus with maintenance of the position all suggest the diagnosis of benign paroxysmal positional vertigo, especially if this maneuver reproduces the patient's symptoms. This condition is rare in children and, when present, is thought to be a childhood migraine variant.

### Caloric Testing

Caloric testing aims to assess each labyrinth separately by producing nystagmus via thermal stimulation of the vestibular system. The patient is placed in a position in which the horizontal semicircular canals lie in the vertical plane (head elevated 30 degrees). Caloric stimulation causes a convection current in the horizontal semicircular canal that causes a deflection of the cupula (into which the hairs of the hair cells are embedded) and a change in activity of the vestibular nerve. Cold irrigation produces a fast nystagmus component away from the irrigated ear; warm irrigation produces a fast nystagmus component toward the irrigated ear. The common mnemonic COWS “cold opposite, warm same,” refers to the direction of the fast-beating nystagmus. Binaural bithermal caloric testing uses stimuli of 30° C and 44° C, and each canal is irrigated for 30 seconds with 250 mL of water. There is a rest period of 5 minutes between irrigations. The most common method of measuring the caloric response is to compute the peak slow-component velocity of the nystagmus induced by the thermal stimulus, which reflects the intensity of the vestibular response. To compare the responsiveness of one ear to the other ear, it is established practice to use Jongkees' formula to compute a percentage of reduced vestibular response:

$$\frac{[(R30^\circ + R44^\circ) - (L30^\circ + L44^\circ)]}{[R30^\circ + R44^\circ + L30^\circ + L44^\circ]} \times 100 \text{ percent}$$

For many laboratories, normal limits are considered to be a reduced vestibular response of more than 24%. A reduced vestibular response suggests a peripheral vestibular lesion.

### Rotational Testing

Rotation is the natural stimulus to the semicircular canals. Rotational testing causes minimal discomfort and is precise and well tolerated, even by infants and young children (who can be placed on a parent's lap). Rotation stimulates both labyrinths at the same time and thus does not provide lateralizing information. Caloric response and rotational testing are complementary. The most common type of rotational testing uses sinusoidal harmonic acceleration. The eye velocity produced by the rotation is compared with stimulus velocity.

Three parameters are derived from rotational testing: gain, phase, and symmetry. Gain is a measure of the size of the response. Reduced gain indicates decreased vestibular sensitivity. Unilateral vestibular loss may or may not reduce gain. Thus reduced gain usually indicates bilateral vestibular loss. Phase describes the timing relationship between the rotational chair

velocity and the eye velocity. Ideal eye movements have zero phase lead, whereas large phase leads are usually abnormal. Phase is a highly sensitive but nonspecific measure of vestibular system abnormalities. The directional preponderance (i.e., deviation from symmetry) of the eye movements is derived by comparing the velocity of the eye movement to right and left. Directional preponderance is a nonspecific sign. Note that gain, phase, and degree of symmetry do not indicate the site or the side of the lesion. However, rotational testing measures change in response to vestibular disease and can be used to monitor a child's progress.

### Computerized Dynamic Platform Posturography

Computerized dynamic posturography, known commercially as EquiTest® (NeuroCom International, Inc.), consists of a floor and a visual scene that can move (Fig. 8-6A). By combining visual and floor conditions, six different sensory conditions can be used to assess the patient's ability to use combinations of sensory inputs (Fig. 8-6B). Conditions 5 and 6 assess how patients use vestibular information when it is the only available sense providing reliable information; reduced or distorted sensory information from the visual system and somatosensory system forces patients to rely on their vestibular sensations to maintain upright balance.

### Posturography and Vestibular Disorders—Results from the Medical Literature

Several studies have suggested that, after successful vestibular compensation, posturography test results normalize and patients lose their “5, 6 pattern” (i.e., their abnormal response to conditions 5 and 6 on posturography testing) and may, in fact, have normal postural sway (Furman, 1995). Thus posturography may provide valuable information regarding the status of compensation for a peripheral vestibular deficit.

### Vestibular-Evoked Myogenic Potentials

Vestibular-evoked myogenic potentials (VEMPs) refer to electrical activity recorded from neck muscles in response to intense auditory clicks. VEMPs provide information about the status of the sacculus and inferior vestibular nerve. A limitation of VEMPs is that it requires normal middle ear function when performed using air-conducted stimuli. VEMPs have been performed successfully in children. Children as young as age 3 can tolerate testing.

### DISORDERS PRODUCING VERTIGO

Vertigo in children can be divided into three broad categories:

1. Acute nonrecurring spontaneous vertigo
2. Recurrent vertigo
3. Nonvertiginous dizziness, disequilibrium, and ataxia (Table 8-1)

A recent study of 2000 children found that vertigo in children was caused by: a migrainous equivalent, 25%; benign paroxysmal vertigo of childhood, 20%; head trauma, 10%; ocular disorders, 10%; inner ear malformations, 10%; vestibular neuronitis, 5%; labyrinthitis, 5%; and posterior fossa tumors, less than 1% (Wiener-Vacher, 2008). A more recent study of 6965 10 year olds in the United Kingdom found a 5.7% prevalence of vertigo. Of these children, vertigo symptoms made them stop their activity, and 60% of them also had headache. A change in hearing while vertiginous was reported in 20% (Humphris and Hall, 2011).

**Figure 8-6.** The EquiTest® system. **A**, EquiTest® system (NeuroCom International, Inc.) shows the child standing on the platform surrounded by a visual scene. A safety harness is attached to the child in case loss of balance should occur. The platform surface and visual surround are capable of moving independently or simultaneously. Pressure-sensing strain gauges beneath the platform surface detect the patient's sway by measuring vertical and horizontal forces applied to the surface. **B**, The six sensory testing conditions of the EquiTest® posturography platform. **TABLE 8-1** Comparison of Disorders Causing Childhood Dizziness

Disorders	Duration of Symptoms/Episodes	Hearing	Vestibular Laboratory Abnormalities
<b>Nonrecurrent Vertigo</b>			
Vestibular neuritis	Days	Normal	Unilateral caloric reduction
Trauma-labyrinthine concussion	Days	Often impaired SNHL*	Possible unilateral caloric reduction
Perilymphatic fistula	Variable	Often impaired SNHL	Possible unilateral caloric reduction
<b>Recurrent Vertigo</b>			
Ménière's disease	Minutes to hours	Low-frequency SNHL	Unilateral caloric reduction
Migraine	Variable	Normal	Directional preponderance
Anxiety	Minutes	Normal	Directional preponderance
Seizure disorder	Seconds to minutes	Normal	Normal
Periodic ataxia	Hours to days	Normal	Normal
<b>Nonvertiginous Dizziness</b>			
Bilateral vestibular loss	Constant	Usually normal but may be impaired	Bilateral caloric reduction/reduced gain on rotation
Otitis media	Constant	Conductive	Abnormal posturography
Cerebellar lesions	Constant	Normal	Abnormal ocular motor testing

\*SNHL; sensorineural hearing loss.

## Acute Nonrecurrent Spontaneous Vertigo

Acute nonrecurrent spontaneous vertigo is unusual in children. In an acute vestibular syndrome, the vertigo that is experienced results in a reduction in the normal baseline activity in the ipsilateral vestibular nerve. Because the brain responds to differences in activity between the two vestibular nuclear complexes, the patient experiences vertigo. Additionally, the child may experience autonomic symptoms, including nausea and vomiting. Typically, children adapt to an acute loss of unilateral peripheral vestibular function within several days.

### Head Trauma

Head trauma can cause an acute episode of vertigo via a labyrinthine concussion. The mechanism of injury in labyrinthine concussion is poorly understood but may relate to pressure waves transmitted to the labyrinth. Other mechanisms of vertigo after head trauma include injury of the CNS, specifically, a brainstem or cerebellar contusion, or a temporal bone fracture. Another diagnostic consideration for a patient with head trauma followed by vertigo or nonspecific dizziness is that of perilymphatic fistula, i.e., an anomalous connection between the inner ear and middle ear spaces that has been well documented in children.

Vertigo is a common complaint in patients with postconcussion syndrome, with 81% reporting dizziness.

### Vestibular Neuritis

Vestibular neuritis is rarely seen in children younger than 10 years old. It should be considered when a viral syndrome is followed by symptoms suggestive of an acute unilateral peripheral vestibular loss. It presents with acute severe vertigo, nystagmus, nausea, and vomiting. The vertigo is worsened by head movements, and patients often prefer to lie down, usually with the affected ear up. There is no hearing loss or tinnitus. Management is supportive and symptomatic, with early ambulation. Vestibular suppressants such as meclizine may be given, but only for a short course, as they may delay long-term recovery.

## Recurrent Vertigo

Recurrent vertigo in children can be a result of disease of the peripheral or central vestibular system. However, most recurrent vertigo in children is due to a CNS disorder rather than a peripheral vestibular disorder.

### Migraine-Related Dizziness

Migraine is probably the most common cause of recurrent vertigo in children. Whereas migraine typically presents as headache in adults, other manifestations of migraine, including recurrent vertigo and disequilibrium, are more common in children. Benign paroxysmal vertigo of childhood, which is likely to be of migrainous origin, as well as paroxysmal torticollis of infancy, can present with recurrent vertigo in children. Nonvertiginous symptoms of vestibular dysfunction can also be related to migraine. The manifestations of migraine in childhood are quite varied (Balkany and Finkel, 1986).

Benign paroxysmal vertigo of childhood was first described by Basser (Basser, 1964). Vertigo occurs in isolation, without tinnitus and hearing loss. The age of onset is usually by 4 years, but can be as late as 12 years. Vertigo usually lasts less than 1 minute but may last only seconds. Vertigo may occur while sitting, standing, or lying. Pallor, nausea, sweating, and occasionally vomiting occur. Consciousness is not impaired, and the child can recall the episode. There may be no pain or headache associated with the attacks. Immediately after the

attack, the child resumes normal activities. The interval between the attacks varies from weekly to every 6 months. Vertigo attacks usually cease spontaneously after a few years. Physical examination, including a neurologic evaluation, is normal, as is imaging of the skull and temporal bones. Basser reported a moderate or complete canal paresis on caloric testing. However, the response to bithermal caloric testing has been found to be highly variable (Finkelhor and Harker, 1987; Mira et al., 1984). Other testing is normal. Children with benign paroxysmal vertigo of childhood often have a positive family history of migraine, and migraine headaches may develop in later years (Koebler, 1980; Lanzi et al., 1994) and may respond positively to antimigraine treatment. The initial treatment of migrainous vertigo in children is dietary restrictions of foods known to provoke migraine. If this is unsuccessful, the next step is symptomatic treatment with a vestibular suppressant, such as meclizine, during episodes. However, the episodes are usually very brief. If the spells are frequent and especially if they impair school performance, use of a prophylactic antimigraine agent, such as propranolol or topiramate, should strongly be considered (Cass et al., 1997). In younger children, cyproheptadine has also been used successfully.

### Ménière's Disease

Ménière's disease, a syndrome presumably caused by endolymphatic hydrops, can occur spontaneously or as a delayed sequela of a previous insult from trauma or viral infection. The disorder rarely occurs in children. Ménière's disease is characterized by a combination of dizziness, unilateral hearing loss, and unilateral tinnitus, which are usually preceded by a feeling of fullness in the affected ear. Following episodes, children are more likely to recover auditory function than are adults. Ménière's disease can be bilateral. Also, with time, a reduction in the responsiveness of the involved peripheral vestibular system occurs. Management of endolymphatic hydrops in children includes reassurance and explanation of the condition to the parents, in addition to salt restriction and a diuretic (Cyr et al., 1985).

### Seizure Disorders

Seizure disorders are often accompanied by some sense of dizziness and disequilibrium, although seizures are not frequently associated with true vertigo. However, the term *tornado epilepsy* has been used to describe seizures that are associated with a sense of spinning that can mimic the symptoms of a peripheral vestibular ailment. If a typical vertiginous spell is followed by a generalized tonic-clonic seizure, the diagnosis becomes clearer.

### Familial Episodic Ataxia

Familial episodic ataxia is a rare syndrome with autosomal-dominant inheritance and is characterized by episodes of dizziness, disequilibrium, and gait instability that may last for several hours. At least eight types of the syndrome have been identified, and genetic testing is available. These syndromes differ in the duration of the paroxysms of ataxia and associated features. Treatment with acetazolamide can be very helpful for those responsive to it.

## Nonvertiginous Disequilibrium

Patients with both peripheral and central vestibular disorders can have nonvertiginous disequilibrium, imbalance, and ataxia. Indeed, many disorders affecting the CNS are symptomatic in this way. Bilateral peripheral vestibular disorders

typically occur without vertigo and thus may mimic a central disorder. Numerous CNS abnormalities can be associated with nonvertiginous dizziness. Many of these abnormalities involve the cerebellum and include cerebellar hypoplasia or atrophy, posterior fossa tumors, and Chiari malformations. Also, medication side effects should not be overlooked when evaluating a child with dizziness and disequilibrium.

### Bilateral Peripheral Vestibular Loss

Bilateral peripheral vestibular loss can be either congenital and due to inner ear malformations or acquired from meningitis, ototoxicity, and autoimmune disease of the inner ear. Regardless of etiology, bilateral vestibular loss, if severe, is called Dandy's syndrome. Dandy's syndrome is characterized by two specific symptoms: oscillopsia (i.e., jumbling of the visual surround during head motion) and severe gait instability in darkness. Children with bilateral vestibular loss often learn to use alternative sensory inputs, such as vision and proprioception. Also, they modify strategies of eye movements. Environments and tasks that require vestibular function, such as ambulating in dimly lit spaces or trying to maintain stable vision during walking, are extremely challenging for individuals with bilateral vestibular loss.

### Central Nervous System Disorders

Numerous CNS disorders cause dizziness, disequilibrium, imbalance, and ataxia. In childhood, cerebellar abnormalities, such as cerebellar vermian hypoplasia, posterior fossa tumors, and Chiari malformation, are the most common disorders encountered. Cerebellar atrophy and ataxia syndromes, such as those caused by familial spinocerebellar ataxia disorders, can also cause these symptoms and are typically progressive. The clinical presentation of such patients may be confusing because they are unlikely to have vertigo and may not display evidence of limb ataxia if their abnormalities affect solely midline cerebellar structures.

### Drug-Induced Dizziness

Many drugs can cause nonvertiginous dizziness. For example, the aminoglycosides, especially gentamicin, can cause ototoxicity, which may result in bilateral peripheral vestibular loss. In the pediatric age group, phenytoin is used in the treatment of epilepsy and may produce dizziness and nystagmus as signs of intoxication. With this in mind, any child in whom dizziness develops while on a regular medication should be viewed as a possible case of iatrogenic dizziness.

### Nonneurotologic Disorders

Another cause of dizziness in children is psychosomatic dizziness, which usually occurs in children of school age. It may be associated with depression, adjustment reaction of adolescence, and behavior problems. Such children usually have normal vestibular and auditory testing, normal electroencephalograms, and normal imaging studies. When evaluating a child with dizziness, it is essential to determine whether the patient has an associated anxiety disorder, either as the sole cause of their vertiginous complaints, as an accompaniment to an underlying balance system abnormality, or indirectly related to the dizziness, e.g., through a common brainstem ailment causing both disequilibrium and an anxiety disorder.

Treating anxiety disorders in children is challenging because of medication side effects. If the anxiety symptoms are severe, patients should be referred to a child psychiatrist.

Some children with sensory integration disorder, with or without developmental delay, may be overly responsive to vestibular stimulation. An early intervention therapeutic program that helps desensitize the child may help immensely.

### Treatments

In addition to the medications that have been discussed, vestibular rehabilitation therapy (VRT) may also be helpful in the treatment of vertigo. Exercises designed to help compensate for an inner ear deficit are taught by specialized physical therapists. VRT can be helpful for benign paroxysmal positional vertigo (BPPV), Ménière's disease, labyrinthitis, vestibular neuritis, and postconcussion vertigo when the symptoms persist for more than a few weeks.

## Taste and Smell

Julie A. Mennella, Nuala Bobowski, and Djin Gie Liem

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

### CHEMICAL SENSES

The chemical senses of taste, smell, and chemical irritation convey a range of information, warning us of environmental hazards and determining the flavor—good or bad—of ingested foods and liquids (Doty, 2015). The pleasure or displeasure experienced upon ingesting food results from a complex process mediated by the chemical senses in the periphery and then by multiple brain substrates, which are remarkably well conserved phylogenetically. The degree to which the chemicals that stimulate these flavor senses are liked or disliked is determined by interactions of innate factors and experience. Hard-wired from birth, the basic biology of humans steers us to seek out sweet foods dense with energy, salty foods dense with minerals, and savory foods rich in proteins and to reject bitter-tasting toxins and unripe sour foods (Mennella, 2014). In essence, these senses function as gatekeepers throughout the life span: they control one of the most important decisions an animal is required to make—whether to reject a foreign substance or consume it.

### Taste, Smell, and Flavor

#### The Taste System

Taste, or gustation, refers to the sensation that occurs when chemicals stimulate taste receptors located on a large portion of the tongue's dorsum and other parts of the oropharynx, such as the larynx, pharynx, and epiglottis. The taste system is attuned to a small number of perceptual classes of experience, the so-called basic tastes (i.e., sweet, salty, savory, bitter, and sour), each of which specifies crucial information about nutrients or dangerous substances. These basic tastes either stimulate intake (sweet, salty, and savory) or inhibit it (bitter and perhaps sour). From an evolutionary perspective, these taste qualities likely evolved to detect and reject that which is harmful (e.g., bitter) and to seek out and ingest that which is beneficial (e.g., sweet, salty). Unlike our modern, commercially produced diet, which has led to the widespread use of added sugars and salts in many parts of the world, the diet of our primitive past was drastically different: salt and sugar were rare and difficult to obtain. Thus the preference for salty and sweet tastes, which is heightened during childhood (Mennella, 2014), is thought to have evolved to attract us to minerals and energy-producing sugars (and their accompanying vitamins) during periods of maximal growth, whereas rejection of bitter-tasting and irritating substances evolved to protect us from poisons, and rejection of concentrated sours evolved to protect us from unripe fruits.

The hedonics of taste are intimately connected to the ingestion or rejection of foods and beverages and thus can pose a nutritional risk when foods and beverages containing highly preferred tastes (sweet, salty) are consumed in excess. Indeed, many chronic diseases (e.g., hypertension, obesity) that plague modern society derive in large part from poor food choices, dictated by our taste preferences. The senses can also pose a

risk when healthful foods such as bitter-tasting vegetables are avoided and when children fail to comply with a medication regimen due to the bad taste of the drugs. Many active pharmaceutical ingredients taste bitter or irritate the mouth and throat. Although encapsulating the medicine in pill or tablet form to avoid unpleasant tastes is effective for adults, this is problematic for children, many of whom cannot or will not swallow pills and thus often consume their medication in a liquid formulation. Children cannot benefit from medicines they will not take, and their heightened sensitivity to some bitter tastes makes this especially challenging (Mennella et al., 2013).

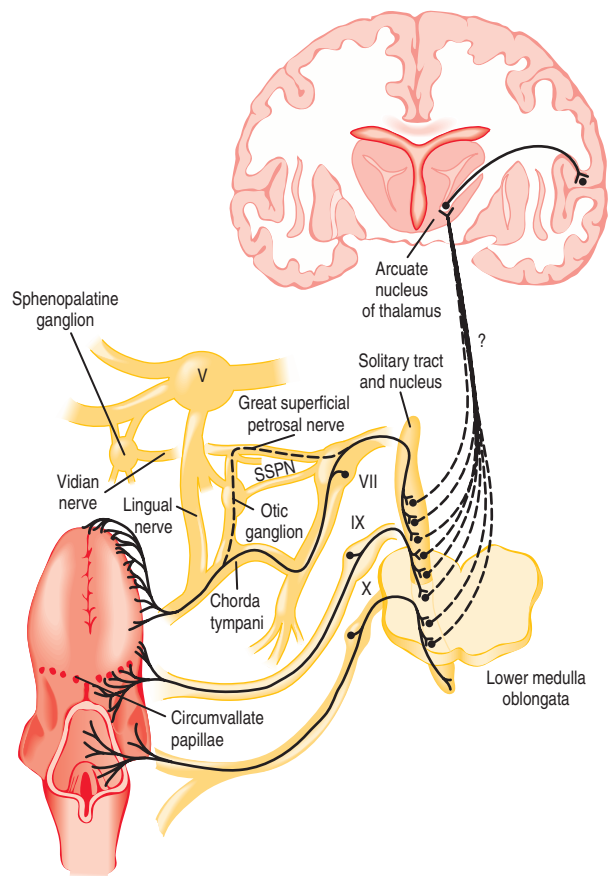

The taste receptors in the oral cavity are localized in taste buds, which are innervated by branches of three cranial nerves: the facial (VII), glossopharyngeal (IX), and vagal (X) nerves (Fig. 9-1). Major progress has been made in identifying the initial events in taste recognition. It appears that two different strategies have evolved to detect taste molecules (Bachmanov et al., 2014). For salty and sour tastes, it is widely believed that ion channels serve as receptors. Here H<sup>+</sup> (sour) and Na<sup>+</sup> (salty) ions are thought to flow through the channels into the cell. However, for both of these taste qualities, the molecular identity of the receptors and their exact mechanisms are still under investigation.

For sweet, umami (savory), and bitter tastes, G-protein-coupled receptors (GPCRs) appear to play the most prominent roles. These GPCRs bind taste molecules in a sort of lock-and-key mechanism. For sweet and umami, a family of three GPCRs, named T1R1, T1R2, and T1R3, act in pairs (T1R1 + T1R3 for umami, and T1R2 + T1R3 for sweet) to detect molecules imparting these taste qualities. The bitter receptors, the T2Rs, comprise a substantially larger family of GPCRs, with about 25 members (Bachmanov et al., 2014). Not only are the chemicals that elicit these three taste qualities detected by specialized receptors on the tongue and other parts of the oral cavity, but many of these receptor proteins are expressed in a wide variety of other tissues, including the gastrointestinal tract, testes, respiratory epithelium, brain, and heart. Although their function in these tissues is still under investigation, this is an emerging area of research. For example, it was recently discovered that bitter receptors expressed in the ciliated cells of the sinonasal epithelium can trigger immune responses when stimulated with chemical signals from bacteria. Thus the expression of these bitter taste receptors in respiratory epithelium may also play a vigilant role in upper airway immunity.

#### The Olfactory System

Smell, or olfaction, occurs when chemicals stimulate olfactory receptors located on a relatively small patch of tissue high in the nasal cavity. Odor stimuli can reach the olfactory receptors in two ways: by entering the nostrils during inhalation (orthonasal route) or by traveling from the back of the oral cavity toward the roof of the nasal pharynx (retronasal route). Individual experiences largely determine how much a person

**Figure 9-1.** Taste innervation is supplied by cranial nerves VII, IX, and X. Filiform, fungiform, and circumvallate papillae are present, with most taste sensation originating from the fungiform and circumvallate papillae. The anterior two thirds of the tongue is innervated by the chorda tympani, a branch of cranial nerve VII; the posterior one third of the tongue and palate are innervated by cranial nerves IX and X. Central connections of the pathways of the cranial nerves in the nucleus solitarius ascend through the thalamus to the parietal operculum. SSPN, small superficial petrosal nerve.

likes or dislikes an odor, although there is some evidence that some odors may be innately biased in a positive or negative direction.

### Flavor

Flavor, as an attribute of foods and beverages, is defined as the integration of multiple sensory inputs of the taste, retronasal olfaction, and irritation (e.g., sensations of burn, viscosity, and temperature, resulting from stimulation of nerve endings in the soft membranes of the buccal and nasal cavities of a substance in the oral and nasal cavities). However, the perceptions arising from the taste and smell senses are often confused and misappropriated—odors perceived through the mouth (retronasally) are referred to the oral cavity, whereas odors perceived through the nose (orthonasally) are referred to the external world. For example, the sensations of vanilla, fish, chocolate, and coffee are often erroneously attributed only to the taste system, but much of the sensory input results from retronasal olfaction. Holding the nose while eating interrupts retronasal olfaction and thereby eliminates many of the subtleties of food or medicines, leaving only the taste components.

## Clinical Disorders of Taste and Smell

The common confusion between taste and retronasal olfaction is highlighted when patients, young and old, report they cannot taste when they suffer only from olfactory loss. Approximately two thirds of patients who present to specialized chemosensory clinics complain of taste loss, but most patients are diagnosed with a measurable smell dysfunction, rather than a gustatory one, as the basis of their “taste” complaint. A retrospective review of patients evaluated for chemosensory dysfunction complaints revealed that severe, generalized taste deficits (i.e., complete or nearly complete taste loss) do occur but are extremely rare, whereas profound olfactory deficits are more common.

Although complete taste loss is rare, clinical disorders that influence taste and smell perception are more common (Mott and Leopold, 1991; Cowart et al., 1997). As shown in Box 9-1 and Box 9-2, disorders of taste and smell can arise from a variety of sources (Mott and Leopold, 1991; Scheckmann et al., 2013; Doty, 2015); however, many of the conditions listed are based on adult patients’ reports and not on standardized test assessments of chemosensory functioning or controlled clinical trials. This lack of systematic analysis, as well as patient confusion between taste and retronasal olfaction, underscores the need for careful sensory evaluation of these causes. Moreover, clinical disorders that influence taste and olfactory perception involve multiple organ systems and require a multidisciplinary approach for appropriate diagnosis and management.

Despite advances in our understanding of the mechanisms and functions of the chemical senses, there are no internationally accepted standards of impairment for the chemical senses, and the treatment options for taste and smell disorders remain limited. Olfactory dysfunctions resulting from impairment of odor access to the olfactory receptors may be treated. For example, patients may experience improvements in olfactory ability after adenoidectomy or surgical management of nasal polyps, which can reestablish nasal airflow. However, individuals whose deficit involves the olfactory neuroepithelium or central olfactory or cortical pathways typically have no treatment options other than time and possible spontaneous recovery. Similarly, the prognosis for severe taste loss is mixed, and gradual recovery was the most common pattern observed in such patients.

In addition to a careful medical history and otolaryngologic examination, assessment of a smell or taste complaint should involve standardized testing using a variety of psychophysical techniques (e.g., detection thresholds, magnitude estimates, quality identification) in a clinical setting. This is particularly important for evaluating olfactory and taste functioning in young children (younger than 5 years of age), who are more prone to attention lapses, tend to answer questions in the affirmative, have limited ability to read and identify labeled choices, and are likely to be unfamiliar with many stimuli used in adult tests. To address the need for brief, comprehensive assessment tools that can be used by clinicians and researchers in a variety of settings, the National Institutes of Health (NIH) Blueprint for Neuroscience Research established and then funded the Toolbox Initiative to assemble tools to assess the domains of cognition, emotion, motor function, and sensation. Included in the sensation tool set is a validated, specialized battery of tests to assess taste and smell for diverse populations from 3 to 85 years of age (Coldwell et al., 2013). Information on the NIH Toolbox tests to assess taste and olfaction can be obtained from the NIH website ([www.nihtoolbox.org](http://www.nihtoolbox.org)) and from a special issue of the journal, *Neurology* (vol. 80, no. 11, suppl. 3).

**BOX 9-1** Conditions Associated with Disturbances of Taste

- Genetic conditions
  - Familial dysautonomia
  - Turner syndrome
- Endocrine, metabolic, and autoimmune conditions
  - Adrenal insufficiency
  - Cronkhite-Canada syndrome
  - Diabetes mellitus
  - Hypothyroidism, pseudohypoparathyroidism
  - Hyperthyroidism
  - Lupus erythematosus
  - Primary amyloidosis (affecting tongue)
  - Reiter syndrome
  - Scleroderma
  - Sjögren syndrome
- Gastrointestinal and liver diseases
  - Acute hepatitis
  - Chronic liver disease
  - Obstructive jaundice
- Hypertension
- Iatrogenic conditions
  - Acoustic tumor removal
  - Hypophysectomy
  - Laryngectomy
  - Tonsillectomy
  - Cerebellopontine angle meningioma removal
  - Chorda tympani injury or stretching
  - Radiation or chemotherapy
  - Temporal lobectomy
- Infectious conditions
  - Upper respiratory tract infection
  - Candidiasis
- Ulcerative lesions (e.g., gonorrhea, herpes simplex, mycoses, syphilis, varicella zoster)
- Local processes
  - Glossitis
  - Hansen disease
  - Oral mycosis
  - Otitis media
  - Parotid infection or tumor
  - Submandibular gland carcinoma
- Neurologic conditions
  - Bell palsy
  - Brain tumor
  - Guillain-Barré syndrome
  - Head trauma
  - High-altitude syndrome
  - Migraine
  - Multiple sclerosis
  - Seizure disorders
- Uremia or dialysis
- Miscellaneous conditions
  - Bulimia
  - Acquired immunodeficiency syndrome (AIDS)-related periodontitis
  - Cancer
  - Dental caries
  - Gastric reflux disease
  - Gingivitis (acute and chronic)
  - Occupational exposure

Clinical disorders affecting taste: Evaluation and management. In: Doty RL, ed. Handbook of olfaction and gustation, 2nd ed. New York: Marcel Dekker, 2003:935.*)

For further information about taste and smell disorders, see the National Institute on Deafness and Other Communication Disorders (NIDCD) Information Clearinghouse, a national resource center for information about hearing, balance, smell, taste, voice, speech, and language for health professionals, patients, industry, and the public ([www.nidcd.nih.gov/health/misc/pages/clearinghouse.aspx](http://www.nidcd.nih.gov/health/misc/pages/clearinghouse.aspx)), as well as the NIDCD website ([www.nidcd.nih.gov](http://www.nidcd.nih.gov)) and the National Institute of Dental and Craniofacial Research website ([www.nidcr.nih.gov](http://www.nidcr.nih.gov)). Specific clinical questions can be addressed to the NIDCD, the Monell Chemical Senses Center, or the University of Pennsylvania Health Taste and Smell Clinic.

## THE ONTOGENY OF TASTE PERCEPTION AND PREFERENCES

The convergence of findings from the scientific literature suggests that human infants, as well as children, have functioning gustatory and olfactory systems that modulate their feeding and expressive behaviors. This responsiveness is not the same as that of adults; these chemosensory systems mature postnatally (Table 9-1) and are influenced by experiences in ways we are just beginning to understand (Mennella, 2014). Little is known about the infant's perception of chemical irritation (e.g., sensations of burn, viscosity, and temperature). Thus this section focuses on the senses of taste and smell, but we acknowledge that other chemical senses may play important roles in the behavior of infants.

The fetus and newborn infants have functioning chemosensory systems, and infants' feeding and expressive behaviors are modulated by taste and smell stimuli. Although these sensory systems are operable early in ontogeny, the fetus and newborns are not merely miniature adults because their sensory systems mature postnatally and are influenced by experience in ways not yet fully understood. Like other sensory systems, taste is experienced through a "sensory window" that changes with age and experience and is partially defined by genetics. Children have well-developed sensory systems for detecting tastes, as well as smells and chemical irritants, and their basic biological preferences for sweet and salty and rejection of bitter tastes are heightened during childhood until late adolescence, when they decline to levels observed in adults. These sensory and biological considerations shed light on why children are so vulnerable to the current food environment rich in added sugars and salt (Mennella, 2014) and why children often reject the bad taste of medicines (Mennella et al., 2013).

## Clinical Significance of Taste in Infants and Children

Taste dysfunctions are described by several terms (Coward et al., 1997). Ageusia refers to a complete loss of gustatory function, whereas hypogeusia refers to diminished sensitivity to detect a specific taste quality or class of compounds (e.g., phenylthiocarbamide). Dysgeusia and phantogeusia refer,

**BOX 9-2** Conditions Associated with Disturbances of Olfaction

- Genetic conditions
  - Cleft palate (males)
  - Down syndrome
  - Familial dysautonomia

respectively, to distortion in the perceived qualities of a taste stimulus and the experience of a taste sensation in the apparent absence of a gustatory stimulus. The study of clinical abnormalities in taste perception in pediatric populations has received little scientific attention, in part because, as discussed earlier, the clinical assessment of taste is not well developed. Some reports in these age groups, although limited, are highlighted here. **Box 9-1** lists conditions that sometimes are associated with taste disorders in adults.

A few disorders with neurologic symptoms have been associated with taste disturbances in infants and children. Familial dysautonomia is a hereditary autonomic and sensory neuropathy that affects almost exclusively Jewish children of Ashkenazi extraction. Patients with this disorder could detect but failed to label correctly salty, bitter, sweet, and water stimuli, but sour taste and the sense of smell were preserved. Surgical procedures of the head or neck may sometimes result in taste distortion. For example, tonsillectomy

has been associated with taste dysfunction, perhaps because of damage to the lingual branch of the glossopharyngeal nerve. Approximately one third of patients experience taste disturbance 2 weeks after undergoing a tonsillectomy; levels decrease to 8% at 6 months and 2% at 18 months after surgery.

Surgical procedures that involve the middle ear may damage the chorda tympani nerve (branch of cranial nerve VII), which mediates taste perception on the anterior tongue. Damage to or anesthesia of the chorda tympani nerve can increase taste sensations (particularly bitter) from the glossopharyngeal branch of cranial nerve IX and cranial nerve X and blunt retronasal olfactory sensations from cranial nerve I. Likewise, middle ear infections or oral infections that reach the middle ear through the eustachian tubes may affect the chorda tympani nerve as it passes between the malleus and incus and thus affect taste perception. Insults to the chorda tympani nerve may explain some taste disruptions. In particular, occurrence of otitis media during childhood was associated with losses of bitter taste on the tip of the tongue and, when severe, reduced perception of sweetness throughout

the mouth, which was associated with a higher risk for obesity.

Endocrine, metabolic, and nutritional disorders causing loss of taste are rare in adults and presumably in pediatric populations. Children with chronic renal failure exhibited reduced preference for sweet-tasting foods, which was unrelated to plasma zinc levels, whereas infants and children diagnosed with second- and third-degree protein-energy malnutrition preferred soup to which savory tastes (e.g., casein hydrolysate) had been added over soup alone. Such findings provide information that may be useful for clinicians in planning palatable diets for these patients.

The most common etiologic factor contributing to taste disturbances in adults appears to be medication use (Schiffman, 1983), but there are few reports regarding similar effects in pediatric populations. Not all individuals taking a particular drug are affected, and the mechanisms by which these medications alter chemosensory function are not well understood. Nevertheless, a variety of medications have been reported sometimes to cause taste (and smell) dysfunction in adults (see Table 9-2).

**TABLE 9-2** Drugs Associated with Taste and Smell Dysfunction\*

Medication Class	Specific Drug	Chemosensory Dysfunction
Anesthetic	Benzocaine Lidocaine Cocaine Tetracaine	Ageusia Anosmia Anosmia Ageusia
Antibacterial	Procaine penicillin Metronidazole Tetracycline Doxycycline	Metallic dysgeusia Metallic dysgeusia Metallic dysgeusia Anosmia, parosmia
Antiepileptic	Carbamazepine Tegretol	Hypogeusia Hypogeusia
Antidiabetic	Biguanide	Metallic dysgeusia
Antifungal	Amphotericin B	Hypogeusia
Antiinflammatory	Phenylbutazone Azelastine	Ageusia Bitter, metallic dysgeusia
Immunosuppressive/antineoplastic	5-Fluorouracil Methotrexate Cisplatin	Sour, bitter dysgeusia Sour, metallic dysgeusia; ageusia Ageusia
Antirheumatic	Allopurinol Penicillamine	Metallic dysgeusia Metallic dysgeusia
Antithyroid	Methylthiouracil	Ageusia and anosmia
Cardiovascular	Captopril Diltiazem Nifedipine	Increased taste thresholds Hypogeusia, hyposmia Dysgeusia and parosmia
Dental products	Chlorhexidine Hexidine Sodium lauryl sulfate	Ageusia, loss of salty taste, persistent aftertaste Altered taste Loss of sweet and salty taste; dysgeusia
Muscle relaxant	Baclofen	Ageusia, hypogeusia
Opiate	Codeine Morphine	Olfactory depression Olfactory depression
Sympathomimetic	Amphetamines	Bitter dysgeusia; parosmia
Tranquilizers	Chlormezanone	Ageusia; metallic and bitter dysgeusia
Vasopressors	Midodrine	Metallic dysgeusia; antiseptic ("Dettol/Pine-Sol") parosmia

\*This is a partial listing of the medications associated with taste and smell disturbances in adults. Not all individuals taking a particular drug are affected, and the mechanisms by which these medications alter chemosensory function are not well understood.

## THE ONTOGENY OF OLFACTORY AND FLAVOR PERCEPTION

Infants are able to detect and discriminate a wide variety of odors shortly after birth. They hedonically respond to differences in odor quality, appear to be as sensitive to odors as adults (if not more so), and are capable of retaining complex olfactory and flavor memories.

The early state of maturity and plasticity of the olfactory system favor is related to its involvement in adaptive responses to development. First, experience-induced plasticity in response to odors is a means to tune the olfactory system to stimuli deemed relevant in an individual's environment. Second, salient memories formed during the first 10 years of life will likely be olfactory. Autobiographical memories triggered by olfactory information mainly occurred during the first decade of life, whereas those associated with verbal and visual cues more often occurred later in adolescence and early adulthood.

The normal fetus has open airway passages that are bathed in amniotic fluid and inhales more than twice the volume it swallows during the latter stages of gestation; thus the fetus may be exposed to a unique olfactory environment before birth. This experience represents the first exposure to flavors (tastes and retronasally perceived odors) that will subsequently be provided in mother's milk and then in table foods. Such retronasal perception of odors in amniotic fluid and then in mother's milk provides the infant with the potential for a rich source of various chemosensory experiences and facilitates transition from a diet consisting exclusively of human milk to a mixed diet by providing the infant with bridges of familiarity, such that the infant experiences common flavors in the two feeding situations (Mennella, 2014). Because the infant's first flavor experiences occur before birth in amniotic fluid, breast milk forms a bridge between the experiences of flavors in utero and those in solid foods. The types and intensity of flavors experienced in breast milk may be unique for each infant and serve to identify the culture to which the child is born and raised. When an infant is exposed to a flavor in the amniotic fluid or breast milk and is tested sometime later, the exposed infants accept the flavor more than infants without such experience. This pattern makes evolutionary sense because the foods that a woman eats when she is pregnant and nursing are likely the ones to which her infant will have the earliest exposure.

Breastfeeding conferred an advantage when infants first tasted a food, but only if their mothers regularly eat similar-tasting foods. If their mothers eat fruits and vegetables, breastfed infants will learn about these dietary choices by experiencing the flavors in mother's milk, thus highlighting the importance of a varied diet for both pregnant and lactating women. These varied sensory experiences with food flavors may help explain why children who are breastfed are less picky and more willing to try new foods; this, in turn, contributes to greater fruit and vegetable consumption in childhood.

Learning about foods and flavors continues during and after weaning. Regardless of whether infants are breastfed or formula-fed, they can learn through repeated dietary experience and dietary variety. Both formula-fed and breastfed infants ingest significantly more of a particular pureed fruit or vegetable after repeated exposure (8 to 10 days) to that particular food. Merely looking at the food does not appear to be sufficient because children have to taste the food to learn to like it. Furthermore, the dietary experience does not have to include the specific food, because exposure to a variety of foods between and within a meal, not just repeated exposure to a single food, facilitates acceptance of novel fruits and vegetables within that particular food category.

The food habits established during infancy track into childhood and adolescence for both nutrient-dense and nutrient-poor foods. Such dietary patterns, which begin to be identified during childhood, are significant determinants of the quality of the adult diet. This raises important issues about high-risk neonates, whose early sensory experiences are often drastically different from those of a typical infant, lacking continuity with prenatal sensory experiences. For example, preterm infants are often unable to coordinate sucking, swallowing, and breathing, so nasogastric or orogastric tube feeding is used to provide adequate nutrition. When fed by a tube, infants likely have a relatively constrained olfactory and flavor experience in the context of feeding because their nutrition bypasses the oral and nasal cavities.

High-risk infants are also faced with a wide array of medical conditions that contribute to temporary or permanent alteration of taste and smell as adults. Many medications, including antibiotics and antiinflammatory agents (Schiffman, 1983), have been shown to alter taste and smell (see Table 9-2), and these medications are commonly given to high-risk neonates. Gastroesophageal reflux disease is another common problem in preterm infants and results in a sour or bitter taste in the mouth from reflux of stomach acid up the esophagus and into the throat. The long-term effects of these alterations on the development of flavor preferences in the child are not known.

### Clinical Significance of Olfaction in Infants and Children

The terminology used to describe olfactory dysfunction parallels that used for taste disorders (Doty, 2015). Anosmia refers to the complete absence of olfactory functioning, whereas hyposmia refers to diminished olfactory functioning. In some patients, there may be a deficit in the perception of only a specific odorous compound (e.g., androsterone) or a class of compounds; this condition is commonly referred to as specific anosmia. Hyperosmia refers to an increased sensitivity to smell, dysosmia or parosmia refers to distortions in the perceived qualities of an odor stimulus, and phantosmia refers to the perception of an odor when the odor stimulus is not present.

Box 9-2 lists several conditions that are associated with olfactory disorders in adults. Paranasal sinus disease, prior upper respiratory tract infection, and head trauma account for more than two-thirds of adult cases of olfactory dysfunction. One of the more common forms of head trauma among athletes, concussion, is also associated with olfactory dysfunction, particularly difficulty in identifying odors. Of particular relevance to the neurologist is the fact that a cardinal feature of several neurodegenerative diseases (e.g., Alzheimer, Parkinson) is an olfactory deficit. The loss of smell (and hearing) is less common after head trauma in children than in adults. Common causes associated with impaired olfactory sensitivity in children include nasal obstruction; allergic, chronic, or hypertrophic rhinitis; and nasal polyps (frequently seen in children suffering from cystic fibrosis). Olfactory functioning improves after adenoidectomy in children with nasal obstruction caused by adenoid hypertrophy. Evaluating a child with partial or complete loss of smell may require referral to an otorhinolaryngologist to determine whether there are any local pathologic findings (e.g., foreign body, nasal polyp). Shearing of the olfactory nerves, hemorrhage into the olfactory bulb, fractures of the cribriform plate, and frontal lobe contusions have all been reported in children, but their effects on chemosensory functions remain unknown.

As for the sense of taste, little is known about genetic and congenital disorders of smell perception in infants and

children. Although the majority of cases of anosmia are acquired, a small minority of individuals is born anosmic; however, the exact cause for this congenital condition remains unknown (Feldmesser et al., 2007). The principal genetic syndrome associated with permanent anosmia, Kallmann syndrome, is associated with mutations in a variety of genes, many of which are related to defects in neuronal migration. Like the sense of taste, a variety of medications can affect olfactory perception in adults (Schiffman, 1983) (Table 9-2). Moreover, certain metals (e.g., cadmium, zinc, mercury), tobacco products, and a variety of industrial substances cause olfactory loss or distortion.

Several psychiatric conditions are associated with olfactory dysfunction among adults (Box 9-2). Although many posit that relationships exist between olfactory dysfunction and neuropsychiatric disorders among children (Schecklmann et al., 2013), the lack of standardized methodologies and control measures, and potential confounds such as attention and medication use make definitive diagnoses or conclusions difficult. Nevertheless, many disorders are often associated with changes in feeding behaviors (e.g., “picky” eating), which may involve each of the chemical senses.

In assessing picky eating, a thorough medical history and physical examination are recommended to assess the child’s growth and nutritional status and to determine the presence of underlying conditions that may result in feeding problems, such as premature birth, gastroesophageal reflux, swollen tonsils, viral infection, or food allergies. A focused feeding history should be completed, including the duration of the feeding problem, whether the child has shown signs of difficulty swallowing, whether the child was ever placed on nothing-by-mouth (*nil per os* [NPO]) for prolonged periods of time, and whether associated medical interventions centered on the mouth area. Parents should be asked to report on the child’s behaviors associated with the feeding problem, including whether anything specific aggravates or alleviates the problem, whether the child indicates hunger or demonstrates an appetite, typical meal duration, and even parental temperament and expectations during feeding times. Because underlying causes of picky eating are oftentimes not due to a medical condition but may be due to lack of prior experience—for example, limited exposure to particular foods or a variety of foods and flavors—understanding all aspects of a child’s feeding history is imperative to developing treatment strategies to help the child improve eating behavior.

## SUMMARY

The chemical senses of taste, smell, and chemical irritation convey information that warns us of environmental hazards and determines the flavor of ingested foodstuffs. The complex process that generates pleasure or displeasure upon ingesting food is mediated both by the chemical senses in the periphery and by multiple brain substrates, which are remarkably well conserved phylogenetically. Hardwired from birth, the basic biology of humans steers us to seek out sweet (energy-dense), salty (mineral-dense), and savory (protein-rich) foods and to reject bitter-tasting toxins and unripe sour foods.

The fetus and newborn infants have functioning chemosensory systems, and infants’ feeding and expressive behaviors are modulated by taste and smell stimuli. Although these sensory systems are operable early in ontogeny, the fetus and newborns are not merely miniature adults, because their sensory systems mature postnatally and are influenced by experience in ways not yet fully understood. Like other sensory systems, taste is experienced through a “sensory window” that changes with age and experience and is partially defined by genetics. Children’s basic biological preferences for sweet and

salty and rejection of bitter tastes are heightened during childhood. These sensory and biological considerations shed light on why it is difficult to make lifestyle changes in young children and why it is difficult for children to eat nutritious foods when these foods do not taste good to them or take medicines that taste extremely bitter. We cannot easily change the basic ingrained biology of liking sweets and avoiding bitterness.

What we can do is modulate children’s flavor preferences by providing early exposure, starting in utero, to a wide variety of healthy flavors and moderating exposure to salt. The reward systems that encourage us to seek out pleasurable sensations and the emotional potency of food- and flavor-related memories initiated early in life together play a role in the strong emotional component of food habits throughout the life span. An appreciation of the complexity of early feeding and a greater understanding of the cultural and biological mechanisms underlying the development of food preferences will aid in our development of evidence-based strategies and programs to improve the diets of our children. Better understanding of the scientific basis for distaste and how to ameliorate it is a public health priority for advancing availability of formulations of drug products that will be accepted by children and getting children off to a good start in food choices and preferences. The study of smell and taste perception in clinical populations of infants and children and the influence of chemosensory dysfunction on nutritional status have received little scientific attention, and they remain important areas for future investigations.

## Neuropsychological Assessment

Margaret Semrud-Clikeman and Kenneth F. Swaiman

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

### INTRODUCTION

Pediatric neuropsychology differs from adult neuropsychology because development is incomplete and brain differences emerge through childhood and adolescence that interact with the environment changing brain structure and neural pathways (Giedd, 2004). A discussion of neuropsychological assessment can be found in several excellent texts (Lezak et al., 2004). The teaming of neurology and neuropsychology can provide state-of-the-art service to children, particularly those with complex and refractory disorders.

Because development is an important aspect at both ends of the life span, it is important to recognize the neuropsychological differences that may occur and the manner in which they may relate to interventions. Moreover, an important aspect for children is the ability to do well in school. Executive functioning is an important aspect of academic and social success. Executive functioning in the areas of planning, organization, emotional control, and inhibition are all important skills for success. Frequently physicians are consulted about difficulties in these areas. An important reference to assist physicians, teachers, and parents in working with children with difficulties in this area has been published by Lynn Meltzer (Meltzer, 2007). Finally, studies that link brain imaging differences in children with autism (Adolphs, 2002) and attention-deficit/hyperactivity disorder (ADHD) (Semrud-Clikeman et al., 2006) are providing new windows into our understanding of these disorders.

### NEUROPSYCHOLOGICAL ASSESSMENT

#### What is a Neuropsychological Assessment?

Neuropsychological assessments are frequently completed to provide additional information about a variety of developmental disorders. The most common referral questions concern medical disorders including genetic disorders, concussion/traumatic brain injury, recovery from cancer/brain tumors, and other neurologic concerns such as epilepsy and movement disorders. In addition, children who have acquired disorders such as those resulting from exposure to lead or other teratogenic substances are also frequently referred for an evaluation. Disorders such as dyslexia, ADHD, autism spectrum disorder, and fetal alcohol spectrum disorder are common reasons for referral for assessment, particularly when typical interventions have not been successful. Psychiatric disorders such as obsessive-compulsive disorder, anxiety and depression, and behavioral dysregulation are referred for evaluation to more fully understand the child's difficulty and to provide recommendations for intervention in the home and at school.

Child clinical neuropsychology is best viewed within an integrative perspective for the study and treatment of child and adolescent disorders. By addressing brain functions and the environmental influences inherent in complex human behaviors, such as thinking, feeling, reasoning, planning, and executive functioning, clinicians can assist neurologists and

pediatricians in providing the most appropriate service to children with severe learning, psychiatric, developmental, and acquired disorders (Chapters 50 and 58 and chapters in part XIX). Although clinical psychologists and neuropsychologists use similar measures, the interpretation differs. A neuropsychologist views test findings through the lens of neurodevelopment. With our burgeoning knowledge of neural development from studies of serial magnetic resonance imaging, we are able to more fully understand how the environment, genetics, age, gender, and experience can alter brain activity and brain development (Shaywitz et al., 2004). Attention to the scope and sequence of development of cortical structures and related behaviors that emerge during childhood allows further understanding of the effect of interventions, instructional opportunities, and enrichment on the neurodevelopmental process.

Due to the complexity of the brain, and in particular the developing brain, it is most appropriate to utilize a transactional approach to the study and treatment of childhood and adolescent disorders. A description of a transactional approach is that it takes into consideration how abnormalities or developmental complications interact with the environment, how development itself affects the nature and severity of impairment, how to most efficiently assess these difficulties, and how to determine the most appropriate interventions. In this model, neuropsychological assessment—correctly completed—is therapeutic. In this view, the child's performance on appropriate measures plus the feedback to the medical professional, parent, and school provide a basis for understanding the child's strengths and weaknesses and for participating in the development of appropriate interventions. A transactional approach stresses consultation and collaboration with the caregivers of the child (as well as assisting the child in adjusting to his/her areas of challenge) but also with medical practitioners. In summary, child clinical neuropsychology is best viewed within an integrated framework, incorporating behavioral, psychosocial, cognitive, and environmental factors into a comprehensive model for the assessment and treatment of brain-related disorders in children and adolescents.

Current theory posits that regions of the brain have a bidirectional influence on various neural functional systems, which in turn affect the intellectual and perceptual capacity of the child. The child's behavioral, psychological, and cognitive manifestation of a childhood disorder is likely influenced by the interaction of these functional systems. In addition, the child's neurologic functioning also interacts with his/her social, family, and school environments that facilitate compensatory or coping skills in the individual child, which are either helpful or problematic.

Theorists have hypothesized that developmental regulation underlies behavioral and biological functioning. In other words, biological vulnerabilities influence and are influenced by coping skills and stresses experienced in the child's life. Such adaptation may or may not be efficient or "healthy" but can be viewed as the child's attempt to achieve self-stabilization. In such a paradigm, the individual reacts to both internal and

external environments as he or she attempts to make his or her way in the world. Children who experience severe neglect and/or abuse in utero have been found to exhibit significant dysregulation and disruption of the hypothalamic-pituitary-adrenal axis affecting emotional and neuropsychological development (Tarullo and Gunnar, 2006).

The transactional model incorporates these findings by assuming a dynamic interaction among the biogenetic, neuropsychological, environmental, cognitive, and psychosocial systems. Further, biogenetic forces shape the child's experiences and are most predominant during embryogenesis and early infancy. As the child develops, the social and cultural environment in which he or she lives begins to influence the child's neurologic development. Moreover, the child's temperament also interacts with all of these environments and causes changes in these environments.

The quality of fit between the caregiver's and the child's temperaments can result in adaptation to difficult behavior or exacerbation of this behavior. For example, a child who is fussy and difficult will not fare as well with an anxious or domineering parent as with a more even-tempered parent. Similarly, an "easy" child will generally work well with any parent. A "difficult" child-"easy" parent match may be advantageous in that the parent can help reduce the adverse effects of the child's inborn biological tendencies. So, although parental caretaking may not change the biological tendencies of the child, it may buffer biological vulnerabilities (Rothbart and Sheese, 2007). For those children who experience early deprivation and/or abuse, parental caretaking begun at later ages may not be able to fully buffer neurologic differences that are laid down early on. Rather, the child may always have these difficulties and will need additional support to develop appropriate coping mechanisms. The physician is well placed to understand neurologic development within the lens of transactional theory.

## MULTICULTURAL FACTORS

It is important to note that most neuropsychological measures have not been standardized on ethnicities beyond middle-class whites. Cultural expectations and mores have just begun to be studied in neuropsychology. In the past, neuropsychology has suggested that the brain may not be culturally bound. Currently, culture and neurodevelopment has been implicated in handedness, specialization of the cerebral hemispheres for tasks, and self-reports of behavioral functioning (Carlson et al., 2000). Differences in language may also affect neuropsychological assessment even when an interpreter is utilized. Some words or concepts do not readily translate from English. Moreover, the standardized norms may not apply to the patient's ethnicity.

An example of these difficulties is exemplified in a study by Keith and Fine (2005) which focused on possible ethnic differences in learning. Quality and quantity of instruction, previous achievement, and motivation were statistically evaluated across Anglo-American, African American, Hispanic, Native American, and Asian American groups. Although higher quality of instruction was found to lead to better achievement across the groups, quality of instruction appeared to be less important for Native American groups than quantity of instruction. Quantity of instruction was also found to be important for the Asian American population. In contrast, academic motivation and prior achievement were the best predictors for learning for the Anglo-American students. There were also differences for African American and Hispanic students where motivation, previous achievement and coursework were the strongest influences on their resultant learning. These findings indicate that children of different ethnicities

may benefit from differing strategies and that cultural differences may play a major role in task performance.

## NEUROPSYCHOLOGICAL TESTING

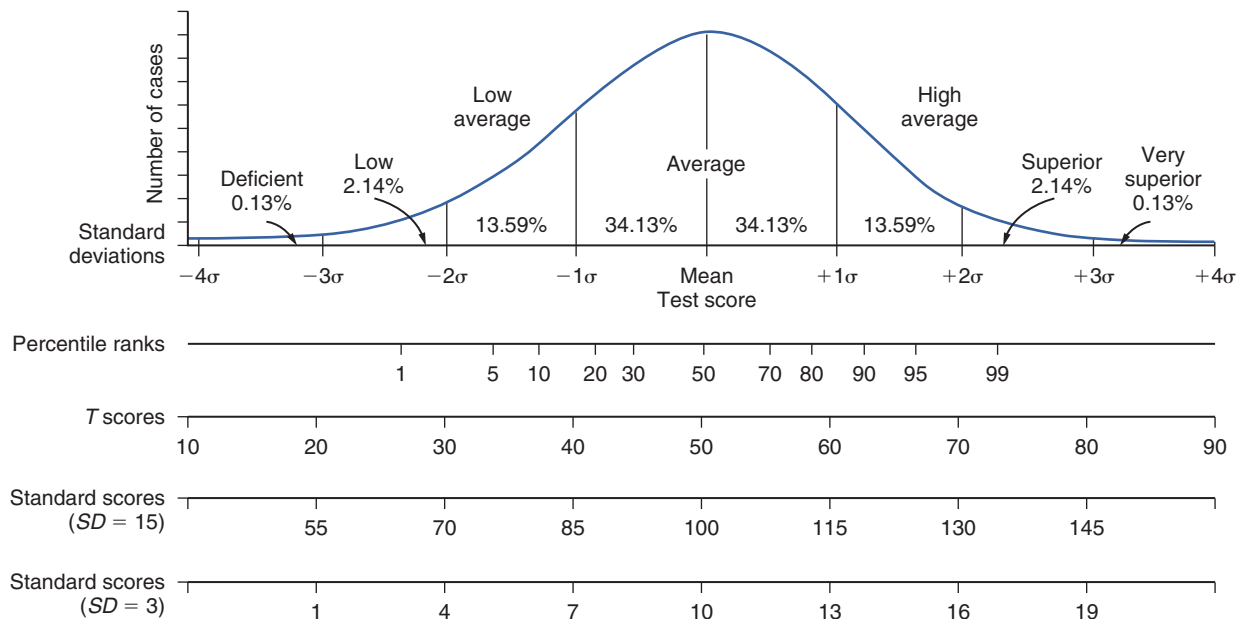

Neuropsychological testing can be very useful to the neurologist in assisting in developing appropriate interventions. Neuropsychological testing is generally an adjunct to the neurologic assessment and can be helpful in establishing areas of strengths and weaknesses that can then be translated into assistance in the school setting. Most neuropsychologists use a flexible battery that covers the main domains of functioning to assess children. Generally, the focus in neuropsychological assessment with children and adolescents revolves around the following tenets:

- It is important to discriminate between behaviors present within a normal neurodevelopmental framework from those which are delayed or which are a result of alterations of the central nervous system given the child's social-environmental context.
- Learning deficits/disorders and behavioral difficulties are examined within the context of brain function.
- Recovery of function after brain injury, neurosurgery, and radiologic/chemotherapy treatment is monitored to assess the effect of these treatments on normal development and emotional/behavioral adjustment.
- Focus is present on the different neuropsychological domains of functioning, particularly in the areas of cognition, executive functioning, memory, motor, behavior, and emotion during recovery or during a neurodevelopmental course.
- Neuropsychology investigates the psychiatric disorders of children with severe neurologic disorders.
- Neuropsychology assists in the design of remediation programs, particularly when used within an integrated clinical framework.

Scores on neuropsychological measures are generally one of four types. *Scaled scores* are generally found on the subtests of major measures including the Wechsler Intelligence Scales, executive functioning scales, as well as some of the achievement batteries. *Average scaled scores* are between 7 and 13 with a mean at 10. Scores between 5 and 7 are below average and those 4 and lower are considered significantly below average. Scaled scores between 13 and 15 are above average and those above 15 are significantly above average. [Figure 10-1](#) illustrates these different types of scores. *Standard scores* are those with a mean of 100 and average performance between 85 and 115. Most overall IQ measures, adaptive functioning, and executive functioning measures are based on these standard scores. As seen in [Figure 10-1](#), scores 116 to 130 are considered high average and those above 130 superior. Scores from 70 to 84 are considered low average and those below 70 are considered significantly below average. *T scores* are used with some ability measures (Kaufman Assessment Battery for Children and Differential Ability Scales) and with developmental measures (Mullen Scales of Early Learning) as well as with many behavioral rating scales. Average T scores range from 40 to 60 with scores above 60 classified as high or above average and those below 40 as below average or low average.

In some cases, scores will be presented with percentiles. Percentiles cannot be used as precisely as scaled, standard, or T scores and cannot be subtracted or added. Rather, they give an idea of how the child compares to other children his/her age. At times, age equivalents and grade equivalents may be reported, but these are only rough estimates and should be used with extreme caution. A child in third grade who scores at a first grade level is not performing as a first grader would

**Figure 10-1.** Normal curve showing standard scores, T Scores, Percentiles, and Z-Scores. (Modified from [www.assessmentpsychology.com](http://www.assessmentpsychology.com). ©2005–2014. William E. Benet, PhD, PsyD. All rights reserved.)

on the material; rather, it means that the child shares with the average first grader the number of items correct on the test and should only be interpreted in reference to the child's current grade comparison group. Similarly, age equivalents are obtained by computing the average raw score obtained by children at different ages.

Table 10-1 describes the major measures used by most child neuropsychologists. It is not meant to be an exhaustive list of all available measures as that is beyond the scope of this chapter. Table 10-1 is intended to provide basic information about the measures frequently reported in neuropsychological assessments. Unless noted otherwise, higher scores are desirable.

## WHEN TO REFER FOR NEUROPSYCHOLOGICAL EVALUATION

Neuropsychological evaluations are generally recommended under the following conditions:

1. Conditions affecting the central nervous system, such as head trauma, chemotherapy/radiation treatment, genetic disorder, neurodegenerative disorders, transplant (solid organ or bone marrow), and seizures. Serial evaluations are particularly important for these children in order to monitor recovery as well as to assess treatment efficacy.
2. Learning difficulties that have not responded to traditional educational intervention, particularly when there are soft neurologic signs present. Soft signs include toe-walking, concurrent movement in a body part not required for a motor task (synkinesia), problems with perception of finger location as well as tactile sensations (agnosia), problems with completing rapid alternating movement in a limb or body part (dysdiadochokinesis), and tactile localization as well as minor reflex asymmetries in the presence of normal cognitive development.
3. Severe mood and behavioral dysregulation that have been resistant to traditional psychopharmacological, psychological, or behavioral interventions.

4. Acute onset of memory, cognitive, academic, motor, speech/language, behavioral, and behavioral dysregulation disorders.
5. Regression of skills previously mastered.

## THE NEUROPSYCHOLOGICAL REPORT

A good neuropsychological evaluation and report will include measures of cognition, executive functioning, learning/memory (visual and oral), fine motor, visual-motor, behavior, and emotion. Generally, neuropsychological reports begin with an explanation of the referral question and then move into background information concerning the child's gestation, delivery, early development, and medical history.

One of the most important aspects of the neuropsychological report is the section describing the behavioral observations. This section describes the child's reaction during the session as well as any unusual observed behaviors. Particular emphasis is given to the child's attention to task, frustration tolerance, and the ease with which rapport is established. These aspects of the child's behavior affect the results that are found and are very important for understanding the validity and reliability of the assessment. Good neuropsychological reports not only synthesize in an understandable manner the findings from tests, but they also incorporate the background information, medical history, and behavioral observations into a coherent story to assist with treatment. In addition, the report should provide tailored recommendations for home, school, and if appropriate, medical treatment. Table 10-2 provides the aspects of a good neuropsychological report. A Roman numeral will highlight these aspects in the following excerpts.

The sample report contained in this section is representative of a report that was found to be useful by the neurologist who referred the child:

*I. Reason for Evaluation: Sasha Small is a 9-year, 10-month old, right-handed male who was referred to the Pediatric*

**TABLE 10-1** Most Commonly Used Neuropsychological Measures

Neuropsychological Measure	Age Range	Description	Comments
<b>DEVELOPMENTAL SCALES</b>			
Bayley Scales of Infant Development III (BSID III)	1–42 mos	Provides overall cognitive scores as well as scores in the areas of language, motor, and behavior.	Excellent overall measure. Reliability and validity are very good. Must be administered by a trained professional.
Mullen Scales of Early Learning	Birth to 68 mos	Provides scores and age equivalents for expressive language, receptive language, fine motor, gross motor, and visual reception (measure of problem solving).	Very child friendly—attractive tasks which are quite hands on. Can be administered by trained nurses as well as psychologists.
Denver Developmental Screening Test II	Birth to 6 yrs	Provides age equivalents in the areas of motor, language, and social.	Good screening measure and should be used to refer for further testing if needed. Nurses and nurse practitioners can administer.
<b>COGNITIVE</b>			
Wechsler Primary and Preschool Scale of Intelligence (WPPSI) IV	2–6:7–3	Provides overall score as well as scores on verbal comprehension, perceptual reasoning, working memory, and processing speed.	Excellent measure of cognitive ability for children without language difficulties.
Wechsler Intelligence Scale for Children V	6:0:16–11	Similar to WPPSI.	One of the best measures of overall ability, providing information about working memory and processing speed as well as general language and perception. Very strong psychometric properties. Requires advanced training for administration and interpretation.
Kaufman Assessment Battery for Children II	3–18	Provides a measure of cognitive functioning with less dependence on language. Results in scores for planning, knowledge, simultaneous, and sequential reasoning; also has a nonverbal score.	Good measure for children of different cultures or whose first language is not English. Is relatively easy to administer and score. Usually administered by psychologists/neuropsychologists.
Stanford-Binet Intelligence Scale 5	2–85+	Provides scores for verbal ability, perceptual reasoning, working memory, and overall ability.	Excellent measure for younger children with difficulty with attention and motor control. With older ages, the load on language is substantial.
Differential Abilities Scale II	2–6:17–11	Provides measures of verbal skills, memory, and nonverbal processing. Also has an achievement scale.	Excellent measure for children with reduced attentional skills, autism, and behavioral regulation difficulties.
Woodcock-Johnson Test of Cognitive Abilities Cognitive Battery IV	2–85+	Measures of fluid reasoning, auditory processing, memory, attention, visual-motor skills. More like an academic test.	Very long battery than can take over 90 min to administer. Not frequently used by neuropsychologists—more often used in education.
Universal Nonverbal Intelligence Test	5–0:17–11	Provides an overall measure of ability—does not use language.	Excellent measure for hard-of-hearing children as well as English-as-a-second-language learners.
Leiter International Intelligence Scale-3	3–75+	Nonverbal test.	Good for deaf, hard-of-hearing and English-as-a-second-language learners.
Comprehensive Test of Nonverbal Intelligence 4	6–0:89–11	Nonverbal measure.	Fairly good screen for ability but as defined there is no language component.
<b>EXECUTIVE FUNCTIONING</b>			
A Developmental NEuroPSYchological Assessment (NEPSY II)	3–16	Comprehensive test of measures of memory (verbal and visual), attention, inhibition, verbal fluency, sensorimotor skills.	Excellent measure for executive functioning as well as for memory and motor skills. Most clinicians do not use the full battery as it can take more than 2 hours to administer. Requires a psychologist/neuropsychologist to administer.
Delis-Kaplan Executive Function System	8–89	Comprehensive measure of executive functioning including measures of working memory, metacognition, perspective taking, attention, planning, and organization.	Excellent measure of executive functioning. Requires a skilled neuropsychologist for interpretation. Most clinicians use some subtests rather than full battery as it can take more than 2 hours to administer.
Behavior Rating Inventory of Executive Functioning	2–18	Parent, teacher, and self-rating of basic executive functioning skills.	Provides measure of emotional control, behavioral regulation, and metacognition. Computer scored. Can be administered by medical personnel as well as psychology.
Wisconsin Card Sorting Test	6–6:89	Measure of cognitive flexibility, attention, distractibility, and problem solving.	Complex administration and scoring require additional training—generally administered by neuropsychologists.

**TABLE 10-1** Most Commonly Used Neuropsychological Measures (Continued)

Neuropsychological Measure	Age Range	Description	Comments
<b>MEMORY</b>			
California Verbal Learning Test—Children's version	5–16:11	Requires the child to learn a list of words and provides 4 additional practice trials. Also provides a delay as well as cues to remembering the list.	Good and relatively easy measure of short- and long-term memory as well as learning rate.
Wechsler Memory Scale-IV	16–0:90–11	Appropriate for patients 16 yrs and older. Provides a comprehensive evaluation of memory as well as individual scores of visual and auditory memory.	Good measure of memory, both long and short-term. Full test requires more than 1 hour to administer. Most clinicians use a part of the measure. Generally administered by psychologists.
Rey-Osterrieth Complex Figure Test	5–0 to adult	Requires the patient to copy a very complex figure and then 20 minutes later to draw from memory.	Easy to administer—requires some training for interpretation. Measures planning and organization as well as visual-motor skills.
Test of Memory and Learning-2	5–0:59–11	Measures of visual and auditory memory as well as the patient's ability to learn a novel task.	Good measure of overall memory.
<b>MOTOR</b>			
Purdue Pegboard Test	3–adult	Measure of fine motor dexterity.	Can compare dominant, nondominant, and both [hands] together scores. Easy to administer and score.
Grooved Pegboard Test	5–adult	Measure of fine motor dexterity.	Can compare dominant and nondominant hands. More complex than Purdue as it has pegs that fit only one way into the hole.
Tapping	5–adult	Measure of fine motor speed.	Provides scores for dominant and nondominant hands. Patient must tap quickly on a key. Easy to administer and score.
Grip Strength	6–adult	Measure of hand strength.	Provides measure of hand strength for dominant and nondominant hands. Easy to administer and score.
<b>ACHIEVEMENT</b>			
Gray Oral Reading Tests IV	6–0:23–11	Measure of reading accuracy, rate, and comprehension.	Good and fairly quick measure of overall reading ability.
Woodcock-Johnson Test of Achievement Battery V	2–85+	Provides a detailed measure of reading ability, mathematics, written language, and auditory comprehension.	Requires some training for administration. Must be computer scored.
Wechsler Individual Achievement Test III	4–0:50–11	Provides a detailed measure of reading, mathematics, and written language as well as oral comprehension.	Requires some training for administration, scoring, and interpretation.
<b>BEHAVIOR RATING SCALES</b>			
Behavior Assessment System for Children-2	2–adult	This is a comprehensive measure of behavior and emotional development. Provides T scores for externalizing, internalizing, and adaptive behaviors.	Has a parent, teacher, and self-report form. Easy to administer and relatively easy to interpret. Has computer scoring. Is unique as it also has adaptive behavior scales. Different forms for preschool, ages 8–11, ages 12–21, and adults.
Achenbach System of Empirically Based Assessment (Child Behavior Checklist)	18 mos–90+	This is a comprehensive measure of behavior and emotional skills. T scores are available for internalizing and externalizing behaviors.	Widely used. Has a teacher, parent, and self-report form. Easy to administer and relatively easy to interpret with computer scoring. Assessment has multicultural applications in Africa, Asia and South America.
<b>ADAPTIVE BEHAVIOR SCALES</b>			
Vineland Adaptive Behavior Scale	0–90	This measure provides parent, caregiver, and/or teacher input as to the child's performance in communication, daily living skills, socialization and for children ages 5 and under, fine and gross motor skills. There is also a measure of problematic behaviors.	Relatively easy to administer and score. The scale can be compared with ability scores as well as to language skills. There are two forms—the rating scale completed independently by the parent or the interview scale. The interview scale requires additional training.
Adaptive Behavior Assessment System, 3rd edition	0–89	Has 5 forms based on age. Is completed by parents and teachers. Provides 3 adaptive domains (communication, socialization, daily living skills).	Very easy for parents to complete. Has parent, teacher/day care provider forms as well as an adult form.

**TABLE 10-2** Details of an Optimal Neuropsychological Report

Report Aspect	What is Included
I. Reason for Referral	Clear, concise, explanation for referral; name of referring professional; relevant medical information.
II. History	Provides relevant information about parental education, family composition and history, current stressors, medical and social history.
III. Behavioral Observation	This very important section provides information about how the child approached the tasks, attention, language, mood, and how easily rapport was established. It also includes a statement as to how valid and reliable the results are which were obtained.
IV. Tests Administered	This is a brief list of what measures were utilized.
V. Test Interpretation and Impressions	This is the body of the report and includes information as to how the child scored on measures of cognition, language, attention, memory, and motor skills. It concludes with a summary statement that not only provides information as to what these findings mean and what diagnoses are appropriate, it also links these findings to neurologic and psychological functioning.
VI. Recommendations	This section provides recommendations and is generally grouped into three sections: school, medical, and home.

*Neuropsychology Clinic by the Neurofibromatosis Clinic. Sasha has a history of neurofibromatosis type 1 (NF1), a genetic syndrome that is associated with physical manifestations such as skin abnormalities, as well as increased risk for learning disabilities and behavioral problems. At present, Sasha attends fourth grade in a regular education classroom. He receives speech therapy to address concerns related to articulation. His parents reported several behavioral concerns, including immature behaviors, difficulty making friends, and frequent angry outbursts. The purpose of the current evaluation was to assess Sasha's neurocognitive functioning and to assist with educational and treatment planning.*

The next part of the report should provide a short synopsis of the family and social history. This section should include information about the parents and their education, the family makeup, and any stressors currently being experienced. In addition, the developmental and medical history should provide information about the pregnancy and delivery as well as developmental milestones and any concerns that were present during infancy and toddlerhood. It should also provide information as to whether the child has had any head injuries, experienced any domestic violence or other trauma, and information about the child's vision, hearing, sleep, and appetite. After this section, information about the child's school history is very helpful, particularly outlining whether the child has any special accommodations, has been evaluated by his or her school or another clinician, and what reports the teachers have made as to the child's academic progress and social and behavioral functioning. It should also provide information about what psychological services (therapy) have been put into place for this child. Finally, within this section,

it is optimal to have a summary section that concisely discusses the child's current level of functioning. The following excerpt illustrates this summary:

*II. Current Functioning: Sasha's parents reported primary concern regarding Sasha's difficulties with behavioral regulation and social development. His mother indicated that Sasha's behavior can be difficult to manage when he is angry or he does not get his way. He will have long "fits" if his parents tell him to do things he does not want to do (e.g., brush teeth, change clothes, take a shower, turn off electronics, or practice math/reading). Sasha frequently becomes angry or jealous of his sister, who does not tend to misbehave or get into trouble. He will frequently yell at her and sometimes he will become aggressive and hit her. His parents noted that despite these behaviors, Sasha can also be sweet, kind-hearted and gentle at times.*

As stated, the behavioral observations section is very important for understanding how the child was during the assessment, his/her level of engagement, how difficult/easy it was to establish rapport, and to describe areas of functioning such as language, attention, and mood. By reading the next excerpt one should be able to picture Sasha during the assessment and whether to have faith in the results.

*III. Behavioral Observations: Sasha's mother accompanied him to the evaluation. Sasha presented as a casually dressed boy who appeared his chronological age. He was appropriately dressed, but frequently walked around with untied shoelaces. He willingly accompanied the examiner and his mother to the testing room. After being seated and beginning the testing, Sasha did not take off his heavy winter coat until the examiner had prompted him to do so. Sasha was able to transition into testing without difficulty. Rapport was easily established and maintained. Sasha's speech was fluent, but he had difficulties with articulation and made several sound substitutions particularly the "r" sound (e.g., "three" = "thwee," "break" = "bwake"). His speech was usually intelligible, although the examiner occasionally needed to prompt him to repeat himself to understand what he said. Sasha asked questions or commented on the tests frequently, and occasionally made requests (e.g., asking for a break or a snack). Sasha frequently made comments when he felt that a test item was difficult. Sasha's eye contact was appropriate. No problems were apparent with fine or gross motor skills, and no unusual motor movements were observed. He wrote and drew with his right hand. It was notable that during a pegboard task, Sasha dropped pegs several times when trying to place them in the board.*

*Sasha was generally pleasant and cooperative throughout the evaluation. He had some difficulty regulating his body and would frequently stand up in his chair during the tasks. On some tasks he had difficulty waiting for directions to be completed before attempting to start the task, and the examiner often needed to prompt him to listen to all of the instructions. He was generally attentive to the tasks, although toward the end of the session he appeared more distracted and often looked elsewhere when the examiner talked with him. He was occasionally distracted by looking at some playground equipment outside the testing room window. His affect varied according to the topic but was appropriate to the situation. He appeared fatigued toward the end of testing and occasionally asked how much time was left. He took multiple long bathroom breaks during testing. Sasha showed a few behaviors that seemed more typical of a younger child. For example, when asked a question about whether he had ever purposefully hurt himself, he began hitting his head and joked that it was*

*“fun.” When the examiner followed up with additional questions, he denied a desire to hurt himself. Overall, Sasha seemed to put forth good effort on the testing and worked to the best of his abilities. Therefore the results of testing are thought to be a valid and accurate indicator of Sasha’s functioning in the areas assessed.*

The next section discusses the findings and should provide a concise and systematic review of the measures. Discussion of cognitive ability, memory, executive functioning, and behavioral/emotional functioning should be discussed. It is also important to tie these results to whatever medical, genetic, or brain difference is present. The following is very short excerpts of a much longer report to give a flavor of what should be included in a good neuropsychological report. Tests that were used are in italics and underlined allowing more efficient use of [Table 10-1](#).

**IV. Result and Impressions:** *Sasha Small is a 9-year, 10-month old boy with a history of neurofibromatosis type 1 (NF1). NF1 is an inherited neurologic disorder that can affect multiple systems of the body. It is associated with symptoms such as skin changes, neurofibromas (tumors that form on the nerves under the skin), skeletal abnormalities, and other complications. Additionally, problems with behavioral health can be one of the most significant features of the syndrome for many individuals. Research indicates that children with NF1 are at higher risk for cognitive and learning disabilities than unaffected children, as well as for social and behavioral difficulties. Due to this increased risk, it can be useful to obtain periodic developmental assessments to inform educational and treatment planning.*

This paragraph sets the stage for understanding the relationship between NF1 and the neuropsychological findings. The report then moves into the various domains that were assessed beginning with cognition:

*Results of the current evaluation indicate that Sasha’s overall intellectual abilities are broadly within the average range (Wechsler Intelligence Scale for Children-V). Sasha performed slightly weaker on verbal tests (i.e., those assessing his knowledge of verbal concepts and his ability to reason with words), scoring mildly below average. Finally, like many individuals with NF1, Sasha performed below average range on tests of working memory, suggesting a relative weakness in the ability to hold information in mind for short periods of time while solving a problem. Taken together, Sasha’s profile suggests that he has intact intellectual functioning, but he does better on tasks that require him to process visual information than tasks that depend on verbal or working memory abilities. Consistent with his overall average cognitive abilities, Sasha performed within the average range on a measure assessing his verbal learning and memory (California Verbal Learning Test-Children’s Version).*

The next section begins to characterize attention and executive functioning, two areas that significantly impacted children with NF. These findings did not result in a diagnosis of ADHD but did result in a finding of frontal lobe executive dysfunction. Frontal lobe executive dysfunction is a disorder characterized by difficulties with organization, working memory, and planning. These difficulties often translate into problems in academic skills particularly in the areas of mathematics:

*Attention skills are an area of concern for many children with NF1, and many children with this diagnosis also qualify for a*

*diagnosis of attention-deficit/hyperactivity disorder (ADHD). Results of the current assessment indicate that Sasha does demonstrate some weaknesses in attention, but at the current time these symptoms are not sufficiently impairing to warrant a diagnosis of ADHD (Test of Variables of Attention). Sasha does show evidence of difficulties with managing his impulses. On a questionnaire measure of executive functioning skills Behavior Rating Inventory of Executive Function (BRIEF), Sasha’s mother indicated significant concerns related to initiating tasks, managing his emotions, and monitoring his behaviors. On a similar questionnaire (BRIEF), his teacher indicated significant concerns related to inhibiting behaviors and self-monitoring. Sasha performed within normal limits on clinic-based measures of executive functioning (e.g., his ability to quickly generate words according to letter and category cues and his ability to rapidly scan and sequences sets of numbers and letters) (Delis Kaplan Tests of Executive Function). Results of the current evaluation suggest that Sasha does well with tasks when provided guidance and prompting by the examiner, but struggles with impulse control and self-monitoring when working independently. These results are consistent with a frontal lobe and executive function deficit, which is commonly seen in children who exhibit ADHD symptoms and encompasses Sasha’s difficulties with organizing an approach to schoolwork tasks.*

A good neuropsychological report also addresses the child’s psychological/emotional/behavioral functioning. The following section is an example of how a diagnosis of NF1 can affect the child’s adjustment.

*Emotionally, parent and teacher ratings did not indicate problems severe enough to indicate a mood or anxiety disorder, although his NF1 diagnosis and family history indicates that Sasha is at risk for these problems in the future. Therefore his social-emotional well-being should be monitored over time. On a questionnaire measure, his mother reported significant aggressive behaviors (e.g., often argues with parents, loses temper too easily, annoys others on purpose) and has depressive symptoms (e.g., is easily upset, complains about not having friends, is negative about things), suggesting that Sasha may be developing frustration surrounding his difficulties managing his behaviors and directs this frustration toward others (Behavior Assessment System for Children-2). Indeed, Sasha’s responses to a self-report measure indicated mild concerns related to negative thinking patterns and depression (e.g., feeling that he has too many problems, doesn’t seem to do anything right, and is not understood by others).*

Finally, a summary of the test results is very useful, and it is frequently the paragraph that most physicians turn to as the bottom line for the child:

*In summary, we are pleased to note that Sasha is functioning at age-expected levels in a variety of areas including intellectual functioning, his ability to learn and retain new information, and his mental flexibility. Overall, Sasha does not show significant intellectual or learning problems seen in some children with NF1, consistent with his overall mild features. These strengths suggest that Sasha has the capability to continue to do well academically. Sasha’s weaknesses with impulse control, social awareness, and mood regulation are commonly seen in children with NF1 and can be addressed in the classroom, at home or in recreational settings.*

The final section of the report should include recommendations that are reasonable and which can be implemented (Part VI in [Table 10-2](#)). Generally, recommendations in three

areas are provided: academic, behavioral, and psychological. The academic recommendations are written to assist schools in providing appropriate services for children and may recommend assessment for an Individual Educational Plan required under law for children suspected of a disability. In Sasha's case, he may qualify under the category of "Other Health Impaired" or, in some states, "Other Health Disability" due to his diagnosis of NF1. If he does not qualify for special education, he may qualify for assistance under the Americans with Disabilities Act that allows for support within the regular classroom for children with medical disorders.

The behavioral section often addresses the need for psychotherapy as well as for additional supports for emotional development. In this section, recommendations for parental support are also provided as well as directions for further evaluation if the child experiences more difficulty. For example we made the following recommendations:

*V. We recommend that Sasha's family, school professionals, and therapist continue to monitor Sasha for symptoms of a mood disorder. In the future, if his caregivers observe an increase in behavioral outbursts, diminished interest or pleasure in activities, withdrawal from activities he previously enjoyed, increased irritability, or if Sasha is experiencing increased worries that become distressing or difficult to control, they may wish to have him re-evaluated by a psychologist or a neuropsychologist to determine whether further mental health supports are needed.*

*We recommend that Sasha's caregivers focus on praising/rewarding Sasha for his effort and for improvements in his ability to regulate his behavior (e.g., "Wow! I liked how you kept thinking about that problem until you figured out a solution; nice work, buddy!," or "Awesome job listening!") rather than praising him for specific achievements or successes. For children like Sasha, too much focus on outcomes (e.g., grades, test scores, athletic achievements such as points scored in a game) may serve to create high levels of competitiveness and self-doubt. Praise that is focused on accomplishments and achievements can actually serve to increase negative self-perceptions if the child finds himself struggling to meet a goal. Instead, reinforcement of things like Sasha's effort, persistence and good attitude can help to take his focus off of "winning" and "achieving" and will likely result in Sasha being able experience more fun and enjoyment in his daily activities.*

As a follow-up to this case, the school used this report to develop a treatment plan to provide Sasha with appropriate interventions to assist with his development. Sasha had been participating in play therapy, which was not providing any

success in changing his behaviors or mood. After our discussion, therapy was shifted from play therapy to a more directed therapy that provided Sasha with tools to manage his behaviors.

## CONCLUSION

Pediatric neuropsychological assessments can serve as an important adjunct to clinical practice. A good neuropsychological report will not only provide a summary of the findings but will also provide appropriate interventions and support. The feedback to the parents of the results is an important therapeutic tool that can assist them in adjusting to some of the child's difficulties while also emphasizing the strengths that the child possesses. Neurology and neuropsychology are a natural alliance that can assist with appropriate support for children and their families.

## 11

## Spinal Fluid Examination

David J. Michelson

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

**INTRODUCTION**

For more than a century, physicians have employed lumbar puncture (LP) and examination of the cerebrospinal fluid (CSF) in the diagnosis and management of neurologic diseases. Major and lasting contributions to the study of CSF are represented by the textbooks written by [Merritt and Fremont-Smith \(1938\)](#) and [Fishman \(1992\)](#). CSF evaluation is contributing to our still-evolving understanding of the pathophysiology of central nervous system (CNS) disorders, while continuing to play an as yet indispensable role in the clinical management of many of those disorders.

**CEREBROSPINAL FLUID FORMATION, FLOW, AND ABSORPTION**

CSF is principally formed by secretion from the choroid plexus, villous invaginations of the walls of the lateral, third, and fourth ventricles that are richly vascularized and lined by a ciliated epithelium. The choroid plexus of the lateral ventricles is continuous through the foramina of Monro with the choroid plexus of the roof of the third ventricle. The arterial supply to this portion of the choroid plexus originates from the anterior choroidal arteries, which branch off from the internal carotid arteries, and from the posterior choroidal arteries, which are branches of the posterior cerebral arteries. The posterior inferior cerebellar arteries usually supply the choroid plexus of the fourth ventricle. Blood flow to choroidal vessels is almost 10 times greater than that to the cerebral cortex.

The capillaries of the choroid plexus, unlike those found in most other areas of the brain, have large fenestrations that offer little resistance to the passage of fluid, ions, and small macromolecules. Passage of blood past these capillaries creates an ultrafiltrate of plasma within the interstitial space at the basolateral surface of the epithelial cells.

CSF secretion depends on active transport proteins that are differentially localized on the apical and basolateral membranes of the choroid plexus epithelial cells. Water follows the flow of sodium ( $\text{Na}^+$ ) and chloride ( $\text{Cl}^-$ ) ions from the interstitial fluid (ISF) into the CSF. Carbonic anhydrase within the epithelial cells catalyzes the formation of carbonic acid ( $\text{H}_2\text{CO}_3$ ) from water ( $\text{H}_2\text{O}$ ) and carbon dioxide ( $\text{CO}_2$ ). Carbon dioxide diffuses freely into the epithelial cells from the bloodstream, but the dissociation products of carbonic acid, bicarbonate ( $\text{HCO}_3^-$ ), and hydrogen ( $\text{H}^+$ ), are exported across the basolateral membrane by  $\text{Na}^+/\text{H}^+$  and  $\text{Cl}^-/\text{HCO}_3^-$  exchangers. Sodium is then transported across the apical membrane, into the CSF, via  $\text{Na}^+/\text{K}^+$  ATPases ([Figure 11-2](#)). Water flows passively along the osmotic gradient created by this net ion flux from the ISF to the ventricles through aquaporin-1 channels.

Other specific active transport proteins present along the basolateral membrane allow transport into the CSF of essential hydrophilic micronutrients, including glucose, amino acids, purines, nucleosides, and vitamins. Transport proteins along the apical membrane work to clear the CSF of potentially toxic metabolites, such as organic acids and bases.

Tight junctions link the choroid plexus epithelial cells, limiting the free diffusion of ionic molecules and creating the blood-CSF barrier. Although protein diffusion is largely restricted, most of the small amount of protein found in the CSF is nevertheless of plasma origin. Maintenance of a relatively stable CSF composition, despite wide variation in the composition of the plasma, reflects the integrity of the blood-CSF barrier and the work of active transporters against concentration gradients.

The choroid plexus produces from 70% to 90% of the CSF, with the remainder deriving from movement of brain parenchymal ISF across the ependyma into the ventricles and across the pial membrane into the subarachnoid space. The rate of CSF formation in healthy adults averages 0.35 mL per minute, or roughly 500 mL each day. Children produce proportionally less CSF, depending on their height and weight, with as little as 25 mL produced per day in newborns. Postmortem studies have provided estimates that total CSF volume ranges from 50 mL in term neonates to 150 mL in adults, with only a small percentage contained within normal-sized ventricles. The total volume of the CSF undergoes complete replacement three to four times each day.

CSF production can be greatly reduced in experimental animals given the sodium-potassium ATPase inhibitor ouabain. Carbonic anhydrase inhibitors, such as acetazolamide, can reduce CSF production by 50% to 100% in rats. Acetazolamide reduces CSF production in humans just 6% to 50%, which explains the limited clinical effectiveness of this medication in the treatment of increased intracranial pressure. Furosemide and other loop diuretics also weakly inhibit carbonic anhydrase activity but also reduce CSF production through inhibition of sodium, potassium, and chloride cotransporters.

CSF produced in the lateral ventricles passes through the foramina of Monro into the third ventricle and then flows through the aqueduct of Sylvius into the fourth ventricle. CSF exits the ventricular system through the lateral foramina of Luschka to enter the prepontine cistern and cerebellopontine angles. Alternatively, CSF can leave the fourth ventricle through the midline foramen of Magendie, entering the cisterna magna, from which it can flow upward over the cerebellar hemispheres or downward into the spinal subarachnoid space and around the brainstem into the basal cisterns, including the interpeduncular cistern. CSF flows predominantly

**Figure 11-2. Major processes involved in cerebrospinal fluid secretion.** 1, Carbonic anhydrase catalyzes the production of bicarbonate ( $\text{HCO}_3^-$ ) ions and protons ( $\text{H}^+$ ) from water ( $\text{H}_2\text{O}$ ) and carbon dioxide ( $\text{CO}_2$ ). 2, Bicarbonate is exchanged for chloride ( $\text{Cl}^-$ ) across the basolateral membrane. 3, Bicarbonate and chloride flow into the CSF through anion channels, down an electrochemical gradient, and through sodium ( $\text{Na}^+$ )-potassium ( $\text{K}^+$ )-chloride cotransport. 4, Sodium is exchanged for protons across the basolateral membrane and for potassium across the apical membrane. 5, Water follows the osmotic gradient created by the combined secretion of sodium, chloride, and bicarbonate into the CSF. (With permission from Damkier HH, Brown PD, Praetorius J. *Physiology [Bethesda]*. 2010;25[4]:239–49.)

downward posterior to the spinal cord and upward anterior to the cord. The fluid eventually reaches the basal cisterns, from which flow is mainly upward over the brain convexity.

In the steady state, the rate of CSF absorption is equal to that of its production. Most CSF is absorbed into the venous sinuses across the arachnoid villi and granulations, arachnoid membrane invaginations through the dural lining of the sinuses that are concentrated near the sagittal sinus. Absorption across the arachnoid villi occurs by vesicular transport. This action demonstrates a dependence on the hydrostatic pressure gradient across the villous surface, such that the villi act as one-way pressure valves that open above a threshold pressure, usually 20 to 50 mm  $\text{H}_2\text{O}$ . Modern research utilizing radioactive tracers has shown that significant CSF absorption also occurs across the capillaries, veins, and lymphatics of the spinal cord and spinal roots, and, via the perineural subarachnoid space around olfactory nerve rootlets, through the cribriform plate and nasal lymphatics (Kapoor et al., 2008).

## CEREBROSPINAL FLUID FUNCTION

The CSF provides buoyancy and physical protection to the brain, absorbing the stretching and compressive forces generated by normal head movement and lessening the impact of the deceleration and rotational forces created by head trauma. A second protective function derives from the ability of the CSF to redistribute in response to acute changes in other intracranial contents, helping to maintain normal intracranial pressure. The CSF is also thought to serve as a route for the transport of centrally acting hormones, such as for the diffusion of hypothalamic releasing factors across the third ventricle.

The CSF aids in the excretion of metabolites through bulk absorption of the ISF of the brain and spinal cord. This “sink

action,” along with the various mechanisms by which the CSF composition is maintained, suggests that the CSF plays a significant role in normal physiology and in the compensatory response to pathologic situations.

## DIAGNOSTIC SAMPLING OF CEREBROSPINAL FLUID

### Indications

Changes in the composition of the CSF have been associated with a wide variety of neurologic conditions. Sampling of the CSF is considered helpful in the diagnosis and management of several such conditions in children, and may be most useful in cases of suspected meningitis, encephalitis, subarachnoid hemorrhage, intracranial hypertension (as in pseudotumor cerebri), leptomeningeal carcinomatosis, pediatric neurotransmitter diseases, and neurodegenerative diseases. In each case, the potential benefits of the information that can be obtained should be weighed against the risks of the procedures used for CSF sampling. Families should be involved as much as possible in the decision-making process to allow them to provide truly informed consent.

### Contraindications and Cautions

LP through a soft tissue infection such as cellulitis is discouraged because of concern that this can introduce bacteria into deeper tissues and cause an epidural abscess, osteomyelitis, or meningitis. The risk of a bleeding complication, other than a bloody tap, from a diagnostic or therapeutic lumbar puncture in patients with even severe thrombocytopenia is very low. Many pediatric hospitals follow a protocol for holding anticoagulants prior to lumbar puncture (low-molecular-weight heparin [LMWH] for 24 hours and unfractionated heparin [UH] for 4 hours) and restarting several hours afterward (4–6 hours for UH and 6–9 hours for LMWH), with a low risk of complications reported (Avila et al., 2014).

There is considerable and understandable fear that LP in patients with a CSF obstruction can unbalance the pressure across the area of obstruction and contribute to cerebral herniation or spinal cord compression. Neuroimaging, usually with cranial computed tomography (CT), is often performed before LP, especially in patients with suspected meningitis. However, herniation has been reported after normal neuroimaging, and LP has been performed safely in patients with abnormal CT scans, leading many to continue to debate the appropriate use of neuroimaging before LP. Because it is considered essential that antibiotic administration not be delayed when meningitis is suspected, especially with meningococcal disease, current recommendations are to start antibiotics as soon as possible, regardless of when LP can be performed (Gaieski et al., 2012).

### Procedure

The success of an LP is determined by the correct positioning of the needle and the patient, and depends almost as much on the relaxation of the patient and on the skill and experience of the assistants as it does on that of the needle-wielding physician. Local analgesia, with or without the use of additional anxiolytics, may be sufficient for cooperative older children, but moderate to deep sedation is often necessary for younger children. Although aggressive assistants can easily overpower neonates and young infants, obviating the need for sedation, they must take care not to cause airway compromise. Patients with abnormal lumbar spine anatomy, such as that resulting from a congenital defect such as spina bifida or an acquired

deformity such as scoliosis, may require direct imaging of the spine with fluoroscopy or ultrasound.

The lower end of the spinal cord, the conus medullaris, is found by MRI to be at the L1-L2 vertebral interspace in most subjects and safely above the L3 vertebral body in all subjects without spinal deformity. To avoid damaging the conus, only the interspaces below L3 are used for LP. With a patient lying in the lateral recumbent position, the L3-L4 interspace can be found at the level of the superior iliac crests. This area should be carefully palpated and marked to ensure that it can be identified after the patient is cleaned and draped. Having the patient curl with the neck and hips flexed can maximize the size of the interspace. Whether the patient is placed in a lateral recumbent or seated position, care should be taken to maintain the alignment of the shoulders and hips, avoiding rotation of the spine. Having the patient's back near the edge of the bed and at a proper height can aid in the comfort and success of the physician.

The patient's skin should be prepared using a microbicidal agent, such as a 10% solution of povidone-iodine. The skin should be given time to dry and then wiped clean and draped with sterile towels. A local anesthetic, such as a 1% solution of lidocaine, can be injected into the area to minimize the pain of repeated needlesticks. Anesthesia provides little benefit when the LP can be accomplished with a single needlestick, because the pain of the anesthetic injection often equals or exceeds that of the spinal needle insertion. A reasonable alternative is the use of a topical analgesic cream, such as the 5% emulsion of lidocaine and prilocaine commonly referred to as eutectic mixture of local anesthetics (EMLA). EMLA requires 20 to 30 minutes of application but has been associated with a decreased pain response, even in neonates.

The most commonly used spinal needles are 2.5- or 5-cm-long, 20- or 22-gauge Quincke needles, which are beveled and fitted with a stylet. The sharply beveled tip of the Quincke needle should be turned to face the patient's side so that its cutting edge can push between, rather than cut, the longitudinal fibers of the dura. Atraumatic needles, such as the Whitacre and Sprotte needles, have duller tips that make dural injury less likely. These needles are also more flexible, encounter more tissue resistance, and require the use of an introducer, making them more difficult to position. Advancing the needle without its stylet in place may increase the chances of successful and nontraumatic CSF collection, but has been discouraged because of concern that this will introduce cells that might later form a spinal epidermoid tumor.

The needle is gradually advanced, the ligamentum flavum and dura are pierced, and a slight popping sensation is felt as the subarachnoid space is entered. The stylet is removed to allow CSF to drain to the needle hub. If no fluid appears, the needle should be rotated a quarter-turn in case a nerve rootlet or strand of arachnoid is obstructing the opening. If this does not initiate CSF flow, the needle can be introduced a few millimeters more, sometimes resulting in a second popping sensation. If there is still no CSF, the stylet should be replaced and the needle slowly withdrawn for redirection of the needle toward the same interspace or for selection of another interspace.

After CSF is flowing from the needle, a stopcock and manometer should be attached to the needle hub. The opening pressure should be measured with the child relaxed and in the lateral decubitus position. There should be no direct pressure on the abdomen during the measurement. Slow CSF flow may be caused by partial needle obstruction or by low CSF pressure. One way to ensure that a low manometry reading is a true reflection of the CSF pressure is to apply firm pressure to the patient's abdomen. In the absence of an outflow obstruction or disconnection between the needle and manometer,

there should be a rapid rise in the manometer reading, followed by a rapid fall as abdominal pressure is released. An accurate manometry reading should also be accompanied by small fluctuations in the height of the fluid column with the pulse and respirations.

Opening pressures in adults and older children have historically been considered normal between 120 and 200 mm H<sub>2</sub>O, with pressures as high as 250 mm H<sub>2</sub>O considered normal for obese adults. A prospective multicenter study of opening pressures in children without medical conditions found a mean of 196 mm H<sub>2</sub>O, with the 90th percentile being 280 mm H<sub>2</sub>O (Avery, 2014). Pathologic elevations of the CSF pressure are discussed in Chapter 105.

After the opening pressure has been recorded, CSF can be collected for analysis. Abdominal pressure or Valsalva maneuvers can be used to increase slow flow. In the case of very slow flow, gentle aspiration with a syringe may be attempted, although this may increase the risk of pulling a nerve rootlet or strand of arachnoid into the needle. At least 5 mL of CSF should be collected; the first three tubes of 1 to 2 mL are sufficient for routine studies: Gram stain, bacterial culture, cell count and differential, and glucose and protein concentrations. If the first tubes are grossly bloody, a fourth tube of at least 2 mL should be collected to aid in the differentiation of subarachnoid hemorrhage from a traumatic tap. This tube can also be held in reserve for additional studies, such as special microbiologic, immunologic, or metabolic tests.

Replacing the stylet before withdrawing the spinal needle is recommended to avoid pulling a strand of arachnoid through the dura, creating a channel for continued CSF leakage and increasing the risk of postprocedural headache.

In special situations, CSF can be obtained by ventricular shunt or by ventricular or cisternal puncture, usually with the assistance of a neurosurgeon.

## Complications

Transient complications during the procedure include pain and paresthesias in the distribution of a lumbar nerve root resulting from contact with the needle. The discomfort should subside with repositioning of the needle toward the midline, and permanent nerve injury is highly unlikely.

More serious complications of LP do occur, although rarely. These mainly involve subarachnoid, subdural, and epidural hematomas resulting from a breach of the epidural venous plexus, radicular arteries, or radicular veins. Patients commonly have signs and symptoms of meningeal irritation or local pain. Severe symptoms, such as sensory, motor, or sphincter dysfunction, suggest the need for surgical hematoma evacuation.

Infectious complications, including meningitis, epidural abscess, and osteomyelitis, can result from the use of incompletely aseptic technique. LP in the setting of bacteremia or active hematologic malignancy is not strictly contraindicated.

The most common complications of LP are back pain and postprocedural headache. Postprocedural headache may occur within 72 hours of the puncture, may be worsened by an upright position and relieved by recumbency (orthostatic), and may be associated with neck stiffness, nausea, vomiting, and cranial nerve palsies. Pathologic reductions of the CSF pressure are discussed in Chapter 105.

Several technical aspects and patient factors appear to lessen the incidence and severity of postprocedural headache in adults, including the use of small-diameter needles or atraumatic needles, low body mass index, male gender, and lack of a history of headache. Bed rest after LP has not been found to prevent headache, but it is effective in reducing pain after it has developed. Similarly, prophylactic epidural blood patches

do not prevent headaches but are very successful in the treatment of refractory postprocedural headaches. Studies have been contradictory or negative regarding the use of steroids, hydration, or caffeine for the prevention or treatment of postprocedural headaches.

## CEREBROSPINAL FLUID ANALYSIS

### Appearance

Normal CSF is clear and colorless, indistinguishable from water when held up to white light in identical tubes. A cell count greater than 50 cells/mm<sup>3</sup> can cause a snowy scattering of light, but the eye cannot easily distinguish between white blood cells (WBCs) and red blood cells (RBCs). With RBC counts between 500 and 6000 cells/mm<sup>3</sup>, the CSF color becomes pink or xanthochromic.

### Cells

Counting chambers can provide CSF WBC and RBC counts, with a pathologist reviewing a stained slide for confirmation. Normal values for infants have been difficult to obtain, in part because LP is rarely done without an indication such as fever, but also because many early studies had small samples and included children with conditions known to elevate CSF cell counts, such as viral meningitis (Chadwick et al., 2011). Older infants and children have normal values similar to those of adults (Table 11-2).

Centrifugation and staining of the CSF are suitable for most clinical cytology. The WBCs found in normal CSF are typically 70% lymphocytes and 30% monocytes. An elevated WBC count or more than a few polymorphonuclear cells may indicate inflammation or infection within the CNS, but counts are not specific enough to allow ready differentiation, for example, of bacterial from viral meningitis. Neoplastic cells, plasma cells, stem cells, and eosinophils within the CSF are always considered abnormal. However, because cytologic analysis has such a low sensitivity, CSF testing for leptomeningeal metastasis of a systemic malignancy should be repeated multiple times and should employ large collection volumes. These points are examined in detail in Chapters 114 to 116, which discuss CNS infections, and Chapters 122 to 133, which discuss CNS malignancies.

Excessive RBCs in CSF can be diagnostic of subarachnoid hemorrhage (SAH), but can also occur with a traumatic LP.

Clot formation within the tube of CSF suggests a traumatic LP. RBC counts in serial tubes always decrease in cases of traumatic LP, but this should not be used to exclude the possibility of SAH unless the later tubes have a RBC count approaching zero.

A formula for the correction of the CSF WBC count in patients with suspected traumatic LP is widely used, in which 1 WBC is subtracted for every 500 to 700 RBCs found in the CSF. However, the use of corrections of this kind is unhelpful in the clinical diagnosis of meningitis.

### Microorganisms

The first 1 to 2 mL of CSF, even if contaminated with blood from a traumatic puncture, should be stained and cultured for microorganisms. Gram staining allows for an early bacteriologic diagnosis, and results may influence the choice of antibiotic treatment. Outside of a strong clinical suspicion, there is probably no benefit to the routine use of acid-fast stains and mycobacterial cultures, India ink preparations and fungal cultures, or viral cultures.

Latex agglutination tests for common bacterial antigens have shown diagnostic value in patients who had been treated with antibiotics before LP for suspected meningitis. Other studies have strongly questioned the value of such tests, finding high false-positive rates, low sensitivity, or no added benefit over Gram staining and culture. Several biomarkers, such as serum procalcitonin, have been tested for their ability to distinguish bacterial meningitis from viral meningitis in patients with a negative CSF Gram stain (Viallon et al., 2011).

Immunologic tests for antigens and antibodies and polymerase chain reaction tests for DNA and RNA can greatly aid in the identification of organisms that are difficult to culture. These techniques can be applied to cases of bacterial meningitis but are particularly useful in the evaluation of immunocompromised hosts, encephalitis, and chronic meningitis, when viral, fungal, rickettsial, and other unusual organisms are more likely to be identified (Baron et al., 2013).

### Glucose

Facilitated transporters on the membranes of capillary endothelial cells are responsible for the entry of glucose into the brain ISF. Normal CSF glucose concentrations range between 45 and 80 mg/dL, or about two thirds of the plasma glucose concentration. A CSF glucose concentration less than 40 mg/dL (i.e., hypoglycorrhachia) or a ratio of less than two thirds of the plasma glucose level is considered abnormal.

Very low CSF glucose values, sometimes below the limits of laboratory detection, are seen with diverse causes of severe meningeal inflammation, probably resulting from a combination of increased glucose use by the brain and spinal cord, glucose use by leukocytes within the CSF, and inhibition of glucose transport into the CSF.

Patients with defective transport of glucose across the blood-brain barrier resulting from mutations in the *SLCA1* gene encoding the GLUT-1 transporter typically present with low CSF glucose levels (<40 mg/dL), a low ratio of CSF glucose to plasma glucose (<0.6), and a medically refractory epileptic encephalopathy that shows response to treatment with the ketogenic diet. Patients may have fixed and/or paroxysmal movement disorders, sometimes as an isolated phenotype.

### Protein

The protein content of CSF is very low relative to plasma concentrations, with most plasma proteins excluded from the CSF by the blood-CSF barrier. The total protein content of the

\*N, the number of samples studied; SD, standard deviation.

†Protein concentrations (mg/dL) are reported as means ± standard deviations.

CSF is higher in neonates than in older infants and children (Table 11-3).

Combination of established techniques of two-dimensional gel electrophoresis with advances in mass spectrometry is leading to the development of a new field of study, quantitative neuroproteomics (Craft et al., 2013). Detailed CSF analysis of a variety of small molecules is advancing our understanding of the pathophysiology of CNS disorders and holds great potential for future clinical use in diagnosis and prognosis.

### Immunologic Analysis

CSF immunoglobulins, particularly immunoglobulin G (IgG), are increased with many inflammatory, infectious, and neoplastic conditions of the CNS. This increase is in large part a reflection of the impaired blood-CSF barrier, permitting increased entry into the CSF of all proteins, including albumin. Specific intrathecal production of IgG may also occur in these conditions, as can be demonstrated qualitatively with tests for oligoclonal banding and quantitatively with calculations such as the IgG index:

$$\frac{([\text{IgG}]_{\text{CSF}}/[\text{IgG}]_{\text{plasma}})/([\text{Alb}]_{\text{CSF}}/[\text{Alb}]_{\text{plasma}})}{}$$

Among patients with clinically definite multiple sclerosis, for example, up to 95% have intrathecal oligoclonal bands, and more than 70% have an elevated IgG index. Positive intrathecal oligoclonal bands are demonstrated for patients with other inflammatory disorders, from which multiple sclerosis must sometimes be differentiated. The utility of CSF analysis in the diagnosis of acquired demyelinating diseases is discussed in Chapter 100.

### Neurometabolic Studies

The usual laboratory evaluation of a child with unexplained encephalopathy consists of plasma, urine, and radiologic studies. When CSF is collected as a part of the evaluation,

metabolic tests can be expanded to include lactate, pyruvate, 5-methyltetrahydrofolate, and quantitative amino acid measurement. The appropriate patient selection and testing is discussed in Chapter 36, which provides an overview regarding metabolic disorders, and Chapter 44, which reviews neurotransmitter-related disorders.

## Pediatric Neuroimaging

Nathaniel D. Wycliffe, Barbara A. Holshouser, Brenda Bartnik-Olson, and Stephen Ashwal

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

A clear understanding of various clinical signs and symptoms of neurologic diseases in children and knowledge of normal neuroanatomy and its alterations in various disease processes are prerequisites for the correct performance and interpretation of the many powerful neuroimaging techniques available. In this chapter we provide an overview of the strengths and weaknesses of pediatric ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI). A discussion of the neuroimaging changes associated with normal brain development is beyond the scope of this chapter, but several excellent monographs are available (Barkovich and Raybaud, 2001; Provenzale, 2009; Tortori-Donati Rossi, 2005). Figures for this chapter appear solely in the online chapter version.

### CRANIAL ULTRASOUND

In the prenatal and perinatal period, real-time sonography is currently the most frequently used neuroimaging modality. The various methods of acquiring ultrasound images are discussed in the online chapter. Fetal sonography has had a marked effect on patient counseling and management but is limited by (i) nonspecific sonographic appearance of some anomalies, (ii) technical factors that make visualization of the side of the brain near the transducer and of the posterior fossa difficult to assess, and (iii) subtle parenchymal abnormalities that cannot be visualized sonographically. Figures 12-1 to 12-9 demonstrate some of the normal and abnormal features that can be detected. A wide array of central nervous system (CNS) pathology detected by prenatal sonography includes fetal seizures via abnormal movements, holoprosencephaly, encephalocele, schizencephaly, lissencephaly, hydrocephaly, Dandy-Walker malformation, spina bifida, and congenital astrocytoma.

In newborns, the open anterior fontanel provides an excellent window for the evaluation of the infant brain. Postnatally, sonography is helpful in the evaluation of hypoxic-ischemic encephalopathy, including complications of hemorrhage into the germinal matrix, ventricles, or surrounding parenchyma. For infants younger than 30 weeks' gestation, routine cranial ultrasonography screening should be performed once between 7 and 14 days of age, and should be repeated optimally between 36 and 40 weeks' postmenstrual age to detect lesions such as intraventricular hemorrhage, periventricular leukomalacia, ventriculomegaly, and intrauterine infections. Major migrational anomalies, such as agyria-pachygyria and lissencephaly, or tuberous sclerosis may be delineated; however, smaller heterotopias or other subcortical dysplasias may be overlooked. Sonography can be used to screen for myelodysplasia (see Chapter 19). It can also reveal the presence or absence of cord pulsations, a sign of tethering as well as other dysraphic lesions, such as meningocele, lipoma, hydro-myelia, Arnold-Chiari II malformation, diastematomyelia, and lipomyelomeningocele.

Intraoperative sonography is an important modality for the safe and specific guidance of neurosurgical biopsy or lesion resection, for the accurate placement of ventricular shunts,

drainage of intraparenchymal fluid collections, localization of brain or cord tumors, drainage of hydrosyringomyelias, delineation of posttraumatic intraspinal bone fragments, and for monitoring resection of arteriovenous malformations.

### COMPUTED TOMOGRAPHY

CT has been available since the 1970s for clinical use in children. Ionizing radiation resulting from x-ray CT is effectively restricted to the immediate body part and several generations of scanners are available, including the helical CT introduced in the early 1990s and the multidetector or multislice scanner. This availability has resulted in an increased number of computed tomographic scans of children, increasing the potential for inappropriate use and excessive radiation dosing. The risk of cancer from low-level radiation such as from a single CT scan is unproven. The life-saving benefits of these examinations in the care for individuals of all ages are proven and widely known. The cancer risk from CT is cumulative and special consideration must be given to children, who have a longer lifetime in which to manifest radiation-related cancer. It is necessary to limit radiation from CT in children and follow the ALARA ("as low as reasonably achievable") principle as discussed in the online chapter. All new CT scanners sold in the United States now comply with the National Electrical Manufacturers Association XR 25 CT Dose-Check Standard. Compliant CT scanners can be configured to inform operators when scan settings would likely yield radiation doses that would exceed preassigned values, allowing users to confirm or correct settings that might otherwise lead to unnecessarily high exposures.

The digital tomographic image is composed of a matrix of voxels (i.e., pixels with volume resulting from the finite thickness of the tomogram). Each voxel is assigned a numeric value called a CT number, which is related to tissue density. CT has good soft-tissue resolution and is especially useful along high-contrast interfaces, such as air-water, fat-water, and bone-water in the orbits, sinuses, and temporal bones. CT is limited by streaking artifacts in areas adjacent to thick bone or metallic objects such as dental fillings and gunshot wound pellets. These artifacts are particularly troublesome in the posterior fossa because of the dense temporal petrous bones.

CT scanners are fast and widely available for emergencies and for medically unstable patients. Direct scanning is routinely performed in the axial plane and if needed in the coronal plane. Multiplanar reformatting of axial image data can be accomplished; however, reformatted images have less resolution. Direct coronal computed tomographic examinations can be obtained for the enhanced evaluation of the orbits, sinuses, temporal bones, and temporomandibular joints. Coronal plane images can be used to evaluate patients for intrasellar, skull-based, midline, or vertex intracranial lesions. Three-dimensional reconstructions have been useful for surgical planning of craniofacial reconstructions.

Abnormalities can be characterized with CT as having low density, isodensity, or high density in relation to the brain.

Lesions that appear lower in density include edema, necrosis, infarction (Figure 12-10), neoplasms, leukodystrophies, inflammation, and cysts. Loss of gray–white matter differentiation may be seen with diffuse brain edema after hypoxic-ischemic injury or a demyelinating process. Fat-containing lesions usually appear less dense than water or of mixed density, as in patients with a teratodermoid type of tumor. Air appears as the lowest density (posttraumatic or postsurgical pneumocephalus). Isodense lesions are difficult to recognize unless there are changes that demonstrate displacement or replacement of normal structures or intravenous contrast materials that separate the lesion from normal structures. High-density lesions usually indicate hemorrhage or the presence of calcium (Figure 12-11). Pathologic intracranial calcifications can be seen with congenital infections, neurocysticercosis, intracranial tumors, tuberous sclerosis, Sturge–Weber syndrome, neurofibromatosis, Cockayne syndrome, hypoparathyroidism, arteriovenous malformations, Galen’s vein malformations, encephalomalacia, cerebral infarction, or the sequelae of perinatal asphyxia. Hypercellular neoplasms may also appear as high-density lesions on CT. Computed tomographic imaging can be used for precise localization during needle-biopsy procedures or volumetric resection of pediatric brain tumors. In neonates, non-contrast-enhanced CT after ultrasound is helpful in evaluating acute hemorrhage (Figures 12-12 and 12-13), developmental anomalies (Figures 12-14 and 12-15), acute trauma (Figures 12-16 and 12-17), suspected infarction (see Figure 12-10A), and hydrocephalus.

In childhood neurodegenerative diseases, CT may reveal decreased basal ganglia attenuation and cerebral white matter or focal or generalized cerebral atrophy. Noncontrast CT can evaluate patients with neurocutaneous syndromes to detect calcifications as in tuberous sclerosis (see Figure 12-15) and for the evaluation of patients with acute onset of seizures. After closed-head injury (accidental or nonaccidental), CT without contrast material is usually optimal for evaluation of the skull, intracranial hemorrhage, orbits, sinuses, facial or temporal bones, and osseous spine for fractures. Imaging patterns of intracranial hemorrhage in children younger than 3 years have been reported to predict whether the injury was intentional and include convexity or interhemispheric subdural hemorrhages, hygromas (i.e., nonhemic subdural fluid) with intracranial hemorrhage, and/or absence of a skull fracture with intracranial hemorrhage.

Iodinated contrast enhancement is normally seen as a high-density area within the brain and other normal tissues, including vascular and dural structures, pituitary gland, infundibulum, pineal gland, and choroid plexus, but normal parenchymal enhancement usually is too subtle to appreciate. Mechanisms of contrast enhancement include blood–brain barrier disruption, extravasation of intravascular contrast material, or accumulation of contrast material in hyperperfused regions.

Contrast-enhanced CT is helpful in the evaluation of suspected or known vascular malformations, neoplasms (Figure 12-18 and 12-11A), abscesses (Figure 12-19), and empyemas. In infants and children with chronic subdural hematomas, contrast enhancement may reveal an enhancing membrane and may differentiate infarction from neoplasm or abscess. In patients with suspected metastases or seeding of neoplasms, contrast-only CT scan may be sufficient. However, in all the clinical situations previously described, MRI is considered more definitive.

## MAGNETIC RESONANCE IMAGING

MRI is the most powerful neuroimaging modality for adults and children. It involves no ionizing radiation as in CT and

no acoustic window that restricts cranial ultrasound to the period of infancy before the fontanels close. MRI provides multiplanar imaging with excellent resolution without repositioning of the patient or the machine. Bone does not interfere with soft-tissue resolution; however, metallic objects often produce signal void or field distortion artifacts. Some ferromagnetic or electronic devices, such as non-MR safe aneurysm clips, pacemakers, and implanted defibrillators, contraindicate the use of MRI. MRI has less tolerance for patient movement and sedation is required for most young children. Sedated and intubated patients require MR-compatible monitoring of vital signs and ventilator support. MRI is generally more expensive than CT; however, it is less expensive than more invasive procedures such as angiography, CT myelography, and cisternography.

MRI uses magnetic fields and radiofrequency pulses to obtain high-resolution images. Hydrogen nuclei (protons) are used to generate detectable signals in MRI. MR images are created by sending radiofrequency pulses into a patient lying in an external magnetic field, thereby perturbing hydrogen nuclei into producing signals of various intensities from different body tissues. The resulting signals are mapped on to a grayscale digital image and the intensity MRI signals is determined by several intrinsic factors, such as the proton density, the mobility of the protons within the molecular lattice (T1 relaxation), the effect of local magnetic fields produced by magnetic nuclei within the tissue (T2 relaxation), and susceptibility effects (i.e., from paramagnetic biologic substances such as hemorrhage) on local magnetic fields within tissue (T2\* relaxation). Programmed sequences, such as spin echo (SE), inversion recovery, and gradient-recalled echo (GRE), use a sequence of radiofrequency and gradient magnetic field pulses to acquire images weighted with one of the aforementioned factors. On T1-weighted (T1W) images, typically produced with SE or GRE sequences, tissues with short T1 relaxation times, such as fat and intracellular and extracellular methemoglobin, produce a high signal intensity (i.e., bright or hyperintense). Cerebrospinal fluid (CSF), muscle, deoxyhemoglobin, hemosiderin, tissues, and substances with long T1 relaxation times appear dark on T1W images.

On T2-weighted (T2W) images, tissues or structures with long T2 relaxation times, such as CSF, edema, many tumors, extracellular methemoglobin, infarcts, and multiple sclerosis plaques are bright, whereas tissues or substances such as muscle, cortical bone, deoxyhemoglobin, and hemosiderin are dark as a result of short T2 relaxation times (see Figures 12-22, 12-25, and 12-29). Inversion recovery sequences are used to nullify or eliminate signal from a particular tissue. Fluid-attenuated inversion recovery (FLAIR) sequences nullify signal from fluids, causing CSF to appear dark rather than bright as on T2W images. This sequence is used to increase conspicuity of lesions that are bright on T2 (multiple sclerosis plaques, infarcts) and located near the ventricles, and is particularly useful for identifying subacute subdural hemorrhage. Another sequence called short tau inversion recovery (STIR) nullifies signal from fat and can be used to identify lesions in fatty areas such as the orbits or neck. GRE sequences are used to provide T2W contrast to identify hemorrhage. Because of the increased use of higher-field-strength clinical imaging magnets at 3T, GRE is routinely used to provide T1W contrast. Routinely, T1W and T2W images in various planes are acquired and followed by T1W images with contrast, if needed. The most commonly used contrast agent for MRI contains gadolinium, which shortens the T1 relaxation time of tissues that take up gadolinium contrast agent and thus produce a bright or hyperintense signal on T1W images.

GRE sequences, also routinely used to perform magnetic resonance angiography (MRA), are programmed to show

moving protons as bright and are often added to image the vasculature.

MRI is the only modality that provides accurate assessment of brain myelination. Contrast-enhanced MRI is also more sensitive than contrast-enhanced CT for detection of encephalitis, brain abscess (Figure 12-20), ventriculitis, or small foci of leptomeningeal involvement. MRI is often better than CT in demonstrating traumatic injuries, particularly diffuse axonal shearing injury, posttraumatic olfactory injury, brainstem contusion, subacute hemorrhage, encephalomalacia, gliosis, migrational anomalies such as gray matter heterotopias, closed-lip schizencephaly, lissencephaly (Figure 12-21), pachygyria, and hemimegalencephaly, and neurocutaneous disorders such as neurofibromatosis.

MRI is useful in the evaluation of patients with movement disorders, such as Wilson disease, because it demonstrates abnormal T2 signal in the basal ganglia, especially the outer rim of the putamen and in the substantia nigra; in juvenile Huntington disease, it reveals atrophy of the caudate nuclei and increased T2 signal in atrophic caudate nuclei. In pantothenate kinase deficiency (formerly designated as Hallervorden-Spatz syndrome), MRI demonstrates areas of symmetric low-signal intensity in T2W images with high signal intensity in the anteromedial aspect of the globus pallidus, the so-called eye of the tiger sign. MRI shows multifocal cortical infarctions and the presence of lactate peaks in proton magnetic resonance spectroscopy (MRS) in mitochondrial disorders, such as mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS) syndrome. In other mitochondrial disorders, such as myoclonic epilepsy with ragged red fibers (MERRF) syndrome, Kearns-Sayre syndrome, Leigh disease, Alpers disease, and Menkes disease, symmetric white matter T2 hyperintensities with involvement of deep cerebral nuclei are observed.

For focal (Figure 12-22) and diffuse white matter disease, T2W MRI is more sensitive than CT. MRI should preferentially be used to evaluate children with acute disseminated encephalomyelitis (Figure 12-23), human immunodeficiency virus (HIV) encephalitis, sickle cell disease, vasculitis such as systemic lupus erythematosus, Lyme disease, progressive multifocal leukoencephalopathy, and multiple sclerosis. Patterns of white matter involvement can be seen in certain inherited leukodystrophies. Early, diffuse involvement of the peripheral subcortical white matter is seen in Pelizaeus-Merzbacher disease, Canavan disease, and Alexander disease. In Canavan disease, patients have macrocephaly, and on proton MRS, a larger-than-normal *N*-acetyl-aspartate (NAA) peak is produced. In Alexander disease, there is predilection for T2 lengthening in frontal white matter and enhancement after contrast administration. A predilection for occipital white matter involvement is seen with adrenoleukodystrophy. In globoid cell leukodystrophy, T2 hyperintensity can be seen in the cerebellum and deep cerebral white matter, whereas the thalami and basal ganglia may be hypointense.

MRI can demonstrate mesial temporal sclerosis (Figure 12-24) in patients with epilepsy and can reveal small tumors in the aqueduct, sella turcica, or brainstem (Figure 12-25). MRI can also detect hippocampal dysplasia, hippocampal atrophy, and dual pathology with cortical dysplasia. These high-resolution scans help in the surgical evaluation and treatment for refractory epilepsy. MRI is also the preferred procedure when children have symptoms and signs that suggest a CNS tumor (Figures 12-11 and 12-25 to 12-27). Figure 12-28 shows an unusual presentation of subependymal giant cell astrocytoma in a newborn. In the evaluation of pediatric head and neck lesions, MRI is essential for assessment of possible intracranial extension of disease.

MRA has added a new dimension to the evaluation of pediatric cerebrovascular disease and can be used to evaluate vascular malformations, vasooclusive disease (see Figures 12-13C and 12-22B), and vascular neoplasms. MRA may demonstrate occlusions or stenoses of the supraclinoid internal carotid arteries, the proximal anterior and middle cerebral arteries, collateral vessels, and parenchymal lesions in moyamoya disease, as well as proximal large-vessel stenotic lesions in children with sickle cell disease.

MRI may detect silent infarctions in children with Kawasaki or sickle cell disease as well as small white matter and basal ganglia infarctions in children with migraine or sickle cell disease (Figure 12-22). MRI is helpful in identifying and staging hemorrhage and clot formation as a function of the evolution of hemoglobin breakdown products (Figure 12-29) and can differentiate arterial from venous occlusive disease. It is also useful in identifying sinovenous thrombosis and associated venous infarction or dural sinus thrombosis. In evaluating intracranial hemorrhage caused by angiographically occult lesions such as cavernomas (see Figure 12-29), MRI is the procedure of choice. MRI can differentiate between various infantile extra-axial fluid collections and may distinguish effusions and hygromas from subdural hematomas. Special MRI sequences (FLAIR) can differentiate CSF-containing lesions (e.g., arachnoid cysts) from other lesions (e.g., epidermoid tumors). MRI is excellent in delineating midline abnormalities (Figure 12-30). Absence of T1 hyperintensity in the posterior pituitary on a sagittal MR image is diagnostic of central diabetes insipidus in children. For evaluation of hypopituitarism in children, MRI is critical. Hydrocephalus also may be evaluated with MRI (Figure 12-31). Likewise, in patients with CNS tumors and CSF seeding, MRI with gadolinium enhancement is very sensitive and is used for planning surgery, radiotherapy, and chemotherapy.

## MAGNETIC RESONANCE SPECTROSCOPY

MRS is a clinically useful, noninvasive tool for identifying the biochemical state of the CNS (Bluml, S., Panigrahy, A., 2012). Certain atomic nuclei such as  $^1\text{H}$  (protons) are magnetic, and when exposed to a strong magnetic field, they align in a particular orientation. If the nuclei are then excited by a radiofrequency pulse at their resonant frequency, they produce a detectable signal during relaxation back to equilibrium. Because of their local chemical environment, each proton produces a signal at a slightly different frequency, called a chemical shift. After a Fourier transform analysis, the plots of the resulting nuclear magnetic resonance spectra appear as peaks of signal intensity versus signal frequency or chemical shift and the area underneath the peak represents the relative concentration of the metabolite.

MRI uses the strong signals from  $^1\text{H}$  nuclei of water and their spatial location to reconstruct anatomic images, whereas proton MRS is interested in the much weaker signals from nonwater protons to obtain quantitative information about biologic molecules within tissue. Small concentrations of brain metabolites can be detected using acquisition sequences, such as stimulated-echo acquisition mode and point-resolved spectroscopy. Initial studies in children used phosphorus ( $^{31}\text{P}$ ) MRS to investigate spectral changes seen after neonatal asphyxia. Now the majority of studies focus on the use of proton MRS.

### Spectral Metabolites Using Proton Magnetic Resonance Spectroscopy

Proton MRS ( $^1\text{H}$ -MRS) is used to investigate a wide range of neurologic disorders. Unlike  $^{31}\text{P}$  MRS,  $^1\text{H}$ -MRS can be

obtained using the same coils as imaging. Metabolites measured with <sup>1</sup>H-MRS include NAA, a neuronal marker; creatine (Cre) composed of phosphocreatine and creatine, which are bioenergetic metabolites; choline-containing compounds (Cho), including free choline and phosphoryl and glycerophosphoryl choline that are released during membrane disruption; lactate (Lac), which accumulates in response to tissue damage or anaerobic glycolysis; and other metabolites only seen when acquired with short echo time sequences, such as the neurotransmitters glutamate and immediately formed glutamine (Glx) and myoinositol (mI or Ins), an osmolyte and astrocyte marker. During normal maturation of the brain, NAA, Cre, and Glx levels increase, and Cho and Ins levels decrease (Figure 12-32). It is not uncommon to detect small lactate peaks in spectra from normal newborn brain, but if lactate levels are high or appear after the neonatal period, it may indicate possible hypoxic-ischemic injury, a metabolic disorder, or infection.

### Diseases Studied with Proton Magnetic Resonance Spectroscopy

Characteristic proton spectra in adults have been described in stroke, hepatic encephalopathy, dementia, diabetic ketoacidosis, tumor, multiple sclerosis, acquired immunodeficiency syndrome-related leukodystrophies, and trauma. In children, abnormalities have been observed in a variety of metabolic and mitochondrial encephalopathies, brain tumors, and certain neurodegenerative conditions (Bluml, S., Panigrahy, A., 2012).

Proton MRS has been used after acute traumatic and non-traumatic injuries. Typically, NAA is reduced as a result of neuronal loss or dysfunction and Cho is elevated because of diffuse axonal injury (DAI) shearing of myelin and cellular membranes and/or repair. Lac elevation is more common in children with nonaccidental trauma. Reduced NAA/Cho and elevated Cho/Cre ratios correlate with impaired neuropsychologic functioning after traumatic brain injury. Spectral sampling in areas of the brain that did not appear to be visibly injured has shown altered metabolite ratios that suggested definite injury. The time interval before MRS acquisition after injury and location of sample within the brain might affect findings. MRS also holds great promise for research of mild traumatic brain injury and sports-related concussion as it provides a sensitive, noninvasive assessment of neurochemical alterations. Several studies suggest the strong potential for using MRS to provide accurate estimates of long-term neurologic and neuropsychologic function after traumatic brain injury. More recently, a longitudinal study using more advanced MR imaging techniques such as susceptibility-weighted imaging (SWI) and diffusion tensor imaging (DTI) along with MRS has shown these techniques to be capable of detecting posttraumatic hemorrhagic lesions and the corresponding abnormalities on DTI, as well as metabolite abnormalities on MR spectroscopic imaging (MRSI) (Figure 12-33).

MRS with diffusion-weighted imaging (DWI) has been used to evaluate children with stroke and hypoxic-ischemic injury. Confirmation of the death of tissue is provided on proton MRS by a rise in Lac from anaerobic glycolysis and a loss of NAA from neuronal death. The combination of MRI and MRS can provide prognostic information in children after near-drowning. MRI and MRS have been found particularly useful in the evaluation of neonates with perinatal encephalopathy. Reduced NAA-derived metabolite ratios, elevated Cho or Ins, as well as abnormalities on DWI have been shown to

reflect the severity of injury. Neonates with elevated Lac levels and decreased NAA/Cre ratios have been more likely to have a poor outcome compared with age-matched control subjects (Figure 12-34).

Proton MRS combined with MRI is useful in screening patients for metabolic and mitochondrial disorders based on the detection of increased cerebral lactate or the presence of other elevated metabolite peaks. Disorders include glutaric aciduria type 2, pyruvate dehydrogenase deficiency, Leigh disease, X-linked adrenoleukodystrophy, MELAS, and a variety of other conditions. In phenylketonuria, elevated phenylalanine levels can be seen with MRS, and in Canavan disease, MRS shows marked elevation of the NAA peaks. In Leigh disease, as in other mitochondrial or metabolic disorders, MRS reveals an abnormally high Lac peak and a decreased NAA peak in the basal ganglia and occipital gray matter (Figure 12-35). In some metabolic diseases, Lac is present during the acute illness, and with improvement, serial spectra can demonstrate its resolution. Elevated cerebral Lac has also been detected when blood Lac levels have been normal in symptomatic patients. In children with global developmental delay, proton MRS has also been useful in detecting creatine deficiency associated with disorders of creatine synthesis or transport.

Proton MRS also has been used in the evaluation of children with epilepsy showing decreased NAA, increased Cho, and increased Lac levels in epileptic foci compared with non-ictal or contralateral regions. It is likely that studies will demonstrate a role for proton MRS in the selection of patients with intractable seizures for surgery.

The use of proton MRS has been examined in children and adults with CNS tumors. Malignant tumors are characterized by an increase in Cho caused by an increase in active cell proliferation and a decrease in NAA because of replacement of neurons with tumor cells. In one study, the pretreatment total Cho peak was the most reliable indicator of malignancy. In another study, Cho signal intensities were highest in astrocytomas and anaplastic astrocytomas, and creatine signal intensities were lowest in glioblastomas. However, tumoral metabolic characteristics exhibited large variations, precluding diagnostic accuracy of MRS in differentiating low- and high-grade lesions. In children, it has been suggested that proton MRS may be useful in differentiating various types of cerebellar tumors.

An acquisition technique commonly used to evaluate CNS tumors is MR spectroscopic imaging (MRSI) or chemical shift imaging (CSI); it allows simultaneous acquisition of multiple spectra within a single imaging plane (2D MRSI), or in multiple planes to cover the entire brain (3D MRSI). This allows evaluation of the entire tumor volume and surrounding brain to determine the extent of involvement outside an enhancing area or spectroscopic differences in a nonhomogeneous tumor.

MRS is useful in differentiating tumor recurrence from radiation necrosis. Patients with postirradiation necrosis are more likely to have reduced NAA, Cre, and Cho peaks with presence of lactate and lipids, compared with patients with tumor recurrence in which Cho is increased. MRS has prognostic significance in predicting outcome in children with certain brain tumors. Patients with a Cho/NAA ratio greater than 4.5 were found to have a higher mortality rate. In adults, MRS has been used to determine whether metastatic CNS tumors from distal primary sites are present. However, MRS data cannot be used alone because of significant overlap and nonspecificity of the results. It is difficult to distinguish non-neoplastic lesions such as hamartomas, histiocytic lesions, or dysplastic lesions from low-grade neoplasms by MRS. Part XVI of this book reviews imaging and spectroscopy data across the different tumor types that occur in children.

## DIFFUSION-WEIGHTED IMAGING

Diffusion-weighted imaging (DWI) uses MRI to measure the diffusion of water through tissues. Random displacements of water molecules (i.e., diffusion) are modified by structural and physiologic factors in a medium. In a medium in which diffusion of water molecules is identical in all directions, the process is called isotropic diffusion. When the process depends on direction, it is called anisotropic diffusion. In brain white matter, diffusivity of water molecules is not the same in all directions. DWI has been used to investigate stroke and hypoxic-ischemic injury in children, to differentiate solid (e.g., epidermoid tumors) from cystic CNS lesions, and to evaluate patients with demyelinating disease. The most important factors regulating diffusion include tissue and fluid viscosity, membrane barriers to the free movement of water, chemical interaction of water with macromolecules, and local tissue temperature. MRI can be used to measure apparent diffusion by using an additional pair of strong gradient pulses to the standard pulse sequence. Such data are used to calculate apparent diffusion coefficient (ADC) maps. On an ADC map, the signal intensity corresponds to the ADC value; thus, low ADC values (representing restricted diffusion) correspond to a dark signal on an ADC map. The same area of restricted diffusion would show up bright on a corresponding diffusion-weighted image.

The ADC of water protons is greater in regions of unimpeded water molecular motion, such as that from CSF from the ventricular system or cystic brain lesions. In normal brain parenchyma, where diffusion of water molecules is relatively restricted, the ADC is lower. Regions of restricted or slower molecular motion appear hyperintense. For example, with ischemic injury, water accumulates intracellularly and is reflected as hyperintense regions on DWI with a corresponding hypointense signal on the ADC map. The hyperacute decrease in the ADC seen during ischemia is related to the development of cytotoxic edema associated with an increase in intracellular volume because of sodium and water influx. DWI is useful in differentiating cystic brain lesions (high ADC) from epidermoid tumors (lower ADC). In high-grade cerebral gliomas, DWI can differentiate components of the tumor and distinguish areas of nonenhancing tumor from areas of peritumoral edema.

DWI has been used to study aspects of myelination. In white matter, diffusion has been found to be anisotropic; there is greater water mobility along myelinated fiber tracts than perpendicular to them. By measuring these differences, DWI allows investigation of myelin orientation and development. This finding may be of particular interest in evaluating children with closed-head injuries. In one report, DWI was found to have increased utility in detection of brain injury in children with nonaccidental trauma. DWI may also identify evidence of corpus callosal and subcortical white matter injury, and restricted diffusion in white matter has been associated with poor neurologic and neuropsychological outcomes.

During early brain myelination, anisotropy in DWI precedes myelination changes and is helpful in evaluating the normal progression of myelination in infants. DWI obtained during the acute phase of periventricular leukomalacia is more sensitive than conventional MRI and ultrasound in detecting hyperintensities that evolve to damaging lesions at follow-up MRI. In neonates, DWI is useful in the evaluation of acute ischemic brain injury and seizures. In children younger than 2 years, DWI is useful for evaluating acute ischemic injuries, metabolic disorders, and leukodystrophies. In patients with sickle cell disease and an acute CNS event, DWI is an essential part of the investigation. DWI is helpful for earlier identifica-

tion of the changes in acute carbon monoxide poisoning or dural sinus thrombosis. In patients with posterior reversible encephalopathy syndrome, DWI shows reversible vasogenic edema and, in severe cases, its conversion to cytotoxic edema, which is associated with a poorer outcome.

Children with new-onset prolonged seizures can develop unilateral hippocampal sclerosis. The presence of diffusion restriction in the affected hippocampal region can herald subsequent development of mesial temporal sclerosis. DWI can be helpful in the evaluation of CNS tumors, as it may show diffusion restriction. However, hyperintensity on DWI has been observed in solid portions of glioblastomas, and in combination with spectroscopy, may be helpful in determining an appropriate site for biopsy and in evaluating tumor recurrence. Hyperintensity also can be seen in lymphomas on DWI.

DWI is useful for evaluating children with intracranial infection. Cerebral abscesses, tuberculomas, subdural empyemas, and epidural abscesses demonstrate hyperintensity with DWI. Neurocysticercosis cysts and encephalitis appear hyperintense on DWI, whereas toxoplasmosis lesions produce variable signal intensity. In pyogenic ventriculitis, DWI shows signal intensity in dependent intraventricular fluid. DWI may be of some prognostic value in children with herpes simplex encephalitis. These lesions can exhibit low or high signal intensity indicating vasogenic or cytotoxic edema. Patients with cytotoxic edema have fulminating disease and are more likely to have a complicated clinical course and poorer outcome. Patients with vasogenic edema are less seriously ill.

DWI has assumed an important role in the early evaluation of patients with stroke. DWI reveals hyperintensity in an acute infarct soon after the onset of ischemia. Significant DWI lesions have been associated with little clinical recovery. Stroke in children is an unexpected event, and the causes are more diverse than in older populations. Imaging plays an important role in the evaluation and management of children with stroke (see Part XIII Cerebrovascular Disease in Children).

The combination of MRI, DWI, DTI, perfusion-weighted imaging (PWI), MRA, and MR venography, as clinically indicated, offers the best sensitivity for the detection of the lesion, determination of its extent, and evaluation of the degree of underlying vascular compromise. In neonates, DWI is helpful for the early diagnosis of stroke, and findings may be more pronounced than those seen on conventional MRI. It is not unusual in the evaluation of neonatal strokes to have positive findings on DWI and MRI but negative findings on MRA or MR venography. Venous infarcts are common in newborns. They are usually adjacent to the dural sinuses and show hemorrhagic components (Figure 12-38). Stroke in the newborn can also be hemorrhagic (Figures 12-39 and 12-40).

## DIFFUSION TENSOR IMAGING

With diffusion tensor imaging (DTI) it is possible to have in vivo localization of neuronal fiber tracts. DTI uses the anisotropy inherent within white matter axons of the brain. Alignment of fiber tracts determines the water diffusion anisotropy or directionality. Diffusion of water is preferential along the longitudinal axis of the axon; at the same time, the diffusion of water along the perpendicular axis is restricted. In DTI, each voxel has one or more pairs of parameters—a rate of diffusion and a preferred direction of diffusion—described in terms of three-dimensional space. Three gradient directions are applied, sufficient to estimate the trace of the diffusion tensor or “average diffusivity,” whereas DTI derives neural tract directional information from the data using three-dimensional or

multidimensional vector algorithms based on a minimum of 6 and up to 256 diffusion-sensitized gradient directions, sufficient to compute the diffusion tensor. Mathematically, the preferred direction of diffusion is described as the diffusion ellipsoid or tensor. The tensor has three Eigen values:  $\lambda_1$ ,  $\lambda_2$ , and  $\lambda_3$ . The  $\lambda_1$  value points to the direction of the axon and is called the longitudinal, axial, or parallel diffusivity. The  $\lambda_2$  and  $\lambda_3$  values are the two small axes tensors, which are often averaged to produce a measure of the radial diffusivity, also called the perpendicular diffusivity. Longitudinal or radial diffusivity can reflect pathologic processes; for example, during evaluation of white matter infarct, radial diffusivity is considered to be related to membrane integrity.

The directional information can be exploited to select and follow neural tracts through the brain—a process called tractography. From the diffusion tensor, diffusion anisotropy measures, such as the fractional anisotropy (FA), can be computed. Fractional anisotropy is a scalar value between 0 and 1 that describes the degree of anisotropy of a diffusion process. A value of 0 means that diffusion is isotropic; that is, it is unrestricted in all directions. An FA value of 1 means that diffusion occurs along one axis only and is fully restricted along all other directions. FA is a measure often used in diffusion imaging, where it is thought to reflect fiber density, axonal diameter, and myelination in white matter.

DTI is increasingly used to evaluate normal brain development and changes associated with a wide variety of neonatal and pediatric neurologic disorders, as well as the brain's response to injury. DTI has been highly instrumental in advancing knowledge regarding early structural cerebral organization and maturation. DTI has been used in preterm and term infants to evaluate changes in cortical connectivity after white matter injury.

DTI has been found to be valuable in surgical planning for resection of brain tumors to map tracts associated with motor and language cortex (Figure 12-41) or temporal lobectomy for intractable epilepsy. Eloquent white matter tracts, such as the pyramidal tracts and optic radiations, can be assessed in relation to the tumor. When temporal lobectomy is contemplated for epilepsy surgery, DTI may be used to predict visual field deficits after temporal lobe resection. DTI has been found to be valuable in imaging of stroke to assess the relation between eloquent fiber tracts and infarcts, and in the prognosis of gross motor functions. It also has been found to be useful in the evaluation of various adult diseases, such as Alzheimer disease, multiple sclerosis, amyotrophic lateral sclerosis, spinocerebellar atrophy, and Parkinson disease.

DTI has been useful in evaluation of spinal cord lesions in differentiating traumatic from neoplastic and inflammatory causes. Patients with trauma may show reduced FA values (Figure 12-42). DTI has also been used to study axonal injury of the corticospinal tract in patients with Arnold–Chiari II malformations, suggesting developmental white matter damage in the corpus callosum beside that exerted by hydrocephalus. DTI also has been studied in children with global developmental delay. In one study, bilateral absence of the arcuate fasciculus was observed in some patients and FA was reduced in the right inferior longitudinal fasciculus.

Challenges for tractography remain. Validations of the tractography images are mostly based on known neuroanatomy. This remains a limitation of this technique. Intraoperative electrophysiological testing has been used to correlate preoperative tractography, which indicated that tractography might underestimate the fiber tracts. Ongoing development of tractography must be pursued to increase the signal-to-noise ratio while shortening the scan time, improving the in-plane image resolution, and reducing partial volume averaging because of slice thickness. Higher-field-strength scanners using multi-

channel head coils and parallel imaging techniques are being used to provide some of these crucial improvements.

## PERFUSION MAGNETIC RESONANCE IMAGING

Perfusion-weighted imaging (PWI) is an extension of MR technology that allows evaluation of blood volume, blood transit time, and blood flow as relative measures. PWI is used in the evaluation of patients early after symptoms of cerebral ischemia, although other clinical applications are being investigated. Two techniques have been developed based on the magnetic susceptibility effect of gadolinium-containing contrast agents and on the noninvasive magnetic labeling of arterial blood. The first, referred to as contrast-enhanced dynamic susceptibility-weighted perfusion imaging (DSC-PWI), can image relative differences in blood volume over time. Paramagnetic compounds (e.g., gadolinium-DTPA), which are used as MRI contrast agents, possess strong magnetic susceptibility, and susceptibility differences between the contrast agent and the surrounding tissue create local magnetic field gradients that can be used to acquire images after contrast injection. Images can be viewed dynamically to assess contrast entry and clearance through the tissue, with calculation of the transit time. The relative cerebral blood volume can be estimated by measuring the area under the tracer concentration–time curve, as can the relative cerebral blood flow from the ratio of the cerebral blood volume and mean brain transit time.

The second method involves blood flow imaging by magnetically labeled protons of the arterial inflow using a radio-frequency pulse and following the label through the brain's circulation. This method is known as arterial spin labeling (ASL). Deoxyhemoglobin contained within erythrocytes is paramagnetic, and on deoxygenation, the magnetic susceptibility of deoxyhemoglobin is increased and creates local field gradients, the so-called *BOLD* effect. The blood oxygen level-dependent (BOLD) technique takes advantage of this phenomenon to quantify cerebral blood flow. Although not widely used because of technical issues (low spatial resolution, difficulties with quantification, etc.), this technique has an advantage in the pediatric population as it does not involve the injection of intravenous contrast agents. Figure 12-43 shows cerebral blood flow (CBF) maps derived from a pulsed arterial spin labeling sequence in a pediatric patient being evaluated for a possible head injury.

Several studies have suggested that PWI can aid in the evaluation of acute ischemic injury, particularly by determining which patients have the potential for recovery and which may benefit from thrombolytic therapy. In patients with sickle cell disease, abnormalities on PWI are associated with neurologic symptoms although the areas of abnormality may not be seen in conventional MRI, MR angiography, or transcranial Doppler examination. PWI has also been used to differentiate tumor types. In one study, differences were observed in patients with glioblastomas, anaplastic gliomas, and low-grade gliomas. Combined with spectroscopy, PWI findings can help differentiate progression from stable tumors. Another area of interest for DWI and PWI is in children with acute disseminated encephalomyelitis. In children with cerebral arteriovenous malformation and other proliferative angiopathies, PWI may be helpful in determining areas of hyperperfusion, hypoperfusion, or venous congestion adjacent to the lesion.

## SUSCEPTIBILITY-WEIGHTED IMAGING

A sequence using a high-spatial-resolution, three-dimensional, fast, low-angle MRI technique that is extremely sensitive to

susceptibility has been described (Tong et al., 2008). This sequence, which can be performed on conventional scanners, was originally designed for MR venography using the paramagnetic property of intravascular deoxyhemoglobin.

This technique, known as SWI, has been very useful in detecting hemorrhagic lesions associated with diffuse axonal injury, and it has depicted significantly more small hemorrhagic lesions than conventional T2\*-weighted, gradient-echo techniques. In children with traumatic brain injury and diffuse axonal injury, the number and volume of hemorrhagic lesions detected with SWI have correlated with the initial severity of injury as measured by the Glasgow Coma Scale scores, duration of coma, and long-term outcome. SWI can also be used to categorize tissue as normal-appearing or with nonhemorrhagic or hemorrhagic injury.

Neonatal strokes, which are sometimes related to dural sinus thrombosis, can be hemorrhagic (Chapter 20). SWI is more sensitive than CT or conventional MRI sequences (including GRE T2\*) in detecting hemorrhage in patients with acute strokes. This blood-sensitive sequence has been found to be extremely valuable in detection of hemorrhage in children with accidental or nonaccidental trauma, infarctions, tumors, proliferative angiopathies, and vascular malformations, including Sturge-Weber syndrome and cavernous angioma (Figure 12-44), and in patients with hypertensive encephalopathy (Figure 12-45). In the examples of SWI (see Figures 12-44 and 12-45), both cases exhibit a markedly increased number and more intense abnormal signal on SWI than with other MRI sequences.

## FUNCTIONAL MAGNETIC RESONANCE IMAGING

Functional MRI (fMRI) is a technique that measures changes in tissue perfusion based on changes in blood oxygenation. It is used to study regional brain activity in response to sensory, motor, and cognitive stimulation based on the assumption that neuronal activation induces an increase in glucose metabolism and blood flow. fMRI can be used to study the distribution of cerebral hemodynamic changes associated with various sensory stimuli, including vision, sensorimotor, olfactory, and auditory function, and to investigate complex cognitive functions, such as speech and language processing and reading (see Part VII: Neurodevelopmental Disorders).

Echoplanar fMRI combined with appreciation of the BOLD contrast mechanism is the most frequently used technique. The BOLD contrast mechanism relies on the fact that an increase in regional blood flow (and oxyhemoglobin) occurs in response to task performance or stimulation but is not accompanied by a concomitant increase in local tissue oxygen extraction. Because of this inflow of oxyhemoglobin, the amount of deoxyhemoglobin in the stimulated cortex does not significantly increase. This regional imbalance of oxyhemoglobin and deoxyhemoglobin reduces the net "susceptibility effect" of deoxyhemoglobin, which can be detected by magnetic susceptibility-sensitive imaging techniques using GRE methods. MRI scanners equipped with echoplanar imaging can obtain gradient images of the stimulated cortex within seconds of stimulation and display increased signal in the stimulated cortex. More-detailed technical descriptions and applications of this technique are beyond the scope of this chapter, but several sources provide excellent reviews of this technology (Viallon et al., 2015).

With the aid of fMRI, the development of brain function can be followed, and deviation from the normal pattern can be established. Early diagnosis of functional deficits has the potential to reduce residual deficits because of the earlier implementation of cognitive or other forms of rehabilitation. Acquisition of fMRI data from children is associated with a

number of methodological challenges, primarily compliance and head motion; however, good data can be obtained.

fMRI is being used in patients with various neurologic diseases, including medically refractory epilepsy and brain tumors. Preoperative evaluation of such patients includes MRI and scalp, subdural, or depth electrode electroencephalography (EEG), and often includes endovascular amobarbital testing to determine which cerebral hemisphere is dominant (Wada test). Preoperative fMRI has been used to determine the feasibility of a proposed surgical resection and to select patients for invasive surgical functional mapping. fMRI appears to be as sensitive and specific as the Wada test for speech localization, preoperative memory lateralization, and intraoperative cortical mapping. fMRI performed immediately before surgery can help determine the location of neighboring eloquent functional area of concern. Some have used fMRI and DTI together with anatomic imaging to improve functional outcomes after tumor resection (see Figure 12-41).

## MAGNETIC SOURCE IMAGING

Magnetic source imaging uses magnetoencephalography (MEG). When source localizations modeled from the magnetoencephalographic signal are registered with high-resolution MRI, the resulting images display functional information in an anatomic context. In functional mapping of the sensorimotor cortex, a combination of magnetic source imaging and fMRI allows improved sensitivity, fewer false-positive results, and high spatial and temporal resolution. One of the important clinical applications of functional brain imaging is pretreatment mapping to allow definition of eloquent cortex in relation to mass lesions that may be surgically resected or treated with focused irradiation (e.g., gamma knife and protons) or combinations of irradiation and chemotherapy. Magnetic source imaging may also have future applications in studying developmental plasticity after injury.

MEG is a powerful and accurate tool for the presurgical evaluation of children with refractory epilepsy and helpful in evaluating patients with dyslexia. Studies have demonstrated aberrant activation maps consisting of reduced activity in left temporoparietal areas (including the posterior part of the superotemporal, angular, and supratemporal gyri) and increased activity in homologous cortex from the right hemisphere. Studies using MEG in patients with normal MRI scans who had acquired aphasia and suspected Landau-Kleffner syndrome have demonstrated unilateral and bilateral perisylvian MEG spikes, as well as spikes from nonsylvian regions. MEG is also being used in association with three-dimensional MRI in neuronavigational systems and is a promising tool that can potentially be used in more extensive surgical procedures to lessen injury to eloquent brain areas.

Among the advantages of fMRI, magnetic source imaging, and MRS are noninvasiveness, absence of ionizing radiation, and superior spatial resolution. Functional MRI is also complementary to anatomic MRI because functional imaging takes into account normal individual variations in the functional topography of the brain. It can detect altered topography or functional plasticity, which may present because of functional reorganization in patients with various forms of cerebral injury.

## SPINAL IMAGING

Initial assessment of spinal abnormalities in children includes plain films or, in the very young child, ultrasound. CT is usually indicated for acute spine injuries to determine whether a fracture, dislocation, or spondylolysis is present. CT is also helpful for the evaluation of benign tumors or vertebral body

anomalies (Chapter 106). For most infants and children, MRI has replaced myelography and CT myelography as the definitive procedure for spinal neuroaxis imaging, including spinal dysraphism, other developmental anomalies of the spine (Figures 12-46 and 12-47), and acquired processes, such as neoplasms. CT myelography may have an advantage over MRI in patients with spinal dysraphism for demonstrating the location of cord tethering and for demonstrating nerve root avulsions after trauma. In the evaluation of the spinal bone marrow for metastatic disease, MRI is the procedure of choice (Figure 12-48). Detailed information on spine imaging of children is beyond the scope of this chapter, but several excellent reviews (Van Goethem et al., 2007) are available and Chapter 106 reviews spinal cord injuries.

## ANGIOGRAPHY

The role of angiography has diminished since the emergence of CT, MRI, and MRA in pediatric neuroimaging. Contrast angiography in children requires sedation and anesthesia, and may have complications such as death, stroke, and thrombosis of the femoral artery. It is usually restricted to the evaluation of vascular malformations, vasculopathy, vasculitis, and vaso-occlusive disease (see Figure 12-10E) (Part XIII, Cerebrovascular Disease in Children), and occasionally to CNS tumors (Part XVI: Pediatric Neurooncology).

## SINGLE-PHOTON EMISSION COMPUTED TOMOGRAPHY AND POSITRON EMISSION TOMOGRAPHY

Single-photon emission computed tomography (SPECT) uses one or more gamma cameras rotating around the patient and acquiring numerous transmission scans after injection of a labeled radiopharmaceutical. Technetium 99m ethylene cysteinyl dimer, a radiopharmaceutical used for brain perfusion, and Tc 99m hexamethylpropyleneamine oxime are the main radiotracers used for clinical brain SPECT imaging. They have the advantage of a Tc 99m label with its optimal imaging characteristics. The indications for brain SPECT imaging in children include planning for epilepsy surgery, evaluation of brain death, acute neurologic loss (including stroke), language disorders, hypertension resulting from renal vascular disease, traumatic brain injury, and migraine. Pediatric psychological conditions in which regional cerebral blood flow studies are occasionally obtained include anorexia nervosa, autism, Gilles de la Tourette syndrome, and attention-deficit/hyperactivity disorder. Considerable research is taking place in neuro-receptor imaging using iodinated- and technetium-labeled neuroligands to measure certain critical components of neurotransmission. Ongoing research is using SPECT and positron emission tomography (PET) in the study of psychiatric disorders such as schizophrenia, anxiety disorders, depression, autism, and stress and mood disorders. Iodine-131-labeled metaiodobenzylguanidine (MIBG) localizes in adrenergic neurons and is helpful in evaluating patients with neural crest tumors or neuroblastoma.

Studies using PET scanning have made major contributions during the past decade to understanding the developmental neurobiology of the nervous system, particularly with reference to cerebral and cerebellar glucose, and oxidative metabolism and blood flow. However, because of its limited availability, a comprehensive review of the technology and its clinical applications is not included here; several good sources are available (Purz et al., 2014).

PET has been used to study patients with many different pediatric neurologic disorders, including various forms of epilepsy (Figure 12-24), Rasmussen encephalitis, autism,

language disorders, attention-deficit disorders, movement disorders, neonatal hypoxic-ischemic encephalopathy, moyamoya disease, tuberous sclerosis, Langerhans cell histiocytosis, and CNS tumors.

The most common clinical application is for pediatric epilepsy, particularly those with drug-resistant epilepsy (Chapter 78). Such patients frequently have infantile spasms, focal ictal abnormalities in the frontal or temporal regions, or CNS malformations. PET is most useful for patients who have normal neuroimaging studies but clinically and electrographically have a focal seizure disorder or a generalized seizure disorder with significant asymmetries of activity. Interictal PET studies demonstrate areas of hypometabolic glucose metabolism using 2-deoxy-[<sup>18</sup>F] fluoro-D-glucose in areas considered epileptogenic. Ictal PET scans demonstrate more variable metabolic changes. In patients with refractory localization-related seizures, temporal lobe abnormalities can frequently be detected with PET. Studies have indicated congruence between focal temporal EEG abnormalities, hippocampal atrophy on MRI, hypometabolism in corresponding interictal regions with PET, and reductions in the metabolite ratios using proton MRS.

Patients with infantile spasms may also have significant EEG and PET cortical or subcortical asymmetries that have been shown useful in the evaluation for epilepsy surgery. PET may reveal lateralized or localized regions of hypometabolic glucose use that corresponds to localized EEG abnormalities and cortical dysplasias or other structural abnormalities. Surgical resection of regions with one hypometabolic area usually results in improved seizure control; patients with multiple hypometabolic regions are unlikely to benefit from such treatment.

PET has also been of particular value in children with intractable seizures who have subtle or major CNS malformations. These cases include children with tuberous sclerosis, Sturge-Weber syndrome, hemimegalencephaly, and focal cortical dysplasias and other migrational disorders. PET imaging of children with CNS tumors is useful. Brain tumors can be histologically heterogeneous, and stereotactic biopsies may lead to inaccurate diagnosis or grading. Increased uptake with fluoro-D-glucose-PET may represent more malignant or aggressive tumors. By combining PET and MRI in the planning of a stereotactic brain biopsy, it may be possible to improve the diagnostic yield and reduce sampling from high-risk or functional areas.

## Pediatric Neurophysiologic Evaluation

Mark S. Scher

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Pediatric neurophysiologic studies are an integral part of the diagnostic evaluation of the infant or child with suspected brain dysfunction; electroencephalography (EEG), polysomnography, evoked responses, and computerized neurophysiological analyses comprise four general diagnostic modalities. Genotype-phenotype comparisons are now being investigated that will redefine neurophysiological studies as endophenotypes to study gene-environment interactions (Scher and Loparo, 2009). Several excellent reviews supplement this discussion and can assist the physician with the evaluation of children who exhibit these phenomena (Kaminska et al., 2015).

### UTILITY OF PEDIATRIC NEUROPHYSIOLOGICAL STUDIES

#### Guidelines for Interpretation

EEG analysis requires a systematic, orderly process in which a series of steps are followed to reach a proper interpretation. The rhythmicity of spontaneous EEG signals gives a continuous admixture of scalp-generated oscillatory potentials. EEG frequencies used for clinical studies are classified in four band ranges. Delta activity is less than 4 Hz; theta activity is 4 to less than 7 Hz; alpha activity is 8 to less than 14 Hz; and beta activity is greater than 14 to 30 Hz. Although DC (usually lower than 3 Hz) and gamma-frequencies (higher than 30 Hz) can be recorded with appropriate filter settings, these rhythms are currently applied only to research recordings. In general, the amplitude of EEG activity is inversely proportional to frequency.

For pediatric EEG studies, the amount of slow activity decreases with increasing age, and the persistence and frequency of slow activity vary in different brain regions. It is important to appreciate the presence and degree of expression of frequencies in various regions at different ages, and other parameters such as waveform, manner of occurrence (e.g., random, continuous), and amplitude are essential to visual analysis.

#### Newborn Electroencephalographic Patterns

There are expected changes in the scalp-generated EEG patterns for neonates of different gestational ages. The experienced encephalographer can approximate the electrical maturity within 2 weeks of the gestational age. Changing electrical patterns reflect the postconceptional age of the neonate independent of birth weight. Maturation of the neonate's sleep-wake behavior follows maturation of the CNS and is independent of the birth weight. Preterm neonates, when corrected to term postconceptional age, should have EEG patterns and sleep behavior similar to those of term, appropriate-for-gestational-age newborns.

### Normal Electroencephalographic Patterns in Infancy Through Adolescence

#### Waking Patterns

Although sleep patterns predominate for the newborn, state development during infancy prepares the child for sustained periods of wakefulness. Waking EEG patterns are the first part of the discussion of normal EEG patterns in childhood.

One of the fundamental characteristics of the waking EEG pattern is the dominant background activity. Berger initially described how the dominant frequency increased as ages advanced during childhood. By 3 to 4 months of age, a discernible occipitoparietal rhythm of 3 to 4 Hz is observed (Fig. 13-11A). The activity approximates 5 Hz by 6 months and increases to 6 to 7 Hz by 9 to 18 months of age (Fig. 13-11B). The 6-Hz to 7-Hz frequency remains fairly stable until 2 years of age, when it varies between 7 and 8 Hz. By 3 years of age, the dominant waking rhythm of childhood is within the alpha range in 82% of children (Fig. 13-11C). The mean frequency is 9 Hz by 7 years of age and 10 Hz by 15 years of age (Fig. 13-11D). Quantitative analysis of the EEG posterior-dominant rhythms in healthy adolescents has documented that the maturation of the posterior dominant rhythm is nearly complete by age 16. Further, the frequency range of this rhythm is substantially narrower than the alpha range.

The amplitude, asymmetry, and locus of the dominant rhythm also change with increasing age. Higher amplitudes are seen at younger ages, with maximum amplitudes at 6 to 9 years that subsequently decline during adolescence. Asymmetries of this activity can be expected, with higher amplitude on the right in 20% of children, although differences of 50% or greater must be considered with suspicion. No correlation to hand dominance has been demonstrated. About 70% of adults and 95% of children have an occipital location to the dominant rhythm, but at least three independent alpha rhythms can be recorded over the scalp—occipital, temporal, and central regions—which may differ in frequency as much as 2 Hz. More anterior expression of the dominant rhythm becomes evident during adulthood.

#### Mu Rhythm

The mu, or central, rhythm commonly is 9 to 10 Hz and should not be confused with the central dominant rhythm of 7 to 9 Hz in infants. Although the mu rhythm is observed in less than 5% of children younger than 4 years, it can be observed in 18% of children between 8 and 16 years of age and occurs somewhat more frequently in females. It can be blocked by movement of the opposite limb rather than eye opening. Although the mu rhythm may frequently appear asymmetrically and alternately in either hemisphere, a persistent asymmetry suggests a structural lesion on the attenuated side or irritation on the predominant side (e.g., after head injury).

**Figure 13-11.** Posterior dominant rhythms (line markings) at four different ages during childhood while the patient was awake with eyes closed. **A**, A 4-Hz dominant rhythm at 4 months of age. **B**, Dominant rhythm of 6 to 7 Hz at 16 months of age. **C**, Dominant rhythm of 9 Hz at 3 years of age. **D**, Dominant rhythm of 10 to 12 Hz that is well regulated in a 16-year-old adolescent.

### Beta Activity

Three distinctive band ranges are described for beta frequencies in waking EEG recordings of children. Limited diagnostic use can be applied to the overall description of fast activity. Beta activity in the range of 18 to 25 Hz is most commonly encountered, with ranges of 14 to 16 Hz and 35 to 40 Hz observed less frequently. Symmetric distribution over each anterior head region is usually observed. Asymmetries of as much as 30% to 40% can be encountered without the presence of a structural lesion. Important diagnostic conclusions can be assigned if beta activity is reduced by more than 50%, especially when associated with delta or theta slowing in the same head region. Prominent scalp edema can also attenuate the high-frequency EEG signals in the absence of cerebral pathologic conditions. Symmetric prominence of beta activity is commonly encountered with the administration of certain sedative medications, especially barbiturates or benzodiazepines. Skull defects can contribute to an asymmetric exaggeration of beta activity over the bony defect—that is, breach rhythm.

### Theta and Delta Slowing

Theta rhythms are commonly encountered in the frontocentral regions and are usually related to drowsiness or heightened emotional states. In the past, theta rhythms were associated with a variety of clinical conditions, including epilepsy, but their common occurrence is now better appreciated as a normal variant.

Posterior slow waves located in the parieto-occipital regions, commonly referred to as posterior slow waves of youth, constitute the most frequently observed normal delta slow activity in the waking EEG record of children (Fig. 13-12). Commonly located in the occipitoparietal or occipitotemporal

**Figure 13-12.** EEG of a 16-year-old female who is awake with her eyes closed demonstrates a bioccipital posterior slow wave of youth (line marking).

regions is a 2.5-Hz to 4.5-Hz monorhythmic or polymorphic delta wave with an amplitude of less than 100  $\mu\text{V}$ . Superimposed alpha activities are also observed with these delta waves, which can have symmetric or asymmetric occurrences. The neurologist should view an asymmetry of greater than 50% between regions with suspicion. It will block with eye opening and disappear with the alpha rhythm during drowsiness. Rarely seen before 2 years of age, it has maximum expression between 8 and 14 years, especially in females. Approximately 25% of normal children have this pattern. The distinction between this pattern and other abnormal slow-wave activity should be based on complexity of the waveform, persistence, symmetry, and amplitude, all in the context of closed-head injury, hypoxia, or other encephalitides.

### Lambda Waves

Lambda waves can be observed in normal patients when they are viewing a well-illuminated picture of complex design. Sharply contoured occipital transients with a prominent surface-positive phase lasting 75 to 150 msec are described, although an extremely sharp appearance may cause suspicion of an abnormality. Eye closure or darkening of the room eliminates lambda waves, whereas occipital spike discharges persist. These transients are observed in young infants and can be seen occasionally in neonates.

### Hyperventilatory Response

In the past, a response to hyperventilation was considered evidence of a brain abnormality in children. However, it has become commonplace to observe prominent high-amplitude slowing in normal children, with maximum expression between 8 and 12 years that persists as a less significant electrographic change into adulthood. A greater degree of response

has been associated with lower blood glucose or carbon dioxide concentrations. Standardization of hyperventilation is necessary for the clinician to best judge the EEG slowing relative to age differences reported for children. This activation maneuver, as well as photic stimulation, continues to be an important part of the EEG reviewing for children (Ahdab and Riachi, 2014).

Proper testing procedure usually requires 3 to 5 minutes of overbreathing by the child to elicit the response, although shorter time intervals have been suggested for specific purposes (Waternberg et al., 2015). Careful notation of artifact and an anticipation of spikelike, high-amplitude sharp waves are emphasized. Superimposed faster frequencies that may appear to be spike discharges are followed by slow waves during hyperventilation and are commonly overinterpreted as an abnormal finding (Fig. 13-13).

### Photic Stimulation

Photic stimulation may produce a variety of electrographic phenomena that can be useful to the neurologist. It is suggested that a strobe light be used with 500,000-foot to 2 million-foot candles of intensity at a distance of 12 inches from the face and at multiple flash frequencies. Both occipital and parietal channels should be included, with one channel recording the output signal from the light source.

Two artifacts should be anticipated. The photoelectric effect usually appears in the frontopolar electrodes and is caused by high resistance or defective grounding of these electrodes. Simply shielding these electrodes from the light source may be sufficient to determine whether it is present. A second artifact results from the photomyoclonic effect. Muscle contractions, usually around the anterotemporal, frontal, and frontopolar electrodes, are recorded in response to the light flashes.

Taking these possible sources of artifact into consideration, the normal phenomenon is a sharp surface-positive waveform, maximal in the parietal and occipital electrodes, which matches the flash frequency (Fig. 13-14A). Photic stimulation might induce drowsiness, including a normal sharp-wave phenomenon known as posterior occipital sharp transients (Fig. 13-16C). Slower flash frequencies result in more prominent responses in younger children. However, the spike discharges in these posterior leads can be diffusely distinguished by their waveform, field, symmetry, and persistence relative to the start and end of the flash of light. The abnormal photoparoxysmal response (Fig. 13-14B and C) is discussed in a subsequent section, including its relationship to epilepsy and withdrawal states.

### Drowsy Patterns

A drowsy state represents a transition from wakefulness associated with the disappearance of the occipital alpha rhythm and the emergence of central-parietal theta activities. Pendular eye movements may be detected in the anterior, temporal, or frontopolar channels. EEG changes may precede behavioral evidence of sleepiness, especially in the younger child. This period of successively greater amounts of rhythmic and paroxysmal slow activity has been called hypnagogic hypersynchrony and may be overinterpreted by the inexperienced clinician. Similar to the notched, sharp-wave activity during hyperventilation, superimposed activity may be seen during drowsiness and misinterpreted as abnormal spike or sharp-wave discharges.

The EEG recording should be obtained continuously from wakefulness through drowsiness into sleep so that the complete succession of changes in background activities can be

**Figure 13-13.** **A**, EEG of an 8-year-old female during hyperventilation. Arrow indicates notching of the high-amplitude slow activity in the absence of epileptiform discharges. **B**, EEG of a 3-year-old female during drowsy, light sleep. Notched, high-amplitude delta activity occurs (arrow) in the absence of epileptiform discharges.

**Figure 13-14.** Types of EEG photic responses. **A**, EEG of an 8-month-old male with prominent driving in a slow-flash frequency in the occipital regions. **B**, EEG of a 12-year-old male with a photoparoxysmal response confined within the duration of the stimulus at six flashes per second. **C**, EEG of an 11-year-old female with suppression of driving in the left hemisphere and with intermixed slowing in the same head region. Encephalomalacia in the left posterior quadrant was demonstrated on imaging studies. (**A**, Courtesy of Dr. P Crumrine, Children's Hospital, Pittsburgh.)

observed. A slowing in the alpha rhythm with an increase in amplitude already described can be seen in a diffuse distribution or regionally over the anterior or posterior scalp areas in association with more prominent beta activity.

The first and more common pattern is rhythmic beta activities over the central or frontocentral region of approximately 200  $\mu$ V. It is most pronounced between 3 months and 4 years of age, and is not encountered after 7 years of age. Typically, the frequency of this rhythmic pattern will increase to 6 Hz with age. A second pattern consists of prominent bisynchronous bursts of 2 to 5 Hz greater than 350  $\mu$ V from 6 months to 5 years of age. This pattern is commonly misinterpreted as spike-and-wave discharges because of the superimposition of the faster frequencies.

### Sleep Activation Procedures

Based on an extensive review of the subject of sleep and sleep deprivation, there is general agreement that sleep and sleep deprivation have a substantial activating effect on the occurrence of interictal epileptiform discharges. Recent updates addressed the activating effect of sleep deprivation over and beyond the effect of only sleep. Most published guidelines do not recommend sleep deprivation for the initial study because of the burden to the patient. However, sleep deprivation has been considered superior to sleep alone in one study, although other investigators suggest that sleep state can be better achieved during routine EEGs by simply ordering the sequence of activation procedures. By performing hyperventilation first with photic stimulation at the end of the study the

neurophysiologist can maximize the yield of attaining sleep during a routine recording. The inclusion of sleep as part of the child's study ensures a greater likelihood for the activation of specific epileptiform features associated with specific epileptic syndromes such as benign rolandic epilepsy of childhood, Landau-Kleffner syndrome, and electrical status during slow-wave sleep.

## SLEEP PATTERNS

### Electroencephalographic Neonatal Sleep as an Ultradian Rhythm

In normal term newborns, sleep alternates with waking states over a 3-hour to 4-hour cycle at night and during the day. Within the first month or two of life after birth for the term infant, sleep-wake state organization begins to adapt to the light and dark cycles, as well as regularly recurring social cues. Circadian rhythmicity of body temperature and heart rate occurs in approximately 50% of preterm infants at 29 to 35 weeks conceptual age. However, longer-run ultradian rhythms of 3 to 4 hours duration correspond to feeding and social interventions. Increases in body movement activity and heart rate and decreases in rectal skin temperature are present during interventions, reflecting changes in the infant's micro-environment and the infant-caretaker interactions. Even the ultradian EEG sleep cycle length of the preterm infant, as defined by changes in EEG discontinuity, shows a positive correlation of cycle length and increasing postconceptional age. By postconceptional term age, the ultradian EEG sleep

cycle is longer for the preterm than for the term infant. Regardless of the cycle length, the architecture remains the same between preterm and term groups and is composed of active sleep segments interrupted by transitional or indeterminate sleep segments. Reactivity or arousal periods punctuate within and between sleep segments. Indeterminate sleep and arousal phenomena represent important expressions of sleep continuity.

The neonatal ultradian EEG sleep cycle is approximately 30 to 70 minutes. The sleep segments that constitute this cycle include two active and two quiet sleep segments, usually beginning as an active sleep portion on falling asleep. Transitional sleep segments within and between active sleep segments are commonly called indeterminate sleep segments. Reactivity or arousal periods also punctuate within and between sleep segments. Indeterminate sleep and arousal phenomena represent important expressions of sleep continuity.

### Infant and Childhood Sleep

The infant's ultradian sleep cycle lengthens with maturation to 75 to 90 minutes. The idealized sleep architecture after sleep onset consists of one REM sleep segment that follows four non-REM (or quiet sleep) segments. Regional EEG patterns are identified during these sleep segments, which assists in the assessment of sleep organization.

### Vertex Waves and Sleep Spindles

The transitional state of drowsiness is sometimes referred to as stage 1 of sleep and may include sharp-wave discharges that are maximal in amplitude over the vertex and central regions. Commonly, symmetric central diphasic waveforms become better expressed and more abundant during stage 2 sleep, which coincides with the appearance of sleep spindles. These waveforms usually have an initial surface-negative wave, followed by a surface-positive phase. The onset of vertex waves can be between 2 and 5 months of age and can appear asymmetric, particularly at younger ages. If this asymmetry exceeds 20%, the neurologist must consider the presence of a lesion on the attenuated side. Excessively asynchronous appearance of vertex waves has been associated with increased intracranial pressure or structural midline defects such as agenesis of the corpus callosum.

Sleep spindles primarily define stage 2 of sleep and are not clearly expressed until 3 to 4 months of age. Synchrony is gradually achieved with increasing age, and most spindles are bilaterally synchronous by 18 months. The waveform morphology of sleep spindles in infants differs from that of older patients. The duration of spindles is 1.5 to 1.8 seconds at 4 to 6 months. At this age, they frequently reach 4 to 6 seconds, which subsequently shortens to 0.5 second by 25 to 54 months.

Spindles lasting as long as 4 to 6 seconds are frequently observed in infants younger than 1 year, but "extreme" spindles have been described in neurologically abnormal children of older ages (Fig. 13-15B). The common frequency range is 13 to 14 Hz, but slower spindle frequencies of 10 to 12 Hz are also documented in about 5% of children older than 5 years. Spindle density is highest at 3 to 9 months and at a minimum at 27 to 54 months. Faster bursts of 18 to 22 Hz may resemble spindles but are usually associated with medications such as benzodiazepines and barbiturates. Sleep spindle evolution from infancy to adolescence has been described. Sleep spindle activity changes with maturation in terms of length and density. The establishment of age-related normative data of sleep spindle activity will improve the identification of non-REM 2 in infancy, childhood, and adolescence and will

enable detection of delayed neuronal maturation and/or sleep stability.

### Occipital Sharp Transients

Two types of sharp transients can occur in the occipital region during sleep. Posterior sharp transients of sleep are surface-positive, checkmark-like waveforms, which usually occur in runs of 4 to 5 Hz but may occur singly. Although appearing asymmetrically, these waveforms are bilaterally synchronous. Although posterior sharp transients of sleep can appear between 4 and 5 years of age, they are most commonly encountered during the early sleep of young adults 15 to 35 years of age. The other form of occipital transients in children also appears during drowsiness. It has a cone-shaped configuration or a diphasic sharp wave resembling a vertex transient.

### Frequency Distribution During Sleep

More pronounced beta activity can accompany drowsiness. As stage 2 sleep emerges, a definite frequency and amplitude gradient can be appreciated between the anterior and posterior head regions. Higher-frequency, lower-amplitude activity predominates in anterior head regions, with the converse situation occurring in posterior head regions. With deeper sleep, this gradient is less well defined. Its absence or poor organization has been observed in children with developmental delays. The quantitative measure of slow-wave sleep provides a measurable biomarker of developmental neuroplasticity (Wilhelm et al., 2014).

### Arousal Patterns

Infants younger than 2 months of age have only a diminution of background amplitude with arousal. By 2 to 3 months of age, diphasic slow waves accompany this desynchronization and may merge with delta waves by 5 months of age. With further arousal, 4-Hz to 8-Hz rhythmic waveforms appear diffusely or in the frontocentral regions, last for several seconds, and disappear by 4 years of age. More monorhythmic 4-Hz to 5-Hz activity may persist into young adulthood and can be seen in 40% of children 10 to 14 years old. Postarousal hypersynchrony of 2.5 to 3.5 Hz generally appears frontally but may also be expressed posteriorly with further arousals. Such electrographic changes cease at any time, with the recording reverting back to the previous sleep pattern.

### Patterns of Uncertain Significance

The most commonly encountered pattern is the 14-positive and 6-positive spike discharge (Fig. 13-16A). Although initially assigned clinical significance, this pattern subsequently has been identified in several control populations. These surface-positive waveforms appear in the posterotemporal regions or adjacent areas during sleep, with a 60- $\mu$ V to 70- $\mu$ V, comb-shaped configuration that may last as long as 3 seconds. It is best demonstrated with a referential montage and has a peak incidence during adolescence.

The 6-Hz spike-wave complexes are less common waveforms, having maximal amplitude in the centroparietal regions. Historically considered clinically important in patients with headache and autonomic symptoms, they can be seen in normal control subjects, especially adolescents. These complexes can be induced by diphenhydramine in 30% of normal volunteers (Fig. 13-16B). Small, sharp spikes and psychomotor variants, benign epileptiform variants, are uncommonly observed in children. Small, sharp spikes occur

more frequently in a normal rather than a patient population. Psychomotor variant patterns also are described in as many normal, asymptomatic individuals as in study patients.

## ABNORMAL ELECTROENCEPHALOGRAPHIC PATTERNS

### Abnormal Neonatal Electroencephalographic Patterns

Numerous medical complications can contribute to an encephalopathic state in the sick neonate, consisting of diffuse, multifocal, or focal brain dysfunction. Many times, focal and diffuse processes exist simultaneously, creating a more difficult interpretative situation. EEG findings can substantially add to clinical assessments, given the limited clinical repertoire of the immature infant and the practical limitations of a sick neonate who is confined by catheters, intubation, pharmacologic paralysis, and an isolette. Visual and computerized analyses of EEG patterns will assume greater significance as outcome measures are developed that will assess the efficacy of neuroprotective interventions. Comparison of the neonate's EEG background activity with that expected for a particular gestational or postconceptional age can rapidly estimate the severity of a neonatal encephalopathy.

Four general guidelines must be recognized before applying EEG analysis to the assessment of the newborn with suspected CNS dysfunction. First, neonatal EEG abnormalities are nonspecific with respect to etiology; a specific diagnosis is only infrequently associated with a particular EEG pattern. Second, it is difficult to determine by only a single EEG study if the observed EEG abnormalities are reflective of a transient or more permanent encephalopathy unless serial studies are obtained. Third, EEG abnormalities alone cannot be interpreted by the clinician with respect to the timing of the brain insult. Fourth, despite the degree of severity regarding EEG patterns, abnormalities usually disappear rapidly over time. This "normalization" of EEG disturbances can occur even in infants who will later suffer severe neurologic sequelae. Obtaining several EEG studies is recommended for all high-risk infants, beginning during the acute phase of the illness and repeated judiciously over the first days of life into the second week until normal studies are obtained, or alternatively, electrographic abnormalities are noted to persist.

### Assessment of Prognosis

Serial EEG studies during the neonatal period offer more information than can be obtained from an isolated recording. None the less, some reports emphasize the prognostic significance of single recordings with severely abnormal features (Watanabe et al., 1980), whereas other reports suggest that serial studies provide the clinician with a sensitive prognostic indication of neurodevelopmental outcome. Monod and colleagues analyzed 691 neonatal EEG studies of 270 children whose clinical conditions were documented from 3 to 14 years. Certain EEG abnormalities were related to neurologic sequelae. Examples of suppression-burst (paroxysmal), isoelectric, multifocal sharp-wave patterns, and an invariant pattern are shown in Figures 13-17 to 13-20. Sharp and colleagues subsequently adapted these abnormalities to preterm neonates. From a retrospective analysis of 184 neonatal EEG studies of 81 infants born at or before 36 weeks gestation, and subsequent clinical assessment of 64 survivors, a severely abnormal pattern was of prognostic value. Table 13-1 summarizes the major EEG abnormalities discussed in these two studies. Severe EEG disturbances help establish a reference

point for the neonatologist. Improving or worsening trends may have important prognostic implications in the context of the neonate's evolving clinical condition.

### Focal Abnormalities

Neonatal EEG patterns assessments have been shown to be helpful in the evaluation of focal, regional, or hemispheric brain abnormalities. Parasagittal and lateralized EEG abnormalities (central or midline regions) have been correlated with a variety of brain lesions. In a population of 60 neonates with midline EEG abnormalities and cerebral lesions identified with neuroimaging or neuropathologic studies, intraventricular hemorrhage was the most common hemorrhagic lesion, whereas periventricular leukomalacia and cerebral infarction were the most common ischemic lesions associated with parasagittal abnormal patterns. Midline EEG abnormalities include amplitude attenuation, positive sharp waves, seizures, and discharges associated with myoclonus. Other studies have also demonstrated the association of positive vertex sharp waves with intraventricular hemorrhage (Fig. 13-21) or periventricular leukomalacia, and the association of midline electrographic seizures with infarction. Late chronologic changes in neonatal EEG findings with periventricular leukomalacia have also been described, after positive sharp waves and other midline or rolandic abnormalities have been noted in the acute time period. Chronic stage changes consist of persistent amplitude and frequency suppression of varying degrees of severity, emphasizing the greater efficacy of serial recordings.

Lateralized EEG abnormalities, including neonatal seizures, have been associated with congenital or acquired brain lesions (Fig. 13-22). After the seizure, the prominent abnormality is an attenuation of background frequencies or amplitude.

Transient asymmetries have also been described in asymptomatic neonates during the initial portion of quiet sleep. Judgment must be used before proceeding to imaging procedures to assess such patients for structural lesions.

### Neonatal Seizures

Despite the need to diagnose neonatal seizures promptly, unique clinical and electrographic features may delay timely recognition and treatment. The varied and less organized clinical expression of neonatal seizures makes the diagnosis more difficult. Accepted clinical criteria may not always distinguish seizure movements from pathologic nonseizure movements. Classifications have been developed that have improved the clinical accuracy of the observer. Technologies using prolonged EEG or synchronized video EEG-monitoring sessions will likely prove more valuable in diagnosing clinical and electrographic seizures (Shellhaas, 2015). Computer-assisted and automated detection systems continue to be presented with varying degrees of specificity and sensitivity for seizure detection, as exemplified by several reports. Amplitude-integrated EEG in neonates has also been compared with conventional EEG for a variety of neonatal diagnostic and prognostic purposes. This simplified technology will need to be combined with more extensive neurophysiological monitoring paradigms; several proposed classification schemes have been discussed.

Neonates may have seizures that are not detected unless an EEG is performed. Some of these patients are pharmacologically paralyzed for ventilatory care, whereas others fail to demonstrate clinical seizures despite the appearance of electrographic seizures in the absence of a paralytic agent. Electroclinical uncoupling after antiseizure medication use can

suppress clinical signs associated with seizures. EEG seizures are recognized by the electroencephalographer based on the evolution of discharges that can be clearly distinguished from the background and are not related to artifact. The frequency of these discharges is usually in the slow range with a variety of waveforms. The evolution of discharges implies a gradual change in the location, amplitude, waveform, or distribution. The arbitrary definition for the minimum duration of a seizure is 10 seconds, with the average duration being 1–5 minutes for term or preterm neonates, unless status epilepticus occurs. Clinical ictal activity may accompany the electrical seizure (Fig. 13-23A and B). Only a few patterns are associated with a particular clinical presentation. For example, alpha-range rhythms have been associated with respiratory disturbances such as apnea as the clinical correlate appearing with an electrographic seizure.

Five categories of clinical seizure types have been historically described and may be associated with any number of EEG seizure patterns. These five categories are subtle, focal clonic, multifocal clonic, tonic, and myoclonic. Focal or multifocal EEG seizures can be observed, and generalized discharges are seen rarely. The infrequent occurrence of a clinical seizure without a coincident EEG accompaniment has been described (Fig. 13-23C). Although one explanation is that this is a nonseizure movement disorder originating from a subcortical location, the possibility of a subcortical seizure focus may also exist.

### Focal Periodic Patterns

Focal and multifocal periodic abnormalities have been described in neonatal recordings. These discharges do not have an acceptable evolution in EEG features to be identified as an electrographic seizure. Instead, stereotypic, repetitive discharges at slow frequencies are observed, and they are usually brief (Fig. 13-24). More prolonged and lateralized periodic discharges have also been described for many clinical situations, specifically for neonates with asphyxia and herpes encephalitis. Short runs of periodic discharges are more commonly observed. Parasagittal discharges occur in preterm and temporal patterns in term neonates, and they are associated with EEG seizures and brain lesions such as infarction. This association of periodic patterns with brain lesions is reminiscent of the association between periodic lateralized discharges and brain lesions in adults and children. Repetitive EEG patterns such as periodic discharges do not satisfy arbitrarily defined descriptions of electrographic seizures but may have important relationships to clinically observed seizures.

### Spikes and Sharp Waves

In most situations, the electroencephalographer has difficulty assigning clinical significance to sporadic epileptiform features on neonatal recordings. These epileptiform characteristics may be seen in asymptomatic, apparently healthy infants. Several features, however, may help distinguish normal from abnormal spike or sharp waves. Epileptiform discharges that are frequent and multifocal and persistently occur throughout sleep may have pathologic significance. Several investigators have proposed that five-spike or sharp-wave discharges per hour suggest an abnormality. Other features such as positive sharp waves, periodic discharges, and midline discharges commonly are associated with CNS insults.

Spike and sharp-wave discharges have been described in specific neonatal populations based on serious medical disorders, principally seizures. Hughes and colleagues described spike and sharp-wave discharges in 236 neonates whose postconceptional age ranged from 24 to 48 weeks. Approxi-

mately 55% had recordings because of a clinical suspicion of neonatal seizures. Sporadic sharp waves, more frequent in the right hemisphere, were found primarily in the centrottemporal regions in 85% of the total population. An additional 15% had positive sharp waves or repetitive sharp waves. No control group in which epileptiform discharges were observed was included nor was follow-up reported. Rowe and associates documented sharp-wave discharges in 51% of 74 neonates. These infants were followed up to 33 months of age, and the presence of sharp waves on the neonatal EEG correlated with early developmental outcome. However, the investigators stress that EEG background abnormalities were more predictive than isolated epileptiform features. Spike discharges rarely occur in the neonate at any gestational age. Sharp-wave discharges are, however, common in frontopolar, right temporal, and left central regions in otherwise asymptomatic neonates. Sharp waves in occipital or midline locations are rarely seen in healthy neonates and may have greater clinical significance.

### Epileptiform Abnormalities

EEG remains the principal investigation for children with epilepsy. However, the technique has been historically accepted, without strict reliability assessments. The clinician's classification of a child's seizure disorder, as well as possible diagnostic and therapeutic decisions, is based on interictal EEG results. The neurologist relies on interictal EEG recordings performed particularly close in time to the occurrence of the seizure event. However, demonstration of epileptiform abnormalities in the EEG patterns of patients with seizures does not occur in approximately 50% of the first routine interictal EEG recording. Repeated EEG recordings may increase the diagnostic yield. A retrospective study of adults with the diagnosis of epilepsy found the chance of detecting interictal epileptiform activities to be approximately 20% for the second EEG and less than 10% after the fourth negative repeat EEG recording. In a study of children between the ages of 1 month and 16 years with one or more idiopathic or symptomatic newly diagnosed seizures, a repeat EEG was obtained in children who expressed no epileptiform activity on their initial EEG recording. Of 552 children studied, 56% had epileptiform activity on the initial EEG; for the overall group who had a repeat EEG recording, 30% had epileptiform activity when the initial EEG pattern was normal. Epileptiform activities were more likely if the repeat EEG included sleep. These findings are in accord with earlier reports in the literature on repeat EEG recordings after sleep deprivation in children with suspected epilepsy; between 32% and 75% of children had epileptiform activity on repeat EEGs after sleep deprivation. Other reports warn against obtaining a repeat EEG that may yield different and sometimes conflicting information for the clinician in children with absence seizures or generalized motor seizures. These investigators describe repeat EEG recordings in 159 infants, with 40% to 70% discordance for the type of abnormality on the second EEG compared with the first.

Among a variety of abnormal EEG patterns, certain features have been associated in patients with seizure disorders and are commonly referred to as epileptiform. Epileptiform waveforms include spikes, sharp waves, spikes and waves, sharp and slow waves, and multiple spikes. The sharp wave has a waveform that is characteristically negative in polarity with a duration of 70 to 200 msec. This finding is contrasted with the spike morphology, which is of shorter duration (20 to 70 msec) and sharper morphology. The slow-wave complex that may accompany either waveform generally is between 1 and 5 Hz (i.e., 200 to 1000 msec).

Epileptiform features are not necessarily associated with clinical seizures. One study found that 2.7% of 743 normal children had epileptiform EEG activity. This percentage increased to 8.7% during sleep. Although a more recent study claimed a lower percentage of 0.70% (Bihege et al., 2014), digital EEG studies may detect a higher percentage than analog studies used historically (Borusiak et al., 2010).

In certain forms of genetic epilepsy, family members are asymptomatic but have abnormal EEG discharges. Conversely, patients with well-documented seizures may have normal EEG studies, particularly children younger than 2 years. Only 56% of patients with seizures in one study had epileptiform activity on the first EEG recording.

Epileptiform discharges not accompanied by obvious clinical events usually are regarded as subclinical or interictal. However, careful observation with psychometric testing can reveal brief episodes of impaired cognitive function during such discharges. This feature has been observed in 50% of patients who exhibit discharges during testing, and it may contribute to behavioral and cognitive deficits. Limited evidence-based analyses suggest that suppression of discharges is associated with improved psychosocial function. Specific pediatric epileptic syndromes may have a greater association with such deficits.

After a patient with recurrent epileptic seizures is treated with antiseizure medication and becomes seizure-free for some period, the clinician is eventually challenged with the decision about whether treatment should be continued. In making this decision, the neurologist must weigh the risk of side effects of drugs against the risk of seizure relapse. Certain indicators of prognosis continue to be of important clinical value. The EEG study has remained one predictor of outcome after withdrawal of treatment, but many children who become seizure-free during drug treatment continue to manifest epileptiform activity in their EEG recordings. Correlations between EEG findings and clinical outcome after discontinuation of treatment have been reported in many studies, as reviewed by Andersson and colleagues, but there is a lack of unanimity, given the fact that different EEG variables have been assigned prognostic importance. Children whose last EEG before discontinuation of treatment displays generalized irregular spike-and-wave activity relapse more often than other children; 67% of children with such activity in their final EEG studies relapsed, compared with a relapse rate of 33% for children without epileptiform activity or with other epileptiform abnormalities. Children who were treated for only 1 year and in whom irregular, generalized spike-and-wave activities were present in one or more recordings had a high relapse rate. Apart from treatment of children with irregular, generalized spike-and-wave activity, most physicians discontinue treatment after 6 months to 2 years of seizure control. The presence of epileptiform activity does not necessarily influence the prognosis for the recurrence of seizures, with the exception of certain types of abnormal epileptiform activity or patient groups. For example, in a cohort of children with cryptogenic localization-related epilepsy who were followed for more than 5 years after drug withdrawal, 8 of 82 (9.8%) experienced seizure recurrence. Two independent risk factors were 6 years of age or older at seizure onset and 5 years or more from the start of drug therapy. Another report of children with cryptogenic partial epilepsy recommended EEG studies during drug withdrawal, even with a previously normal EEG study, because the presence of EEG abnormalities was associated with a high probability of seizures.

**Spike-and-Wave Patterns.** The most frequently encountered spike-and-wave pattern is a bilaterally synchronous, single or polyspike discharge, followed in frequency by rhythmic slow

waves. Both features are surface-negative, and these discharges can be 100 to 200 msec long. Discharges in certain regions (e.g., frontal) appear slightly before the generalized burst or are maximally expressed in one particular location. The examiner may see fragments of the spike-and-wave pattern, depending on the montage or sensitivity setting, because of cancellation effects of bipolar recordings or the low amplitude of the complexes. The fastest frequency of the discharges (3 to 6 Hz) is at the onset of seizures, with slowing to 2.5 to 4 Hz during the electrographic seizure. Augmentation of the discharges can be seen with hyperventilation or non-REM sleep, although the spike-and-wave pattern can become slower and more complex in morphology during sleep. Two nonspecific phenomena are often associated with a generalized spike-and-wave pattern and consist of bursts of 2-Hz to 4-Hz, rhythmic slow waves or a more monorhythmic, occipital delta activity.

Photic stimulation may elicit a spike-and-wave discharge (Fig. 13-14B) but can only support the evidence for seizures suggested by the clinical evaluation. This pattern also appears in 3.4% of normal control subjects and in 20% of siblings of patients with photoparoxysmal seizures who have never had clinical seizures. Only 10% of these siblings had clinical seizures. A prolonged response that outlasts the stimulus may be a stronger indication that a seizure disorder is present, but there is also an age-dependent expression of this abnormal pattern between 5 and 15 years. Even self-limited photoparoxysmal responses that do not outlast the stimulus can be highly correlated with epilepsy. This pattern is most easily elicited with a frequency of 10 to 16 flashes per second. Clinicians must anticipate that children with photosensitive epilepsy can still have an excellent prognosis that is independent of the persistence or disappearance of photosensitivity on the EEG study.

Patients on dialysis, with electrolyte disturbances, or exhibiting withdrawal from drugs such as barbiturates and alcohol are more susceptible to photoparoxysmal responses with or without clinical accompaniment. Even for the nonepileptic pediatric patient, photoparoxysmal responses may be present in the absence of acute encephalopathies, with persistence for as long as 6 years after the initial documentation. Suppression of photic driving responses may also occur in the presence of structural nervous system disorders (Fig. 13-14C).

**Sharp-Wave and Slow-Wave Complexes.** The sharp-wave and slow-wave complex pattern consists of a sharp wave of negative polarity lasting 100 to 200 msec and slow waves lasting 350 to 400 msec at a frequency of 1 to 2 Hz. Although diffusely distributed over the scalp in most patients, it may be asymmetric or confined to anterior or posterior quadrants. This waveform is augmented only during sleep and can be associated with sudden desynchronization of the record, which is associated with a burst of beta activity called an electrodecremental response. Although the highest incidence of sharp-wave and slow-wave complexes occurs between 1 and 5 years of age, they are also evident well into adulthood. Hypsarrhythmia can precede the sharp-wave and slow-wave complex during the first year of life.

Of clinical seizures with sharp-wave and slow-wave complexes, 90% are tonic, and these seizures are resistant to therapy, persisting at least 15 years after beginning treatment. Other types of clinical seizures can also occur, depending on the age of onset: tonic seizures at 16 months, absence seizures at 32 months, myoclonic seizures at 39 months, and tonic-clonic seizures after 43 months.

Mental subnormality is identified in 30% of patients at diagnosis. When seizures are present before 2 years of age and are caused by CNS disease, the child will more likely exhibit

delayed development. The clinical and EEG syndrome that includes the three features of seizures—mental subnormality, and sharp-wave and slow-wave complexes—is called the Lennox-Gastaut syndrome.

**Hypsarrhythmia.** Hypsarrhythmia is the most common interictal EEG pattern associated with infantile spasms. The most common clinical description is a sudden, symmetric, tonic muscle contraction producing flexion/extension of the trunk and extremities, although a variety of movement patterns have been described. The EEG pattern is a chaotic mixture of high-amplitude slow waves, multifocal spikes, and intrahemispheric-interhemispheric asynchrony. This EEG pattern usually is observed in children 3 months to 5 years old, and it can be preceded by a burst-suppression or low-voltage invariant pattern in the newborn period. Hypsarrhythmia can also be preceded by a normal EEG pattern. During a spasm, an electrodecremental response interrupts the high-amplitude slowing by a sudden diminution of all activity with a duration of 1 second to 1 minute. The role of EEG is limited to diagnosis only, with no reliable correlation with cause, course, or prognosis, including mental development.

**Generalized Periodic Discharges.** Generalized periodic discharges are distinguished from bilateral synchronous spike-and-wave discharges by the broader waveforms in the context of a periodic quality. This pattern has been historically identified with two clinical situations: Creutzfeldt-Jakob disease in adults and subacute sclerosing panencephalitis in children.

The periodic complexes in subacute sclerosing panencephalitis appear at approximately 4-second to 14-second intervals but have no relation with the clinical progression of the disease. Similarly, there is no relation between the myoclonic movements and these discharges. The periodic discharges may first arise from a normal background and may initially be observed only during sleep.

### Focal Epileptiform Patterns

The incidence of focal-spike discharges in the normal population (1.5% of 1000 children) has been previously estimated. More recently, an overall prevalence of 6.5% was detected in 383 healthy children 6 to 13 years of age; 4 showed generalized or bifrontal spikes, 12 showed constant focal localized discharges, and 9 showed multifocal discharges. Spike discharges in symptomatic patients should be correlated with the clinical context in which the discharges are observed. Focal spikes are identified in children with cerebral palsy in the absence of clinical seizures; however, the presence of focal spikes in children younger than 2 years of age implies severe neurologic impairment. Spike foci on a single EEG examination are not a reliable indicator of structural brain lesions because the location of the spike discharges on subsequent EEG studies may be shifted to different foci. However, the absence or rare occurrence of a spike discharge on a routine EEG usually predicts better outcome, compared with more frequent spikes in any head region associated with EEG background slowing.

**Rolandic Spikes.** Rolandic spikes are associated with the most common genetic epilepsy of childhood. High-amplitude spike and slow waves are prominently observed singly or in runs in the central and midtemporal regions. Shifting laterality occurs in the same or subsequent EEG studies, and these focal discharges may be associated with generalized spike-and-wave discharges in 5% of children. The EEG background activity is otherwise normal, and certain patients have rolandic spikes that appear only during sleep, commonly during non-REM sleep. An unusual polarity relationship is associated with the discharges, consisting of a simultaneous negative and positive

phase-reversal in two different locations of the spike discharge. This polarity may represent a horizontal rather than the more common vertical dipole, and is associated with abnormal EEG activity.

**Occipital Spikes.** Benign childhood epilepsy with occipital paroxysms (benign occipital epilepsy) typically presents between 4 and 12 years of age. One study by Panayiotopoulos suggests that this is a common form of epilepsy in children. Of 94 patients, 18 (20%) fulfilled the criteria for benign epilepsy of childhood with occipital paroxysms. The clinical presentation may be emesis and visual phenomena in older children with simple or complex visual hallucinations or distortions with preservation of consciousness. In younger children, seizures are less frequent and are often nocturnal but may be dramatic with periods of prolonged unresponsiveness. The EEG patterns for both clinical presentations are composed of repetitive occipital spike discharges on eye closure. It has been debated whether this syndrome is related to the reflex epilepsies in which generalized seizures and EEG abnormalities can be initiated by video games and other visual stimuli. However, the presence of occipital epileptiform EEG abnormalities may be associated with children with migraine headaches, with or without accompanying epilepsy. Specific electroclinical features help distinguish these two groups.

Besides the benign occipital epilepsy syndrome, a greater proportion of children with occipital discharges have symptomatic epilepsy, although neonates may also reflect occipital spike discharges after as a result of brain disorders and the EEG study can assist in predicting better outcome based on the presence of generalized spike-and-wave discharges or normal EEG background rhythms.

### Temporal Spikes and Sharp Waves

Although not associated with a distinctive epileptic syndrome, temporal spike discharges must be distinguished from the spikes associated with rolandic epilepsy. The electroencephalographer can ascertain a difference by determining whether there is a more limited temporal location to the spike discharge without expression of a dipole, as described previously. According to a study by Eeg-Oloffsson, temporal spikes are rarely seen in normal children (2 of 743 patients) but are frequently seen in epileptic patients (92% of 666), including children with complex partial seizures.

Complex partial seizures commonly begin during childhood, and anatomic abnormalities have been detected in some of these patients. Static lesions, such as mesial temporal sclerosis, hippocampal herniation, or hamartoma, have all been described, and several of these patients also demonstrate homonymous hemianopsia or quadrantanopsia on visual field testing, presumably because of perinatal occlusion of the posterior cerebral artery.

### Multiple Independent Spike Foci

Patients with spike discharges in at least three noncontiguous electrode positions are considered to have multiple independent spike foci. No patients in a normal population have this pattern, whereas 63 of 1500 patients with seizures and EEG recordings demonstrate this pattern. Of patients with multiple independent spike foci, 90% had clinical seizures, most of which were generalized motor seizures. Although 66% of patients had subnormal intelligence, normal cognitive abilities were more likely if there were few spike discharges and a normal EEG background. Sleep can augment spikes and activate new foci, but hyperventilation or photic stimulation cannot. Of these patients, 25% had previous EEG studies with hypsarrhythmia or sharp-wave and slow-wave complexes.

## Periodic Discharges

Generalized periodic discharges and neonatal periodic patterns have already been discussed. The present description pertains to the EEG phenomenon that consists of repetitive stereotypic focal discharges that remain lateralized with a duration of at least 10 minutes, or 20% of the recording time. Waveform morphologies can be varied and are collectively referred to as periodic lateralized epileptiform discharges. This phenomenon represents an acute or a subacute process in adults or children. Usually, a brain lesion such as infarction, contusion, or cerebritis can be identified. Periodic discharges in the temporal region may suggest an encephalitic process caused by a herpetic infection.

Biphasic or polyphasic discharges of 100 to 200 msec and 100 to 200  $\mu$ V have a frequency of 1 to 2 Hz. These discharges persist for a limited number of days or weeks in adults and are replaced by focal polymorphic delta slowing. Multifocal periodic patterns can also occur. In children, more subacute or chronic processes have been associated with focal or multifocal periodic lateralized epileptiform discharges. Similar to adults, periodic lateralized epileptiform discharges can also be seen in acutely encephalopathic children from infection or toxin exposure and are highly associated with seizures. Stimulus-induced rhythmic, periodic, or ictal discharges can be documented in older patients undergoing continuous EEG monitoring in the intensive care setting, which need to be distinguished from spontaneous seizures. Stimulus-evoked seizures have been described for neonates, but older pediatric populations have not been systematically identified. In adults, 90% exhibit a depressed level of consciousness, whereas 70% demonstrate focal neurologic defects. Periodic discharges are commonly observed after a seizure, particularly if it is focal in onset; about 80% of these patients have frequent seizures. An unusual seizure disorder in children has been described, consisting of agitation and confusion, in which periodic discharges in the frontal regions are observed when the patient is awake or asleep.

TBSS	Tract-based spatial statistics
TEA	Term-equivalent age
t-fMRI	Task-based functional MRI
VBM	Voxel-by-voxel morphometry

## INTRODUCTION

Neurobehavioral disorders are a major pediatric public health problem. Of the world's children, 10% suffer intellectual and developmental disabilities, 1 in 68 is diagnosed with autism spectrum disorder (ASD), as many as 9% are affected with attention-deficit/hyperactivity disorder (ADHD), and 2 to 2.5 per 1000 live births suffer cerebral palsy. The annual lifetime care costs for children and adolescents with these diagnoses in the United States alone exceeds \$50 billion, reflecting both educational and medical costs in addition to loss of productivity. Organization of structural and functional brain networks is necessary for typical neurodevelopment, and converging data suggest that many neurodevelopmental disorders are attributable to alterations in connectivity (Dennis and Thompson, 2013; Di Martino et al., 2014).

The nervous system is a network of interconnected neurons, and the architecture of cerebral circuits is influenced by both the genetically determined program of cortical development and the environment. A major goal is to create a comprehensive map of these connections, or connectome. Noninvasive neuroimaging technologies provide important information about microstructural and functional neural connectivity, and when combined with powerful network modeling tools, these methods offer new opportunities to understand the developing connectome.

Cerebral network studies include both microstructural, functional, and effective connectivity. Diffusion tensor mag-

netic resonance imaging (dMRI) techniques combined with graph-theory analysis permits the mapping of anatomic regions and their interconnecting pathways with high spatial resolution, and the resulting networks provide large-scale maps of the brain's microstructural connectivity (Sporns et al., 2005). Similarly, maps of functional connectivity derived from MRI provide important information about neural regions that are functionally coupled, whether or not they are structurally connected (Friston, 2011). Finally, effective connectivity attempts to capture a network of "directed causal effects" between neural elements, and allows identification of models that best fit the data. Together, these strategies offer the opportunity to examine the influence of both genetic and epigenetic influences on the developing brain.

## Assessment Strategies for Connectivity

Tools of network science include microstructural, functional, and effective connectivity as defined by noninvasive MRI strategies (Table 14-1). Although it is less commonly employed, anatomic covariance is also reviewed in this chapter.

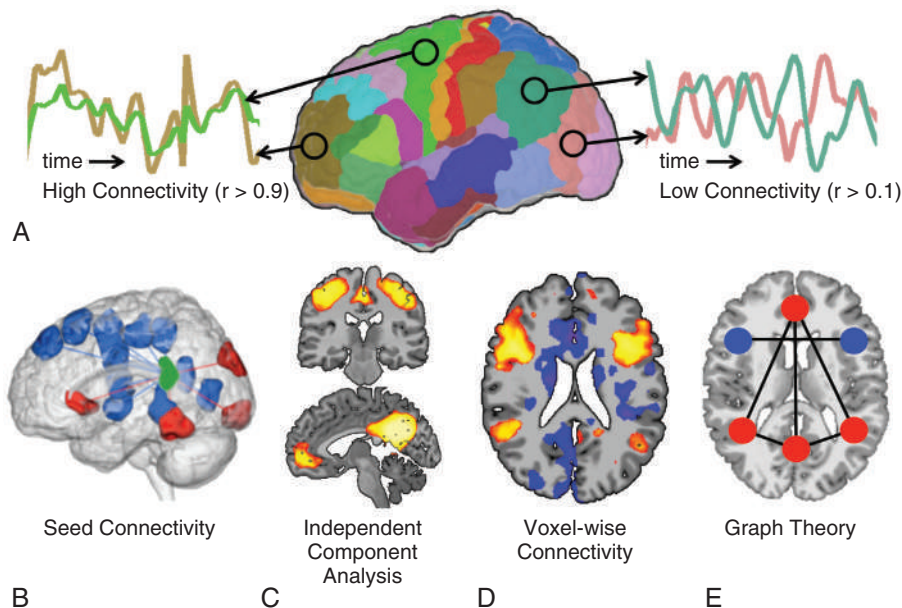

*Microstructural connectivity* describes the anatomic connections linking a set of neural elements. Diffusion-weighted imaging assesses the diffusion of water along axons and thus permits visualization of axonal pathways (Sporns, 2013). By modeling the directional diffusion of water as an ellipsoidal shape, or *tensor*, at each voxel in the brain, dMRI permits the assessment of major white matter fiber bundles. Eigenvector maps can be color-coded to indicate the orientation of the major eigenvector and thus provide a visible indicator of the axis in which water diffusion is the highest. The first eigenvector,  $\lambda_1$ , describes the direction of maximal diffusion, and the second and third eigenvectors define diffusivity perpendicular to this principle axis. Radial diffusivity represents the average of  $\lambda_2$  and  $\lambda_3$ , and is affected by changes in axon caliber and myelination. FA is the ratio of  $\lambda_1$  to  $\lambda_2$ , and  $\lambda_3$  is dependent on axonal integrity. Fractional anisotropy (FA), the degree to which water diffuses in one direction (along the axon), is the most common measure used to assess axonal integrity.

The apparent diffusion coefficient (ADC) is a measure of the magnitude of the diffusion of water in a tissue, independent of direction. In contrast, mean diffusivity (MD) is a measure of the degree of restriction to diffusion of water molecules, irrespective of direction. Low values for MD are consistent with greater organization, whereas high values of FA suggest more highly organized, strongly myelinated tracts. Studies comparing FA and ADC in subjects with a wide variety of diseases to healthy controls show lower FA and higher ADC in the affected group, but this is not universally applicable.

**TABLE 14-1** Methods for Assessing Connectivity

Strategy	Variables	Definitions
dMRI	Fractional anisotropy (FA)	Degree to which water diffuses in one direction (along the axon)
	Apparent diffusion coefficient (ADC)	Measure of the magnitude of diffusion of water, independent of direction
	Mean diffusivity (MD)	Measure of the degree of restriction to diffusion of water molecules irrespective of direction
	Axial diffusivity	Magnitude of diffusion along the axon
	Radial diffusivity	Magnitude of diffusion perpendicular to the axon
	Fiber tracking	Matrix-based connectivity analysis—white-matter connections between gray-matter nodes
fMRI	Spatial-temporal patterns	Similarity of spontaneous brain signal fluctuations reflecting functional connections between distinct brain regions
	Measures of brain activity	Task-driven changes in local activity

**Figure 14-1. Overview of functional connectivity.** **A**, Functional connectivity is defined as the correlation between blood-oxygen-level-dependent (BOLD) time course for any two regions or voxels in the brain. A higher correlation between time courses implies higher functional connectivity between the regions. Common methods for functional connectivity include seed, matrix, and voxel-wise connectivity. **B**, Seed connectivity involves identifying key regions or “seeds” and assessing connectivity between these seeds and all other voxels in the brain. This analysis is the most common. **C**, Independent component analysis (ICA) is a statistical approach in which resting-state data are decomposed into time courses and associated maps describing the temporal and spatial characteristics of the components comprising the data. **D**, Voxel-wise connectivity involves assessing connectivity for every voxel in the brain to every other voxel in the brain and summarizing these correlations with a summary statistic. This method is highly data driven because no a priori region needs to be specified (unlike in seed and matrix connectivity). However, any information about a specific connection is lost. **E**, Graph theory provides models for connectivity that best explain empirical data and is characterized by the set of definitions shown in Table 14-2. A network is composed of a set of nodes (or neural elements) and edges, their mutual connections.

Importantly, microstructural connectivity data do not provide information on the direction in which information travels along fiber pathways.

The three main approaches to analyzing dMRI data, region-of-interest (ROI) quantification, tract-based analysis, and tractography, are shown in Figure 14-1, but recent studies also demonstrate the importance of whole-brain voxel-by-voxel morphometry (VBM). ROI selection and quantification is the most frequently used, whereas VBM is an alternative method designed to quantify regional changes in volume measured with high-resolution three-dimensional anatomic MRI. Tract-based spatial statistics (TBSS) is based on the realignment of the FA maps of all subjects projected onto an FA map skeleton. Tractography permits the reconstruction of white-matter pathways from point to point and demonstrates the brain’s global connectivity.

*Functional connectivity* is based on the blood-oxygen-level-dependent (BOLD) signal and is derived from time-series

data. It assesses “temporal correlations between spatially remote neurophysiological events” (Friston, 2011). fMRI data can be collected either in the presence of a task (t-fMRI) or in the resting state (rs-fMRI). Temporal variations in fMRI signals appear to arise spontaneously, and the synchronicity in these temporal variations indicates functional connectivity, the strength of which may be modulated by tasks and/or sensory stimuli.

The four major methods to assess fMRI data are also shown in Figure 14-1 and include seed-based, independent components analysis (ICA), voxel-wise connectivity, and graph theory. In the seed-based approach, the time course of a seed placed in an ROI is correlated with time courses for the rest of the voxels in the brain to search for synchronous temporal patterns. Brain regions with a high degree of positive correlation with the seed are thought to be “functionally coupled” (Friston, 2011). In contrast, ICA is a statistical approach in which resting-state data are decomposed into time courses

and associated maps, describing the temporal and spatial characteristics of the components comprising the data. Voxel-wise connectivity is a model-free, whole-brain voxel-by-voxel analysis strategy.

*Effective connectivity* defines networks of directed causal effects between neural elements. This strategy provides a model that best accounts for the observed data, and recent advances in effective connectivity have been employed for network discovery. Although effective connectivity offers much promise, most studies investigating the connectome are accomplished using either microstructural or functional connectivity data, and these strategies are the focus of this chapter.

## Anatomic Covariance

Morphologic features of different brain regions are not independent of those of other areas, and the brain shows a high level of coordination between different structures. This coordination, or covariance, of morphologic features is often referred to as *anatomic covariance* and is a key marker of typical development in early childhood. Using ROIs, patterns of anatomic covariance have been linked to developmental disorders. Similarly, network-level approaches investigate the covariance patterns of every pairwise combination of brain regions, forming a network to provide a more complete anatomic description of the candidate disorder.

## Tools of Network Science

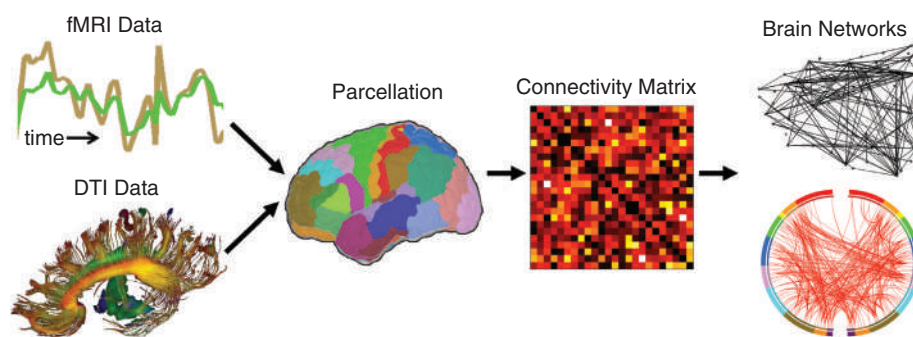

Similar to ROI strategies, graph-theory analyses are suitable for both microstructural and functional connectivity data. Graph theory provides models for connectivity that best explain empirical data and is characterized by the set of definitions shown Table 14-2. A network is composed of a set of nodes (or neural elements) and edges, their mutual connections. Nodes may be derived by parcellating cortical and subcortical gray matter according to anatomic borders or by defining a random parcellation scheme in which the brain is divided into evenly spaced and sized clusters. Following the definition of nodes, structural or functional couplings can be estimated, and the full set of couplings can be assembled into a connectivity matrix, as shown in Figure 14-2. Three important measures are *integration*, *segregation*, and *small-worldness*. Network *integration* refers to how densely connected all nodes are to one another. Networks with nodes that are all connected to one another exhibit high integration, whereas those with few connections show low integration. Network *segregation* refers to the extent

to which a network is organized into a collection of subnetworks. A fully connected network in which each node is connected to all others has low segregation; a network formed of disconnected parts has high segregation. Finally, a *small-world* network has evidence of both segregation and integration. A small-world network has nodes grouped into subnetworks, with efficient travel between these subnetworks.

*Rich club (RC) organization* is another graph-theory measure for summarizing connectivity; important (or “rich”) nodes connect preferentially to other important nodes. Whereas microstructural RCs remain largely consistent over the lifespan, functional RCs evolve during development as hubs mature to accomplish the efficient long-range transfer of information.

**TABLE 14-2** Graph-Theory Tools for Assessing Connectivity

Variables	Definitions
Nodes	Neural elements
Edges	Connections between nodes
Integration	Measure assessing how densely connected all nodes are to one another
Path	Unique sequence of edges that connects one node to another
Characteristic path length (CPL)	Global average of all distances across the entire network
Global efficiency (GE)	Average of the inverse of all distances
Segregation	Measure of the extent to which a network is organized into a collection of subnetworks
Modularity (ML)	Measure of the strength of division of a network into communities
Clustering coefficient (CC)	Density of connections among a node's topological neighbors
Small-worldness	Measure combining both segregation and integration to assess network efficiency
Influence	Statistical attempt to quantify the importance of a given node or edge for a network
Degree	Number of edges attached to a given node
Rich club (RC)	Nodes that connect preferentially to other important nodes

**Figure 14-2. Schematic of connectivity analysis.** To construct a brain network, dMRI or fMRI data are conventionally put into a parcellation scheme whereby the gray matter is subdivided into 100 to 400 regions of interest. The pairwise association between each gray-matter regions is then computed, forming a connectivity matrix. For dMRI data, this association is typically based on the number of white-matter fibers connecting the gray-matter regions. For fMRI data, this association is the correlation between BOLD time courses for the gray-matter regions. A brain network is then constructed from the nodes (gray-matter regions) and the edges (pairwise associations). These brain networks may be converted to sparser networks by removing edges with an association below a chosen threshold.

## Intrinsic Connectivity Networks

Spontaneous intrinsic coherent low-frequency (<0.1 Hz) fluctuations between distant neuronal regions measured using fMRI suggest functional connections, and these identify intrinsic connectivity networks (ICNs). ICNs detected during rs-fMRI correspond to networks observed across functional tasks and are present during mild anesthesia and sleep, making them advantageous for studying infants and young children.

In adults, ICNs include the visual, default mode, cerebellar, sensorimotor, auditory, executive control, and salience networks. There are three visual networks; these correspond to the medial, occipital pole, and lateral visual areas. Visual behaviors correspond to specific networks, and cognition–language–orthography and cognition–space have been found to lateralize to the occipital pole and lateral visual maps, respectively. The default mode network (DMN) is the most studied ICN and includes the posterior cingulate cortex/precuneus, medial prefrontal cortex, inferior parietal cortex, and medial temporal lobe. The DMN most commonly “deactivates” in t-fMRI experiments, subserves internally directed mentation, and is inversely correlated with networks supporting externally directed attention.

Resting-state networks emerge during the 21st to 38th weeks of gestation, and fragmentary networks resembling adult ICNs have been demonstrated in typically developing children shortly after birth. Maturation profiles of these networks are both genetic and environment dependent.

## Categorization of Disorders of Connectivity

During development of the human brain from fetal life to adulthood, white-matter tracts undergo significant changes. Likewise, functional connections develop, mature, and respond to environmental perturbations. The source of alterations in connectivity may include genetic, epigenetic, or traumatic disorders. Conditions such as autism are widely believed to represent connectivity disorders of genetic origin. In contrast, the alterations in functional organization that characterize the preterm population are most likely attributable to environmental changes. Finally, injuries such as stroke and concussion are reported to result in acquired disturbances of connectivity.

## Fetal Development

### Microstructural Studies

Important anatomic and functional networks are established in the fetal brain during the second and third trimesters (Ouyang et al., 2015). Defining these networks during the different stages of human fetal brain development provides insight not only into typical development, but also into the neurobiological foundations of developmental disorders (Dennis and Thompson, 2013), and the emergence of fetal dMRI studies followed by rs-fMRI has permitted examination of human fetuses in real time.

dMRI studies in human fetuses between 18 and 37 weeks postmenstrual age (PMA) with no structural brain pathologies have visualized bilateral, cranio-caudally oriented, and callosal trajectories in addition to sensorimotor tracts and smaller fiber bundles such as thalamocortical fibers, corticopontine fibers, and corticospinal tracts. FA values are highest in the splenium of the corpus callosum, followed by the genu and the posterior limbs of the internal capsules. Limbic system tracts including the fornix and the cingulum bundle are present as early as 14 to 17 weeks PMA. Likewise, internal capsule fibers also appear as early as 14 weeks, and the general

maturation pattern for the internal capsule is anterior-posterior from weeks 14 to 37.

The anterior commissure and the corpus callosum comprise the major *commissural tracts* and are also observed at 14 to 17 weeks, and an anterior-to-posterior maturation pattern for the corpus callosum from 17 to 37 weeks PMA has been described. Finally, the uncinate fasciculus and inferior longitudinal fasciculus represent the earliest association fiber tracts and can both be traced at 19 weeks. In contrast, the arcuate fasciculus is not detectable during fetal development.

## Fetal Functional Imaging

Recent developments in magnetic resonance (MR) techniques permit the identification of processes that underlie the development of the fetal functional connectome. Cross-sectional examination of connectivity in healthy human fetuses of 24 to 38 weeks PMA has demonstrated increasing interhemispheric connectivity with advancing fetal age, and the strength of fetal functional connectivity has been significantly correlated with the spatial location of the ROI on the medial-lateral but not the anterior-posterior axis, in contrast to dMRI data. Long-range functional connections exhibit a linear increase with no periods of peaking development, whereas a region-specific increase of functional connectivity is reported to follow a sequence of occipital, temporal, frontal, and parietal expansion.

Likewise, graph-theory analyses demonstrate that the fetal brain is organized in a modular structure, wherein connections are much stronger within than among modules. With advancing PMA intermodule connection strength increases, sensorimotor modules become more connected to the cerebellum, prefrontal areas become more connected to the posterior parietal cortex, and a ventral-frontal-temporal cortex module becomes more left lateralized and functionally integrated with regions that develop into Broca’s and Wernicke’s areas, which are critical for language acquisition in the developing brain. Finally, motor, visual, default mode, thalamic, and temporal networks have been reported in the human fetal brain between 24 and 38 weeks PMA.

## Environmental Perturbations

Environmental influences ranging from socioeconomic status to prenatal drug exposure may influence connectivity. Although it is difficult to parse the contributions of parental education, household food insecurity, and maternal stress, preliminary studies suggest that connectivity decreases in the frontotemporal regions subserving language and behavior in infants and toddlers from the most affected homes.

## Connectivity in Typically Developing Children

The advent of sophisticated neuroimaging strategies is propelling the study of brain maturation in older children and adolescents. However, early brain growth and connectivity in typically developing infants and young children have not been extensively studied, leaving considerable gaps in knowledge about these important periods. The cerebrum increases in size through early adulthood, and white-matter volumes continue to expand throughout adolescence and into middle age. In addition, a recent longitudinal MRI analysis across the first 3 months of life suggested that brain development is most rapid in the days immediately following birth, when the whole-brain growth rate is approximately 1% per day, slowing to 0.4% per day by the end of the first 3 months, with overall growth of 64% in 90 days.

## Maturation of Microstructural Networks: Increases in Anisotropy, Decreases in Diffusivity

White-matter myelination is intense throughout the first year of life, and increases in FA and decreases in ADC are rapid in the first postnatal year and continue throughout the second, reflecting increasing myelination and coherence of fiber tracts. These changes continue across development and have been most frequently reported in the corpus callosum, internal capsule, white matter of the frontal and prefrontal cortex, and subcortical regions. Different white-matter regions follow different developmental trajectories, and the age at peak FA for varying tracts ranges from 23 years for the fibers connecting the subcortical, temporal, and occipital regions to 39 years for the cingulum (Dennis and Thompson, 2013). The last tracts to reach maturity are those responsible for executive control of behavior and interhemispheric connectivity.

Although there are few developmental studies using structural graph theory in typically developing children, increases in both local and global efficiency have been reported with age in children across the first 18 years of life. Additionally, a single study reported the presence of a microstructural RC network similar to that in older subjects from adolescence through adulthood.

Finally, FA is highly heritable; genetic influences are reported to be greater in adolescence than in adulthood and greater in males than females, and heritability is higher in those with higher socioeconomic status. In contrast, environmental factors contributing to FA in typically developing children and adolescents have been less well defined.

## Functional Maturation: Increases in Integration and Segregation

The developmental trajectories of functional networks studied in infants, children and adolescents employ both seed-based and ICN approaches (Power et al., 2010). Typically developing term neonates show networks in the visual, auditory, motor, somatosensory, and prefrontal cortices, and a recent investigation employing rs-fMRI in infants ranging in age from birth to 2 years suggested a maturation sequence from primary sensorimotor/auditory to visual, to attention/default mode, and finally to executive control networks. The sensorimotor and auditory networks are relatively mature at birth; likewise, the salience-thalamus connectivity network is also present in neonates. In contrast, the executive network shows limited maturation in network topology and is far from adultlike at the end of the first postnatal year, whereas the DMN is detected in neonates in the first weeks of life and matures across the first 2 years.

Children have sparser connections between DMN seeds and fewer long-range connections than do adults, mainly in areas responsible for conflict monitoring, emotion regulation, and processing of complex information. Similarly, graph-theory analyses show that children have both lower intranetwork integration and less internetwork segregation than do adults. With development, there is a shift from stronger short-range connections in children to stronger long-range connections in adolescents and young adults.

## Influence of Genes and the Environment

The extent to which genes influence the functional brain network early in development is just beginning to be explored. Emerging heritability analyses suggest that global efficiency among brain regions is under strong genetic control ( $h^2$  lambda = 42%), irrespective of the total number of brain connections. Likewise, the molecular mechanisms supporting

functional connectivity are just beginning to be defined. Recent data suggest, however, that many genes contributing to functional connectivity subserve ion channels and synaptogenesis (Richiardi et al., 2015). Likewise, environmental factors ranging from nutrition to maternal education to child neglect and maltreatment alter connectivity in typically developing children.

## Preterm Birth Results in Long-Term Alterations in Connectivity

Preterm (PT) birth represents a global health problem, with PT infants at high risk of brain injury, altered brain development, and future neurobehavioral impairment. Language delays and problems with executive function are common in PT individuals; alterations in connectivity have been postulated as contributing to these developmental outcomes, suggesting that PT birth is a developmental disorder.

## dMRI Studies Provide Evidence of Widespread Microstructural Abnormalities

FA values in the white matter of PT neonates are lower than those of PMA-matched term controls in several regions, including the centrum semiovale, frontal white matter, genu of the corpus callosum, and both external and internal capsules. Likewise, ADC values are significantly higher in both frontal and occipital white matter, suggesting widespread microstructural abnormalities, even in the absence of major focal lesions.

dMRI measures are related to gestational age at birth, PMA, comorbidities such as bronchopulmonary dysplasia, sepsis, and painful procedures. dMRI is also helpful for assessing ischemic white-matter lesions, characterized by restricted diffusion and low ADC values during the acute phase of injury detectable on diffusion-weighted imaging and dMRI before they are noted on conventional MRI. In infants with cystic periventricular leukomalacia, dMRI changes are seen in areas distant from the focal lesions at term-equivalent age (TEA); in more diffuse injury, ADC values are elevated in periventricular and subcortical white matter, suggesting widespread dysmaturation of white matter in the prematurely born.

dMRI measures correlate with neurodevelopmental performance in the prematurely born. FA in the optic radiations correlates with visual performance at TEA, and increased ADC values in white matter at TEA are associated with adverse neurodevelopmental outcome at 2 years corrected age. Likewise, FA values in the posterior limb of the internal capsule are associated with cognitive outcomes in the first postnatal year.

Finally, PT birth is associated with long-lasting and widespread alterations in white matter, and these alterations correlate with a variety of behavioral sequelae, ranging from language to executive function and, in young adulthood, psychiatric symptomatology.

## Functional Studies: Alterations in Neural Networks in the Prematurely Born

Resting-state ICNs have been identified in PT infants at TEA; these are fragmentary at PMA 25 through 27 weeks and form at significantly different rates across the putative third trimester of gestation. Additionally, although these ICNs mirror those of term control infants, network analyses suggest less complexity in the neural systems of PT neonates.

These differences persist into childhood in the prematurely born. ROI studies demonstrate auxiliary right hemisphere connections for language and increased connectivity between

both frontal cortices and the salience, default mode, and executive networks, suggesting alterations in neural networks for language, attention, and behavior in the prematurely born. Similarly, ICA analyses suggest global increases in connectivity in PT subjects compared with term controls, consistent with the ROI data. Finally, both years of maternal education and language testing scores are predictors of connectivity in PT subjects at young adulthood, suggesting that the alterations in functional connectivity unique to the PT population have significant functional implications.

### Graph-Theory Analyses Support These Data

The topology of ICNs in PT neonates is positively correlated with structural networks, and this coupling increases with PMA. In contrast, PT subjects show reduced covariance in both language and frontoparietal functional networks compared with controls at TEA, suggesting that functional connections in PT subjects are less complex than those in term neonates. Similarly, RC analyses of microstructural networks confirm altered network architecture and reduced network capacity in PT subjects at TEA.

Graph-theory evidence for altered network function persists in adolescents and young adults born preterm. Increased functional connectivity within the posterior DMN and increased anticorrelation within the executive network have been reported in adolescents who were born PT. In contrast, Granger causality analysis reveals widespread reduction in between-network connectivity in preterm infants, particularly in connections between the salience network and the DMN.

### Environmental Factors Alter Connectivity in the Prematurely Born

Pain and neonatal stress influence microstructural connectivity, as does housing in single rooms and daily exposure to the mother's voice during the critical putative third trimester of gestation. PT infants with white-matter injury show reduced connectivity between homologues compared with those without injury, and the severity of injury correlates with the loss of connectivity.

## Autism Spectrum Disorder

Autism spectrum disorder (ASD) affects nearly 1 in 88 children and is widely thought to represent a disorder of connectivity, in which the environment may interact with the genome. dMRI studies report widespread disruptions in microstructural connectivity, particularly in those tracts subserving social cognition, in children, adolescents, and young adults with ASD. (Ameis and Catani, 2015).

dMRI studies across the past decade demonstrate both increases and reductions in FA across frontal, parietal, and temporal regions in subjects with ASD compared with age-matched typically developing controls, and little consistency had been noted across patient populations until the advent of two longitudinal analyses. Both supported altered early development and age-related changes that may underlie impaired brain functioning, particularly in social behavior and communication in children, with ASD. A first study of infants at risk for autism showed that those subsequently diagnosed with autism exhibited increased FA for a majority of sampled white-matter tracts at age 6 months, no FA differences compared with no-autism subjects at 12 months, and decreased FA at 24 months, demonstrating altered brain growth in ASD across corticocortical, projection, and interhemispheric white-matter tracts over the first 2 years of life. A second, larger investigation confirmed that the frontal tracts in toddlers with ASD showed greater FA values and volume than normal at younger ages, but an overall impaired rate of development subsequent to that time. As shown in Table 14-3, dMRI studies of ASD suggest far-ranging alterations in FA. Both long-range and short-range connections are reported to be involved, and fibers that mediate both frontal and temporal connectivity are most frequently affected. Microstructural changes differ in younger subjects with ASD compared with those found in affected adolescents and young adults, suggesting that ASD alters the developmental trajectory of interregional connections.

TBSS studies confirm these findings. Older individuals are most likely to demonstrate widespread decreases in FA, whereas young children with ASD show increases in this parameter. Studies using an ROI approach in younger children

**TABLE 14-3** Disorders of Development

Developmental Disorder	Microstructural and Functional Alterations	Network Perturbations
Autistic spectrum disorder (ASD)	Age-related changes in both Younger subjects—hyperconnectivity Older subjects—hypoconnectivity Preferential involvement of frontal and temporal regions	Hyperconnectivity within the default mode network (DMN)
Attention-deficit/hyperactivity disorder (ADHD)	Decreased fractional anisotropy (FA) in fronto-striato-cerebellar tracts Decreased FA in fronto-temporal tracts Decreased functional connectivity in frontal, striatal, temporo-parietal, and cerebellar regions	Reduced default mode network (DMN) segregation Alterations in intranetwork connectivity in DMN, dorsal attention network, and visual network
Tourette syndrome (TS)	Decreased FA in the corpus callosum and frontal-caudate connections Decreased functional connectivity in frontal-parietal and cingulo-opercular regions	Hypoconnectivity within networks subserving adaptive online control and set maintenance
Preterm (PT) birth	Decreased FA in centrum semiovale, frontal white matter, genu corpus callosum, internal, and external capsules; increased apparent diffusion coefficient (ADC) in frontal and occipital white matter Resting-state intrinsic connectivity networks (ICNs) present at term-equivalent age (TEA), but less complex than in term controls In older subjects, increased functional connectivity in language centers; also between frontal cortex and salience network, executive network, and DMN	Reduced covariance in language and fronto-parietal networks at TEA; rich club demonstrates reduced network capacity In older PT children, increased intranetwork connectivity for both executive network and DMN

demonstrated increased FA in the anterior cingulate and superior temporal gyrus, changes that correlate with behavioral measures, whereas ROI studies of older subjects revealed decreases in FA in the corpus callosum, left uncinate, and longitudinal fasciculus. Alterations within the left uncinate forecast autism symptoms, and recent data suggest left-hemisphere impairment, particularly in the thalamic and fronto-parietal networks, in high-functioning children with ASD.

Recent work has investigated functional networks in children, adolescents, and young adults with ASD. Early studies suggested reduced network integration in autism, especially in areas important for social behavior, but other studies report hyperconnectivity. Further, although functional connectivity studies of older subjects support the hypoconnectivity theory, several recent studies of school-aged subjects with ASD compared with control children demonstrated hyperconnectivity in ASD subjects at the whole-brain and subsystems levels. Regions of greatest significance included the primary sensory, paralimbic, and association areas, and greater frontal connectivity was positively associated with severity of social deficits. Similarly, graph-theory analyses suggest preferential involvement of the DMN in adolescent subjects with ASD, and hyperconnectivity within the DMN has been related to Autism Diagnostic Observation Schedule scores in adolescents with ASD.

Together, the reported age-related changes in microstructural and functional data in children with ASD suggest the need for longitudinal, standardized imaging investigations with genetic analyses to optimize diagnosis and intervention strategies.

## Tourette Syndrome

Tourette syndrome (TS) is a neurodevelopmental disorder characterized by the presence of multiple unwanted and irresistible motor and phonic tics, and imaging studies across the past decade suggest that it is in part attributable to abnormal processing in major cortical control networks. Volumetric MRI studies of children and adolescents with TS report reductions in the corpus callosum and the putamen, globus pallidus, and lenticular nuclei bilaterally. Volumetric abnormalities have also been reported in the frontal and parietal cortices, suggesting involvement of both corticocortical and corticosubcortical circuitry.

Because the corpus callosum is the major commissure connecting homologous cortical regions and cortical networks are thought to be altered in TS, researchers have investigated microstructural connectivity in the corpus callosum in children with TS. dMRI studies have demonstrated decreased FA throughout all subregions of the corpus callosum in TS subjects compared with controls, although FA values do not correlate with the severity of tic symptoms. Similarly, tractography studies have shown decreased connectivity between the caudate nucleus and the left anterior-dorsolateral frontal cortex.

Likewise, fMRI analyses suggest impaired functional connectivity throughout the brain in adolescents with TS. Significant alterations have been reported in the frontoparietal network subserving rapid, adaptive online control and a cingulo-opercular network important for set maintenance in TS subjects compared with controls, suggesting that TS is a developmental movement disorder that alters adaptive, rapid control signaling. Together, published data suggest widespread alterations in microstructural and functional networks subserving cerebral control systems in children and adolescents with TS, but the clinical implications of these findings remain largely unexplored (Table 14-3).

## Attention-Deficit/Hyperactivity Disorder

Attention deficit hyperactivity disorder (ADHD) is characterized by age-inappropriate inattention, hyperactivity, and impulsivity. Although ADHD is disproportionately diagnosed in males and is a heterogeneous disorder, ADHD patients exhibit deficits in executive functions long attributed to alterations in fronto-striato-parietal and fronto-cerebellar networks, and—similar to other developmental disorders—ADHD is thought to be a disorder of connectivity.

Whole-brain cross-sectional analyses have demonstrated reduced subcortical gray matter in subjects with ADHD, and microstructural studies of children and adults with ADHD report reduced white-matter microstructure integrity in ADHD patients relative to healthy controls in several fronto-striato-cerebellar white-matter tracts, including the right anterior corona radiata, left cerebellar white matter, internal capsule, forceps minor close to the genu of the corpus callosum, and cingulum. Similarly, graph-theory analyses have shown that males (but not females) with ADHD have decreased FA in prefrontal circuits, but increased FA in the orbito-fronto-cerebellar-striatal circuitries; these FA levels reportedly correlate with inattention and hyperactivity/impulsivity symptoms.

fMRI studies demonstrate that ADHD subjects exhibit deficits in function of specific frontal, striatal, temporoparietal, and cerebellar regions, and that ADHD patients also have abnormalities in functional interregional connectivity between these regions during both rest and task conditions. rs-fMRI studies of 757 participants in the ADHD-200 study showed altered connectivity between the DMN and ventral attention network, including significantly increased connectivity between the posterior cingulate cortex in the DMN and right anterior insula and supplementary motor area in the ventral attention network.

Recent studies have addressed the functional organization of subjects with ADHD, as shown in Table 14-3. ICA analyses of participants in the ADHD-200 sample demonstrated reduced DMN segregation co-occurring with structural abnormalities in the dorsolateral prefrontal cortex and anterior cingulate cortex, two important cognitive control regions. ADHD subjects also showed altered intranetwork connectivity in the DMN, dorsal attention network, and visual network, with co-occurring distributed structural deficits. In these analyses, gray-matter changes predicted alterations in fMRI. Likewise, ADHD subjects exhibited lower FA and functional connectivity inside RC networks, but a higher number of axonal fibers outside the RC compared with typically developing controls.

## Sports-Related Concussion

The incidence of reported concussion in the pediatric population has been steadily increasing, and approximately one-fifth of pediatric patients with sports-related concussions will have persistent cognitive symptoms at 4 weeks following injury. These symptoms include slowed processing speed, poor concentration, and difficulties with memory, and emerging MRI studies suggest that these symptoms are attributable not only to changes in neuronal metabolism and perfusion but also alterations in neural connectivity. (Ashwal et al., 2014).

Recent data suggest both regional and network vulnerability in the pediatric population. Microstructural analyses of adolescents 1 month following concussion demonstrated higher FA values in multiple regions in the concussed group compared with age-matched control subjects; these include primarily frontal white-matter regions bilaterally. In contrast, when pediatric subjects 8 to 17 years of age with persistent

neurocognitive deficits 3 to 12 months following a sports-related concussion were compared with control subjects, they showed decreased FA in the right anterior and posterior internal capsules. Furthermore, differences in dMRI metrics differentiated patients with persistent cognitive symptoms; FA values were lower and diffusivity values higher in subjects with cognitive symptoms.

Similarly, fMRI studies of adults have demonstrated frontal vulnerability to mild traumatic brain injury. Connectivity is decreased within the DMN during the acute, subacute, and chronic phases of injury, with additional findings of increased connectivity between the rostral anterior cingulate gyrus and ventrolateral prefrontal cortex. Interhemispheric connectivity is disrupted in the visual cortex, hippocampus, and dorsolateral prefrontal cortex, and longitudinal studies have demonstrated long-lasting decreases in frontal connectivity.

Likewise, an fMRI study in adolescents 1 month following sports-related concussion demonstrated alterations in the DMN, increased connectivity in the right frontal executive function network, and increased connectivity in the left frontal operculum cortex associated with the ventral attention network. Microstructural studies of this cohort demonstrate abnormalities within the anterior corona radiata bilaterally, the anatomic connection for the primary nodes of the DMN.

## Epilepsy

Children with epilepsy are at high risk for developmental delay, ADHD, and behavioral problems such as depression and anxiety. In adult subjects epilepsy disrupts microstructural and functional connectivity, and these measures correlate with cognition and behavior. Although there are fewer studies of neural connectivity in children with epilepsy, emerging data suggest that epilepsy syndromes are associated with focal and widespread influences on the developing brain. Reported findings differ for different epilepsy syndromes, and published genetic correlations are not yet available.

*Childhood absence epilepsy* is a nonconvulsive, idiopathic epilepsy characterized by sudden and brief changes in consciousness. Clinical findings are accompanied by bilateral, synchronous, 2.5- to 4-Hz generalized spike wave discharges, and children with this disorder are at high risk for impairment in attention and executive function. Preliminary microstructural studies of children with absence epilepsy have demonstrated decreases in network strength and global and local efficiency, particularly in the orbitofrontal region, subcortical structures, and limbic cortex. fMRI investigations have shown significant alterations in functional connectivity within the salience network in patients compared with controls, with decreased connectivity in the right anterior insula, anterior temporoparietal junction, and bilateral dorsolateral frontal cortex, and increased connectivity in the anterior and middle cingulate gyri and caudate nucleus. The salience network subserves attention, and, together, data from both microstructural and functional connectivity studies support alterations in this important network as a possible cause of attentional dysfunction in children with absence epilepsy.

*Rolandic epilepsy* is a focal childhood epilepsy, presumably genetic, characterized by language impairment, inattention, and impulsivity. Although these seizures largely resolve during adolescence, interictal electroencephalogram (EEG) rolandic discharges may interfere with local brain maturation, resulting in alterations in cognition and behavior. Microstructural studies of children with rolandic epilepsy have shown reduced FA and decreased connectivity compared with controls, predominantly over the left pre- and postcentral gyri ipsilateral to the electroencephalographic focus; significant negative

correlations between FA in these regions and measures of attention and anxiety have also been reported. fMRI investigations have demonstrated reduced connectivity in the left inferior frontal gyrus, or Broca's area, compared with controls, suggesting alterations in systems for both attention and language.

Children with *frontal-lobe epilepsy* have lower FA values in both the posterior white matter and in the second component of the superior longitudinal fasciculus. The latter tract connects parietal association areas with the prefrontal lobe and is frequently associated with spatial attention and perception of visual space. In contrast, a single study examining dMRI and fMRI in children with frontal-lobe epilepsy suggested more global changes. Microstructural network alterations included increased clustering, increased path length, stronger within-module connectivity, and weaker between-module connectivity compared with healthy controls. Functional connectivity within networks was related to cognitive performance, and structural modularity increased with decreased cognitive performance, suggesting decreased coupling between large-scale functional network modules in childhood frontal-lobe epilepsy.

## Perinatal Stroke

Perinatal arterial ischemic infarcts preferentially involve the anterior circulation, and most occur within the left hemisphere, although there is considerable variability in terms of lesion etiology, onset, size, and location. Many children with early injury demonstrate remarkable recovery of language function, but there are considerable differences in the degree of recovery. There are few studies available, but t-fMRI and rs-fMRI assessments suggest refinement of the prevailing notion that language recovery following left-hemisphere perinatal stroke relies on the contribution of the contralateral hemisphere. Preliminary reports demonstrate no difference in functional imaging during language tasks. Similarly, the few published t-fMRI studies argue against the "right-hemisphere takeover" theory of recovery and suggest that increasing interhemispheric connectivity between posterior-superior-temporal language regions may be of benefit for testing scores, although these data require rigorous replication.

## Imaging Genetics

The emergence of sophisticated imaging strategies has permitted not only the more accurate phenotyping of developmental disorders, but also the large-scale investigation of the role of genetic variants in neural connectivity. Emerging data across the past decade suggest the strong influence of the genome on the underlying architecture of functional brain communication during development, and both the Human Connectome Project and the Enhancing Neuroimaging Genetics through Meta-Analysis (ENIGMA) Consortium provide large data sets valuable for assessing the degree of genetic influence contributing to neural connectivity. The former will soon enroll neonates, children, and adolescents, and the ENIGMA Consortium is an effort coordinated by 125 institutions in 12 countries.

Likewise, pediatric populations with imaging and genetic data are now becoming available. One excellent example is the Pediatric Imaging, Neurocognition and Genetics (PING) study, which already has been employed to demonstrate that genetic variation in the neuregulin-1 gene alters brain developmental trajectories as assessed by dMRI in typically developing children. The PING study is a cross-sectional database of 1400 typically developing children ages 3 to 18 years collected at 10 academic institutions in the United States.

**Figure 14-7. Microstructural connectivity in a 10-year-old male with occipital glioma.** A 10-year-old male presented with seizures and headache. Brain MRI (*left panel*) demonstrated a left occipital mass, later diagnosed as a glioma. The photic-stimulation task fMRI and dMRI (*right panel*) shows a typical activation pattern (*white region with pink borders*) in the left hemisphere, but not the right. Similarly, dMRI microstructural imaging demonstrates occipital fiber tracts in green in the left hemisphere, but displacement of these visual fibers around the tumor in the left occiput. (Figure courtesy of CC Duncan, MD, Yale School of Medicine.)

### Undiagnosed Developmental Disorders: The Role of Connectivity

Global developmental delay, intellectual disability, and neurobehavioral disorders are relatively common conditions, but state-of-the-art strategies, including genetic, imaging, and metabolic assessments, provide diagnoses for less than 3 to 4 in 10 children. These data suggest that other strategies must be employed, and MRI-based connectomics has the potential to develop biomarkers for adverse neurodevelopmental outcomes in children with prenatal or perinatal disorders. Additionally, the monitoring of brain plasticity changes could provide a basis for the development and testing of therapies to improve outcomes in children with disorders of connectivity.

### Current Clinical Applications

Functional and microstructural MR imaging have become part of routine brain mapping in pediatric patients with epilepsy or supratentorial tumors requiring surgery, as shown in [Figure 14-7](#). fMRI protocols can localize most relevant language, visual, and/or motor regions in individual children and appear to be a valuable complementary tool for surgical planning of epileptogenic foci and brain tumors. In contrast, the role of fMRI and dMRI strategies in cerebral plasticity and intervention/treatment studies is just beginning to be evaluated. Recent data from an ongoing intervention trial of children with cerebral palsy suggest that microstructural connectivity increases concurrently with functional improvement, pilot data from a cognitive-behavioral therapy trial suggest that rs-fMRI data forecast symptom severity in obsessive-compulsive disorder up to 1 year after treatment, and fMRI has recently been employed to demonstrate widespread changes in functional connectivity of the brain's reading network as a result of

intervention in children with ASD, suggesting the clinical potential of this strategy.

### CONCLUSIONS

The role of neuroimaging studies in developmental disorders of childhood is transitioning from a basic science tool to an integral part of the translational research cycle, with promise not only for early identification of disorders of connectivity, but also for the monitoring of therapeutic interventions.

## Stem Cell Transplantation for Childhood Neurologic Disorders

Jean-Pyo Lee, Marcia Pereira, Rodolfo Gonzalez, Milton H. Hamblin, and Evan Y. Snyder

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Research into neural stem cells (NSCs) and their potential therapeutic applications for the central nervous system (CNS) has grown dramatically in the past decade. In pediatric neurologic disorders, NSCs show promise as therapy against lysosomal storage disorders (LSDs) and inborn errors of metabolism, including Tay–Sachs disease (TSD) and Sandhoff disease (SD). Moreover, NSCs may have potential benefit as a treatment against cerebral hypoxia and stroke.

The goal of stem cell transplantation for childhood neurologic disorders is to protect host cells and/or replace damaged cells with healthy cells and, in doing so, restore the functioning of original tissues and organs. NSCs may be derived from human embryonic stem cells (hESCs) or induced pluripotent stem cells (iPSCs). Whatever the benefits of each of these derived cell types, there are trade-offs between safety, effectiveness, and cost.

In this chapter, we review the methods used in studying NSCs and outcomes discovered from NSCs transplanted into the mammalian brain of animal models (mainly mouse and rat) of pediatric disorders. This information will provide insight into using NSCs in clinical trials for pediatric diseases.

### NEURAL STEM CELL BIOLOGY

#### Definition of Neural Stem Cells

NSCs are the most primordial and least committed cells of the nervous system. Because immunocytochemically detectable markers that are sufficiently specific have not yet been fully defined, an NSC is still best defined operationally. NSCs must have the following properties: (1) *self-renewal* (produces unaltered daughter cells in response to mitogens) and (2) *multipotency* (generates all three fundamental neuroectodermal lineages—neurons, astrocytes, and oligodendrocytes—in a regional and developmental stage-appropriate manner). There is no consensus yet about how many intermediary steps exist between the stem cell stage and the emergence of a mature functional cell. If a cell type appears to show a more limited self-renewal capacity and a narrower range of fate, it is by convention called a *progenitor* or *precursor* rather than a stem cell.

#### Stem Cell Niche and Function of Neural Stem Cells in the Developing Central Nervous System

The population of NSCs in the adult brain is harbored in special locations called *niches*. To sustain homeostasis of NSC populations, NSCs proliferate and differentiate following an innate genetic program and respond to signals from this specialized microenvironment.

In the early stages of mammalian cerebrogenesis, NSCs are located in a primary germinal zone known as the ventricular zone (VZ). It is estimated that stem cells account for 5%

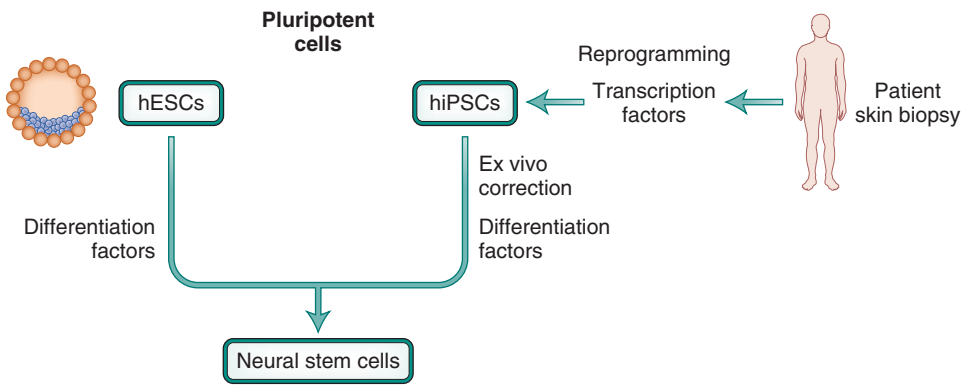

to 20% of the cells in the VZ of the telencephalon of an embryonic day 10 (E10) mouse. The earliest NSCs divide symmetrically to amplify identical daughter cells. A stem cell retains continuous mitotic potential while remaining multipotent. In response to specific developmental signals, somewhat later in cerebrogenesis, NSCs divide asymmetrically to generate partially differentiated neural progenitor cells. Neural precursor cells then begin to express differentiation markers while remaining mitotically active. They differentiate once they exit from the cell cycle, with the final fate of a given progenitor cell depending on extrinsic morphogenic signals, specific patterns of transcriptional activation, and growth factors. Neurons are generated before the generation of glia during development.

The secondary germinal zone, believed to develop from the VZ, includes the subventricular zone (SVZ) of the forebrain, external germinal layer of the cerebellum, and the subgranular layer of the hippocampus. NSCs are believed to populate these areas as well and maintain homeostasis in the brain. The SVZ is known to serve as an endogenous source of multipotent neural precursors that give rise to neurons and glia to replace dead cells and support cell turnover. In rodent SVZ, newly generated neural precursors reach their final destination in the olfactory bulb after long-distance migration through a well-defined path called the rostral migratory stream. However, it is debatable whether the human SVZ can give rise to neurons.

Although endogenous NSCs are present in the mammalian brain, where major neurologic damage occurs, endogenous NSCs are shown to be inadequate or ineffective for repair. One reason the brain does a poor job regenerating function may be that endogenous NSCs are surrounded by a microenvironment that does not promote the differentiation or survival of NSCs. The news is not all bad. Results of several NSC transplantation experiments suggest that neurogenic cues are temporarily transmitted during degenerative processes and that exogenous NSCs are able to sense, home in, and respond appropriately to those cues. Although these mechanisms are not fully understood, it seems that some neurodegenerative processes broadcast neurogenic signals, and these send out developmental and migration cues to which NSCs can respond. For effective stem cell therapy, NSCs must widely distribute throughout the brain. To this end, various methods have been developed to extract and induce NSCs to their optimal proficiency.

#### Isolation and Propagation of Neural Stem Cells in Vitro

Several in vitro methods exist to isolate and expand human or mouse NSC populations in a manner that maintains their stem-like qualities. For example, NSCs can be isolated directly from the neuroectoderm, the primary germinal zone (VZ) of fetuses, or from residual secondary germinal zones such as the subventricular or subgerminal zone in adults. However,

**Figure 15-1. Diagram of generating human iPSC-derived NSCs from patients.** hiPSCs can be generated by reprogramming of patient skin fibroblasts through transduction of four pluripotency genes, *OCT4*, *SOX2*, *KLF4*, and *C-MYC*. hiPSCs can then be genetically engineered using ex vivo gene correction and differentiated into hiPSC-NSCs. hESCs, human embryonic stem cells; hiPSCs, human-induced pluripotent stem cells; NSCs, neural stem cells.

it remains unclear whether adult-derived NSCs can make projection neurons and necessary connections as precisely as that of naturally generated neurons during development.

NSCs can be isolated and propagated in growth medium containing basic fibroblast growth factor (bFGF) and epidermal growth factor (EGF). In vitro, these cells express markers characteristic of undifferentiated NSCs such as nestin, and musashi, which can then differentiate when appropriate induction factors are added. In vivo, these cells have been tested in a variety of neurodegenerative disease models and have proven to be therapeutically beneficial in some cases (Taylor et al., 2006). To achieve optimal migration and engraftment, it is preferable to transplant undifferentiated NSCs than cells that have undergone varying degrees of differentiation ex vivo. NSCs can also be derived secondarily in vitro from human pluripotent stem cells, such as ESCs and iPSCs.

### Generation of Human and Murine Neural Stem Cells from Embryonic Stem Cells

For hESC differentiation in vitro, neural differentiation appears to be a primary default lineage for hESC differentiation under conditions that do not maintain pluripotency. Therefore the earliest methods for generating NSCs from hESCs, although with very low efficiency, were by spontaneous differentiation in the absence of conditions that promote self-renewal (Reubinoff et al., 2001). In subsequent studies, specific stimuli can be added to mimic embryonic neurogenesis as a way of improving the yield of NSCs derived from hESCs (Chambers et al., 2009).

For murine ESCs, retinoic acid signaling promotes generation of NSC. ESCs, which are derived from the inner cell mass of a blastocyst, are capable of giving rise to differentiated progeny from all three embryonic germ layers. Although ESCs, by definition, never senesce, they require a great deal of instruction to direct them toward the NSC lineage fate.

Efficient neural induction of hESCs involves growing them under monolayer feeder-free defined culture conditions and dual SMA and MAD related protein (SMAD) inhibition of the TGF $\beta$ /BMP signaling pathways. After neural induction, NSCs can be derived and expanded under defined culture medium conditions with bFGF and EGF and be used for transplantation studies. The tumorigenic risk can be removed by extending the in vitro culture time of ESC-NSCs for several passages before transplantation.

### Generation of Neural Stem Cells from Induced Pluripotent Stem Cells

NSCs derived from iPSCs are particularly interesting. Direct reprogramming of somatic cells into pluripotent-state cells is an alternative to traditional nuclear transfer and somatic cell

fusion using ESCs. In this way, it has circumvented the ethics controversies of hESCs and therapeutic cloning. Unlike hESCs, iPSCs show no immunologic incompatibility, making them a desirable NSC line for use in therapy. It is anticipated that iPSCs could replace many applications in regenerative medicine suggested for hESCs.

To generate iPSCs, somatic cells are subjected to epigenetic reprogramming by forcing exogenous expression of specific transcription factors. Many different somatic cell types have been reprogrammed to create iPSCs (Takahashi and Yamanaka, 2006). These include foreskin fibroblasts, wherein iPSCs are generated by ectopic expression of chromatin-remodeling transcription factors (e.g., *OCT4*, *SOX2*, *KLF4*, and *C-MYC*) (Figure 15-1).

Fibroblasts, which can be easily obtained from human biopsies, are readily expanded in number and reprogrammed. However, clinical use of these first-generation iPSCs is limited because of risks imposed by insertional mutagenesis by these transcription factors, some of which are oncogenes. Efforts to eliminate these concerns have led to experimentation using transient expression of reprogramming factors with plasmids, adenoviruses, transposon vectors, and even purified recombinant proteins. Although these methods have proven experimentally successful for iPSC generation, their reprogramming efficiency is prohibitively low for practical applications.

Studies show low efficiency of generating iPSCs; resources are thus sufficient but less efficient because of variability in the differentiated state and the age of somatic cells. Residual DNA methylation states inherited from original differentiated cells remain in iPSCs, therefore, the plasticity of iPSC fate can be limited. Additionally, a caveat associated with iPSC generation is overexpression of *c-myc* and viral transduction. Using nonviral techniques and adding chemicals to increase production efficiency would be expected to provide a better approach.

An in-depth analysis using genome-wide transcriptional profiling of iPSCs and ESCs demonstrated that both cell types share a common pluripotency and self-renewal network. iPSCs can differentiate into derivatives representing all three embryonic germ layers and produce nearly identical progeny from neural, hepatic, and mesenchymal lineages.

The differentiation process of iPSCs can be divided into stages. First, embryoid bodies are formed. These are cell aggregates that appear when they are detached from the feeder layer and put into serum containing medium. To enrich for particular cell types, certain exogenous factors influencing the differentiation program need to be supplemented. Next, molecular markers can be selected for detection of expressed cell markers to identify specific cell types and subsequent generation of progenitor cells. As with ESCs, iPSCs can be used to derive NSCs using a monolayer culture and dual inhibition of

SMAD signaling. Alternately and potentially most promising is the ability to generate self-renewable and multipotent NSCs directly from fibroblasts bypassing iPSCs by expression of a single transcription factor, SOX2 or OCT4.

In vitro microarray analysis indicates that iPSC-NSCs (NSCs derived from iPSCs) and ESC-NSCs show similar but not identical gene expression and epigenetic patterns. It would be ideal to be able to use iPSCs derived from a given patient (and corrected ex vivo) because this strategy offers a way to potentially eliminate some degree of inflammation (because of immuno-incompatibility). Therefore, with future improvements in the derivation, quality, and validation, we can be optimistic that an improved version of iPSCs will become available for cell therapy-based regenerative medicine in the times ahead. In the last stage, certain progenitor cells such as NSCs can generate specific cell types. NSCs can further differentiate into neurons, astrocytes, and oligodendrocytes by modifying culture conditions.

## Transplantation of Neural Stem Cells

Whether NSCs are sourced from embryonic or neonatal cells, or the adult CNS of either humans or rodents, once they are transplanted into mouse brains, they can integrate throughout the CNS (Lee et al., 2009; Huang et al., 2014). Unfortunately, differentiated or postmitotic neurons derived from NSCs neither engraft robustly nor migrate extensively. Successful engraftment and integration requires adhering to the following principles: stem cells enter the CNS in an undifferentiated state during the active log growth phase and then they exit the cell cycle in the brain, where they are receptive to environmental cues. For example, NSCs derived from various sources have been transplanted to pediatric or adult neurologic disease mouse brains, demonstrating their ability to migrate and improve the pathophysiology of the brain, oxidative stress, and the damage of blood-brain barrier (BBB).

Regarding optimal transplantation time in many pediatric neurologic disorders, administering NSCs presymptomatically may decrease the demand on host NSCs to replace neurons and reconstruct circuitry. Although neuronal replacement receives more attention, its effects can be complemented, and even surpassed by the range of homeostatic factors and actions that NSCs intrinsically express. It has been demonstrated that NSCs are able to direct their fate in response to an abnormal environment and interact reciprocally with the host CNS (Yandava et al., 1999). The main caveat to this interaction is through exogenous NSCs “reprogramming” host circuitry to correct dysfunction and deficiencies. It may be more efficacious to focus on preserving established circuitry than to attempt to build new connections. Thus transplanting NSCs into cerebral ventricles of newborn mice is proven to be a good strategy in terms of timing (presymptomatic) and achieving extensive stem cell migration in a mouse model of pediatric disease. There has also been evidence that multiple NSC transplantations into different regions of the brain may prove to be more beneficial than a single transplantation. For example, NSCs were transplanted into the cerebral ventricles and the cerebellum of neonate mouse models of SD. The results showed that there was an added benefit to the increased pool of available NSCs and also to the introduction of NSCs to new regions of the brain. Further investigation is of interest because NSC transplantations into multiple regions, or multiple transplantations into the same region, may be necessary for certain diseases that have a global pathology. However, it is uncertain whether increasing the number of transplanted NSCs is safe or if appropriate connections will be made. A more practical application of NSC transplantation therefore lies in the

potential to protect and maintain existing neuronal connections, rather than neuronal replacement.

To evaluate the impact of stem cells on mouse models of pediatric diseases with global brain pathology, NSCs can be transplanted into the cerebral ventricles of newborn mice. Newborn mice are easy to inject, with their soft skulls facilitating penetration. Transplanted NSCs gain access to most regions of the ventricular and SVZ. Cells then migrate to distant CNS regions and participate in normal development of different brain regions at multiple stages of brain development. When NSC transplantation is performed in utero, disease progression may be more effectively arrested. Prenatally or neonatally transplanted NSCs can survive for a long time in the recipient mouse brain without requiring immunosuppressant treatment. The impact of NSCs in engrafted mice can be determined in terms of survival and motor function and varies according to disease models. Electrophysiology on acute slices from engrafted brains can be performed to assess functional integration of donor NSC-derived cells (Figure 15-2).

## Detection of Donor Neural Stem Cells in the Host Mouse Brain

There are many ways to track and identify transplanted donor cells in a recipient brain. One of the most commonly used in vitro stem cell labeling techniques is bromodeoxyuridine (BrdU), which incorporates into DNA during the S phase and can prelabel mitotically active donor cells. Labeled cells can be identified by the anti-BrdU antibody and can be instrumental to determine the number of cell divisions that engrafted cells have undergone in vivo posttransplantation. Donor cells can also be marked by constitutive viral markers such as LacZ or GFP, or other markers using tissue-specific and inducible promoters. Sex mismatch between donor and recipient can be instrumental to detect the cells. For example, donor cells can also be identified by the presence of the Y chromosome if male cells are transplanted into a female host. This detection technique is very useful when donor cells and recipients are the same species. In addition, species mismatch can be instrumental to identify donor cells. For example, human donor cells in the mouse brain can be identified by a human-specific antibody.

In vivo, several molecular imaging techniques are used for noninvasive stem cell tracking. For example, donor cells transduced with vectors encoding Luciferase make it possible to track living donor cells, after injection of animals with D-luciferin, in the recipient brain. Alternatively, in vivo tracking of cells can be done with in vitro labeling with ferromagnetic beads and magnetic resonance imaging (MRI). This MRI setup is expensive and can be technically challenging when nanoparticles leak out of dead cells. These imaging techniques can be efficiently utilized in preclinical studies track the migration of NSCs.

## Homing of Neural Stem Cells

In mammalian brains of all ages, NSCs may be attracted even at a great distance to injury sites and regions of neurodegeneration. Both human and mouse NSCs express many chemokines and chemokine receptors (including CXCR4 and adhesion molecules and immunoglobulins) that mediate homing to sources of proinflammatory chemokines such as chemokine stromal cell derived factor-1 $\alpha$  (SDF-1 $\alpha$ , also known as CXCL12). SDF-1 $\alpha$  signaling through CXCR4 has previously been identified as a key step in the homing of stem cells. Expression of SDF-1 $\alpha$  is often up-regulated within

**Figure 15-2. Flow scheme of neural stem cell transplantation.** Engrafted NSCs into the cerebral ventricles of a newborn mouse model of CNS disease (e.g., Sandhoff mice) migrate extensively to distant CNS regions. Engrafted cells survive for a long time, as determined by *lacZ* (encodes  $\beta$ -galactosidase) staining, which traces donor cells histochemically (X-gal reaction, blue). Effects of engrafted NSCs can then be analyzed at animal, tissue, and cellular levels. Functional integration of engrafted NSC-derived cells can be assessed by electrophysiological recording in acute brain slices. CNS, central nervous system; NSCs, neural stem cells.

injuries in areas such as the brain, heart, and kidney. SDF-1 $\alpha$  is shown to be involved in the pathophysiological process of neurologic disorders and in promoting the directed migration of stem cells and regeneration of injured tissues (Imitola et al., 2004).

The migration of NSCs activated by the chemotactic effect of SDF-1 $\alpha$  is also reported in vitro, showing that SDF-1 $\alpha$  significantly induced the migration of NSCs in a dose-dependent manner. The relevance of SDF-1 $\alpha$  in the migration of endogenous NSCs after brain injury and the contribution of the SDF-1 $\alpha$ -CXCR4 system to NSC homing in traumatic brain injury is also implicated. Thus exploitation of the SDF-1 $\alpha$ -CXCR4 system can be instrumental to improve brain repair.

### Bystander Effects of Engrafted Neural Stem Cells

NSCs do much more than neuronal replacement. NSCs actually possess an array of actions that are potentially therapeutic. In addition to replacing the neural elements of the brain, NSCs have been shown to reduce inflammation in the CNS, secrete trophic factors, provide inherently derived gene products to host cells, and reduce toxic damage. Initially, the goal of NSC transplantation therapy was to replace or replenish dead or dying host cells, but the “chaperone” actions of NSCs prove to be more impactful than neuronal replacement itself and contribute to the many improvements seen in experimental models. Paracrine effects of these neurotrophic factors include alteration of the brain microenvironment by improving host regenerative processes, such as angiogenesis and migration, or by reducing destructive processes, such as apoptosis. CNS inflammation is characterized by both microglial activation and macrophage infiltration. Thus present recognition of inflammation as a key common factor in the pathology of neurologic disorders has further characterized the innate anti-inflammatory capabilities of NSCs (Lee et al., 2007).

### THERAPEUTIC POTENTIAL OF NSCS Lysosomal Storage Disorders

Lysosomal storage disorders (LSDs) (Chapter 41), a group of more than 50 autosomal recessive metabolic neurodegenerative diseases, are caused by deficiencies of specific acid hydrolases. Currently, no effective treatments are available for infantile onset forms of these diseases.

There is a growing appreciation of the multifaceted actions of NSCs in CNS repair. Although functional neuronal replacement has received the most attention, this action can be complemented by a range of other stem cell actions that exert various homeostatic forces. These aspects of therapeutic potential of NSCs are particularly relevant for treating LSDs. LSDs serve as an “easy” target for NSC treatment because of the following factors: (1) most LSDs with CNS pathologies quickly progress to eventual morbidity; (2) the etiology and pathophysiology of most LSDs, which are typically monogenic, are better understood than the more publicized diseases that are typically polygenic or manifest spontaneously in adults; (3) LSDs can be detected early (prenatal/neonatal) presymptomatically when intervention may have a more effective long-term impact; (4) the mutation typically results in a single deficient enzyme that can be cross-corrected to sufficient levels to sustain normal metabolism; (5) the ability of NSCs to diffuse through the BBB and naturally integrate into existing CNS circuitry while producing intrinsic gene products fills in major gaps in effective LSD therapy; (6) the biology of NSCs coincides well with the biology of the pediatric brain; that is, exogenous NSCs transplanted prenatally/neonatally would diffuse and differentiate with host (mutant) cells in response to microenvironmental cues.

#### Bystander Effects of Neural Stem Cells in Lysosomal Storage Disorders

In mouse models of LSDs, transplantation of genetically modified NSCs encoding missing enzyme genes is shown to be

beneficial. (1) MPS VII mouse models, caused by a frameshift mutation in the *B-glucuronidase* (GUSB) gene, demonstrated the potential for treatment of LSDs using enzyme replacement therapies. (2) A mouse model has been used for TSD, a gangliosidosis, which results in the mutation of the  $\alpha$ -subunit of the  $\beta$ -hexosaminidase enzyme (consisting of HexA and HexB isozymes). The pathology of TSD results in progressive and fatal neurodegeneration that is caused by buildup of the ganglioside GM2 in the CNS. It was first demonstrated that cross-corrective enzymes (HexA) produced from exogenous NSCs could function to reduce pathologic accumulation of GM2 in vitro. The same principal has been applied to the TSD mouse model by overexpressing HexA production, where NSC engraftment in vivo has shown reduction in neuropathology. It has also been observed that overexpression of lysosomal enzymes does not seem to have deleterious effects, although overexpression of other factors may or may not be problematic.

Reduction of neuropathology through NSC transplantation depends on (1) whether the corrective enzyme is required in small amounts to maintain normal function, (2) whether it is secreted, and (3) whether it can be taken up by mannose-6-phosphate (M6P) receptors. These traits have been demonstrated in the mouse model of SD, a gangliosidosis caused by a mutation of the  $\beta$ -subunit of Hex. SD is characterized by the deficiency of both HexA and HexB, resulting in the accumulation of the gangliosides GM2 and GA2 in the CNS. The pathologic accumulation of GM2 and GA2 causes rapid and progressive neurodegeneration that is fatal typically in infancy. Evidence in SD mouse models has shown that both human and mouse NSCs transplanted into the brains of neonates have migrated extensively throughout the brain while providing cross-correcting Hex enzyme, resulting in reduced ganglioside storage (both GM2 and GA2) in lysosomes. Engraftment was measured using LacZ-labeled NSCs traced by X-gal, and functionality was measured using electrophysiological methods to detect electrophysiologically active neurons in the CNS after NSC transplantation (see Figure 15-2). These

exogenous NSCs incorporated into the host circuitry through cytoarchitectural interactions and distributed intrinsic homeostatic gene products and, also to a lesser extent, provided neuronal replacement. Transplanted mice showed an increase in lifespan and an improvement in motor function.

Of particular note, in combination with substrate reduction therapy (SRT), the potential for synergistic effects with NSC transplantation was examined in the SD mouse model. SRT is a pharmacologic treatment strategy that targets the amount of substrate to be metabolized. Iminosugars such as *N*-butyldeoxynojirimycin (NB-DNJ) and *N*-butyldeoxygalactonojirimycin (NB-DGJ) are used in SRT to inhibit glycosphingolipid synthesis, thus reducing the amount of substrate available and decreasing storage in lysosomes. This is of particular interest because the addition of an oral pharmacologic agent in combination with NSC transplantation in SD mice improved the enzymatic action of NSCs without the need for genetic manipulation (Figure 15-3). These results suggest that combination therapies that utilize the inherent capabilities of NSCs can provide improved outcomes compared with each method administered separately. Only a small percentage (less than 5%) of donor-derived cells that were neurons probably had the smallest impact. These results show a bystander effect of NSCs and also encourage combination therapy along with NSC transplantation.

### Cell Replacement of NSCs in LSDs

In addition to widespread molecular therapy, there is cell replacement therapy. Neonatal brain injury is accompanied by a broad range of factors, including activation of oxidative stress, inflammation, and excitotoxicity pathways that can lead to damage. In addition to neuronal damage, injury to non-neuronal cell types such as astrocytes and oligodendrocytes might also impair neurodevelopment.

The prospect of replacing oligodendrocytes may be a bit more achievable than neurons, yet, even then, a number of considerations may make this goal less than straightforward.

**Figure 15-3.** Diagram of multimodal therapeutic potential of NSCs in pediatric neurodegenerative diseases. The beneficial effects of transplanted NSCs are mediated by multiple actions, including their ability to produce trophic factors, preserve neuronal function, and reduce astroglial and inflammation. NSCs, neural stem cells.

There have been demonstrations of NSC transplantation to replace oligodendrocytes in disorders of CNS dysmyelination. Dysmyelination plays an important role in many genetic (i.e., inborn metabolic errors and leukodystrophies) and acquired (i.e., traumatic, ischemic, and inflammatory) neurodegenerative processes.

The first application of using NSCs to replenish myelin in the CNS occurred with the *shiverer* (*shi*) mouse model. *Shi* mice have dysfunctional oligodendrocytes and dysmyelination of the CNS because of a deletion mutation in the myelin basic protein (MBP), which is required for myelin function. Both human and mouse NSCs were transplanted into the cerebral ventricles of neonatal *shi* mice. Widespread engraftment throughout the CNS was observed as was an increase in levels of MBP, resulting in decreased tremors in the mice (Snyder and Flax, 1995). The fact that human NSCs were effective is critical because dysmyelination is central to many genetic and acquired neurodegenerative processes in humans. While there is no human version of “shiverer” disease, oligodendrocyte dysfunction and the consequent dysmyelination are prominent features of some important LSDs.

An example of CNS dysmyelination in humans is *Krabbe leukodystrophy*, also known as *globoid cell leukodystrophy* (GCL). GCL is caused by deficient galactosylceramidase (GalC) activity, whose primary substrate is a component of the myelin sheath. GCL presents with CNS dysmyelination, oligodendrocyte degeneration, and macrophage infiltration.

The pathophysiology of GCL has been debated. Whether it is caused by a cell autonomous defect or by a toxic environment that would kill all cells (including host and transplanted cells) is in question. It has been hypothesized that the toxic environment might be caused by the buildup of the glycolipid psychosine because of the deficiency of GalC. Loss of GalC causes the buildup of the toxic glycolipid psychosine. The toxicity of psychosine to neural cells has been shown in *in vitro* experiments, where oligodendrocytes were especially susceptible. An animal model using *twitcher* (*twi*) mice has been used to examine whether transplantation of NSCs could be therapeutic in this toxic environment. Results of NSC transplantation into neonatal *twi* mice showed that NSCs were capable of surviving and differentiating into oligodendrocytes in the CNS. This showed that the toxic environment created by psychosine did not rule out cell transplantation therapies for GCL. The innate resistance that NSCs possess to the toxic environment is also more pronounced in the undifferentiated state. However, although the exogenous NSCs are able to engraft and differentiate into existing circuitry, little to no appreciable relief of symptoms is observed in *twi* mice. Of particular interest though is that a larger proportion (than normal) of NSCs differentiated into oligodendrocytes, suggesting that NSCs may be able to detect what cell type or niche is deficient and act to restore homeostasis by directing its fate. These studies indicated that NSCs may be able to detect what cell type or niche is deficient, and then act to alter its fate. It has become clear that ongoing reciprocal interactions occur between NSCs and damaged host cells.

## Hypoxic Ischemic Brain Injury and Stroke

Hypoxic ischemic injury (HII) during the perinatal period may lead long-term neurologic deficits. HII damages brain parenchymal cells and their connections, causes vascular and BBB dysfunction, and produces an extensive inflammatory response, but it also initiates endogenous protective processes.

NSC transplantation in rodent models of neonatal HII shows that NSCs are successfully engrafted, extensively migrate to injury sites, and replace lost tissue by differentiating into

neurons that integrate with host neuronal networks. Engrafted NSCs migrate toward damaged regions in the neonatal brain in response to endogenous chemokines and can move at a rate of approximately 100  $\mu\text{m}/\text{day}$  where they can survive for up to 52 weeks after transplantation. NSC-engrafted brains showed reduced activation of resident microglia, and increased expression of growth factors for FGF2, GDNF, IGF-1, and the neuroblast marker doublecortin, and oligodendrocyte markers Olig2 and MBP. The driving force of the functional improvements seen after NSC engraftment could be widespread changes in gene expression.

In stroke animal models, it has been shown that NSCs, when injected intravenously 3 days after reperfusion, survived in the brain for at least 1 month, and engrafted mice showed improvement of neurologic deficits. However, most of the cells remained in an undifferentiated state, suggesting that cell replacement was not the main mechanism responsible for the improvement. Undifferentiated NSCs had an anti-inflammatory effect, reduced glial scar formation, and protected striatal neurons. Similar beneficial effects of hNSCs are reported in the early stage of the adult cerebral ischemic-reperfusion mouse model. Engrafted hNSCs 1 day poststroke migrated rapidly and extensively to damaged regions after transplantation into a neurogenic site where migration cues are already underway during stroke onset. The hNSCs then counteracted a number of pathologic processes of stroke and repaired BBB damage. Although long-term effects of transplanted hNSCs on the amelioration of ischemic stroke-induced behavioral dysfunction in a rodent model have been reported, this study is the first to show rapid beneficial impacts on behavioral function (within 24 hours) upon early delivery of hNSCs into the hippocampus. Transplantation of hiPSC-NSCs in the same experimental stroke model showed a similar beneficial effect in the early stage of stroke injury. Transplantation of hESC-derived NSCs into the infarct boundary zone in a rat model of ischemic stroke improved impaired forelimb function. These studies show that the therapeutic effect of hNSCs demonstrated in pediatric disorders can be extended to adult neurologic and neurovascular disorders.

## SUMMARY

The regenerative and homeostatic capabilities that NSCs possess make them prime candidates for use in treating childhood neurologic disorders, including LSDs. Although cell replacement receives more attention, its effects can be complemented by bystander actions of factors secreted by NSCs. The intrinsic qualities of NSCs include anti-inflammatory, anti-apoptotic, proregenerative, proangiogenic, and neurotrophic growth factors. NSC transplantation may work synergistically with other therapies such as substrate reduction, enzyme replacement, gene therapy, and other pharmacologic interventions. For example, the synergistic potential of NSCs in combination with SRT was shown in a mouse model of SD. In such multimodal strategies, NSCs seem to serve as the “glue” that synchronizes different therapeutic actions for childhood neurologic disorders.

## FUTURE APPLICATIONS

The future of NSC therapy in pediatric neurologic disorders is sufficiently encouraging and has the potential to circumvent the onset and/or progression of neurodegenerative processes. Although we may be far away from being able to fully reverse established disease processes that will require cell replacement and reconstruction of damaged CNS, there is great potential for NSCs to circumvent the progression of disease before it manifests. Ideally, early intervention presymptomatically

and/or in utero would provide optimal results. Such an intervention brings up the premise that an early diagnosis, either prenatal or neonatal, has been confirmed. Early detection may be difficult because it would require a high level of suspicion and an extensive knowledge of family history on the part of the clinician and/or a good prenatal/neonatal screening program. However, the ability to translate these findings from animal models to successful human therapies is still ongoing. The successful translation of NSC therapy from animal models to use in human clinical trials will require further characterization of NSC biology and the pathophysiology of diseases in question. Important aspects of NSC biology to be explored further include the following: (1) characterization of the hNSCs to be used, with detailed protocols for their propagation and phenotype determination; (2) Comprehensive examination of the fate of transplanted hNSCs in vivo (i.e., Do they become electrophysiologically active neurons that make proper connections without making improper connections? Do they survive as differentiated glial cells or as undifferentiated progenitors? Do they survive at all in the environment, and if so how long?); (3) determination of whether the amount of enzyme expressed intrinsically by the hNSC enough to establish normal metabolic function, or whether genetic manipulation will be required to increase the production and secretion of the target enzyme; (4) determination of whether there is a measurable improvement in behavioral function after NSC engraftment and whether this is long-term; and (5) determination of how NSCs should be administered in order to reach all areas of the nervous system requiring treatment. Although administration of NSCs directly into cerebral ventricles has shown widespread diffusion throughout the cortex and cerebrum, diffusion to other parts of the CNS, including the cerebellum and spinal cord, and also to the peripheral nervous system may be required in order to fully prevent pathologies. This is of particular interest for some forms of LSDs with infantile onset. However, methods for NSC administration into areas other than the cerebrum and cortex require further examination in animal models.

Extensive characterization of human-derived NSCs, particularly hiPSCs, is needed to pave the way for clinical applications. Some of the key questions are as follows: Should NSCs be obtained from areas of neuroectodermal origin? If so, should they be from a fetal or adult source? Will an adult source be equally as effective? Will nonneural sources be as effective? Should a stable pool of NSCs be used for all patients, or should patient-derived NSCs be used as an autologous source for each patient. Finding the most effective way to obtain NSCs for transplantation therapy will be required to derive an efficacious treatment in humans.

There are many pathologic manifestations that make up individual diseases. In all, if we are to achieve success in treating pediatric CNS diseases, we need to embrace a wide variety

of approaches that include genetics; molecular science; pharmacology; tissue engineering; cell replacement therapy; and antiapoptotic, angiogenic, and anti-inflammatory methods. Although upregulated proinflammatory cytokines can be deleterious in some disease stages, they also serve as a signal for homing of exogenous stem cells into CNS injury sites. What role does inflammation play in different stages of disease progression? Answering this question will be critical for determining how inflammation contributes to brain injury and regenerating damaged tissue. Determining how these methods and factors can be coupled with NSC transplantation in a safe and efficacious manner is essential in the translation to clinical practice.

## INTRODUCTION

Animal models of neurologic disease have played a crucial role in improving our understanding of disease pathology and biological mechanisms, and in the development of treatment approaches. This is true for acquired disorders (such as traumatic injury to the brain or spinal cord, infection or immune-mediated attacks on the nervous system, and vascular lesions) as well as genetic disorders. In this chapter, we review selected topics that pertain to the use of animal and cellular models specifically of *genetic* neurologic disease. We start with a discussion of spontaneously occurring mutations (e.g., mouse models of leukodystrophies) and then move to genetically engineered mouse models. We provide an overview of transgenic mouse technology used to overexpress genes of interest, to “knock out” specific target genes, to “knock in” specific mutations, and to introduce mutations in a tissue-specific and developmental age-specific manner (conditional alleles). We then discuss the latest methods for gene editing (CRISPR-Cas9 RNA-editing technology) for introducing mutations at specifically targeted locations. Finally, we turn to the use of cellular model systems derived from mutant animals and the use of patient-derived stem cells, again for improved understanding of biology and as tools in large-scale compound screens in searches for novel therapeutic agents.

## SPONTANEOUSLY OCCURRING MUTANT ANIMALS

Although mice are probably the most frequently used animals when it comes to modeling human disease, there are other species that have played a key role in the understanding of specific neurologic disorders. Examples include American Quarter Horses with hyperkalemic periodic paralysis, and Irish wolfhounds with hyperekplexia or startle disease. In these cases, parallel studies in humans and in mutant animals have resulted in an improved understanding of the role of sodium channels or glycinergic synaptic transmission, respectively, in these disorders.

The organisms most often used for the study of early development are the fruit fly, *Drosophila melanogaster*, and the roundworm, *Caenorhabditis elegans*. Short generation time; the ease with which large numbers of organisms can be generated, maintained, and studied; and methods for selection of mutations based on specific morphologic or behavioral phenotypes made these ideal organisms for genetic studies. Phenotype-driven screens for mutations allowed for the discovery of many genes that were involved in the determination of the body plan (e.g., segmentation genes and homeobox genes), specific aspects of neural development (e.g., structure of the eye, axon pathfinding, dendrite growth, muscle and nerve development, and learning and memory), regulation of growth and size, and genes encoding families of ion channels. In fact, the unusual and interesting names for many genes important in neural development, including “dunce,” “shaker,” “numb,”

“big brain,” “roundabout,” “commissureless,” and “inebriated,” come from studies in mutant *Drosophila*.

An example of studies in *Drosophila* that were critical to the advancement of our understanding of human disease pathogenesis relates to tuberous sclerosis complex (TSC). Linkage studies in families with TSC led to the identification of the *TSC1* and *TSC2* genes, but the function of the encoded proteins was not clear. Deletion of these genes in mice by gene targeting recapitulated the tumor suppressor function of the *TSC* genes. The breakthrough came with the study of *Drosophila* mutants with altered insulin signaling and a disordered cellular growth phenotype (Pan et al., 2004). In a genetic screen for mutants affecting the structure of the *Drosophila* compound eye, several lines were isolated with enlarged ommatidia, of normal structure, but with enlarged cells. These were shown to be allelic to a previously identified mutant, *gigas*. Cloning of the *gigas* gene showed that it was homologous to the human *TSC2* gene. A series of studies of *Drosophila Tsc1* and *Tsc2* mutants were critical in placing the *TSC1-TSC2* complex downstream of AKT/PKB and upstream of mTOR in a critical cell growth pathway.

Christiane Nusslein-Volhard, who shared the 1995 Nobel Prize in Physiology and Medicine with Edward B. Lewis and Eric F. Wieschaus for their “discoveries concerning genetic control of early embryonic development,” transitioned from studies in *Drosophila* to zebrafish (*Danio rerio*) to see if her ideas applied to vertebrate development (Nobel lecture, December 8, 1995). With the advances in methods of genetic engineering (described later in section “Genome Engineering Using CRISPR-Cas9 Technology”), zebrafish have become a very useful system in which to model human disorders affecting many organ systems, including the nervous system, and a variety of disorders (Kabashi et al., 2010).

A large number of naturally occurring mouse mutants have been described over the years.

The shiverer (*shi*) mouse was first reported as a naturally occurring mutant in 1973, and its shivering phenotype was shown to be an autosomal recessive trait. Shiverer mice develop a generalized tremor (shiver) during activity by 14 days of age. Tonic seizures develop by 30 days and death usually occurs by 50 to 100 days. There is a severe abnormality of central myelin, with abnormal structure (fewer layers of myelin lamellae and absent major dense line) ascribed to a lack of the myelin basic protein (MBP). In one of the earliest successes of gene therapy in mice, introduction of a wild-type *Mbp* transgene into the shiverer resulted in an almost complete rescue of the phenotype.

Although there are no known human diseases caused by mutation of the *Mbp* gene, the shiverer remains a useful model system for studying novel therapies (transplantation of oligodendrocytes, oligodendrocyte precursors, or stem cells) for dysmyelinating disorders.

Twitcher (*twi*) is a model for human autosomal recessive Krabbe disease or globoid cell leukodystrophy, caused by deficiency of galactosylceramidase (GALC). Twitcher mice are

**Figure 16-1.** Diagram of a DNA construct for transgenic mice. The template for a simple transgenic construct includes (1) a promoter sequence (5' regulatory sequences) that drives the expression of transgene, (2) a coding sequence (e.g., green fluorescent protein) with introns and exons, and (3) a polyadenylation signal sequence (3' regulatory sequences) for the stability of mRNA. Transgenic DNA constructs are prepared and cloned into a vector for propagation. The transgene is cut out by appropriate restriction enzymes in linear form before injecting into mouse eggs.

normal at birth, but become hypoactive by 15 to 20 days; by 3 weeks there is rapid deterioration of motor function, with weight loss, progressive weakness, paralysis of hind limbs, and death by 3 months. Pathologic studies show a severe lack of myelin, astrocytic gliosis, and infiltration with macrophages containing periodic acid-Schiff–positive material (globoid cells). Surprisingly, the major substrate of GALC, galactosylceramide, does not accumulate within the brain. There is a significant accumulation of galactosylsphingosine (psychosine), also a substrate for GALC, in brain and other tissues. It is thought that psychosine is cytotoxic and leads to degeneration of oligodendrocytes, leading to myelin degradation. The twitcher mouse has been useful for testing a variety of therapeutic approaches for the leukodystrophies such as bone marrow transplantation or transgenic rescue.

## GENETICALLY ENGINEERED MOUSE MODELS

Models generated by expressing selected genes integrated into the mouse genome (transgenic mice), or by replacing endogenous loci with altered genes (gene targeting) have been useful for studies in neural development and neurologic disease (Joyner, 2000; Arbeit, 2001).

### Transgenic Mice

Animals that carry a foreign gene, such as the one encoding the jellyfish green fluorescent protein (GFP), in their genome are called transgenic animals. The expression of the transgene is usually controlled by promoters or enhancers included as part of the transgene, or by regulatory elements that are located within the integration site. Transgenes such as GFP are useful for tagging and tracing cells expressing the transgene. The transgenic approach is also useful to model a gain-of-function phenotype by overexpression of the gene (e.g., expression of a mutant Huntington disease allele), to examine the effect of gene copy number, to study the function and specificity of gene regulatory elements (promoters and enhancers), or even to detect and clone regulatory elements (enhancer trap methods). A particularly useful application of this technology is the generation of transgenic mice expressing Cre recombinase under the control of a promoter that directs expression of Cre in specific tissues at specific developmental ages. Such animals are used in the production of conditional knock-out animals by breeding with “floxed” animals (as described in the next section).

Key steps in the generation of transgenic mice are as follows: (1) construction and purification of the transgene vector DNA, which includes certain important elements; (2) collection of fertilized mouse eggs (zygote) within 12 hours of fertilization, before fusion of the male and female pronuclei; (3) microinjection of transgene DNA into the male pronucleus of the fertilized egg; (4) implantation of microinjected zygotes into a pseudopregnant host female mouse; (5) genotyping and analysis to detect transgene expression in the newborn pups; (6) comparison and selection of different transgenic lines for study (which may differ by copy number of transgenes and integration site).

The transgene DNA construct is similar to expression vectors used for protein expression in mammalian cells. It typically contains a 5' region including a promoter or enhancer; the coding sequence for the gene of interest, which may include short introns; and a 3' region that includes a polyadenylation signal for the encoded mRNA (Figure 16-1).

The 5' region including the promoter is a crucial part of the transgene, as it regulates the spatial and temporal pattern of transgene expression. Promoter–enhancer combinations from ubiquitously expressed genes drive transgene expression in all the cells. These include the metallothionein, myosin heavy chain (MHC) class I, RNA polymerase II, or beta-actin promoters. Cell type or tissue-specific transgene expression can be driven by using promoter–enhancer elements derived from genes expressed in select tissues and cell types. Examples include the myosin light chain (MLC), or MHC promoter to direct expression in the heart, nestin promoter to drive expression in the brain, and glial fibrillary acidic protein (GFAP) promoter to direct expression in astrocytes.

The coding region may be a complementary DNA (cDNA) corresponding to a specific RNA isoform of a gene of interest, or include an entire gene with exons and introns. In cases where the intent of the experiment is to characterize the 5' region (promoter and enhancer sequences), the coding region might consist only of a reporter gene. In other cases, a reporter gene may be included in addition to a distinct transgene of interest, to track cells in which the transgene is expressed. Commonly used reporters include the bacterial *lacZ* gene encoding  $\beta$ -galactosidase, and GFP and its variants red fluorescent protein (RFP), cyan fluorescent protein (CFP), and yellow fluorescent protein (YFP). The fluorescent reporters having different spectral properties are used in transgenic mice models for identification of cell types, colocalization experiments, electrophysiological studies on specific cell populations in the brain, and high-resolution studies for detailed measures of dendritic spine density, dendrite width, and axonal length. The 3' region typically includes transcription termination signals and polyadenylation signals, which confer mRNA stability.

In spite of the optimal design of a transgenic expression vector, there are often unexpected effects related to sequences at the integration site—these may counter the selected promoter and enhancer elements. Integration might in fact disrupt some other critical genes resulting in a novel phenotype. In addition, transgene expression during early development may cause untoward defects and may not allow the planned studies in older animals. Inducible transgenes were devised to circumvent some of these problems. In such a system, transgene expression is regulated by an exogenous compound administered to the animal.

The tet-operon–repressor bitransgenic system, the ecdysone receptor, the estrogen receptor (ER) ligand–binding domain, the progesterone receptor, and the lac and GAL4 systems have been used to control gene expression in transgenic mice. One transgene expresses a tetracycline operon transactivator or hormone receptor (ER, mutated ER, ecdysone receptor, and progesterone receptor) under control of a selected promoter. A second transgene is engineered that contains a promoter

that is regulated by the appropriate transactivator or hormone receptor (which binds to DNA). In such animals, drug treatment (with tetracycline, estrogen, tamoxifen, and ecdysone) results in suppression or activation of the other transgene of interest.

Once a transgenic expression construct is created and validated, it is purified and a known concentration of DNA is injected as a linear piece of DNA into the male pronucleus (larger of the two pronuclei) of newly fertilized eggs (zygotes) (Figure 16-3). Injection before fusion of the male and female pronuclei greatly increases the rate of transgene integration. Random insertion of the transgenic DNA will occur into the genome of the embryo at the one-cell stage. The integrated transgene will generally be present in all cell types of the developing embryo and be transmitted through the germline. Microinjected zygotes are then implanted into the oviduct of pseudopregnant females, resulting in birth of both wild-type and transgenic founder mice, each of which represents the first generation of a new line of mice. Each transgenic line has to be genotyped, and expression of the transgene at the protein level has to be confirmed.

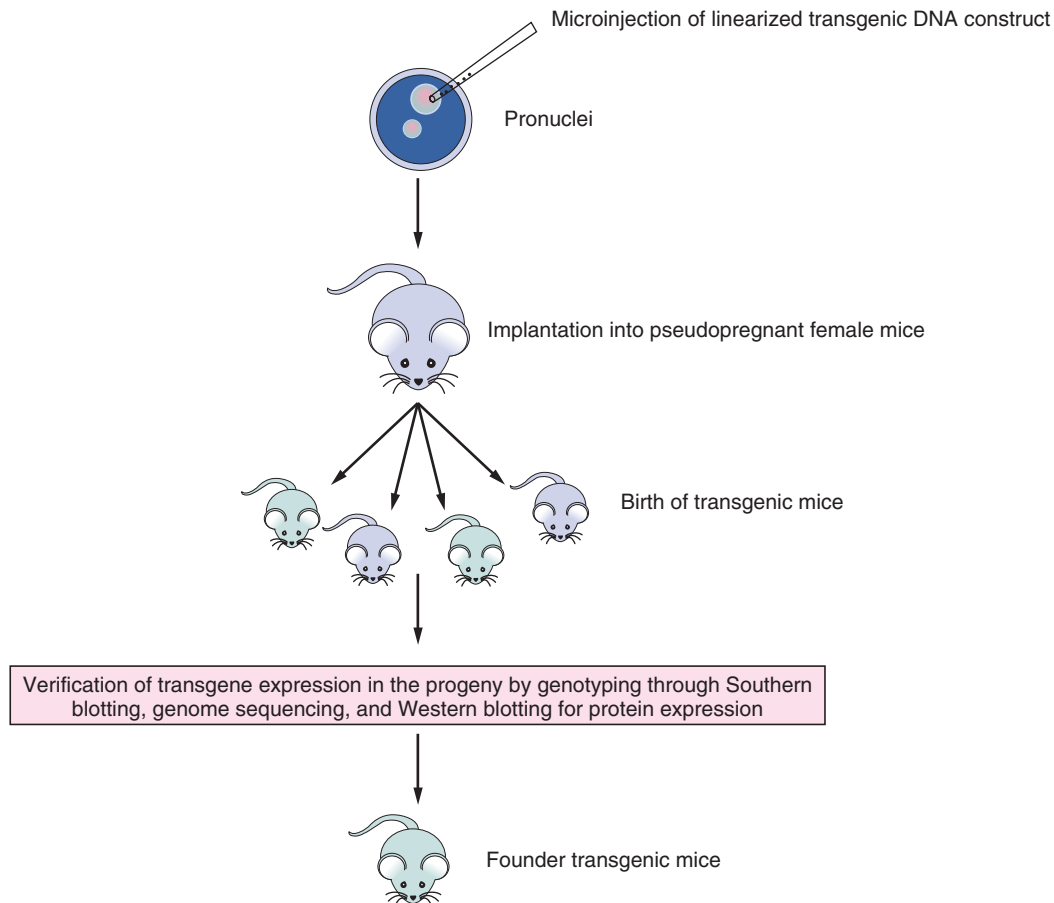

### Knock-out and Knock-in Mice

The ability to generate “designer mice” in which specific genes are altered was a result of several key discoveries: (1) isolation of pluripotent mouse embryonic stem cells (ES cells), (2) the generation of transgenic chimeric by mice introducing ES cells

into host blastocysts, (3) the ability to alter the genome of ES cells by homologous recombination, and (4) the ability to introduce genetically altered ES cells into blastocysts and transmit such genetic modifications through the germline (Capecchi, 2005).

ES cells are derived from the inner cell mass of a blastocyst-stage mouse embryo. Cells are maintained in appropriate culture conditions to propagate them in an undifferentiated, diploid state. Male (40, XY) ES cells are now available from a number of different mouse strains. As depicted in Figure 16-4, ES cells of a specific genotype (A, depicted by dark color) are injected into host embryos (blastocysts) of a different strain (typically a different coat color). These modified embryos are implanted into pseudopregnant surrogate females. Chimeric offspring (composite coat color) often have different compositions (host genotype or modified ES cell genotype) in their germ cells. Chimeras are crossed with wild-type animals and offspring genotyped for transmission of the ES cell genotype. These founder animals can then be bred to homozygosity for phenotypic studies.

Homologous recombination was shown to occur in mammalian cells, and used to introduce mutations into a specifically targeted location of a gene in ES cells. These genetically modified ES cells then could be used to produce chimeric mice, as described earlier. If the intention was to create a null mutant (one in which the encoded protein is not expressed), then we would “knock out” the corresponding gene. If the intention is to reproduce a missense mutation, then one would “knock in” that particular mutation.

**Figure 16-3. Outline of transgenic mice production through transgene microinjection.** A transgenic linear DNA construct is physically microinjected into a male pronucleus of newly fertilized egg. Microinjected eggs are transplanted into the oviduct of a pseudopregnant female host. Random insertion of the transgenic DNA will result in birth of transgenic founder mice.

**Figure 16-4. Generation of embryonic stem (ES) cell-derived chimeras.** Cartoon depicting the injection of ES cells of a specific genotype (A) into host blastocyst followed by implantation into a pseudopregnant host. Chimeric offspring are often detected based on coat color. Chimeras are crossed with wild-type animals and offspring are tested for germline transmission of the desired genotype (A). Founder mice are then maintained in the desired genetic background by breeding.

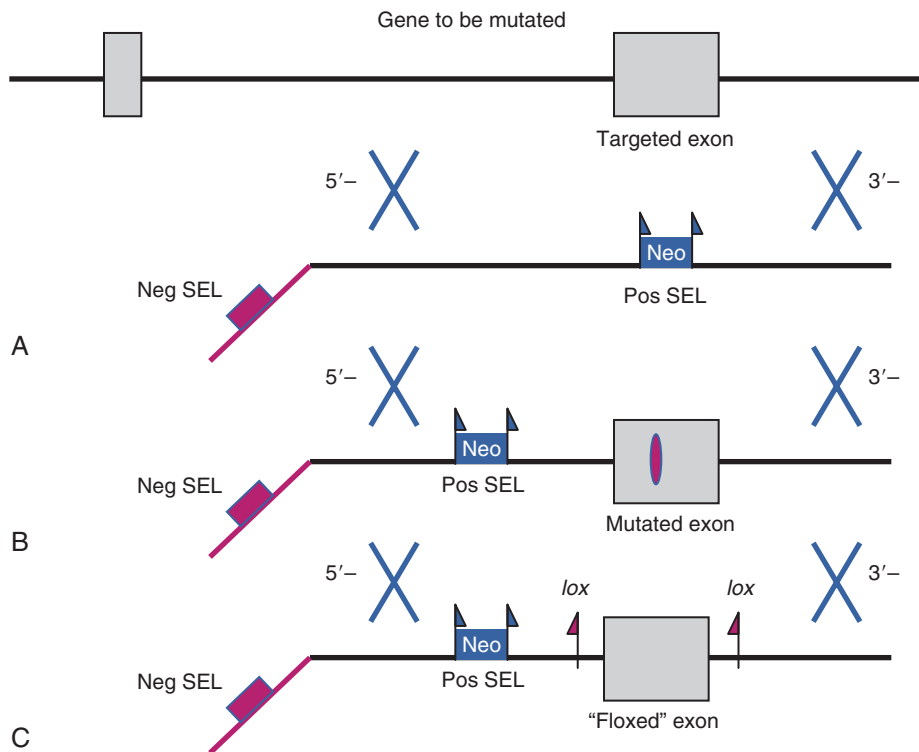

Null mutations are frequently created by eliminating one or more critical exons of a gene. An important element of experimental design is to consider the multiple RNA molecules that may be generated from the gene of interest by alternative splicing, and making sure that eliminating the targeted exon(s) will in fact produce the desired result, and not simply result in a different transcript encoding a different protein isoform.

The first step in creating a gene-targeting vector is the cloning of a segment of mouse genomic DNA containing the targeted exon. This exon is then replaced by a positive selection marker; a commonly used marker is an expression cassette that confers neomycin resistance. As shown in [Figure 16-5A](#), the targeting vector contains long segments (typically longer than 1 kbp) of homologous DNA flanking the targeted site, with the positive selection marker cassette in place of the targeted exon. The targeting vector (linearized DNA) is then electroporated into ES cells. The positive selection marker can be used to select for events in which the targeting vector has integrated into the ES cell genome, but this does not differentiate between random integration and homologous recombination events. Random integration of the targeting vector DNA is a much more frequent event than homologous recombination. A negative selection marker can be included in the vector, outside of the regions of homology, for selection against random integration events. ES cell clones that survive the selection pressure (cultured in the presence of a neomycin analog, for instance) can be expanded, and split for genotyping and storage. DNA is extracted from individual ES cell clones and tested to determine whether only the desired

targeting event has occurred, or whether random integration of the transgene has occurred. This is frequently done by PCR-based assays that detect unique DNA fragments that result from proper recombination on the 5'-side and the 3'-side of the targeted exon.

The cartoon in [Figure 16-5](#) shows several possible targeting vectors. When the targeted exon is either replaced or disrupted by a positive selection cassette (see [Figure 16-5A](#)), the result of homologous recombination is usually a null allele ("knock-out") from which no corresponding protein is made. When the targeting vector is synthesized to include a specific point mutation inserted into the targeted exon, with the positive selection marker in close proximity, flanked by regions of sequence homology, the result is a "knock-in" of that specific point mutation ([Figure 16-5B](#)).

In some cases, a complete knock-out of the gene of interest (null allele) may be lethal during embryogenesis, making it impossible to study the effect of this mutation in adult animals. A system, called conditional gene targeting, that has adapted site-specific recombinases from bacteria gets around this problem. Two commonly used recombinase systems are the Cre-Lox system and the Flp-Frt system. The Cre recombinase, a protein encoded by a bacteriophage, recognizes a specific 34-bp *lox* sequence and catalyzes recombination between two *lox* sites. Cre-mediated recombination between two directly repeated *lox* sites (oriented in the same direction) results in excision of the intervening DNA (deletion), whereas recombination between two inverted *lox* sites causes inversion of the intervening DNA segment. If the targeting vector is designed to introduce *lox* sites flanking a specific exon, the

**Figure 16-5. Homologous recombination strategies.** The gene to be targeted for mutation is diagrammed at the top. **A**, Targeting vector designed to replace the targeted exon with a selection marker (Neo = neomycin resistance expression cassette with flanking Frt sites, denoted by blue “flags”). 5′ and 3′ stretches of homologous DNA favoring recombination are indicated. A negative selection marker is shown located outside of the segments of homologous DNA. **B**, Targeting vector designed to “knock in” a point mutation into the targeted exon. **C**, Targeting vector designed to generate a “floxed” allele. Lox sites flanking the targeted exon are indicated as red “flags.” SEL, selection.

result of homologous recombination is a “floxed” allele (Figure 16-5C). Transgenic mice generated in which these “floxed” alleles are transmitted through the germline are called “floxed” mice, and usually have no abnormal phenotype. A number of transgenic mice are readily available in which Cre recombinase is expressed in restricted cell populations at specific ages, dictated by the promoter driving Cre expression. These include Cre expressed ubiquitously all during development, in specific tissues (liver, immune cells, and nerve tissue), in specific regions of the brain (cerebellum, hypothalamus, and cortex), and during specific developmental stages. There are also transgenic mice in which Cre expression is inducible. When “floxed” mice are crossed with a Cre-expressing mouse, offspring containing both alleles will have the targeted allele excised in a spatially and temporally restricted manner. The availability of a large number of mice bearing “floxed” alleles, and a variety of Cre-expressing transgenic mice has greatly facilitated the study of gene function in specific cell populations within the brain.

## Genome Engineering Using CRISPR-Cas9 Technology

Clustered regularly interspaced palindromic repeats (CRISPR)–associated Cas9 is a recently developed genome-editing technology, and shows promise to be a highly efficient system for manipulating the genome sequence of living cells and organisms (Hsu et al., 2014). Advancement of CRISPR technology allows researchers to “edit” the gene (DNA) sequence on a chromosome in cells and tissues more quickly and precisely. The basic idea is to introduce double-strand breaks in a targeted fashion in the genome of a cell, which is then repaired using endogenous cellular machinery to produce a mutation.

This technology allows a wide range of biological and disease modeling applications, including the modeling or rescue of monogenic disorders and more complex neurologic disorders such as autism. The CRISPR-Cas9 system was first observed in unicellular organisms (archaea and bacteria) as a group of DNA short sequence repeats of 20 bp, which played an important role in bacterial acquired immunity against viral/phage infections. Bacteria, upon a viral infection, can precisely incorporate the viral DNA as short sequence repeats, separated by a short palindromic repeat into a region of its genome, designated as CRISPR. In subsequent infections, these sequences will be transcribed as small RNAs called CRISPR targeting RNA (crRNA), which hybridizes to the target DNA of virus. This in turn activates and guides a multifunctional endonuclease (Cas9) to cleave the hybridized viral DNA.

Because of its conceptual simplicity, a modified version of CRISPR-Cas9 is swiftly becoming the method of choice for genome engineering in living systems. Compared with previous methods of genome editing, such as zinc-finger nucleases (ZFNs) and transcription activator–like effector nucleases (TALENs), which depend on protein–DNA interactions instead of DNA–RNA interactions, this system offers several advantages, including target design simplicity, target efficiency, and the possibility of high-throughput screening and multiplexing. CRISPR-Cas9 consists of a Cas endonuclease that is directed to cleave a target sequence by a single-guide RNA (sgRNA) when followed by a 5′- protospacer-adjacent motif (PAM) in a eukaryotic cell. The sgRNA is a 100-nucleotide molecule formed by fusion of a CRISPR RNA (crRNA) with a transactivating CRISPR RNA (tracrRNA). After Cas9 cuts the double-stranded target DNA, three to four nucleotides upstream of the PAM sequence, two different repairing pathways can be activated, which can be selected based on the

desired genome editing: nonhomologous end-joining (NHEJ) and homology-directed repair (HDR). NHEJ can lead to a “loss of function” by introducing insertion/deletion mutations (indels) of various lengths, which in turn can disrupt the reading frame of target genes or the binding sites of *trans*-acting factors in promoters or enhancers. HDR-mediated repair can be used to modify the gene of interest by introducing specific point mutations or other desired sequences through recombination of the target locus with exogenously supplied DNA donor templates (Figure 16-7A).

The CRISPR-Cas9 system has a wide variety of applications and has been used for the introduction of single point mutations, deletions, or insertions in a particular target gene or transcriptional regulator sequences, either as a knock-in or knock-out models. Other applications of CRISPR-Cas9 include the simultaneous activation of multiple endogenous genes by transcriptional activation (CRISPR-on), the imaging of genomic loci, and epigenetic modification.

Cas9-mediated genome editing has enabled an accelerated generation of transgenic and cellular models. CRISPR-Cas9 can be used to genome-edit primary, immortalized, human induced pluripotent stem cells (iPSCs) and other cells by the transfection of plasmids carrying Cas9 and the appropriately designed sgRNA. There are several advantages to this technology, including the multiplexing ability that allows the study of polygenic disease models and the ability to correct existing mutations in patient-derived cell lines. A major advantage of CRISPR-Cas9 is that it is not limited to mutagenesis in ES cells for the generation of knock-out or knock-in animal models. The Cas9 protein and transcribed sgRNA can be directly injected into fertilized zygotes, bypassing the typical ES cell targeting stage, allowing the fast generation of mutant animals.

Although CRISPR-Cas9 is an easy and efficient strategy for the generation of genetically modified cells, there are some limitations. There are specific sequence limitations on the targeting range of sgRNAs and a careful design is required that is both target specific and shows limited off-target effects. Off-target cleavage is a major concern in CRISPR-Cas9, as several studies show that RNA-guided Cas9 nuclease cleaves genomic DNA sequences containing several mismatches to the guide strand. Several methods have been developed to minimize these off-target effects. A promising study showed that a double-nicking strategy using the Cas9 nickase mutant with paired guide RNAs (Figure 16-7B) has shown efficient genome modification with minimal off-target effects. CRISPR-Cas9 is thus a versatile genome-editing technology that can be used to study and model both monogenic and polygenic disorders and shows potential for the development of therapeutic genome-editing techniques.

## CELLULAR MODEL SYSTEMS: CELL LINES AND PRIMARY NEURONAL CULTURES

Once a specifically targeted transgenic mouse model has been created, the first step is to validate its gene structure and ensure that the mutant allele is indeed expressed as designed. Once this is done, the next step is to phenotype the animals at several levels. This includes measurement of animal growth and survival, appearance of neurologic symptoms (such as seizures or ataxia), studies of strength and coordination, detailed behavioral analysis, tests of learning and memory, tests of social behavior, histopathological studies of various tissues and brain regions, fine structure analysis of neurons from different brain regions, electrophysiological studies in tissue sections or dissociated cells, and studies of gene and

**Figure 16-7. CRISPR-Cas9-mediated targeted DNA mutation.** **A**, Wild-type Cas9 cleaves double-stranded DNA 3 to 4 bp upstream of the 5'-protospacer-adjacent motif (PAM) sequence, activating double-strand break (DSB) repair machinery. In the absence of a homologous repair donor, single DSBs generated by CRISPR-Cas9 are repaired through the error-prone nonhomologous end-joining (NHEJ), which results in insertion or deletion (indel) mutations, disrupting the target sequence. Alternatively, precise mutations and knock-ins can be made by providing a homologous repair template (single or double stranded) through the homology-directed repair (HDR) pathway. **B**, Double nicking mediates genome editing with improved specificity: a D10A mutant nickase version of Cas9 makes a site-specific single-strand nick. Two different guide RNA (gRNA) can be used to introduce breaks, which can be repaired through HDR or NHEJ.

protein expression. Preclinical trials of a small number of candidate compounds are possible in such animals, but it is not practical to do large-scale therapeutic screens of hundreds or thousands of compounds using *in vivo* systems.

One attractive option for large-scale compound screens involves use of cultured cells isolated from genetically engineered mice. Cell lines from most tissues can be established and used for biological studies and therapeutic screens. These include ES cells, which in turn can be differentiated into any desired cell type. For the study of neurologic disease, one could use neuronal cultures prepared from specific mouse brain regions such as the cortex, hippocampus, or cerebellum following established protocols.

An example of the successful use of a genetically engineered mouse model is in the identification of compounds that may potentially be used to treat Angelman syndrome, caused by mutation of the *Ube3A* gene. A transgenic *Ube3a*-YFP (yellow fluorescent protein) knock-in mouse model has been developed as a reporter of *Ube3a* gene imprinting. In cultured embryonic cortical neurons prepared from these mice, *Ube3a*-YFP expression was suppressed when *Ube3a*-YFP was *paternally* inherited (*Ube3a*<sup>m+/pYFP</sup>), but was expressed when *Ube3a*-YFP was *maternally* inherited (*Ube3a*<sup>mYFP/p+</sup>). Neurons from *Ube3a*<sup>m+/pYFP</sup> animals were used to screen for drugs that upregulated YFP fluorescence, as a marker of activation of the imprinted allele. Topoisomerase inhibitors (such as topotecan) were found to unsilence the paternal *Ube3a* allele. Topotecan was then tested in an AS mouse (maternally derived *Ube3a*-null allele) both in primary neuronal cultures and *in vivo*. Topotecan unsilenced and upregulated expression of the paternal *Ube3a* allele in several regions of the nervous system, suggesting that these were potential therapeutic agents for treatment of AS (Huang et al., 2011).

Using well-characterized mutant and wild-type cultures allows for neuronal phenotypic and molecular comparisons. Features such as neuronal size, axon growth, dendrite branching, spine structure, and even development of functional synapses can be studied *in vitro*. These *in vitro* phenotypes may replicate what is seen *in vivo*, but are now amenable to manipulation by gene transfection or siRNA-mediated knockdown. For instance, using cultures prepared from a “floxed” animal, one can study the cellular phenotype of eliminating the targeted gene *in vitro* by transfection with a Cre expression vector.

As with any system, the use of primary cultures of neurons from genetically engineered mice has certain limitations. Neurons have a limited lifespan *in vitro*. If the focus is on neurons from a small brain region (hypothalamus or brainstem), then the number of cells that can be isolated from a single animal may be small, and this may limit the type of experiments that can be done. In some cases where cultures are relatively homogeneous (cerebellar granule neurons, for instance), one could pool together cell preparations from several genotypically identical animals for large-scale high-throughput screens (HTS).

When using primary neuronal cultures in an HTS compound screen, it is important to have a phenotypic biomarker that can be adapted to an HTS system (An and Tolliday, 2010). With a focus on searching for novel small-molecule therapies for Rett syndrome (RTT), such an approach has been used in the development of an HTS assay using cultured hippocampal and cerebellar granule neurons from *MeCP2* mutant animals. In the *MeCP2* A140V knock-in mutant model for X-linked mental retardation, we demonstrated increased cell packing density in various brain regions, a reduction in neuronal size, and reduction in dendrite branching. Quantification and comparison of soma size in cultured hippocampal neurons from *MeCP2* A140V and wild-type mice revealed that soma size was

significantly reduced in mutant hippocampal neurons compared with wild type. The definition of neuronal size as a quantifiable cellular phenotype supports its uses as a biomarker in the development of a high throughput *in vitro* assay to screen for compounds that rescue the small neuronal phenotype (“phenotypic assay”). This offers a novel approach to identification of potential small-molecule drugs for treating RTT and other neurodevelopmental disorders.

HTS rely on the development of an assay that uses a simple and quantifiable phenotypic or biochemical marker. Assays are standardized in traditional laboratory bench-top experiments, and then miniaturized and automated for 96-, 384-, or 1536-well microplate formats. New technologies such as high-throughput, high-content image analysis enable research labs to develop miniaturized cell-based assays to screen tens of thousands of compounds per day. Well-designed secondary and tertiary screens are used to validate the hits detected in the primary screen. For instance, for studies in *MeCP2* mutant animals, cerebellar granule neurons prepared from male mutant and wild-type animals were initially used. As the vast majority of patients with RTT are female, however, any potential therapeutic agent has to be tested in females. Female transgenic mice are engineered to carry the mutant *MeCP2* gene on the maternal X-chromosome and a transgene for GFP on the paternal X-chromosome (wild-type *MeCP2* sequence). Because of X-inactivation, neurons expressing the wild-type *MeCP2* allele from the paternal X-chromosome are GFP(+) and fluorescent, whereas neurons expressing the mutant *MeCP2* allele are GFP(−). Such a system permits the identification of compounds that rescue the size phenotype in mutant neurons, without adversely affecting wild-type neurons. Tertiary screens in culture might include a different phenotype (dendrite growth and branching), leading to tests in patient-derived iPSCs (as described in the next section). Eventually, a small number of selected compounds from such *in vitro* screens can be tested in genetically engineered animal models *in vivo*, with appropriate biological or behavioral phenotypic markers.

Recent advances in HTS have enabled automation in every step of the assay. Integration of robotic systems for plate handling, cell loading in microwell plates, live cell fluorescence image capture, microelectrode arrays for electrophysiological phenotypes, and high-content data analysis has significantly increased the efficiency and shortened time for HTS. HTS approaches in primary cortical neuronal cultures have been utilized to identify small-molecule modulators of synaptic proteins that alter neurotransmission, potentially useful as a novel therapeutic strategy for psychiatric and neurologic disorders. HTS methods are already being used in primary neuronal cultures and cell lines to develop therapies for Huntington and Alzheimer disease. Availability of large compound libraries, sophisticated data acquisition and image analysis tools, and efficient HTS assays will result in rapid identification of potential therapies that can then be tested in secondary screens and preclinical animal models.

## INDUCED PLURIPOTENT STEM CELLS: A NOVEL HUMAN CELL MODEL FOR NEUROLOGIC DISEASES

Pluripotent human embryonic stem cells (hESCs) have been isolated from early stage human embryos (blastocysts), can self-renew, and differentiate into various cell types, offering an unlimited source of cell types for research. By taking advantage of preimplantation genetic diagnosis, hESCs carrying mutations in specific genes known to cause human diseases, including cystic fibrosis, Huntington disease, Marfan syndrome, fragile X syndrome, and other monogenetic diseases, have

been created. Reverse genetics can be used to generate hESC disease models by homologous recombination. Unfortunately, apart from the ethics and political concerns related to hESC line derivation, this strategy is also limited by the availability of human blastocysts and by the number of genes one can manipulate in hESCs. Moreover, complex disorders in which multiple genes are affected, or “sporadic” diseases such as autism spectrum disorders, schizophrenia, or amyotrophic lateral sclerosis, in which the genetic alteration is not known, cannot be modeled using reverse genetics in hESCs.

Reprogramming technology provides a possible solution to this problem as it allows the genomes of human individuals afflicted with neurologic disorders to be captured in a pluripotent stem cell line. Reprogramming of somatic cells to a pluripotent state by overexpression of specific genes was first accomplished using mouse embryonic fibroblasts. Four retroviral-mediated transcription factors, the octamer binding protein 4 (OCT4, also known as POU5F1), SOX2, Krüppel-like factor 4 (KLF4), and MYC, were sufficient to induce the expression of endogenous pluripotency genes in somatic cells. These reprogrammed cells were able to form embryoid bodies in vitro and teratomas in vivo, and contributed to several tissues in chimeric embryos when injected into mouse blastocysts. The report of human reprogrammed cells using the same set of transcriptional factors happened soon after. These cells, named iPSCs, can be derived from cells isolated from peripheral tissues of normal individuals or people affected from several conditions (Marchetto et al., 2010). Differentiation of human iPSCs allows for the recapitulation of brain development in-a-dish, providing a platform with greater accessibility to experimental manipulation and high-throughput assays for drug screening. Ideally, such an in vitro platform should maximize translational potential by recapitulating in vivo brain development and function as much as possible.

As with other models, the iPSC system also has important limitations. Although the iPSC models show great promise, their use in many cases is implicitly based on the assumption that they recapitulate neurodevelopmental milestones of a specified developmental maturity and neuroanatomical region in vitro. Current limitations include nonoptimized culture conditions and differentiation protocols, the intrinsic cellular variability (likely related to the nonoptimal conditions), and the choice of proper controls. Genome-editing technology is becoming a popular method to alleviate concerns about confounding clonal variation from reprogramming and differentiation techniques. Obviously, genome editing will work only where the genetic alterations are previously known. Finally, another big challenge for iPSC models is the validation of phenotypes observed in human neurons. Unquestionably, the iPSC technology still requires a series of optimization steps. Future work will help to answer how well human iPSCs match in vivo development, what level of developmental maturity is achieved after differentiation, and what specific neurodevelopmental processes and molecular mechanisms are preserved, providing a guide for future disease modeling in-a-dish systems. Nonetheless, even with all these caveats, the iPSC is already generating novel insights that should be seen with an open mind for novel perspectives.

## INSIGHTS FROM INDUCED PLURIPOTENT STEM CELLS TO MODEL NEURODEVELOPMENTAL DISORDERS

The utility of iPSCs in the investigation of the functional consequences of mutations in the gene encoding the methyl-CpG-binding protein-2 (MeCP2) in neurons from patients with RTT has been demonstrated. Neurons derived from RTT-iPSCs

carrying different MeCP2 mutations showed several alterations compared with five healthy nonaffected individuals, such as decreased soma size, altered dendritic spine density, and reduced excitatory synapses (Kim et al., 2011). Defects in the number of glutamatergic synapses could be reversed using two candidate drugs, insulin growth factor 1 (IGF1) and gen-tamicin. IGF1 is considered to be a candidate for pharmacologic treatment of RTT and potentially other central nervous system (CNS) disorders in ongoing clinical trials. These observations bring valued information for RTT because they suggest that presymptomatic defects may represent novel biomarkers to be exploited as diagnostic tools and therapeutic targets.

Recently progress has been made toward analogous modeling of nonsyndromic autism in studies from a patient with a *TRPC6* gene mutation. The biological impact of the gene mutation and its functional relationship to autism etiology were evaluated through several analyses using cortical neurons derived from iPSCs. Taken together, these findings suggest that *TRPC6* is a novel predisposing gene for autism that may act in a multiple-hit model. This was the first study to use iPSC-derived human neurons to model nonsyndromic autism spectrum disorders and illustrate the potential of modeling genetically complex sporadic diseases using iPSCs.

Drug-screening platforms using iPSC-derived cell types require robust phenotypes and large numbers of target cells. Whereas most research has focused on neurons, the transition to an HTS platform has intrinsic challenges, mainly because iPSC neurons are particularly difficult to produce in a homogeneous population and challenged to behave in the high-throughput format. Glial cells may also represent exciting novel therapeutic targets. Previous studies have established that astrocytes secrete signaling molecules that stimulate the formation and function of synapses. Thus it is likely that astrocytes also contribute to disease and could be an alternative cell type for some neurologic disorders. Independent of the cell type used, read outs such as cellular morphology can be measured using high-content imaging software, whereas biochemical and gene expression read outs could be valuable alternatives because of the simplicity of these assays.

iPSCs are now a valuable tool for the understanding of the fundamental molecular and cellular mechanisms underlying neurologic disorders. Moreover, they can nicely complement studies using other models, such as animals or postmortem brain tissues. The iPSC system has also the potential to speed and improve drug development, facilitating the identification of ineffective or unsafe drugs earlier in the development process. Human patient-derived iPSCs offer the opportunity for genetics-based personalized medicine, for both understanding disease specifics in a given patient and developing relevant individualized therapeutic strategies.

# 17 Neonatal Neurointensive Care

Hannah C. Glass and Sonia L. Bonifacio

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

The 20th century has brought significant advances in neonatal cardiopulmonary resuscitation and critical care. There are now very high rates of survival among neonates with previously life-threatening conditions, for example, perinatal asphyxia, extreme prematurity, and congenital malformations of the heart and lungs. Despite advances in cardiopulmonary care, neonates continue to suffer neurologic complications of critical illness. Up to 25% of children at high-level intensive care nurseries may be diagnosed with encephalopathy, brain injury, seizures, and other neurologic conditions (Glass et al., 2010). These children are at high risk for long-term disabilities, including cerebral palsy and epilepsy, as well as intellectual and behavioral disabilities.

Neonatal neurocritical care (also called neurointensive or brain-focused care) is a subspecialty that has developed in response to recent advances in brain care and improved understanding of the impact of critical illness on the developing brain. It is now well known that brain injury is exacerbated by alterations in temperature (especially hyperthermia), and glucose (especially hypoglycemia), and that infection is a risk factor for injury and altered brain development in preterm neonates. In addition, technological advances—for example, digital electroencephalography (EEG) with bedside trending (such as amplitude-integrated EEG [aEEG]) and remote access availability—allow the bedside team to assess brain function in real time. Furthermore, safe, high-resolution brain imaging techniques using magnetic resonance (MR) are available to assess the impact of critical illness on brain structure and development.

This important focus on the brain during the period of critical illness allows for medical (including possible neuroprotective) interventions, developmentally supportive care, communication with parents, and decision making while the patient is in the nursery. In principle, neurocritical care can lead to improved outcomes through the following mechanisms: (1) earlier recognition and treatment of neurologic conditions, (2) prevention of secondary brain injury through attention to basic physiology (temperature regulation, glucose homeostasis, oxygenation, and blood pressure support), (3) consistent management using guidelines and protocols, and (4) use of experienced specialized teams at dedicated referral centers.

As the field of neonatal neurocritical care has developed, it has become apparent that certain diseases warrant consideration for having newborns more intensively monitored. Infants who suffer from acute or chronic neurologic conditions may benefit from the teamwork, guidelines, and brain-focused approach of a neurocritical care service. The most common conditions include encephalopathy (and hypoxic-ischemic encephalopathy [HIE]), seizures (both acute symptomatic

seizures and neonatal onset epilepsies), stroke (both arterial and venous), intracranial hemorrhage, and intracranial infection (Glass et al., 2010). Patients who are at high risk for brain injury, such as those who are of extremely low gestational age (<28 weeks' gestation at birth), or have hydrocephalus, congenital heart malformations, need for extracorporeal membrane oxygenation (ECMO), vascular malformations of the central nervous system, or symptomatic hypoglycemia will also benefit from monitoring, imaging, and a team approach as they are at high risk for seizures, and optimal brain care may minimize injury. Finally, children with developmental anomalies, such as brain malformations, multiple congenital anomalies, or dysmorphisms can also benefit from the multidisciplinary neurocritical care approach.

## ESTABLISHING A MULTIDISCIPLINARY NEUROINTENSIVE CARE NURSERY

Establishing a neurointensive care nursery involves a culture change for the entire intensive care nursery toward brain-focused care, such that all patient care providers are continually aware of the neurologic implications of critical illnesses and the impact of management strategies on the developing brain. This can be accomplished by (1) developing a strong leadership team with representatives from neonatology, neurology, and nursing; (2) providing training and education to all providers, including physicians, nurses, nurse practitioners, and respiratory therapists, among others; (3) developing local guidelines for common neurologic conditions; and (4) ensuring adequate technology for brain monitoring, imaging, and application of hypothermia. With these changes, bedside providers learn to consider the brain to be as important as the heart and lungs in day-to-day management.

Leaders from neonatology, neurology, and nursing must work together to develop guidelines and protocols, as well as training and educational programs for their respective specialties. Guidelines and protocols can help to standardize the approach to the neurologic evaluation and treatment and reduce practice variation that can occur in large units with high turnover of medical and nursing staff (Figure 17-1). Buy-in from all team members, especially nurses, who are present at all hours, is critical for promoting the mission of minimizing brain injury and providing brain-focused care and, ultimately, will lead to culture change.

Most neurointensive care nurseries are closed units with the neonatologist acting as the MD of record and the neurologist acting to comanage patients, taking an equal role in decision making and communication with the family. The neonatologist identifies patients at risk of brain injury and provides optimized resuscitation and supportive care to prevent secondary injuries. The neurologist takes an early

active role from the time of the initial presentation of neurologic signs or symptoms. The neurologist can help to guide the initial investigation and management decisions, including rapid implementation of medical treatment, as well as coordinating with the neurophysiology service for application and interpretation of EEG, and with the neuroradiologist for appropriate imaging protocols. The neurologist perspective is important when discussing prognosis and follow-up with the family, especially if the child is expected to have a long-term disabling neurologic condition.

The bedside nurse plays a critical role in the management of neonates with neurologic conditions. Specialized education will help the nurse to become expert in neurologic care. The nurse will learn to recognize signs and symptoms of injury, quickly triage patients and equipment (e.g., EEG machines and the cooling blanket) for faster care, adhere to management guidelines and anticipate next steps in care, safely transport critically ill neonates to the MR scanner, and communicate effectively with families. Other key members of the multidisciplinary team include neurophysiologists or epileptologists, neuroradiologists, developmental care practitioners, physical and occupational therapists, pharmacists, and social workers. The unit itself may be a virtual space or a specific area within the neonatal intensive care unit.

## RESUSCITATION AND SUPPORTIVE CARE TO PREVENT BRAIN INJURY

The concept of the golden hour originated in the adult trauma literature and referred to the hour between identification of the patient and admission to the emergency room. In neonates, the concept of the golden hour can be applied to guide the complex care required for all premature very low-birth-weight (<1500 g) neonates, as well as for preterm and term neonates who are born after signs of perinatal distress and in whom the initial examination demonstrates encephalopathy. During the golden hour, multiple measures are simultaneously performed to resuscitate the neonate. For preterm neonates, birth represents a period of transition that is complicated by physiologic immaturity, which results in a high-risk period for acquired brain injury. In encephalopathic neonates, end organ failure may put the neonate at risk for secondary injury as a result of inadequate brain perfusion or hypoglycemia.

After performing resuscitation guided by Neonatal Resuscitation Program (NRP) practices, care providers should apply brain protective strategies by maintaining physiologic homeostasis to help prevent secondary brain injury. Ventilation must be carefully controlled as both hypo- and hypercarbia can affect cerebral blood flow. Blood pressure should be maintained in the appropriate range for the gestational age to support cerebral blood flow as there may be poor cerebral autoregulation in critically ill and preterm neonates (Kasdorf and Perlman, 2013). Temperature stability is important: hyperthermia is associated with worse outcomes in term neonates with brain injury and hypothermia is associated with worse outcomes in preterm neonates. Finally, glucose levels need to be monitored closely to avoid hypoglycemia, as this is associated with both de novo brain injury and worse outcome in the setting of existing brain injury.

## CURRENT TREATMENT OPTIONS FOR NEONATES WITH HYPOXIC-ISCHEMIC ENCEPHALOPATHY

Neonatal encephalopathy caused by suspected or confirmed HIE is among the common diagnoses encountered in the

neurointensive care nursery (Glass et al., 2010). Therapeutic hypothermia treatment is the only clinically available neuroprotective therapy for neonatal encephalopathy secondary to perinatal asphyxia. Multiple randomized controlled trials (RCTs) have demonstrated benefit with reduction in death or disability at 18 to 24 months of age (RR 0.75, 95% CI 0.68–0.83), and sustained benefits now being observed at school age (Jacobs et al., 2013). For any one child to benefit from treatment, on average 7 (5–10) need to be treated. Therapeutic hypothermia is now accepted as the standard of care for neonates who meet criteria established by the RCTs.

Because neonates who meet criteria must be initiated on treatment within 6 hours after birth, decision making regarding whom to treat must be implemented rapidly and through coordinated efforts between the referring center and the cooling center if the child is born at a smaller center. Outreach to referring centers by a neurocritical care program will include education regarding eligibility criteria, as well as how to perform a neurologic examination to determine eligibility as soon as possible after the resuscitation. Cord gas should be obtained in any neonate with a high-risk event before delivery (e.g., uterine rupture and cord accident) or low Apgar scores. Formal neurologic examination for signs of moderate to severe encephalopathy must be performed after the resuscitation period. Abnormal aEEG background pattern or aEEG seizures can be used as additional criteria, but hypothermia should not be delayed for neonates who qualify by standard criteria. If physiologic criteria are met (i.e., Apgars, gas, and need for resuscitation) but the neonate is not encephalopathic, serial neurologic examinations over the first 6 hours after birth should be clearly documented in the medical record, and neonates who demonstrate signs of encephalopathy initiated on hypothermia as soon as possible.

Once a patient meets criteria, if not already in a center with an established hypothermia treatment program, the treating physician should consult with a hypothermia center and initiate passive cooling by removing or reducing external heat sources as soon as possible. Both animal and human studies show that earlier initiation of therapeutic hypothermia is associated with better outcomes (Gunn and Thoresen, 2006). Before implementation of a servocontrolled device for temperature control, frequent monitoring of core temperature is essential to prevent the temperature from falling rapidly below 33.0°C (which is more common in severely encephalopathic neonates), as this carries an increased risk of cardiovascular compromise. Passive cooling can be safely initiated or maintained on transport, although devices to provide servoregulated treatment during medical transport are now available and appear to effectively reduce the time to achieving therapeutic hypothermia, as well as prevent large temperature fluctuations and severe hypothermia.

In animal models, therapeutic hypothermia has limited efficacy unless the animal receives sedation. One approach is to use a morphine infusion throughout hypothermia starting at a dose of 20 mcg/kg/hr and titrating down each day by 5 to 10 mcg/kg/hr and off once cooling is complete. Shivering can be treated with magnesium boluses (to achieve high normal levels), acral warming, or additional doses of morphine or benzodiazepine.

During hypothermia, neonates should be monitored with continuous, prolonged monitoring, preferably using continuous video EEG. The risk of seizures in neonates undergoing hypothermia is approximately 50%. Clinical indicators such as resuscitation parameters and degree of encephalopathy are not associated with the risk of seizures in neonates undergoing hypothermia. However, the initial EEG background can help to stratify risk of seizures: neonates whose EEG background is abnormal at the onset of recording have the highest risk (70%

for neonates with EEG background that is excessively discontinuous, and >60% if the EEG background is severely abnormal), whereas those with normal EEG background have a lower risk (~10%). In addition to providing information regarding risk of seizures, the early EEG recording provides important prognostic information that can be used to start counseling parents regarding goals of care. Early normal or mildly abnormal EEG is associated with a good prognosis, and parents can be informed even on the first day after birth that there are no signs of severe brain injury. An early severely abnormal EEG (e.g., burst suppression, depressed and undifferentiated, extremely low voltage, or status epilepticus at the onset of recording) is associated with a poor prognosis and brain injury if it persists beyond 24 to 36 hours after birth. This information is useful for counseling families early in the course of hypothermia so that they may process the information and begin to make decisions regarding goals of care before onset of rewarming. Not all neonates who have electrographic seizures will have brain injury, and so if seizures are few, brief, focal, and easily treated with first-line medications and occur in the setting of a normal or mildly abnormal EEG, the prognosis may be good.

Neonates undergoing hypothermia should be imaged with magnetic resonance imaging (MRI) at least once before discharge because MRI is associated with developmental outcome with an accuracy of ~80% for moderate to severe abnormalities indicating death or disability (Rutherford et al., 2010). The optimal timing of imaging may depend on the experience and resources of the center; each center should aim to standardize the timing so as to become experienced with the appearance of images at a given time point. One approach is to image neonates just after cooling has ended (days 4–6). This approach has several advantages: (1) the neonate may need less or no sedation to achieve good-quality images as many remain encephalopathic because of brain injury and or delayed metabolism of morphine or other sedatives; (2) the MRI can serve as a good turning point between the acute phase of the admission and recovery and planning for home, and counseling regarding prognosis and follow-up care can be completed using results of the clinical examination, monitoring, and MRI results; and (3) MRI can be performed before discharge home; many neonates treated with hypothermia are ready for discharge home between 8 and 10 days after birth. Some centers prefer to complete MRI in the second week after birth (days 10–14) as there are reports of evolution of brain injury that is apparent only on a later scan and the patient may be more clinically stable at this time point, although this may require bringing the patient back for imaging after discharge. Another approach is to perform an early (days 4–6) scan and repeat imaging in the second week after birth if the results are discordant (i.e., very abnormal neurologic examination finding or difficulty establishing feeding and EEG results with a normal MRI).

Treatment of HIE in the setting of a specialized neurointensive care nursery may offer the following benefits: (1) quicker onset of cooling by an experienced team; (2) rapid, around-the-clock detection and treatment of seizures; and (3) counseling for parents by experienced physicians and nurses.

Unfortunately, hypothermia does not prevent all patients with HIE from death or developmental disabilities; the rate of such adverse outcomes was approximately 50% in the RCTs. There are multiple ongoing preclinical and clinical investigations of adjunctive treatments to hypothermia. These adjunctive agents target additional mechanistic pathways that are involved in the evolution of hypoxic-ischemic injury. Agents under investigation include erythropoietin, xenon, and melatonin (Johnston et al., 2011).

## BRAIN MONITORING AND SEIZURE MANAGEMENT

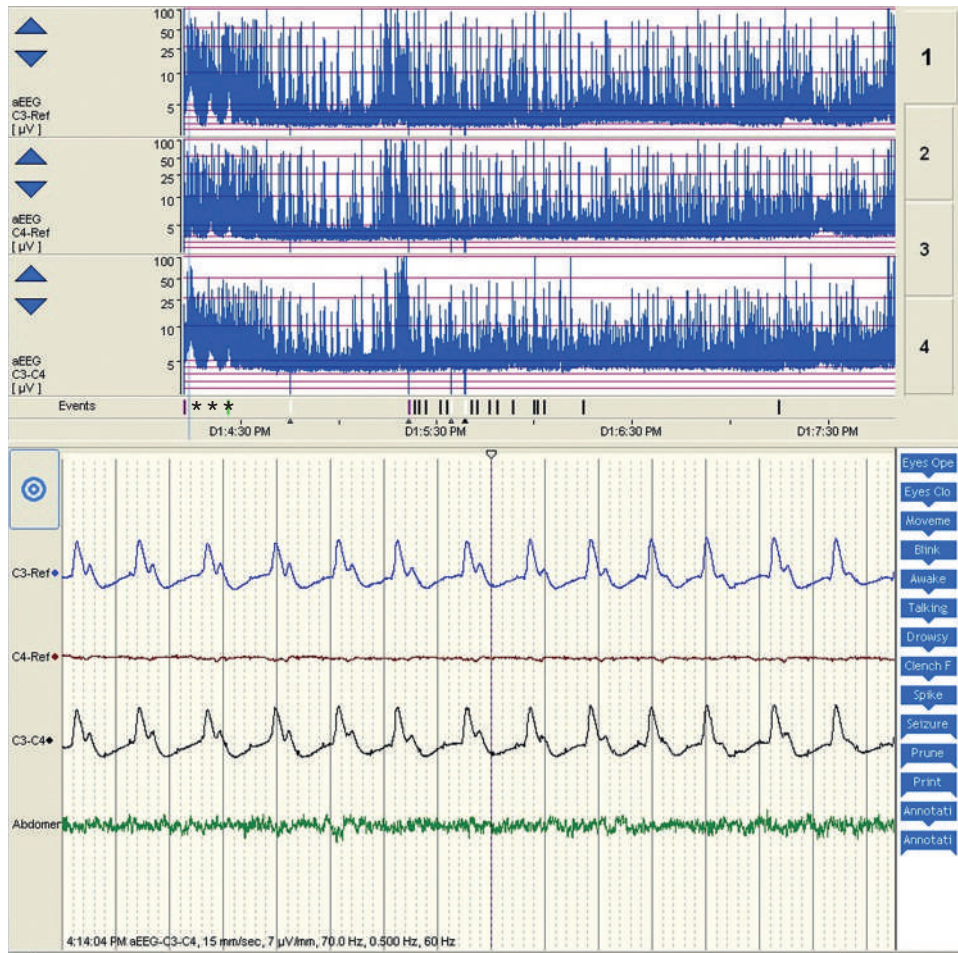

Continuous, real-time brain monitoring is increasingly used to assess background brain function and for accurate diagnosis of seizures, and is recommended for a large number of high-risk populations (Shellhaas et al., 2011). Increased use of monitoring has shown that paroxysmal events at the bedside may or may not have an electrographic correlate, and seizures without obvious clinical correlate (subclinical seizures) are common among critically ill neonates. There are three main indications for monitoring: (1) to assess the differential diagnosis of paroxysmal events (i.e., patients with one or more events that are concerning for seizure), (2) to detect seizures in selected high-risk populations (e.g., neonates with encephalopathy, neonates receiving therapeutic hypothermia, known intracranial hemorrhage or infection, and need for ECMO), and/or (3) to assess for background abnormalities in neonates who are encephalopathic.

Whereas conventional video electroencephalogram (EEG) is the gold standard for seizure diagnosis, bedside monitoring using trending algorithms such as aEEG allow the bedside providers to observe longitudinal trends in brain health, including the impact of medications and procedures, and are useful for detecting some seizures. Both conventional EEG and aEEG are useful and complementary tools, and, used concurrently (and optimally recorded on the same machine), can inform management for both bedside team and the neurologist or neurophysiologist (Glass et al., 2013).

Neurologists working in the neonatal intensive care unit (NICU) should become familiar with the advantages and limitations of aEEG, and be prepared to interpret bedside recordings (Figures 17-2 and 17-3) (Glass et al., 2013). Most pediatric neurologists will find the aEEG relatively easy to interpret, even without formal training in neonatal neurophysiology. aEEG can be very helpful for quickly visualizing changes in encephalopathy (reflected as a change in the background pattern) over time, and can also be useful for quickly identifying seizures. There is fair to good agreement between aEEG and EEG background classification in term newborns with encephalopathy. Reported seizure detection by aEEG ranges from about 25% to 85% and depends largely on the study design, population, and technique. Seizure detection is improved with training and experience, high seizure amplitude and burden, central or parietal positioning of the electrodes, multichannel recording, and use of the raw EEG trace. Like EEG, aEEG is subject to electrical and mechanical artifacts, and so the neurologist should become familiar with the appearance of common artifacts on aEEG. The primary advantage of using aEEG for seizure detection is the enhanced ability for real-time detection and treatment: at most centers, there is only one neurophysiologist available to review the EEG intermittently, whereas the aEEG displayed at the bedside can be continuously reviewed by the bedside nurse, as well as the attending neonatologists and house staff.

EEG and aEEG background patterns provide prognostic information for neonates with encephalopathy. Among neonates with encephalopathy caused by presumed hypoxic-ischemic injury who are not cooled, an abnormal aEEG background within 3 to 6 hours after birth is highly predictive of adverse neurodevelopmental outcome. Among cooled neonates, an abnormal early aEEG/EEG background has a lower specificity for adverse outcome, whereas a normal early aEEG/EEG is reassuring as it is associated with a good outcome. A persistently abnormal aEEG/EEG background at 24 to 48 hours is highly predictive of adverse neurodevelopmental outcome (Bonifacio et al., 2015).

**Figure 17-2. Seizures in a neonate with a burst suppression background.** The repetitive sudden rise in the lower margin at the beginning of the compressed aEEG trace (marked with an \*) corresponds to seizures on the raw EEG trace in the lower panel of the image. EEG, electroencephalography; aEEG, amplitude-integrated EEG.

**Figure 17-3. Status epilepticus (or saw-tooth pattern) followed by a discontinuous background pattern after treatment with phenobarbital.** A high-voltage tracing in an encephalopathic neonate should be carefully examined for repetitive seizures indicating status epilepticus.

Seizures are often the first sign of a serious neurologic condition in a neonate, and are among the most common causes for neurologic consultation by a neonatal neurocritical care service (Glass et al., 2010). Phenobarbital and phenytoin are the only drugs that have been tested in randomized neonatal trials, and both have approximately equal efficacy (~50%) as first-line treatment. Some neurologists favor levetiracetam for its low-side-effect profile; however, there are no good efficacy data to support its use. The traditional approach to seizure treatment, that is, to treat clinical events with or without confirmation of electrographic seizures and to perform brief EEGs every few days or weeks, fails to adequately treat acute symptomatic seizures in neonates. When this paradigm is used, neonates may be exposed to harmful medication by overtreatment of paroxysmal events that are not seizures, or undertreatment of seizures without clear clinical correlate, which may be missed without continuous monitoring. Recurrent seizures and status epilepticus are harder to control than isolated seizures, and so the bedside team should aim for rapid treatment. Seizure medications should be available on the unit for rapid administration that bypasses the hospital pharmacy. Having seizure guidelines for medications for treatment of acute symptomatic seizures can improve the speed of administration by limiting the need for discussion about medication choice. Drug levels are rarely helpful in the setting of acute symptomatic seizures, which should be treated before the results of a level are available. Acute symptomatic seizures in neonates follow a clear tempo, with rapid onset in the first day after birth, fluctuation in frequency, and then seizure termination by 72 to 96 hours after birth. For this reason, prolonged treatment is rarely warranted. Discontinuation of medications within 24 to 72 hours of the last electrographic seizure is safe and can reduce exposure to potentially harmful medications such as phenobarbital.

## BRAIN IMAGING

Brain imaging modalities for neonates include head ultrasonography (HUS), MRI, and computed tomography (CT). HUS is commonly utilized for first-line evaluation of neonates with suspected neurologic conditions or critical illness as it can be easily and safely performed at the bedside in most centers. In preterm neonates HUS is used to evaluate for intraventricular hemorrhages, posthemorrhagic ventricular dilatation, and hydrocephalus, and in the assessment of cystic periventricular leukomalacia. In critically ill term neonates, HUS is useful to evaluate for hemorrhage and hydrocephalus, and can be used to detect some ischemic injuries (mature ischemic stroke and global hypoxic-ischemic injuries), but its sensitivity and specificity are dependent on the timing of imaging, as well as the experience of the examiner and interpreter. In the highest risk preterm neonates (<30 weeks' gestation at birth), HUS is typically performed routinely within the first week after birth, at 3 to 7 days of age, and then serially until term-equivalent age to evaluate for changes in the white matter. Cerebellar hemorrhages are increasingly identified in preterm neonates, and are associated with adverse motor and cognitive outcomes. Large cerebellar hemorrhages can be identified with HUS using a mastoid view, but smaller hemorrhages are not apparent on HUS and, unless the neonate undergoes MRI (and especially blood-sensitive sequences with thin cuts), cerebellar hemorrhages may go undiagnosed. CT scan can be used to evaluate for neurosurgical conditions if HUS is not available, but its use is discouraged because of the poor resolution of gray and white matter pathologies and it exposes the neonate to unnecessary ionizing radiation.

MRI is the best tool to image the neonatal brain as it does not employ ionizing radiation and has high resolution for congenital and acquired abnormalities in the gray and white matter (Counsell et al., 2010). MRI can be performed safely without sedation in many children. In addition, conventional T1- and T2-weighted MRI, diffusion-weighted imaging, susceptibility-weighted imaging, and MR spectroscopy are important to identify areas of acute injury, and characteristic patterns can facilitate the diagnosis of metabolic or infectious processes. Fluid-attenuated inversion recovery (FLAIR) sequences are less useful given the high water content of the neonatal brain. All MR sequences must be optimized for newborn imaging; utilizing a stroke or seizure imaging protocol that has been defined by the MR manufacturer or by the neuroradiologist for adults or older children is inadequate. MRI is prognostic for developmental disabilities in both preterm and term neonates, and is increasingly performed before discharge from intensive care.

## PALLIATIVE CARE

Neurologic conditions that are encountered in the NICU carry high mortality (~20% compared with 7% of overall NICU admissions in one tertiary care center) (Glass et al., 2010). When a child has a neurologic condition that is not compatible with life, or is expected to develop severe and permanent developmental disabilities, in many centers, providers will offer the parents a palliative approach to care. Early predictors of adverse outcome include neurologic examination (persistent severe encephalopathy), EEG (burst suppression pattern or worse persisting 48 hours), severe seizures (status epilepticus, multifocal seizures, and seizures not responding to first- or second-line medications), and MRI (extensive injury) (Bonifacio et al., 2015). Although neonates with severe brain injury may initially be severely encephalopathic, the brainstem usually recovers and the child has eye opening and/or semipurposeful movements that do not necessarily indicate meaningful recovery. Counseling families to anticipate these changes can help build trust. Careful use of clear language can help with communication to families, including avoiding terms that are easily confused, such as "vegetative state" and especially "near brain death." Describing clinical features and ancillary testing that indicate likely adverse prognosis, as well as a range of possible outcomes, can help the family to understand what the future may hold for the child and family if the child survives.

Palliative care requires a team approach with the neonatologist, neurologist, and bedside nurse and house staff providing a consistent message to the family. Involvement of the hospital pediatric palliative care team can be helpful, especially if the infant is expected to survive for longer than a day or two. Team members who are not comfortable with palliative care can be excused from caring for the child. Burnout and compassion fatigue are common among nurses who care for a high percentage of children with adverse outcomes, and so provisions should be made to increase the pool of nurses to ensure adequate breaks for those caring for critically ill children, to provide education about common neurologic conditions such as HIE and updates on children with good outcomes, and to ensure communication between the bedside nurse and the team members so that the nurse is aware of the daily plan and plans for communication with the parents.

## Neonatal Seizures

Renée A. Shellhaas, Hannah C. Glass, and Taeun Chang

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

### INTRODUCTION

Children are at highest risk for seizures during the first month of life. Seizures in newborns are usually symptomatic of an underlying acute injury (such as hypoxic-ischemic injury or stroke) and are only rarely manifestations of epilepsy syndromes. Similar to other critically ill patient populations, most neonatal seizures are subclinical—they have no outward manifestation and are most accurately diagnosed by electroencephalography (EEG). Herein, we review the pathophysiology, epidemiology, diagnosis, treatment, and long-term implications of seizures in neonates.

### PATHOPHYSIOLOGY

The neonatal period presents the highest lifetime risk for seizures. Acute symptomatic seizures caused by birth trauma and hemorrhage, hypoxic-ischemic injury, perinatal infections, and metabolic disturbances account for more than 80% of seizures. Less commonly, congenital brain malformations, inborn errors of metabolism, and epileptic encephalopathies can present in the neonatal period with seizures as the first sign of neonatal onset epilepsy.

The immature brain is highly susceptible to acute symptomatic seizures because of age-dependent mechanisms that lead to excess excitation and reduced inhibition. Results from animal models suggest that acute symptomatic seizures are deleterious to the developing brain. In humans, seizures in the newborn period are associated with brain injury and adverse neurodevelopment. In addition, among neonates with hypoxic-ischemic encephalopathy (HIE), seizures are associated with higher lactate on magnetic resonance (MR) spectroscopy (indicating injury) and higher rates of adverse neurodevelopmental outcome that are independent of the severity of brain injury. These data suggest that seizures may also be harmful to human newborns with underlying brain injury.

### Mechanisms of Excitability in the Developing Brain

The developing brain's propensity to generate seizures is multifactorial. The primary mechanisms of inhibition (through gamma-amino-butyric acid [GABA]) and excitation (through glutamatergic system) favor excitability during the neonatal period.

GABA is the primary inhibitory mechanism of the adult brain. In mature neurons, GABA<sub>A</sub> receptor activation leads to chloride *influx* to produce membrane hyperpolarization and inhibits the neuron's ability to fire action potentials. In immature neurons, however, there is a net chloride *efflux* with GABA<sub>A</sub> receptor activation, which leads to membrane depolarization and increases the likelihood of the neuron to fire an action potential. The developmental changes in neuronal chloride gradients are mediated largely by membrane ion transporters, NKCC1 and KCC2.

In early life, a relatively higher expression of NKCC1 leads to a high intracellular chloride concentration, and subsequent depolarization upon activation of the GABA<sub>A</sub> receptor. With increasing age, the expression of the KCC2 chloride co-transporter becomes dominant, which leads neurons to display the mature pattern of low intracellular chloride and hyperpolarization with activation of the GABA<sub>A</sub> receptor. Thus GABAergic medications (such as benzodiazepines and barbiturates), which are commonly used to treat seizures in neonates, could, in theory, cause a paradoxical excitatory response. Nonetheless, the response to phenobarbital as a first-line agent is approximately 50%, which is similar to the effect of first-line agents in the pediatric intensive care unit and suggests that GABA agents are inhibitory in some populations of neurons in the neonatal period. Bumetanide, a potent diuretic that acts to alter the intracellular chloride concentration in favor of hyperpolarization, has been proposed as an adjunct to improve the efficacy of phenobarbital, but safety and efficacy data are not yet available.

Glutamate is the primary excitatory neurotransmitter. The glutamate receptors are developmentally regulated, and lead to enhanced excitability of the immature brain. N-methyl-D-aspartate (NMDA) receptors are relatively abundant in newborns, and their subunits are configured with a high level of the NR2B subunit, which leads to greater excitability through prolonged current delay and excitatory postsynaptic potentials, as well as a relative insensitivity to magnesium ions.

Finally, excitability is enhanced during the neonatal period as a result of physiologic, use-dependent synaptogenesis, when both synapse and dendritic spine density are at their peak.

### The Effect of Seizures on Early Brain Development

Seizures during early development can lead to developmental changes that alter neuronal circuitry and may impair learning and memory in animal models. Developmental alterations that have been observed in neonatal animal models after induced seizures include (1) reduced density of dendritic spines in hippocampal pyramidal neurons, (2) decreased neurogenesis, (3) delayed neuronal loss, and (4) changes in hippocampal plasticity (e.g., decreased capacity for long-term potentiation, reduced susceptibility to kindling and enhanced paired-pulse inhibition). Furthermore, in the setting of brain injury and hyperthermia, seizures can lead to hippocampal necrosis in animal models. In addition, neonatal seizures increase the susceptibility to unprovoked recurrent seizures (epilepsy) later in the animal's life (Holmes, 2009).

### EPIDEMIOLOGY

#### Incidence of Neonatal Seizures

Current estimates of the incidence of seizures in newborns range from 1 to 3.5 per 1000 live births, or approximately 14,000 newborns annually in the United States (Table 18-1).

Estimates as high as 1 per 20 have been reported for preterm or very low-birth-weight newborns, with incidence inversely related to birth weight and gestational age. Males are more often affected than females, and infants of African American origin have a higher incidence of seizures than those of other races and ethnicities. Seizures in the newborn usually occur in the first week of life (approximately 70% to 85%), particularly in the first 2 days of life.

Although seizure incidence reported in more recent studies is lower than that reported in older studies, differences in case ascertainment or study site(s) may be responsible for this variation. The true incidence of seizures in the newborn is difficult to ascertain as population studies have been based on clinically observed or reported seizure-like activity, without EEG confirmation. Newer data suggest that such case ascertainment may include infants whose events were not, in fact, seizures, while excluding those with exclusively subclinical seizures. Most studies use a case definition of seizures in infants up to 44 weeks' postmenstrual age.

Seizure duration in newborns has not commonly been examined in the published population-based studies as seizures were defined clinically and often retrospectively. Limited data suggest that, similar to EEG-based case cohort studies of newborns with seizures, 85% of seizures lasted less than 5 minutes. Though rare, 5% of affected newborns were clinically observed to have seizures lasting more than 30 minutes. Emergence of continuous prolonged video-EEG recordings with the conversion from pen-and-paper to digital EEG technology has improved our ability to capture and characterize neonatal seizures. Seizures and status epilepticus may be more common than previously realized, but most neonatal seizures remain brief with 60% lasting less than 90 seconds.

## Risk Factors for Neonatal Seizures

Risk factors for neonatal seizures are related to their long list of underlying etiologies (Table 18-2). In addition to low birth weight and gestational age, risks for seizures in a newborn include preexisting maternal diabetes, maternal fever or infection, perinatal or postnatal infection, major morbidities or surgical interventions in the infant, evidence of fetal distress, and postterm delivery. Possible risk factors also include advanced maternal age, maternal nulliparity, and male gender.

## ETIOLOGY

The causes of seizures in newborns are numerous and diverse (see Table 18-2); a single newborn can have more than one cause of seizures. Most neonatal seizure etiologies reflect underlying acute brain injury rather than epilepsy. Our ability to determine etiology has improved with enhanced access to EEG monitoring and brain magnetic resonance imaging (MRI), as well as advances in genetic testing. Determination of seizure etiology is critical, as treatment of the underlying cause may be life-saving (e.g., antibiotics for a newborn with bacterial meningitis), and combining seizure burden with etiology can assist in assessing prognosis.

Etiologies of neonatal seizures can be divided into three broad categories: (1) acute symptomatic seizures (by far the most common), (2) developmental brain abnormalities, and (3) genetic or neonatal epilepsy syndromes.

### Acute Symptomatic Seizures

*Hypoxic ischemic encephalopathy* (HIE) is the most frequent cause and accounts for up to 40% to 45% of neonatal seizures. Therapeutic hypothermia is now standard care for HIE in newborns 36 weeks' or greater gestation and EEG monitoring is recommended for cooled newborns. Prolonged continuous video EEG throughout cooling and rewarming is preferred. If continuous EEG is not available, then continuous amplitude-integrated EEG (aEEG), or daily serial routine EEGs for the first 4 days of life are suggested. Even though cooling may decrease seizure burden, about half of treated newborns still have seizures during therapeutic hypothermia. Seizure onset continues to be within the first 24 hours of life (Boylan et al., 2015).

Cerebrovascular events, including *arterial and venous infarctions and intracranial hemorrhages*, are the second most common cause of neonatal seizures (7% to 18%). Arterial ischemic perinatal strokes (AIS) occur in 1 in 2300 to 5000 live births and are typically the result of embolism from the placenta or umbilical cord, carotid artery or heart. Seizures are their most frequent presenting symptom of androgen insensitivity syndrome (AIS). Almost two thirds involve the left middle cerebral artery territory. Maternal risk factors for perinatal arterial ischemic strokes include oligohydramnios, clinical or histologic chorioamnionitis, premature rupture of membranes, preeclampsia, diabetes, and smoking. Neonatal risk factors include congenital cardiac abnormalities, systemic infections,

coagulation disorders in the infant, placental abnormalities, and male gender.

Cerebral sinovenous thrombosis (CSVT) usually involves the superior sagittal sinus and/or transverse sinus in term infants and medullary vein thrombosis in preterm infants. The incidence is 1 to 2.69 per 100,000 newborns. Venous infarction occurs in approximately 60% of reported cases. Two thirds of affected neonates present with seizures during the first week of life. Maternal, fetal, and neonatal risk factors are similar to arterial strokes. Many infants have a combination of predisposing factors, including neonatal sepsis and dehydration.

Intracranial hemorrhages can result in neonatal seizures. Diagnosis typically requires neuroimaging, and head ultrasonography and brain MRI are the preferred modalities. Computed tomography is not preferred for newborns, given the risk of radiation and lack of benefit relative to ultrasonography for identification of conditions for which neurosurgical interventions are required. Hemorrhages in term neonates may be caused by trauma, coagulopathy, or vascular malformations. Intraventricular hemorrhages (IVH) are common in preterm infants less than 30 weeks' gestation but on occasion can present in term infants with sinovenous thrombosis. IVH is the primary seizure etiology in preterm infants. Seizures are associated with IVH grade 3 or periventricular hemorrhagic infarct (IVH grade 4) and typically occur in the first 3 days of life.

Systemic or central nervous system (CNS) infections are the third most common cause of seizure in newborns (3–10%). This category includes in utero or postnatal infections, meningitis, and meningoencephalitis. Viral etiologies include herpes simplex virus (HSV), cytomegalovirus (CMV), parechovirus, lymphocytic choriomeningitis virus (LCMV), disseminated enterovirus, and parvovirus. Bacterial sources include group B streptococcus (early and late), *Escherichia coli*, and toxoplasmosis. *Lumbar puncture is recommended in all neonates with suspected infection.* Infants too unstable to undergo lumbar puncture should be treated empirically for CNS infection.

Seizures caused by primary *metabolic disturbances*, or metabolic abnormalities associated with acute medical illness, account for 3% to 7% of EEG-confirmed seizures. Such disturbances most often include abnormal glucose, calcium, or sodium levels. Typically, reversal of the abnormal level results in resolution of the neonatal seizures.

Hypoglycemia occurs in 1 to 3 out of 1000 live births. In general, hypoglycemia is defined as less than 45 mg/dL in term infants and less than 30 mg/dL in preterm infants. Risk factors include maternal diabetes, small for gestational age, in conjunction with illness, feeding issues, and/or pancreatic insulinoma. Initial treatment is to provide supplemental glucose. Antiseizure drug administration is necessary only if seizures persist despite glucose boluses. Severe hypoglycemia may result in brain parenchymal injury, which is most often localized to the posterior brain quadrants.

Hypocalcemia is the cause of 1% of all neonatal seizures. It is defined based on free ionized calcium levels rather than total serum calcium. Hypocalcemia within the first 3 days of life is associated with low-birth-weight infants, maternal diabetes, HIE, and endocrinopathies. Late-onset hypocalcemia, after 1 week of life, is now rare but is associated with maternal hyperparathyroidism or maternal vitamin D deficiency, or may be a manifestation of DiGeorge syndrome. Hypocalcemia caused by high-phosphorus-containing formulas or use of cow's milk is uncommon in the United States.

Hyponatremia or hypernatremia is seen most commonly in extremely premature infants. Among term infants, sodium imbalance can be caused by incorrect mixing, because of

incorrect mixing of formula or severe dehydration, or can be a complication of intracranial injury. Severe dehydration with hypernatremia and seizures may be associated with CSVT.

*Inborn errors of metabolism* cause 1% to 7% of neonatal seizures. Prompt diagnosis is necessary to correct the underlying metabolic disorder and minimize irreversible brain injury (Chapter 23). The presence of seizure is related to the degree of metabolic derangement and resultant injury to the brain. Seizures can be associated with urea cycle defects (hyperammonemia), organic acidurias, and aminoacidopathies (metabolic acidosis).

*Metabolic epileptic encephalopathies* are uncommon, but sometimes treatable, causes of seizures in newborns. These disorders can be divided into three broad categories: (1) disorders of neurotransmitter metabolism, (2) disorders of energy metabolism, and (3) biosynthetic defects causing brain malformation, dysfunction, and degeneration.

*Disorders of neurotransmitter metabolism* include nonketotic hyperglycinemia, pyridoxal-5'-phosphate-responsive encephalopathy, pyridoxine-dependent epilepsy (PDE), folinic acid-responsive seizures, mitochondrial glutamate transporter, aromatic amino acid decarboxylase deficiency, D-2-hydroxyglutaric aciduria, and GABA disorders.

*Nonketotic hyperglycinemia* is a defect in the glycine cleavage system. Newborns often present with apnea, hypotonia, encephalopathy, and refractory seizures. Seizures are believed to be the result of overactivation of NMDA excitatory amino acid receptors. Diagnosis is by elevated cerebrospinal fluid (CSF)-to-serum glycine ratio.

PDE is caused by a rare autosomal recessive antiquitin deficiency (*ALDH7A1* gene). The seizures rapidly respond to intravenous (IV) pyridoxine, and so a pyridoxine administration trial is warranted for newborns with unexplained treatment-resistant seizures (see [Treatment](#) section later). Folinic acid-dependent seizures are an allelic phenotype. Diagnosis is by examining alpha-amino adipic semialdehyde levels in urine, and by observation of seizure remittance with pyridoxine treatment. Pyridoxine-5'-phosphate deficiency is related to PDE, but often presents with severe epileptic encephalopathy and is responsive to oral pyridoxal phosphate and not to pyridoxine.

*Disorders of energy metabolism* include glucose transporter deficiency, pyruvate dehydrogenase deficiency, pyruvate carboxylase deficiency, biotinidase deficiency, respiratory chain disorders (Leigh disease and Alpers disease), Menkes disease, fumarate deficiency, sulfite oxidase deficiency, purine disorders, and creatine synthesis and transporter defects. *Molybdenum cofactor deficiency* and *isolated sulfite oxidase deficiency* are rare but can mimic HIE in clinical presentation.

*Biosynthetic defects* causing brain malformation and cerebral dysfunction include peroxisomal disorders, congenital disorders of glycosylation, glycolipid synthesis (GM3 synthase deficiency), cholesterol synthesis (Smith-Lemli-Opitz syndrome), serine and glutamine deficiency syndromes (rare), methylation disorders (homocysteine and folate disorders), neuronal ceroid lipofuscinosis, and lysosomal disorders. *Peroxisomal biogenesis disorders* include Zellweger syndrome, neonatal adrenoleukodystrophy, and infantile Refsum disease. Presentation includes severe encephalopathy, refractory neonatal seizures, and subtle dysmorphic features. The diagnosis is made by measurement of very long-chain fatty acids and phytanic acid.

## Developmental Brain Abnormalities

Congenital CNS abnormalities are relatively common causes of neonatal seizures (5–10%). Diagnosis requires neuroimaging, with MRI the preferred imaging modality. Recognition

and precise classification have increased with brain MR imaging. Affected newborns may have comorbid HIE as they may not tolerate labor and delivery. Common developmental brain abnormalities include focal cortical dysplasia, hemimegalencephaly, lissencephaly, heterotopias, schizencephaly, and polymicrogyria. Neonatal brain abnormalities can also be seen in patients with tuberous sclerosis. Neonatal seizures in the context of developmental brain abnormalities are associated with intractable seizures, chronic epilepsy, and poor neurodevelopmental outcome.

## Epilepsy Syndromes

Neonatal epilepsy syndromes can range from benign (seizures expected to resolve quickly and long-term neurodevelopment likely to be normal) to severe early onset epileptic encephalopathies (seizures expected to be treatment-resistant and long-term neurodevelopment likely to be abnormal).

Severe epilepsy syndromes should be suspected for neonates with no obvious acute symptomatic cause of seizures, especially if the EEG background shows burst suppression. Initial diagnostic testing should include brain MRI, often with MR spectroscopy. MRI findings may help narrow the differential diagnosis and tailor the subsequent workup. An IV pyridoxine challenge (as outlined below in the [Treatment](#) section) should be performed while serum, urine, CSF, and genetic studies are collected and processed.

Familial epilepsies include benign familial neonatal epilepsy (BFNE) and benign idiopathic neonatal seizures (BINS). BFNE is an autosomal dominant epilepsy syndrome with 85% penetrance that is related to KCNQ2 or KCNQ3 voltage-gated potassium channel mutations. Seizure onset is usually in the first week of life and the semiology is commonly focal tonic seizures. Seizures resolve spontaneously in early infancy. Infants have a normal neurologic examination, normal interictal EEG, and a family history of neonatal seizures. BINS usually occur between 4 and 6 days of life and resolve within 2 weeks, and the infant has no family history of neonatal seizures. Some affected individuals have been reported to have KCNQ2 mutations.

A more severe phenotype is also associated with KCNQ2 mutations. KCNQ2 encephalopathy presents with frequent pharmacoresistant seizures in the first week of life. Seizures often have a tonic semiology. The interictal EEG is markedly abnormal and often meets criteria for burst suppression. Brain MRI reveals subtle T1 and T2 hyperintensities in the basal ganglia and thalami—findings that may resolve after the neonatal period. Affected children typically have severe global neurodevelopmental disabilities.

There are two classic neonatal epileptic encephalopathy syndromes ([Beal et al., 2012](#)). *Early myoclonic encephalopathy (EME)* has neonatal onset with erratic focal myoclonic jerks, often accompanied by focal seizures and occasionally by tonic seizures. The typical interictal EEG shows a burst-suppression pattern during sleep. Later, the EEG evolves into atypical hypsarrhythmia or multifocal sharp waves or spikes. EME is typically caused by metabolic disorders, such as nonketotic hyperglycinemia, pyridoxine dependency, and propionic aciduria; molybdenum cofactor deficiency; sulfite oxidase deficiency; Menkes disease; and Zellweger syndrome. *Ohtahara syndrome* presents with frequent tonic spasms in newborns or young infants. It is associated with a burst-suppression EEG pattern during *both* the awake and sleep states, along with severe encephalopathy and treatment-resistant epilepsy. Causes typically include structural brain abnormalities (cerebral dysgenesis, porencephaly, hemimegalencephaly, and Aicardi syndrome) and monogenic mutations (e.g., ARX, SLC25A22, PLC $\beta$ 1, and PNKP).

## DIAGNOSIS

Traditionally, neonatal seizures were diagnosed by clinical observation, with their semiology categorized according to the motor manifestations—focal clonic, multifocal clonic, generalized tonic, myoclonic, and subtle. The “subtle” semiology refers to seizures with signs such as abnormal eye movements, lip smacking, swimming or pedaling movements, or apnea.

Although classic research relied on recognition of clinical signs for the diagnosis of neonatal seizures, modern EEG data have demonstrated that not all clinically suspicious events are epileptic seizures—indeed, most are not. In one study, bedside clinicians (nurses and physicians) were trained to record any events that were suspicious for seizures for a sample of high-risk neonates who were undergoing conventional EEG recording. Only 9% (48 of 526) of all EEG-confirmed seizures had clinical signs that were noted in the bedside logs, whereas 78% (129 of 177) of the abnormal paroxysmal events documented by NICU staff had no EEG correlate (i.e., the events were not seizures) ([Murray et al., 2008](#)).

Imprecise seizure diagnosis has significant consequences: newborns with primarily subclinical seizures may be undertreated, whereas many infants whose paroxysmal events are, in fact, not caused by seizures, may be exposed unnecessarily to potentially detrimental anticonvulsant medications.

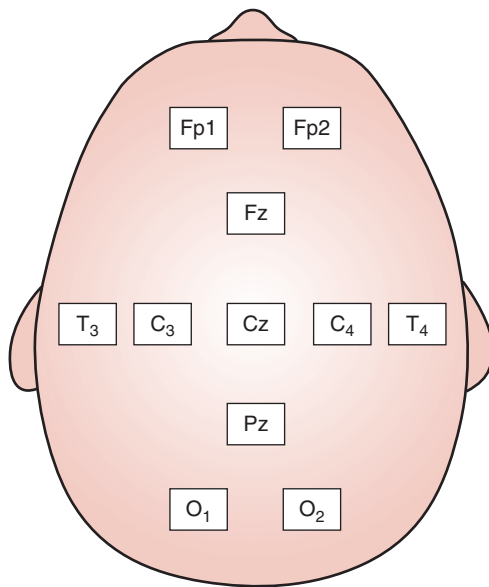

Although some neonatal seizures have associated clinical signs, multiple studies of critically ill newborns have highlighted the fact that most neonatal seizures are subclinical. Subclinical seizures have no outward manifestation, and are therefore only detectable with EEG. That most neonatal seizures are subclinical should not be surprising. Preverbal children cannot communicate their experiences of sensory phenomena caused by seizures (e.g., visual changes associated with occipital seizures, or déjà vu because of temporal lobe seizures), and unless the seizure originates from, or propagates to, the motor cortex, there will be no abnormal movements. Isolated paroxysmal changes in blood pressure or heart rate, without other associated clinical signs, often raise concern for seizures in high-risk newborns, but these events are rarely because of seizures. Even neonates who present with clinically apparent seizure semiologies often experience electroclinical dissociation when medication is administered (e.g., EEG seizures persist even after resolution of the clinical signs).

Because clinical signs of neonatal seizures are uncommon and difficult to identify, EEG monitoring is required for precise diagnosis of paroxysmal events and for quantification of seizure burden. Neonatal seizures are most properly defined by their EEG patterns and they need not have a clinical semiology. A seizure is an abnormal EEG pattern that evolves, is of greater than 2- $\mu$ V amplitude, and has a duration of 10 seconds or greater (Figure 18-1). Distinct seizures are separated by a 10-second or greater seizure-free interval. It is very uncommon for individual neonatal seizures to be more than a few minutes in duration, but the seizures are often very frequent. Therefore neonatal status epilepticus is defined as seizures that occupy more than 50% of any 1-hour EEG epoch (e.g., a newborn with 30 1-minute seizures in an hour would meet criteria for status epilepticus, as would an infant with a single seizure that lasts 30 minutes or greater) ([Tsuchida et al., 2013](#)).

## Neonatal Electroencephalogram Monitoring

### Conventional Video Electroencephalogram

Video EEG monitoring remains the gold standard for neonatal seizure detection and is indispensable for research studies that

**Figure 18-2.** The international 10–20 system for electroencephalography electrode placement, modified for neonates, includes the electrode positions indicated by the boxes. By convention, the odd and even numbers designate the left and right sides of the head, respectively, and “z” labels the midline positions. Additional extracerebral channels, including respiratory and electrocardiogram tracings, are also necessary to exclude artifact and determine behavioral state. Extraocular and surface electromyography leads are often useful, but not always required.

attempt to quantify seizure burden and/or treatment responses. Standard electrode positions, using the international 10–20 system, modified for neonates are recommended (Figure 18-2). In addition to the scalp electrodes, extracerebral leads for respiratory and electrocardiogram recording are required for accurate evaluation of behavioral state and exclusion of extracerebral artifacts. Time-locked video monitoring is highly recommended during the EEG recording to assist in the differential diagnosis of abnormal paroxysmal events. Video is critical to distinguish sources of artifact, such as handling or patting the infant, or electronic interference from intensive care unit (ICU) equipment. Surface electromyography and extraocularography leads are often utilized, but these are not mandatory. A bedside observer (typically the bedside nurse) is also important, as this person can press a patient event marker, or enter information directly onto the digital file through a bedside computer, to alert the neurophysiologist to clinically important events, such as the occurrence of target paroxysmal events or administration of neuroactive medications. Minimum standards for neonatal EEG recording have been defined by the American Clinical Neurophysiology Society.

### Indications for Electroencephalogram Monitoring

Not every sick newborn requires EEG monitoring. Rather, this resource-intensive monitoring should be targeted at those at highest risk for seizures. In general, consideration for EEG monitoring is recommended for neonates with paroxysmal clinical events that are suspicious for seizures, as well as those with proven or suspected acute brain injury and clinical encephalopathy. The American Clinical Neurophysiology Society also provides guidelines on selection of newborns for EEG monitoring (Shellhaas et al., 2011).

### Duration of EEG Recording

A routine-length, 60-minute, neonatal EEG is inadequate to screen for neonatal seizures. High-risk newborns should ideally be monitored with at least 24 hours of conventional EEG if seizures are suspected, because nearly all neonates with seizures will be identified within 24 hours of monitoring. If seizures are identified, experts suggest that they be monitored with EEG until the infant is seizure-free for at least 24 hours. In some circumstances this duration of monitoring is not feasible, or is not in the infant’s best interests (e.g., an infant with a severe neonatal epilepsy syndrome might not be expected to remain seizure-free, or monitoring might be appropriately suspended to allow for neuroimaging).

A 60-minute routine-length neonatal EEG is typically sufficient to assess the EEG background, which might be of interest as a marker of prognosis or as an adjunctive tool for estimating gestational age. The suggested 60-minute duration is longer than routine-length EEGs for older infants or children, because it is imperative that all behavioral states be recorded. It is not unusual for a newborn to have a relatively normal awake EEG background but have clinically significant abnormalities detected during quiet sleep.

If EEG monitoring is initiated in order to clarify whether a newborn’s paroxysmal clinical events are caused by seizures, then the EEG should be recorded until several typical episodes are captured. If the EEG background is stable and the target events are not seizures, then monitoring for this purpose can be terminated.

As discussed under the Acute Symptomatic Seizures sub-heading, HIE is the most common etiology of neonatal seizures. These newborns are now treated with therapeutic hypothermia for neuroprotection. Since at least half of neonates treated with therapeutic hypothermia for HIE have EEG-confirmed seizures, many neonatal neurointensive care programs recommend that EEG monitoring continue throughout cooling and rewarming. EEG background patterns and their prognostic significance are altered by therapeutic hypothermia. Sleep-wake cycling, for example, emerges later in infants who are cooled than those who do not receive therapeutic hypothermia, and not all neonates with a suppressed EEG background in the first day of life will have a poor prognosis. Despite therapeutic hypothermia, severe interictal EEG abnormalities, especially burst suppression, remain ominous if they persist beyond 24 to 30 hours of life.

Because conventional EEG monitoring is resource-intensive and requires specialized equipment, available technologists, and trained electroencephalographers, a reduced-montage EEG has gained popularity in many Neonatal Intensive Care Units (NICUs). aEEG is a simplified trend monitor that displays one or two channels of time-compressed, processed EEG signal on a semilogarithmic scale. Interpretation of the aEEG signal is enhanced by concurrent display of the raw single or multichannel EEG. aEEG background patterns have predictive value for neonates with HIE and other causes of encephalopathy. The use of aEEG for seizure detection is controversial, as this tool is specific but not sensitive in this capacity. There is substantial variability in the reported sensitivity of aEEG for seizure detection (usually 25–35%, but occasionally reported 85% sensitivity for individual seizure detection).

### Diagnostic Considerations for Neonates with Seizures

If the diagnosis of neonatal seizures is being entertained, a complete evaluation for the etiology is warranted (Figures 18-3 and 18-4). The great majority of neonatal seizures are acute symptomatic manifestations of brain injury and many

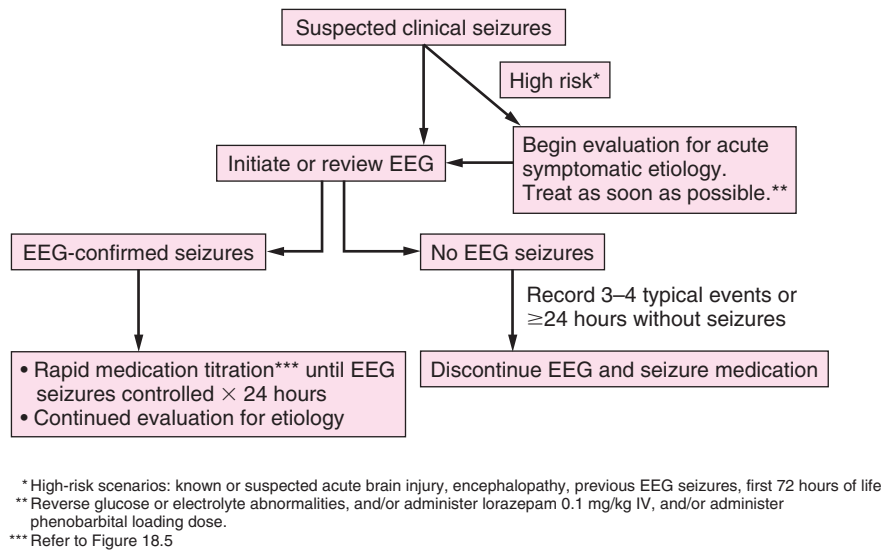

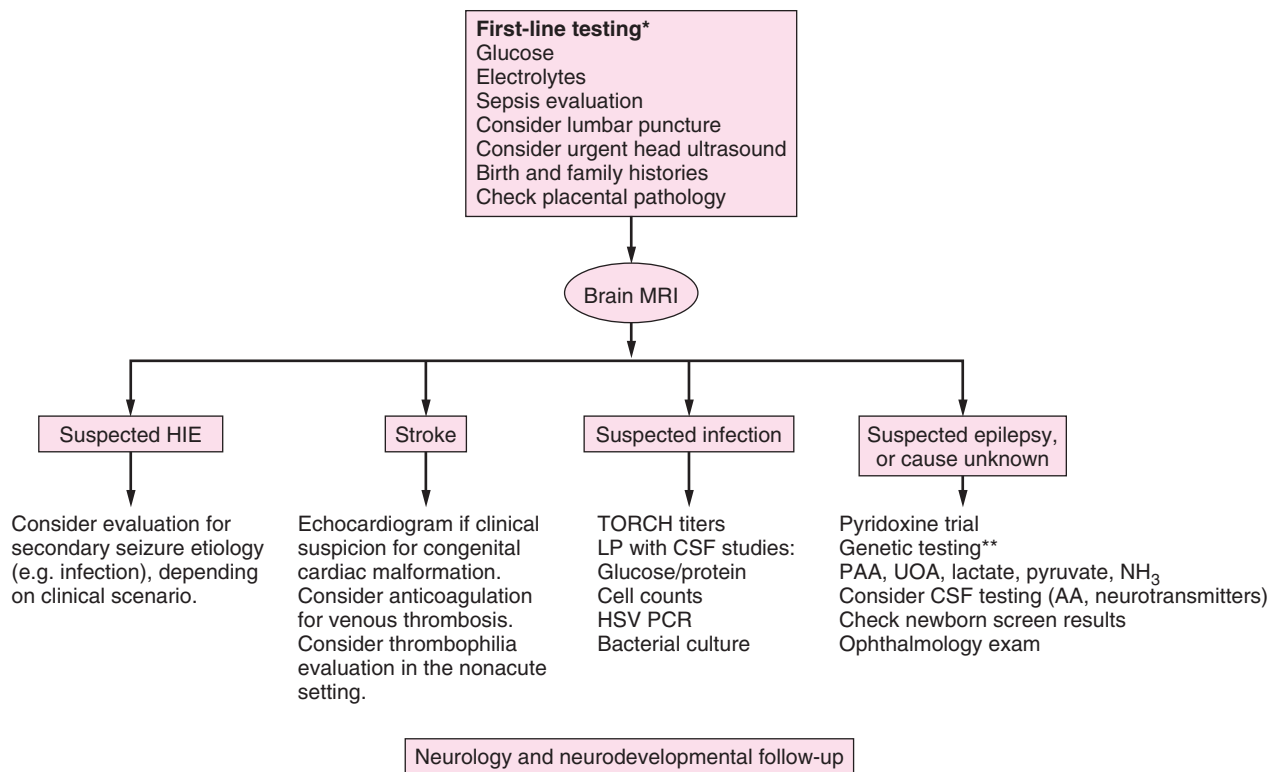

Figure 18-3. Assessment algorithm for newborns with suspected seizures.

\*\*Genetic testing can include: karyotype, chromosomal microarray, epilepsy gene panel, or single gene testing.

Figure 18-4. Assessment algorithm for newborns with seizures. First-line testing should occur simultaneously with initiation of electroencephalography (and empiric seizure treatment in high-risk clinical scenarios). Most infants should receive neuroimaging, and brain magnetic resonance imaging (MRI) is the preferred neuroimaging modality. Second-line testing depends on the clinical scenario and MRI findings. Newborns with seizures are at high risk for long-term neurodevelopmental disability and epilepsy, and so they require careful follow-up by appropriate clinicians.

require urgent, specific treatment. This diagnostic evaluation should occur in tandem with treatment of seizures. Glucose and electrolyte levels should be measured and any abnormality corrected emergently. A full sepsis evaluation, including cultures of blood, urine, and CSF, is strongly recommended (unless the infant is too unstable to undergo a lumbar puncture or a definite alternative diagnosis is made). Empiric

antibiotics should usually be administered until the cultures are negative.

In most hospitals and emergency departments, it is straightforward to obtain a head ultrasound. Despite its low resolution, cranial ultrasonography can be used to screen for obvious hydrocephalus or intracranial hemorrhage. Computed tomography is usually avoided in neonates, because of the concern

about radiation exposure. Rather, MRI is the standard neuroimaging modality for neonates with seizures. If arterial ischemic stroke or vascular malformations are suspected, MR angiogram is recommended. If a venous sinus thrombosis is suspected (e.g., in a term neonate with intraventricular or thalamic hemorrhage), MR venogram may be diagnostic and concurrent MRI may reveal venous strokes.

The maternal and family history must be reviewed. The use of maternal selective serotonin reuptake inhibitors (SSRI) in the third trimester is a common cause of abnormal movements during the first 12 hours of life, but these are usually not seizures. Serotonin-norepinephrine reuptake inhibitors (SNRI) withdrawal may be associated with electroclinical seizures starting in the first 3 days of life. Even if withdrawal from SSRIs, SNRIs, or drugs of abuse is suspected, other serious causes of seizure should be ruled out. Although seizures can occur in the setting of withdrawal from prescribed or illicit drugs used during pregnancy, and neonatal abstinence syndrome incidence is rising, most affected newborns do not have seizures. Convulsions or other abnormal movements *without electrographic correlate* need not be treated with seizure medications. Family history may reveal BFNE as the likely cause in an otherwise well-appearing infant.

Further diagnostic testing depends on the clinical scenario. If the evaluation for infection is negative and there is no other immediately obvious cause of seizures after MRI and basic metabolic workup, then testing for inborn errors of metabolism is reasonable for newborns with abnormal neurologic examinations and pharmacoresistant seizures. This testing may include measurement of lactate, pyruvate, ammonia, plasma amino acids, urine organic acids, and sometime advanced testing of the CSF. If the infant has congenital anomalies and/or dysmorphic features, or if a neonatal epilepsy syndrome is suspected, genetic testing and consultation should be considered. Single-gene testing is occasionally helpful, but clinical availability of early onset epilepsy gene panels is improving and may be more cost-effective. Chromosomal microarray may also reveal clinically significant abnormalities.

## TREATMENT

### Acute Treatment

Because new-onset seizures in a neonate often reflect a serious underlying neurologic condition, they should be treated as a medical emergency. Once the bedside clinician has established that the vital signs are stable and taken note of the clinical manifestations of a suspected seizure, glucose must be checked immediately and electrolytes (including calcium and magnesium) drawn to rule out rapidly treatable causes of seizures. Video EEG should be initiated as soon as possible to confirm that clinical events have an electrographic correlate. If infection is suspected, appropriate cultures should be drawn and treatment initiated, including acyclovir for herpes simplex virus and broad spectrum antibiotics for a suspected bacterial infection.

### Treatment of Acute Symptomatic Seizures

Treatment with antiseizure medications should be initiated as soon as possible once electrographic seizures are confirmed (or immediately in a patient with a high-risk condition such as HIE, acute intracranial hemorrhage, or clonic motor hemiconvulsions indicating a likely stroke; see Figure 18-3). Medication should be administered in adequate bolus doses titrated to abolish electrographic seizures (including electrographic seizures without clinical correlate) as quickly as possible (Figure 18-5) (Hellström-Westas et al., 2015).

Few data from clinical trials are available to guide anticonvulsant management decisions. A suggested treatment algorithm is presented in Figure 18-5. According to international surveys, phenobarbital remains the most commonly used agent for first-line treatment of seizures in newborn infants. Seizures are controlled in roughly half of patients after a single phenobarbital loading dose of 20 mg/kg (Painter et al., 1999). Phenytoin (or, preferably, IV fosphenytoin in the acute setting) has similar efficacy to phenobarbital when used at a loading dose of 20 mg/kg, but maintenance dosing—particularly with oral administration—is challenging in neonates because of less predictable absorption and pharmacokinetics than phenobarbital. Levetiracetam is increasingly used in spite of limited safety and efficacy data. Initial pharmacokinetic data suggest use of a levetiracetam loading dose (40 mg/kg) followed by maintenance dosing (10 mg/kg/dose or greater administered every 8 hours) may be considered.

If seizures are not controlled after repeated loading doses of standard medications, infusions are sometimes indicated. Midazolam infusion is an alternative or add-on agent in refractory cases in the setting of acute brain injury and status epilepticus. Lidocaine infusions can be used for refractory acute symptomatic neonatal seizures. Note that lidocaine is contraindicated for neonates with congenital heart disease and for those who have previously been treated with phenytoin/fosphenytoin, because of the risk of arrhythmia. Additionally, lidocaine dosing must be adjusted for neonates treated with therapeutic hypothermia (phenobarbital dosing does not need to be adjusted).

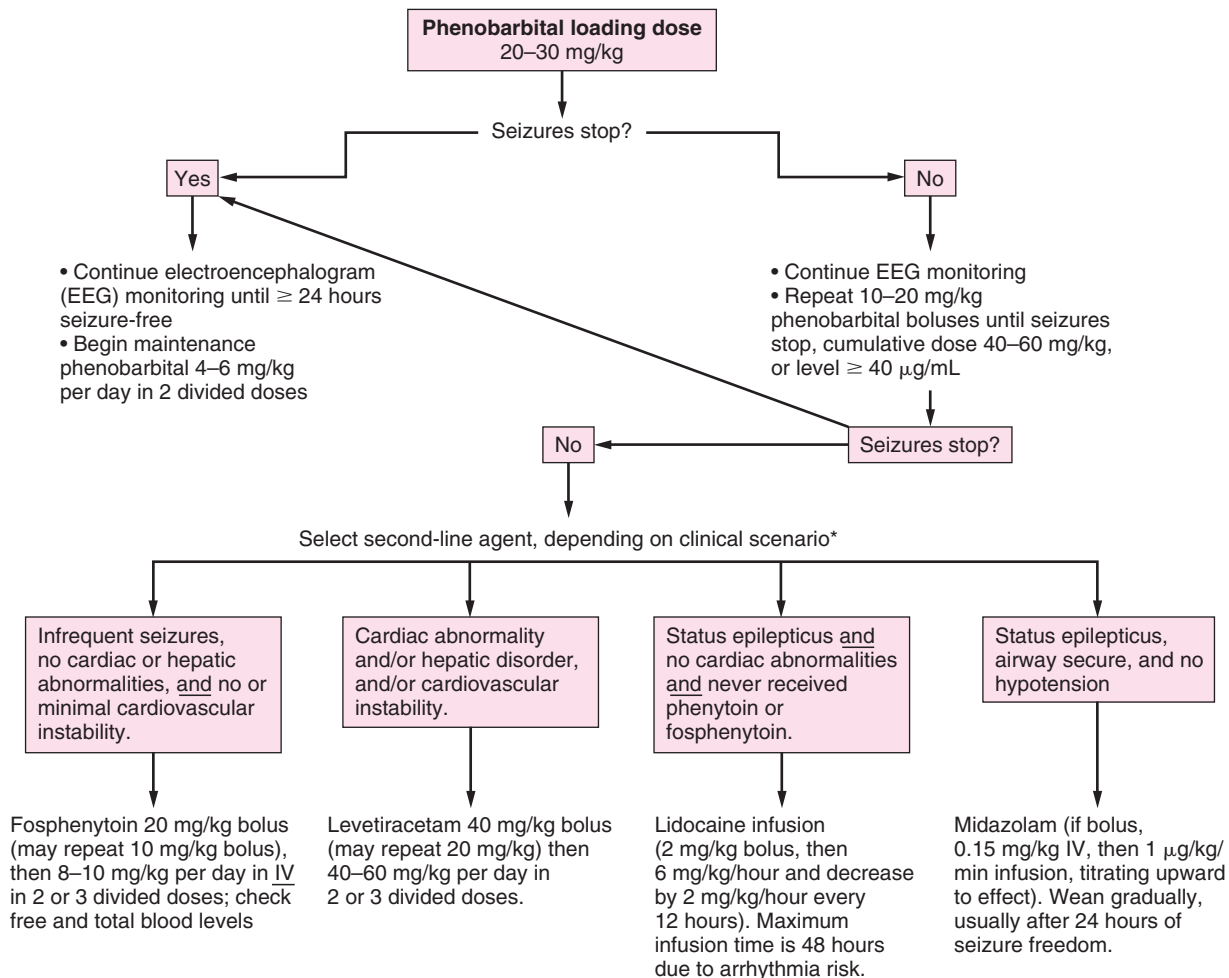

Maintenance anticonvulsant medication dosing should be initiated for neonates who have confirmed electrographic seizures. For newborns with clinical events without proven electrographic seizures, maintenance dosing may be discontinued and the EEG reviewed frequently to ensure that the neonate does not subsequently develop electrographic seizures.

### Discontinuation of Medication for Acute Symptomatic Seizures

Acute symptomatic seizures typically arise within the first 24 to 48 hours of life, after which there is a short period of high seizure burden, followed by a longer period of lower seizure burden. Overall duration of acute symptomatic seizures is typically 48 to 96 hours. Knowing the seizure tempo and careful use of video-EEG monitoring to determine when seizures arise and resolve can help guide duration of seizure medications. Because the recurrence risk in the neonatal period is low, many neonates can be safely discontinued from medications after resolution of acute symptomatic seizures. There is no need to wean medications that have been used for only a short duration (less than 1 week). If the child is to be maintained on medications, the regimen should be simplified and a plan put in place to reassess the infant after discharge from hospital so that anticonvulsants may be discontinued during the first few months of life.

### Treatment of Early Onset Epilepsy Syndromes

If the diagnostic evaluation rules out an acute symptomatic cause for neonatal seizures, early onset epilepsy should be suspected. The treatment of epilepsy in the neonatal period is different from the approach for acute symptomatic seizures. First, rapid treatment of seizures probably does not affect seizure burden or long-term outcome, and so medications should be carefully titrated to maximally tolerated doses to ensure efficacy or failure. Second, neonates with epilepsy must

\*If the infant has acute symptomatic seizures, select from these options, based on co-morbidities and seizure severity. If the newborn has epilepsy (e.g. lissencephaly, tuberous sclerosis), consider levetiracetam, topiramate, or oxcarbazepine as second- or third-line treatments.

**Figure 18-5. Suggested treatment algorithm for neonatal seizures.** The rapidity of medication administration will depend on local guidelines and resources. Frequent assessment of treatment response is recommended.

continue medications after discharge home, even if seizures have been controlled with medical management.

Vitamin-responsive inborn errors of metabolism may present with neonatal encephalopathy and refractory seizures, and so pharmacologic doses of pyridoxine, folic acid, and pyridoxal 5'-phosphate are indicated in this setting. Neonates with suspected PDE should be administered a trial of IV pyridoxine (100 mg IV while EEG is recording). The infant must be monitored during this trial, as apnea and bradycardia can be provoked. If there is a clear response, test urine alpha-AASA and/or plasma pipercolic acid levels and consider confirmation with ALDH7A1 mutation analysis. If there is no response to pyridoxine, a trial of pyridoxal 5'-phosphate (60 mg/kg/day divided 3 times/day for 2–3 days) and then folic acid (2.5 mg IV) may be attempted.

Carbamazepine and oxcarbazepine are effective and well tolerated for neonates with seizures caused by KCNQ2/3 mutations (either BFNE or KCNQ2 encephalopathy). If carbamazepine or oxcarbazepine is not effective, a trial of retigabine, which selectively affects the K<sup>+</sup> channel, may be worthwhile.

## OUTCOMES AFTER NEONATAL SEIZURES

Neonatal seizures are associated with an array of adverse outcomes, including intellectual disability, cerebral palsy, post-neonatal epilepsy, and death (Uria-Avellanal et al., 2013). Most often in the literature, cognitive and behavioral outcomes are not reported separately from cerebral palsy. Instead, outcomes are grouped into "favorable" (survival without impairment) or "unfavorable" (death, or intellectual disability, and/or cerebral palsy, and/or epilepsy). The risk for unfavorable outcomes related to neonatal seizures is difficult to isolate from the underlying cause of the seizures. Additionally, because many infants with neonatal seizures are critically ill, they often have multiple comorbidities that affect long-term outcomes. As an example, a newborn whose seizures are caused by HIE is at risk for impaired neurodevelopment because of the acute brain injury, as well as the seizures, but might also have neonatal sepsis or feeding problems that lead to suboptimal nutrition, all of which may elevate the risk for adverse outcomes.

## Mortality After Neonatal Seizures

Despite modern neonatal intensive care, 10% to 30% of newborns with seizures die during the neonatal period. Risk of death is higher in certain subgroups (e.g., preterm infants). Geographic variation in reported mortality may reflect cultural differences regarding decisions to withdraw intensive care for neonates with extremely poor prognosis. Among survivors of neonatal seizures, those with abnormal neurodevelopment remain at elevated risk of death throughout childhood.

## Cognitive Outcomes After Neonatal Seizures

The longest-term follow-up studies included infants with clinically diagnosed neonatal seizures. Among survivors, 40% to 50% have global developmental delays, and preterm infants are at higher risk than full-term neonates. Among neonates with HIE, a diagnosis of neonatal seizures increases the risk for developmental delays and intellectual disability, after controlling for the degree of encephalopathy. Severe seizure burden increases this risk.

## Cerebral Palsy After Neonatal Seizures

About 25% to 35% of long-term neonatal seizure survivors develop cerebral palsy. Most of those with severe cerebral palsy have comorbid global developmental delays, including intellectual disability. Among survivors of neonatal seizures, having cerebral palsy is also a significant risk factor for postneonatal epilepsy.

## Postneonatal Epilepsy

Postneonatal epilepsy—in which the acute symptomatic seizures subside, but recurrent unprovoked seizures develop later in life—affects 20% to 30% of survivors of neonatal seizures. Most often, epilepsy develops in the first few years of life. Children can have a range of epilepsy syndromes, depending on the etiology of the neonatal seizures. Most studies have not been powered to describe details of the epilepsy syndromes, but several groups have reported a 10% to 16% incidence of West syndrome after clinical neonatal seizures.

Clinical risk factors for postneonatal epilepsy include requirement of more than one medication to control the acute neonatal seizures, moderate or severe neonatal encephalopathy, abnormal neuroimaging, and low birth weight. EEG risk factors include status epilepticus, persistently abnormal interictal EEG background, multifocal (vs. focal) seizures, and ictal spread to the contralateral hemisphere.

Among people with chronic epilepsy, a history of clinical neonatal seizures is a definite risk factor for long-term non-remission of the epilepsy. By extension, because treatment-resistant epilepsy is associated with cognitive and behavioral challenges, early life seizures may predispose to long-term intellectual and behavioral difficulties.

## CONCLUSIONS

The immature brain is predisposed to seizures. Neonatal seizures usually reflect acute underlying brain injury, rather than epilepsy. Thus evaluations to confirm the diagnosis of seizures (with EEG) and to determine and treat their etiology must occur simultaneously. There are very few data from clinical trials to guide treatment decisions. Phenobarbital is the most commonly prescribed first-line agent. Controversy remains regarding the ideal duration of treatment. However, it is clear that neonatal seizures are associated with substantial risk of

mortality and of long-term neurodevelopmental disability and epilepsy. High-quality research is urgently needed in order to determine the best treatment algorithms and, ultimately, to improve long-term outcomes.

## Hypoxic-Ischemic Brain Injury in the Term Newborn

Vann Chau, Donna M. Ferriero, and Steven P. Miller

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

### SCOPE OF THE PROBLEM

Neonatal encephalopathy (NE) is a clinical syndrome characterized by “a subnormal level of consciousness or seizures, and often accompanied by difficulty with initiating and maintaining respiration and depression of tone and reflexes,” in the earliest days of life of a term newborn (Douglas-Escobar and Weiss, 2015). Hospital-based estimates note that it affects up to 6 to 8 per 1000 live births. With the increasing recognition that hypoxia-ischemia is a critical contributor to NE, therapeutic hypothermia has emerged as standard practice in the care of the term neonate with hypoxic-ischemic encephalopathy (HIE). Equally relevant is the emergence of *neonatal neurocritical care units*, which combine the synergistic expertise of neonatologists, neurologists, neuroradiologists, nursing staff, and others involved in the care of the sick neonate (Bonifacio et al., 2011).

### ETIOLOGY OF BRAIN INJURY IN THE TERM NEWBORN

There is increasing recognition that neonatal brain injury is related to antenatal, perinatal, and postnatal factors, and is not always the result of “birth asphyxia.” Many risk factors for neonatal encephalopathy are clearly prenatal. However, recent cohorts evaluated with magnetic resonance imaging (MRI) studies demonstrate that *brain injury actually happens at or near the time of birth*. The revised 2014 American College of Obstetricians and Gynecologists (ACOG) guidelines clearly articulate several pathways to NE, including proximate and distal risk factors that may occur during the prepartum, intrapartum, and postpartum periods (ACOG, 2014). More specifically, postnatal causes may account for up to 10% of neonatal encephalopathy in the *term* infant.

### CLINICAL SYNDROME AND NATURAL HISTORY

#### Clinical Syndrome

Neonatal encephalopathy is usually evidenced by alterations in alertness, tone, respiratory status, reflexes, and feeding, and seizures (Table 19-1). The severity of brain injury, reflecting the duration and magnitude of the hypoxic-ischemic insult, determines the nature of the evolution of this clinical encephalopathy. In newborns with moderate to severe encephalopathy, symptoms usually evolve over days, making *serial* detailed examinations important. As with any neurologically ill newborn, the baby’s gestational age must be considered in the interpretation of physical findings. There is a characteristic progression of signs in newborns with a severe hypoxic-ischemic insult (Table 19-2). The affected neonate exhibits a depressed level of consciousness from the very first hours of life. Periodic breathing with apnea and bradycardia often heralds this initial presentation. Hypotonia is almost universally found. In the first day of life, the pupillary response is often preserved, and abnormalities of eye movements are not detected. In severely injured newborns, seizures may be seen within 6 to 12 hours of birth. Seizures at this stage are

often subtle, manifesting as ocular movements, lip smacking, apneas, or bicycling movements of the extremities. Focal clonic seizures may also occur and often indicate focal cerebral infarction. Seizures in the term neonate with HIE can be difficult to diagnose based on clinical features alone, particularly in those with an abnormal electroencephalogram (EEG) background. Seizures continue to be common in neonates with HIE treated with hypothermia and are seen in almost one third of affected babies.

As described by Volpe, in latter hours of the first day of life, there may be a transient increase in the level of alertness that is not accompanied by other signs of neurologic improvement. This can be falsely reassuring because this apparent increase in alertness is frequently accompanied by more seizures and apnea, shrill cry, and jitteriness. With careful bedside examination, weakness in the proximal limbs and increased muscle stretch reflexes may be observed, but in the very severely injured newborn, diffuse weakness with absent movements and reflexes is common (Volpe, 2008).

By the third day of life in newborns with severe brain injury, the level of consciousness deteriorates, with manifestation of respiratory arrest and other signs of brainstem dysfunction. During this period, cerebral edema resulting from hypoxia-ischemia is maximal and can further impair cerebral blood flow secondary to increased vascular pressure. Those newborns surviving beyond the third day of life begin to show an improved alertness. Yet hypotonia and weakness in the proximal limbs, face, and bulbar musculature persist.

Documenting this clinical evolution is a critical component of the evaluation of an encephalopathic newborn. The use of a simple encephalopathy score as a bedside tool can help the clinician standardize the assessment and monitoring of encephalopathic newborns. In infants with moderate encephalopathy on the fourth day of life, those treated with hypothermia were shown to have a more favorable outcome than those receiving standard care (Azzopardi et al., 2014).

### Management of Neonatal Encephalopathy

Because many etiologies of neonatal encephalopathy have specific therapies, the clinician’s initial task is to determine the underlying etiology through careful history taking, neurologic examination, laboratory testing, and brain imaging studies. The history should elicit indicators of intrauterine distress that may have contributed to decreased placental or fetal blood flow: fetal heart tracing abnormalities, passage of meconium, or a history of a difficulty in labor or delivery. The details of the delivery-room resuscitation, medications, and ventilatory support should be noted. Laboratory tests are critical to exclude reversible causes of neonatal encephalopathy. The management of moderate or severe encephalopathy should occur in a neonatal intensive care unit, with close collaboration between the neurologist and neonatologist. Prompt consideration of the initiation of therapeutic hypothermia is critical because earlier cooling is most effective.

Immediate management requires securing an appropriate airway and maintaining adequate circulation. Ventilatory support with mechanical ventilation or continuous positive airway pressure (CPAP) is often required. Metabolic complications such as hypoglycemia, hypocalcemia, hyponatremia, and acidosis frequently accompany hypoxic-ischemic encephalopathy and should be identified and treated. Liver enzymes and serum creatinine are performed to detect injury in other end organs, and serum ammonia and lactate levels can expedite the investigation of an inborn error of metabolism. Lumbar puncture to evaluate for intracranial infections should be performed if the history is not typical for HIE or if a clinical suspicion of infection exists. If infection is suspected, ampicillin and gentamicin are started, and acyclovir is added if herpes simplex virus is a consideration. The clinician should also be vigilant to diagnose and treat postnatal sepsis given the negative association with outcomes in this population. If the history, examination, or initial laboratory investigations point to an inborn error of metabolism, early treatment is crucial, and a biochemical geneticist should be consulted. The diagnosis of a severe intracranial hemorrhage requires monitoring of platelet levels and coagulation function and should prompt consultation with a neurosurgeon. Because the clinical syndrome evolves considerably over the first 72 hours of life, management of specific complications, such as respiratory compromise or seizures, can often be anticipated.

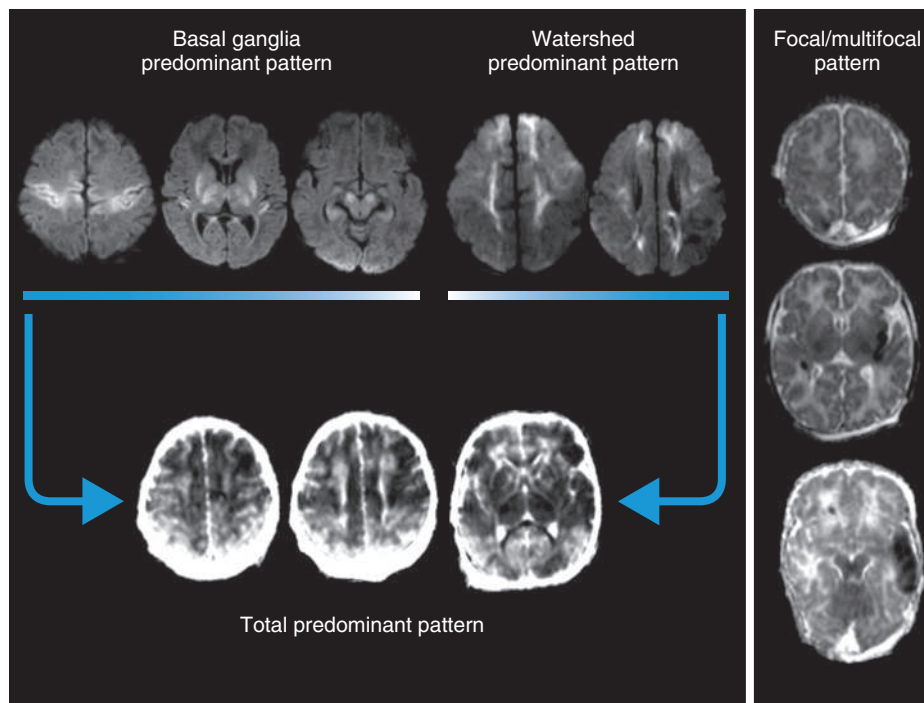

The investigation of term newborns with encephalopathy addresses three primary concerns: (1) identifying the underlying etiology, (2) determining the timing of the brain injury,

and (3) predicting the neurodevelopmental outcome of the affected newborn. Addressing these concerns is critical for the application of “neuroprotection” strategies, such as hypothermia (Papile et al., 2014). Although the severity of brain injury in term asphyxiated newborns is not reliably predicted by clinical indicators, the severity of clinical encephalopathy is a strong predictor of neurodevelopmental outcome. The risk of motor and cognitive deficits appears to be minimal in mild encephalopathy and pronounced in the severe end of the spectrum, but inconsistent in moderate encephalopathy. Newborns with moderate encephalopathy are thus the most likely to benefit from neuroimaging.

### Brain Imaging of Newborns With Encephalopathy

Brain imaging has revealed patterns of brain injury following a hypoxic-ischemic insult that are unique to the immature brain and that depend on the age at which it occurs and the severity and duration of the insult (Fig. 19-1). Neonatal brain injury evolves over days or weeks. This time course “opens the door” for therapeutic interventions, with different interventions needed in the evolution of the injury.

To confirm the diagnosis of hypoxic-ischemic brain injury and determine the extent of injury, MRI and diffusion-weighted imaging (DWI) are optimally obtained between 3 and 5 days of life in term newborns with encephalopathy. In newborns treated with hypothermia, further studies are needed to determine the *optimal* timing of MRI. Cranial ultrasound can be used for the detection of antenatal injury and severe

**Figure 19-1. Predominant patterns of brain injury in term hypoxic-ischemic encephalopathy.** **A**, Basal-ganglia-predominant pattern of injury in a newborn with perinatal asphyxia imaged on the third day of life. Brain injury is demonstrated on diffusion-weighted imaging (DWI) as areas of restricted diffusion (hyperintense, bright areas) in the motor cortex around the central sulcus, thalami, basal ganglia, optic radiations, hippocampi, and midbrain. **B**, Watershed-predominant pattern of injury in a newborn with perinatal asphyxia imaged on the third day of life. Cortical and subcortical brain injury is demonstrated on DWI in the watershed regions, affecting both the cortex and the white matter. Both the basal-nuclei-predominant and watershed-predominant patterns can lead to the total predominant pattern (**C**) if severe enough, as shown on these apparent diffusion coefficient (ADC) maps as areas of restricted diffusion (hypointense, dark areas). **D**, Multifocal white-matter injury in the periventricular and subcortical white matter in a newborn, seen as areas of restricted diffusion identified by arrows (hypointense, dark areas) on the ADC maps. **E**, Stroke: Focal infarct in the left middle cerebral artery territory in the same newborn with perinatal asphyxia, demonstrated on the ADC as an area of restricted diffusion marked by the star (hypointense, dark areas).

intracranial hemorrhage, followed by MRI for comprehensive diagnostic and prognostic evaluation.

**Advanced Magnetic Resonance Techniques.** Advanced magnetic resonance (MR) techniques, such as diffusion and spectroscopic imaging, allow for the observation of the progression of brain injury in the newborn (Counsell et al., 2014).

**Magnetic Resonance Spectroscopy.** MR spectroscopy (MRS) can be used to measure changes in certain brain metabolites from a given region of the brain. N-acetylaspartate (NAA) and lactate are the most useful in assessing brain injury. NAA is found in high concentrations in neurons, and levels increase with advancing cerebral maturity. NAA levels decrease with cerebral injury or impaired cerebral metabolism. Lactate is normally produced by astrocytes and used as fuel by neurons to replenish energy stores via oxidative phosphorylation. Lactate levels are elevated with the disturbed oxidative metabolism seen with hypoxia-ischemia. Elevated lactate and reduced NAA levels are highly predictive of neurodevelopmental outcome. Given this, lactate/NAA ratios are especially discriminatory of newborns with adverse outcomes. Myo-inositol is elevated with neonatal hypoxic-ischemic brain injury.

**Diffusion Imaging.** Diffusion-weighted MR imaging (DWI) detects alterations in free-water diffusion. Diffusion-tensor imaging (DTI) measures the amount (apparent diffusion coefficient [ADC] or average diffusivity) and the directionality of water motion (fractional anisotropy [FA]). With acute injury, intracellular water increases, and water movement is “restricted” by the cell membrane. The ADC or average diffusivity map ( $D_{av}$ ) is a quantitative water diffusion map that shows restricted diffusion as areas of diminished signal intensity. Reduced ADC values in the posterior limb of the internal capsule are associated with a greater risk of adverse neurodevelopmental outcome. FA values in the white matter and basal ganglia are decreased with significant injury during the first week of life in term newborns with encephalopathy. Therapeutic hypothermia is associated with preserved brain microstructure, particularly in the basal ganglia and thalamus. Therapeutic hypothermia modifies the significance of restricted diffusion, such that greater restriction is needed for an adverse outcome.

**Brain Perfusion.** Brain perfusion in the neonate with HIE can be quantified with MR arterial spin labeling techniques. Recent data suggest that higher perfusion values in neonates with HIE predict worse neurodevelopmental outcomes, and that therapeutic hypothermia may be less effective when hyperperfusion is found early after neonatal HIE. These MR assessments can also be complemented by bedside measures using frequency domain near-infrared spectroscopy (FDNIRS) and diffuse correlation spectroscopy (DCS) to measure cerebral hemodynamics.

### Patterns of Brain Injury

In a primate model, the distribution of injury was shown to be associated with the duration and severity of ischemia. Acute-profound asphyxia produces injury in the basal ganglia and thalamus, and partial asphyxia causes white-matter injury. Similar patterns of injury are found in term newborns following hypoxia-ischemia (Fig. 19-1). The basal-ganglia-predominant pattern involves the basal ganglia, thalamus, and perirolandic cortex. The *watershed* pattern predominantly involves the vascular watershed, from the white matter and extending to the cerebral cortex. Maximal injury in both the watershed region and basal ganglia results in the total pattern of brain injury. The predominant pattern of injury appears to be more strongly associated with neurodevelopmental

outcome than the severity of injury in any given region. The focal or multifocal pattern of injury is increasingly recognized in cohorts studied with MRI, especially with stroke or white-matter injury. Recent data suggest that strokes (arterial or venous) are also associated with neonatal encephalopathy in the term newborn. White-matter injury (WMI) is recognized in up to 23% of term newborns with encephalopathy (Fig. 19-1) and tends to be seen in infants with lower gestational age at birth, within the range of term birth. In sequential studies of term newborns with encephalopathy, delayed white-matter degeneration extending past the first week of life is also seen. This delayed white-matter injury might follow injury to the basal ganglia, just as Wallerian degeneration of the corticospinal tract degeneration is found following some middle cerebral artery strokes in the term newborn.

### Progression of Neonatal Brain Injury

Timing the onset and determining the progression of brain injury has been greatly facilitated with the use of diffusion MR techniques and MRS. Recent studies have shown that the reduction in ADC resulting from brain injury seen on diffusion imaging evolves over the initial days of life, reaching its nadir by 2 to 4 days after injury. Thus MR diffusion images obtained before the nadir may not show the full extent of injury. Importantly, diffusion abnormalities persist for 7 to 8 days in the newborn before returning toward normal values (pseudonormalization) and ultimately reflect increased diffusion with tissue degeneration. In the first 24 hours following brain injury in the term newborn, lactate increases, followed by a decrease in NAA in the 3 days following injury. In a proportion of patients, brain injury will progressively worsen over the first 2 weeks of life to involve new brain areas, particularly the white-matter tracts. The prolonged progression of neonatal brain injury is consistent with the mechanisms of cell injury that persist for days following hypoxic-ischemic brain injury in the newborn.

## OUTCOMES

The neurodevelopmental outcome following neonatal encephalopathy depends on the etiology of the encephalopathy and the pattern and severity of the brain injury. Neurodevelopmental deficits resulting from HIE typically involve motor, visual, and/or cognitive functions (Table 19-3). Both genetic and postnatal factors, such as socioeconomic factors (e.g., environmental exposures and parental education), likely modify of an individual’s neurodevelopmental outcome following neonatal brain injury. Postneonatal epilepsy is identified in up to half of the survivors of moderate to severe neonatal encephalopathy, and is particularly common in those with cerebral palsy and developmental delay.

Cognitive deficits may feature prominently following hypoxic-ischemic brain injury (Pappas et al., 2015), even in the absence of cerebral palsy, particularly with the watershed pattern of injury. The ACOG task force on neonatal encephalopathy now concludes that the outcomes following an acute intrapartum event may include cerebral palsy of the spastic quadriplegic or dyskinetic type, and other subtypes of cerebral palsy are less likely. Developmental coordination disorder, autism spectrum disorder, or specific language impairments should also be considered as possibilities in follow up of encephalopathic newborns.

### Motor Function

In term survivors of hypoxic-ischemic brain injury, the risk of cerebral palsy or severe disability may involve more than one

third of affected newborns and is most common in those with a severe encephalopathy. Spastic quadriplegia is the most common type of cerebral palsy, although athetoid or spastic hemiparesis also occur. Minor motor impairments that do not meet diagnostic criteria for cerebral palsy are diagnosed in more than one third of children with moderate encephalopathy and in more than one fourth of those with mild encephalopathy.

## Vision and Hearing

Severe visual impairment or blindness occurs in up to one fourth of children after moderate or severe encephalopathy, especially in the setting of hypoglycemia. Visual dysfunction may result from injury to the posterior visual pathway, including the primary visual cortex, resulting in cortical visual impairment. The pattern of brain injury involving the basal ganglia and thalamus is associated with deficits of visual acuity, visual field deficits, and stereopsis. Sensorineural hearing loss, likely secondary to brainstem injury, is also seen following neonatal encephalopathy, even affecting up to 18% of survivors of moderate encephalopathy without cerebral palsy.

## Cognition

Overall, cognitive deficits are seen in 30% to 50% of childhood survivors of moderate HIE. Intellectual performance in children with severe encephalopathy *without* cerebral palsy is also affected. School-age survivors of moderate neonatal encephalopathy are more likely to have difficulties with reading, spelling, and arithmetic or require additional school resources. Cognitive deficits such as those in language and memory may be seen even when IQ scores are “normal.” Behavioral difficulties such as hyperactivity and emotional problems should also be considered even in those children without motor disability.

## Outcome and Therapeutic Hypothermia

Therapeutic hypothermia, using selective head cooling or whole-body cooling, is now considered the standard of care

for infants of at least 35 weeks of gestation with moderate to severe HIE who meet inclusion criteria used in clinical trials. Therapeutic hypothermia should be continued for 72 hours, with a target rectal (or esophageal) temperature of 33°C to 34°C for whole-body cooling or 34°C to 35°C for selective head cooling. Rewarming should occur over 6 to 12 hours (0.5°C every 1-2 hours).

An initial meta-analysis clearly demonstrated that hypothermia is neuroprotective. Both mortality and disability were reduced at 18 months of age, and survival without disability was increased. Because of concerns that hypothermia may be less beneficial for infants with severe encephalopathy, further analysis showed benefits of hypothermia (death or moderate to severe disability) for both infants with moderate encephalopathy (risk ratio [RR] 0.67; 95% confidence interval [CI], 0.56-0.81) and those with severe encephalopathy (RR 0.83; 95% CI, 0.74-0.92). Survival without neurodevelopmental delay was increased (RR 1.63; 95% CI, 1.36-1.95).

Longer-term outcomes were described in two main multicenter randomized trials. The first trial found that hypothermia resulted in lower death rates and did not increase rates of severe disability among survivors. Moderate or severe disability occurred in 24 of 69 hypothermia children (35%) and 19 of 50 control children (38%) ( $P = 0.87$ ). Attentional or executive dysfunction occurred in 4% children receiving hypothermia and 13% of those receiving usual care ( $P = 0.19$ ), and visuospatial dysfunction occurred in 4% of the hypothermia group and 3% of controls ( $P = 0.80$ ). Hypothermia resulted in lower death rates and did not increase rates of severe disability among survivors. The second trial found that more children in the hypothermia group than in the control group survived without neurologic abnormalities (65 of 145 [45%] vs. 37 of 132 [28%]; relative risk, 1.60; 95% confidence interval, 1.15-2.22). Among the survivors, children in the hypothermia group had significant reductions in the risk of cerebral palsy (21% vs. 36%,  $P = 0.03$ ) and the risk of moderate or severe disability (22% vs. 37%,  $P = 0.03$ ).

## OUTCOME PREDICTION

Several authors reported the utility of evoked potentials, mainly visual evoked potentials (VEPs) and somatosensory

evoked potentials (SSEPs), in outcome prediction. Delayed latencies and absent cortical responses seem to be associated with adverse outcomes. The background of EEG and amplitude-integrated EEG (aEEG) was also found to be associated with long-term outcomes. Abnormal backgrounds (flat trace, continuous low-voltage and burst-suppression patterns) that persist beyond the first 24 hours of life seem to correlate best with outcomes.

The pattern of brain injury on neuroimaging conveys important prognostic information regarding the pattern of neurodevelopmental abnormalities. The basal ganglia pattern of injury and abnormal signal intensity in the posterior limb of the internal capsule are both predictive of severely impaired

motor and cognitive outcomes. The cognitive deficits associated with this pattern are not surprising given the common involvement of the cerebral cortex and cerebellum. In contrast, the watershed pattern is associated with cognitive impairments that are not necessarily accompanied by major motor deficits. In asphyxiated survivors without functional motor deficits, the severity of watershed-distribution injury was most strongly associated with impaired language skills. Neurologic deficits may also be found with normal brain imaging. In these patients, subtle brain injuries may only be detectable with quantitative brain imaging techniques.

The predictive values of these different tests were summarized in a recent meta-analysis (Fig. 19-2) (van Laerhoven

et al., 2013). In the era of therapeutic hypothermia, the optimal timing of these tests warrants further investigations.

## PATHOPHYSIOLOGY OF NEONATAL HYPOXIC-ISCHEMIC BRAIN INJURY AND NEUROPROTECTION

The adverse consequences of cerebral ischemia include deprivation of energy substrates and oxygen and an inability to clear potentially toxic accumulated metabolites. Although linear flow charts cannot accurately convey the complex cascade of interrelated molecular pathways that lead to hypoxic-ischemic neurodegeneration, Figure 19-3 highlights some of the critical mechanisms.

Over the past 25 years, considerable information has emerged about the cellular and molecular consequences of cerebral hypoxia-ischemia and the molecular events that lead to neuronal cell death. Despite the traditional view of greater resistance to central nervous system (CNS) injury in the neonate because of lower metabolic demands and the greater plasticity of the developing CNS, susceptibility to hypoxia-ischemia may be amplified. Specific brain structures and neural cells in the developing brain may be selectively vulnerable to hypoxic-ischemic injury. The following reviews information about the pathophysiology of hypoxic-ischemic brain injury. Several reviews can provide complementary perspectives.

### Cerebral Blood Flow and Energy Metabolism

It is widely accepted that preterm infants have a “pressure-passive” cerebral circulation; however, term infants may remain at risk for impairment of cerebrovascular autoregulation. Several basic physiologic mechanisms may contribute to impairment. Increased expression of inducible and neuronal isoforms of nitric oxide synthase (iNOS and nNOS) may narrow the autoregulatory window, and downregulation of prostaglandin receptors in response to high circulating prostaglandin levels may blunt the prostaglandin-mediated vasoconstrictive response to hypertension and thereby contribute to inappropriately increased cerebral blood flow. A recent

study found an upregulation of proangiogenic proteins in term neonates exposed to hypoxia-ischemia who do not acquire injury relative to those who develop brain injury. After an ischemic insult has occurred, the neonate remains at high risk for further damage in the acute recovery phase, because severe brain injury is often associated with major blood pressure fluctuations postnatally. However, aggressive management of blood pressure may not necessarily affect outcome because these fluctuations may also result from the brain insult and reflect the underlying severity of the brain injury.

An inadequate supply of glucose or alternate substrates plays a pivotal role in hypoxic-ischemic neuronal cell death. Although overall metabolic demands are lower in the neonatal brain than in the adult brain, metabolic needs rise during periods of rapid brain growth. The brain regions most susceptible to hypoxic-ischemic injury in the term infant (e.g., basal ganglia, thalamus) are the same regions that are most vulnerable to mitochondrial toxins. Brain development is associated with a transition from the ability to use glucose and ketones as energy substrates in the neonate to an absolute requirement for glucose in the adult. The deleterious effects of lactate accumulation after hypoxia-ischemia therefore may be attenuated in the neonate compared with the adult.

### Excitotoxicity

Glutamate can activate a variety of excitatory amino acid receptors that are broadly classified based on their selective responses to specific agonists (e.g., NMDA, AMPA, kainate) or their signaling mechanisms (i.e., ionotropic [ligand-gated ion channel] or metabotropic [G-protein coupled]). Excitatory amino acid neurotransmission plays a pivotal role in brain development and in learning and memory. A substantial body of data has emerged documenting that overactivation of excitatory amino acid receptors (i.e., excitotoxicity) contributes to neurodegeneration. Hypoxic-ischemic brain injury disrupts brain glutamate metabolism. Elevated levels of cerebrospinal fluid glutamate have been documented in infants with severe hypoxic-ischemic injury.

Two closely linked mechanisms contribute to ischemia-induced increases in synaptic glutamate: increased efflux from presynaptic nerve terminals and impaired reuptake by glia and

neurons. Any pathophysiologic process that depletes energy supply (e.g., hypoxia-ischemia, hypoglycemia, prolonged seizures) will disrupt these mechanisms and result in increased synaptic glutamate accumulation.

The structure and function of the NMDA receptor channel complex is developmentally regulated. There is compelling evidence that susceptibility to NMDA- and AMPA-mediated excitotoxicity peaks in the immature rodent and that treatment with NMDA and AMPA receptor antagonists confers robust protection against neonatal hypoxic-ischemic brain injury. However, concerns have been raised that NMDA receptor antagonists might have specific risks in the immature brain; blockade of NMDA synaptic activity could disrupt critical neurodevelopmental processes. AMPA antagonists seemingly have fewer potential risks in the immature brain than do NMDA antagonists, but negative data with the AMPA receptor antagonist, such as topiramate, showed no efficacy in a near-term sheep model of cerebral ischemia with delayed administration.

There has been considerable interest in evaluating the neuroprotective efficacy of magnesium sulfate. This interest stems from the intrinsic potentially neuroprotective properties of  $Mg^{2+}$ , including blockade of NMDA receptor activation. In experimental studies, pretreatment with magnesium sulfate was shown to limit subsequent neonatal hypoxic-ischemic injury, but treatment after hypoxia-ischemia was shown to be of limited benefit. Magnesium sulfate has been found to protect in some animal models of white-matter damage, but did not affect CSF levels of excitatory neurotransmitters in asphyxiated human neonates. However, a recent trial showed that exposure to magnesium sulfate before anticipated early preterm delivery did not reduce the combined risk of moderate or severe cerebral palsy or death, although the rate of cerebral palsy was reduced among survivors.

## Oxidative Stress

Oxidative stress describes the alterations in cellular milieu that result from an increase in free-radical production as a result of oxidative metabolism under pathologic conditions. In the brain injured by hypoxia-ischemia, excitotoxicity and oxidative stress are inextricably linked. In cells with normally functioning mitochondria, more than 80% of available oxygen is reduced to energy equivalents (ATP) by cytochrome oxidase. The rest is converted to superoxide anions that under physiologic conditions are reduced to water by enzymatic and non-enzymatic antioxidant mechanisms. An inevitable consequence of mitochondrial dysfunction is an accumulation of superoxide, and any process that depletes antioxidant defenses will result in the default conversion of superoxide to even more reactive species, such as the hydroxyl radical.

With reoxygenation, mitochondrial oxidative phosphorylation is overwhelmed, and reactive oxygen species accumulate. The immature brain is particularly susceptible to free-radical attack and lipid peroxidation. Free-radical scavengers (e.g., alpha-phenyl-n-tert-butyl-nitron [PBN], a spin-trap agent that converts free radicals to stable adducts) and metal chelators (e.g., deferoxamine) can protect neurons from injury mediated by hydrogen peroxide *in vitro* and *in vivo*. These agents also protect neurons from NMDA-induced toxicity.

Nitric oxide (produced constitutively in endothelium, astrocytes, and neurons) metabolism provides another critical link between excitotoxicity and oxidative injury in the brain with hypoxia-ischemia injury. Hypoxic-ischemic increases in nitric oxide (NO) production have multiple potential beneficial and detrimental effects. Nitric oxide regulates vascular tone, influences inflammatory responses to injury, and directly modulates NMDA receptor function. Early endothelial NO is

protective by maintaining blood flow, but early neuronal NO and late inducible NO are neurotoxic by promoting cell death.

Neuroprotection by selective inhibition of nNOS or iNOS has been demonstrated. Regions expressing nNOS correspond to those that express NMDA receptors and correlate with regions of neurotoxicity both *in vivo* and *in vitro*. Few studies have been performed in asphyxiated human newborns in relation to cerebral NO production. Initial results in premature infants treated with inhaled NO for prevention of bronchopulmonary dysplasia showed reductions in ultrasound-diagnosed brain injury and improvements in neurodevelopmental outcomes at 2 years of age; however, in a large European trial, low-dose (5 ppm) iNO started early (<24 hours after birth) for a median of 20 days did not affect neurodevelopmental or other health outcomes at 2 years of age.

Several other antioxidant strategies that either block free-radical production or increase antioxidant defenses have been studied. The most promising of the antioxidant agents appears to be melatonin, which has many targets along the injury cascade, including oxidative stress, inflammation, apoptosis, mitochondrial failure, and nuclear effect. It is a direct scavenger of reactive oxygen species (ROS) and NO. Human neonates treated with melatonin were found to have decreased proinflammatory cytokines. Allopurinol has mixed effects. Early allopurinol in asphyxiated infants improved short-term neurodevelopmental outcomes and decreased serum NO levels after administration; however, no improvement in long-term outcomes was seen for later treatment after birth asphyxia.

Independent of brain injury, oxidative stress is also linked to procedural pain. In asphyxiated term newborns, tissue-damaging procedures without treatment may be more detrimental than treatment with opioids. Compared with opioid-treated neonates, untreated infants showed more impaired brain metabolites in the basal ganglia, thalami, and occipital gray matter, suggesting a certain degree of brain protection.

## Inflammation

Perinatal brain injury activates the immune system and triggers responses that involve mediators such as cytokines and chemokines that act in concert with free radicals and NO in contributing to the excitotoxic cascade (Fig. 19-3) (Hagberg et al., 2015). Cytokines that have been strongly implicated as mediators of brain inflammation in neonates include interleukin-1b, tumor necrosis factor- $\alpha$ , interleukin-6, and membrane cofactor protein-1. Measurements of cerebrospinal fluid and plasma levels of several cytokines in asphyxiated term infants suggest that the injured brain can be the source of acutely elevated cytokine levels. A more recent study linked IL-6 with cerebral palsy, giving credence to the fact that there is an underlying genetic susceptibility in at-risk newborns.

The observed relationship between maternal infection and neonatal brain injury has been documented, but controversy still exists. In a case-control study from the Kaiser Permanente Medical Care Program, it was found that chorioamnionitis or placental infection conferred a fourfold overall risk for cerebral palsy in term infants. Neonates exposed to chorioamnionitis had a lower risk of brain injury and adverse outcomes than did newborns with sepsis. In an independent cohort of term neonates with HIE, decreased placental maturation predicted an increased risk of white-matter watershed injury, whereas chronic villitis was associated with injury to the basal ganglia and thalamus irrespective of white-matter injury.

Several compounds that block microglial activation or cytokine release, such as corticosteroids, melatonin, erythropoietin, Cox inhibitors, cromolyn, histamine receptor

blockers, N-acetyl-cysteine, etanercept, IL-1ra, and simvastatin, have shown promising neuroprotective properties.

## Cell Death

Apoptosis is critical for normal brain development, but it is also an important component of injury following neonatal HI and stroke. Activation of intrinsic or extrinsic apoptotic pathways leads to cleavage and activation of caspase 3, which is maximally produced in the neonatal period. Proapoptotic Bax is present in high concentrations during the first two postnatal weeks. Although necrosis plays a major role in early neuronal death in both the immature and mature brain, there appears to be some aspect of apoptosis within the first 24 hours following neonatal HI. It is likely that apoptosis is not the cause of most acute cell death, but rather of delayed phases of injury and neurodegeneration. This delayed apoptotic cell death likely relates to target deprivation and loss of neurotrophic support. Specific and nonspecific inhibition of caspases or cysteine proteases, which are highly activated after HI, has also been attempted, with some success. Another form of cell death recently implicated in neonatal brain injury is necroptosis, or programmed necrosis.

## OTHER NEUROPROTECTION STRATEGIES

Although neuroprotective interventions consisting of pharmacologic antagonism of glutamate, free radicals, inflammatory mediators, and apoptosis have been successful to some degree in experimental animal models of hypoxic-ischemic brain injury, none of these other strategies has been successfully translated into clinical practice (Juul and Ferriero, 2014). Even if short-term studies of newborns treated with hypothermia showed benefit, improvements in the rate of death or the occurrence of an IQ score of less than 70 at 6 to 7 years of age were not significant. Therefore combinatorial therapy may provide more long-lasting neuroprotection, salvaging the brain from severe injury and deficits while also enhancing repair and regeneration, hopefully providing additive, if not synergistic, protection.

Xenon is approved for use as a general anesthetic in Europe and has shown promise as a protective agent. It is an NMDA antagonist, preventing progression of excitotoxic damage. It appears to be superior to other NMDA antagonists, possibly through inhibition of AMPA and kainite receptors, reduction of neurotransmitter release, or effects on other ion channels, and because of its action as a preconditioning agent. Combination xenon and hypothermia initiated 4 hours after neonatal HI was shown to provide synergistic histologic and functional protection when evaluated at 30 days after injury. More recently, a study delaying both hypothermia and xenon for 5 hours after neonatal HI also showed long-term improvement into adulthood.

N-acetylcysteine (NAC) is a medication approved for neonates that is a scavenger of oxygen radicals and restores intracellular glutathione levels, attenuating reperfusion injury and decreasing inflammation and NO production. Adding NAC therapy to systemic hypothermia was shown to reduce brain volume loss at both 2 and 4 weeks after neonatal rodent HI, with increased myelin expression and improved reflexes.

## Neurotrophic Factors

Erythropoietin (EPO) is a glycoprotein that was originally identified for its role in erythropoiesis. Its functions include modulation of the inflammatory and immune responses, vasogenic and proangiogenic effects through its interaction with vascular endothelial growth factor (VEGF), and effects on

CNS development and repair. EPO plays a vital role in neural differentiation and neurogenesis early in development. Recent evidence suggests that exogenously administered EPO has a protective effect in a variety of different models of immature brain injury. Single- and multiple-dose treatment regimens of EPO following neonatal focal ischemic stroke in rats also were shown to reduce infarct volume and to improve short-term sensorimotor outcomes, but there may be more long-term behavioral benefits in female rats. EPO treatment that was delayed 24 hours after neonatal HI also was shown to attenuate brain injury. A recent trial of EPO for neonatal asphyxia showed that repeated low-dose therapy (300-500 U/kg every other day for 2 weeks) reduced the risk of disability for infants with moderate HIE, and no negative hematopoietic side effects were observed.

VEGF is a regulator of angiogenesis that also promotes neuronal cell proliferation and migration. VEGF-A expression occurs in cortical neurons during early development. Following exposure to hypoxia, there is increased neuronal and glial expression, directing vascularization and stimulating proliferation of astrocytes, microglia, and neuronal cell types. VEGF also has chemotactic effects on neurogenic zones in the brain. VEGF appears to play an essential role in the beneficial and protective effects of hypoxic preconditioning in neonatal mice.

## Stem Cells

Neural stem cells (NSCs) are multipotent precursors that self-renew and retain the ability to differentiate into a variety of neuronal and nonneuronal cell types in the CNS. They reside in neurogenic zones throughout life. In neonatal models, intraventricular implantation of NSCs after HI results in their migration to areas of injury. In both rodent and primate models, these cells were shown to promote regeneration, and nonneuronal phenotypes were shown to inhibit inflammation and scar formation while promoting angiogenesis and neuronal cell survival. Intranasal administration of BDNF-overexpressing mesenchymal cells 3 days after stroke in neonatal rats resulted in reduced gray- and white-matter loss and improved motor function at 14 days after stroke. Although no adverse effects have been noted, efficacy is dependent on time of implantation, and the therapeutic window is not known.

## HYPOXIC-ISCHEMIC BRAIN INJURY IN THE PRETERM INFANT

In preterm infants, the clinical presentation of neonatal encephalopathy is less stereotyped than in full-term newborns, making the identification of eligible candidates for therapeutic hypothermia more challenging.

Among preterm infants born at 33 to 35 weeks of gestation, 2.5% met physiologic criteria for perinatal acidosis (defined as pH < 7.0), and only 27% had neurologic signs of moderate to severe HIE on the first day of life, a proportion similar to that seen in term newborns.

In a retrospective cohort, 55 encephalopathic preterm infants were described. Placental abruption was the commonest identifiable etiology. On MRI, the main sites of injury included the basal ganglia (75%), white matter (89%), brainstem (44%), and cortex (58%). Injury in the basal ganglia was mostly severe, whereas white-matter injury was mild and diffuse. Brainstem lesions were more commonly seen with severe cases. In this series, 2-year outcomes were worse than would have been expected in term newborns. The mortality rate of 32% suggests this was a severely affected cohort. Of the survivors, 26% had cerebral palsy, with severe spastic

quadriplegia most common. Mild impairment was seen in 10%. Only 32% of the surviving children were normal. Clinical seizures preceded quadriplegic cerebral palsy and death in 65%; clinical seizures were more strongly predictive of poor outcome than was infection.

Currently, hypothermia is not recommended in the preterm population. It is thought that immature thermoregulation may predispose preterm newborns to higher risk of cold-related complications. However, studies in preterm animals demonstrated hypothermia to be safe. In a study of asphyxiated preterm sheep fetuses, exposure to prolonged head cooling was associated with significantly less loss of neurons and immature oligodendroglia. Recent studies of mild hypothermia in newborns of very low birth weight with necrotizing enterocolitis demonstrated no increase in mortality, bleeding, infection, and need of inotropes, and no alteration in clot formation. New trials are under way to study the effectiveness of therapeutic hypothermia in late-preterm infants.

## FUTURE DIRECTIONS

Sources of genetic variation that contribute to differential susceptibility to a broad range of illnesses are a subject of intense investigation. Brain imaging, and particularly advanced MRI techniques, may provide important insight into how therapeutic hypothermia operates so that its use can be optimized and synergistic therapies added. Studies are needed to determine whether applying a specific method of cooling to a defined pattern of injury will enable individualized treatment.

## INTRODUCTION

Stroke is brain injury secondary to focal disease of the cerebral vasculature. The perinatal period may be the most focused lifetime period of risk for stroke. Perinatal stroke accounts for most hemiparetic cerebral palsy, and survivors often suffer additional lifelong morbidities. Due to neuroimaging, specific perinatal stroke diseases are now definable by considering mechanism (ischemia or hemorrhage), vessels affected (arteries or veins), and timing (fetal versus neonatal). Pathophysiology remains poorly understood, but outcomes and management are increasingly defined. This chapter reviews the clinical epidemiology of each perinatal stroke disease.

## Definitions

A National Institute of Neurologic Disorders and Stroke workshop on perinatal stroke provided consensus recommendations on the definition of ischemic perinatal stroke (Raju et al., 2007). The working definition for perinatal stroke was "a group of heterogeneous conditions in which there is a focal disruption of cerebral blood flow secondary to arterial or cerebral venous thrombosis or embolization, occurring between 20 weeks of fetal life through the 28th postnatal day and confirmed by neuroimaging or neuropathology studies." This covers ischemic stroke, but here we will also include perinatal intracerebral hemorrhage (ICH).

Timing of injury cannot always accurately be determined but accepted terminologies include "perinatal" (28 weeks gestation to 7 days after birth), "neonatal" (0 to 28 days after birth), and "presumed perinatal" (presenting beyond day 28 of life). Adding consideration of mechanism (ischemia or hemorrhage) and vessels affected (arteries or veins) to these time windows defines five specific perinatal stroke diseases. Acute symptomatic perinatal arterial ischemic stroke (PAIS), the most common and well-studied, provides the template for the remaining disorders of presumed perinatal ischemic stroke (PPS), including fetal periventricular venous infarction (PVI), neonatal cerebral sinovenous thrombosis (CSVT), and perinatal intracerebral hemorrhage (ICH).

## ACUTE SYMPTOMATIC PERINATAL ARTERIAL ISCHEMIC STROKE (PAIS)

### Epidemiology

Brain infarction due to arterial occlusion occurs in 1 per 1600 to 4000 live births. The first week may carry the most focused lifetime risk for stroke. Perinatal stroke may have a male predominance. Most PAIS are large artery occlusions occurring in the middle cerebral artery (Fig. 20-1). Left-sided lesions are more common and may relate to asymmetries in hemodynamics. Lesions may occur in any arterial territory and populations of posterior cerebral artery and perforating artery PAIS are described.

## Pathophysiology and Potential Risk Factors

Many maternal, fetal, and neonatal risk factors have been associated with PAIS, but evidence for true causation is lacking in most cases (Kirton et al., 2011). Discovery of one potential factor should not lead to definitive conclusions. The best evidence comes from four published case-control studies. There is no evidence that PAIS can be anticipated or prevented. There are no modifiable factors a mother can control to prevent perinatal stroke though maternal blame and guilt appear to be common. Most studies have examined similar groups of clinical associations including maternal, antepartum, peripartum, placental, prothrombotic, cardiac, infectious, and genetic factors.

Placental disorders are a suspicious but unproven cause of PAIS. Multiple factors support placental involvement including lack of recurrence and multifocal lesions in 20% to 30% suggesting proximal embolization. Placentas are often discarded before diagnosis but pathological studies support and association with multiple placental disorders including chorioamnionitis, fetal thrombotic vasculopathy, and villitis of unknown etiology. Thrombosis is common in placental disease and strokes are common in fetal thrombotic vasculopathy. Placental disease should be highly considered with tissue pathology acquired when possible.

Maternal and antepartum factors include primiparity and maternal history of infertility. Maternal smoking during pregnancy has been identified as an independent risk factor in one study. The role of other modifiable maternal factors such as nutrition, medications, and substance abuse, remains undetermined. Preeclampsia has been independently associated with PAIS, but evidence for other common disorders such as oligohydramnios and gestational diabetes has been limited. Complicated labor and delivery are more common in PAIS but do not imply causation. Neonatal encephalopathy and global hypoxic-ischemic encephalopathy may occur with PAIS and may reflect common pathogenesis. Many peripartum factors have been inconsistently associated with PAIS including prolonged second stage, prolonged rupture of membranes, maternal fever, meconium-stained amniotic fluid, 5 minute APGAR scores less than 7, cord abnormalities, and the need for intervention during delivery. A relationship with both large and small birth weight has been suggested.

Prothrombotic factors have been associated with PAIS though estimates vary widely. Studies have been limited by variable disease classification, laboratory methods, and age at testing. A meta-analysis including perinatal stroke populations described consistent associations with protein C deficiency, elevated lipoprotein a, factor V Leiden, and prothrombin 20210 mutation (Kenet et al., 2010). Other large studies specific to PAIS have found little or minimal evidence of thrombophilia. Other factors are increasingly disproven such as antiphospholipid antibodies and MTHFR mutations.

Maternal thrombophilia is poorly studied but may also play a role. Evaluation for thrombophilia is complicated in

**Figure 20-1. Acute Symptomatic Perinatal Arterial Ischemic Stroke (PAIS).** Main branch left middle cerebral artery infarct in a term infant with hemiconvulsions. **A, B,** T2 weighted spin echo sequence (T2SE) (TR/TE = 7650/150). **C, D,** Diffusion-weighted images ( $b = 800$ ). Involvement of basal ganglia and cerebral peduncle is best appreciated with DWI.

the newborn, and whether such testing should be deferred to a later age or done at all remains controversial. Complex congenital heart disease is associated with 15% to 20% of PAIS cases with specific treatment implications. Arterial stroke was found in nearly 40% of infants preceding congenital heart disease repair. Certain procedures further increase the risk. Evaluation including echocardiography is indicated in acute PAIS though yield may be low when examination is normal.

Perinatal infection has been well associated with both arterial and venous perinatal stroke.

Neonatal sepsis and bacterial meningitis carry high risk with specific patterns of injury. Maternal fever alone has been independently associated with PAIS. Placental infection is a highly suspicious PAIS mechanism. With readily available treatments, most acute PAIS will be investigated and treated empirically for bacterial infection. Familial recurrence of PAIS is uncommon, but genetic mechanisms may contribute. Single gene mutations such as *COL4A1* are increasingly linked to perinatal stroke (see Fig. 20-7). A case-control study of candidate polymorphisms, involving thrombosis, cytokine, vascular, and cell adhesion function, was negative. Unique risk factors may be present in preterm infants with PAIS, including twin-to-twin transfusion syndrome and hypoglycemia.

## Clinical Presentation

Recognition and diagnosis of acute symptomatic PAIS is usually not complicated. Most neonates present with seizures during the first 72 hours of life. Infants are often initially well, staying with their mother on the ward. Seizures that are focal and present at later than 12 hours of age are clinical predictors of PAIS. Focal neurologic signs such as hemiparesis are rarely seen. Other clinical signs include poor feeding, decreased level of consciousness, hypotonia, and apnea. Preterm PAIS presents with similar signs. Perforator artery PAIS may be less likely to have a typical presentation.

## Diagnosis: Neuroimaging

PAIS is a clinical and neuroradiographic diagnosis. Cranial ultrasound is often the first investigation but is relatively insensitive and nonspecific. Ultrasound can reveal a wedge-shaped area of increased echogenicity within the middle cerebral artery territory diagnostic of PAIS. A CT scan of the head can exclude hemorrhage and accurately diagnose PAIS with hypodensity within an arterial territory but has limited sensitivity and includes radiation.

Modern neuroimaging with MRI has enhanced the detection and classification of perinatal stroke. MRI with diffusion-weighted imaging (DWI) is sensitive and specific and should be performed in any newborn with focal seizures. DWI quickly confirms recent (within days), acute, focal brain infarction with restricted diffusion in an arterial territory (see Fig. 20-1). Most PAIS are large, middle cerebral artery occlusions with combined cortical and subcortical injuries. Multifocal or bilateral lesions are present in up to 30% of cases, suggesting a proximal embolic source. Acute DWI changes may extend to other brain structures connected to a stroke. Restricted diffusion down the corticospinal tract is associated with poor motor outcome (hemiparetic cerebral palsy) (see Fig. 20-1). Hemorrhagic transformation of PAIS may be detected with blood-sensitive MRI. Neuroimaging in PAIS should include assessment of the cerebral vasculature. MR angiography (MRA) of the head and neck may demonstrate focal arterial occlusions. Simple division of lesions by level of middle cerebral artery occlusion may help predict neurologic outcome. For example, proximal M1 middle cerebral artery PAIS includes the lateral lenticulostriate arteries, resulting in infarction of the basal ganglia as well as distal major territories of the frontal, parietal, and temporal lobes. Such main branch involvement is less common in preterm infants. Advanced MRI techniques such as diffusion tensor imaging may also help predict early pathway injury and functional outcomes. Chronic versions of these and other advanced neuroimaging methods such as volumetrics, voxel-based lesion symptom mapping, functional MRI, resting-state functional MRI, and noninvasive brain stimulation are advancing the understanding of developmental plasticity after perinatal stroke with implications for rehabilitation (see later in this chapter).

## Acute Management

Evidence-based management strategies for PAIS are limited within published consensus-based guidelines. Neuroprotective approaches are based on first principles and extrapolation of animal models, adult stroke studies, and neonatal hypoxic-ischemic encephalopathy.

Examples include maintenance of normal blood sugar, ventilation/oxygenation, blood pressure, and temperature. Hyperthermia worsens neonatal ischemic brain injury in animal models and although hypothermia has not been studied in human perinatal stroke, sources of fever should be sought and treated. Consensus guidelines only recommend administration of unfractionated or low molecular weight heparin in neonates with ongoing cardioembolic risk. Thrombolytic agents are not recommended. Evidence from perinatal stroke animal models has advanced the first neuroprotective trials of erythropoietin in PAIS in which early trials are establishing safety data to advance further studies. Continuous or amplitude-integrated EEG may be helpful for recognizing and treating neonatal seizures as they are often subclinical. Prompt recognition and treatment of seizures may prevent secondary brain injury although the ideal agents and duration of treatment have not been established. Acute seizures typically cease within days, suggesting that long-term anticonvulsants are usually not required. Additional investigational considerations relate to possible risk factors and include exclusion of infection, cardiac evaluations, including echocardiography, and placental pathology when possible.

## Outcomes and Rehabilitation

Most survivors of perinatal stroke suffer lifelong neurologic disability (Kirton et al., 2013). Deficits span all areas of

development and function, affecting both child and family. Motor deficits and cerebral palsy predominate, but disorders of sensation, language, cognition, epilepsy, behavior, and mental health are common. Evidence-based rehabilitation strategies are limited but increasing. With most knowledge of outcomes and their management arising from the PAIS literature, the major morbidities and relevant rehabilitation strategies are reviewed here in detail. Outcomes and management are similar in the remaining perinatal stroke diseases that follow in which specific differences are highlighted.

Recovery from early injury to the immature brain is a complex process that occurs continually across development. Outcomes from perinatal stroke and the factors that determine them differ from those of older children or adults with stroke. It is erroneous to assume that the potentially increased plasticity of the very young brain portends better outcomes from perinatal stroke.

## Motor: Cerebral Palsy

Perinatal stroke accounts for most hemiparetic cerebral palsy. Motor deficits affect 25% to 50% of children with PAIS. Most PAIS involve the middle cerebral artery, injuring key components of the motor network and resulting in hemiparesis affecting the upper more than lower extremity. Motor deficits emerge around 4 to 6 months with asymmetry and early hand preference. Unless infarcts are bilateral, most achieve independent walking on time. Motor dysfunction is a complex interaction of brain injury location, developmental plastic adaptation, and multiple physical factors over time such as weakness, dexterity, tone, musculoskeletal issues, and factors inherent to the individual child. A focal injury of defined timing in a healthy brain makes perinatal stroke an ideal human model of developmental plasticity. Combining animal and human neurophysiology and imaging studies has generated new models of developmental motor plasticity after perinatal stroke. The degree of control of affected extremities by the ipsilateral (contralesional) hemisphere is a major determinant of motor function. These models also identify potential targets for neuromodulation.

Validated measures and evidence-based management for perinatal stroke hemiparesis are poorly defined. Early initiation of rehabilitation therapy is considered beneficial. Multidisciplinary teams typically include physical, occupational, and speech therapists, orthopedic surgeons, and pediatric physiatrists. Emerging evidence-based interventions for children with cerebral palsy are applicable and have recently undergone systematic review (Sakzewski et al., 2009). Recommendations for improving motor function include constraint-induced movement therapy (CIMT), bimanual training, goal-directed training, occupational therapy after botulinum toxin, and home programs. Additional recommendations can be found for outcomes, including spasticity, contractures, muscle strengthening, and various psychosocial outcomes. The same guidelines provide evidence on clearly disproven and potentially harmful interventions.

Multiple randomized controlled trials support the efficacy of CIMT in congenital hemiparesis without studies specific to perinatal stroke. The primary tenets include induced constraint of the unaffected upper limb with a removable cast or splint combined with intensive, goal-directed therapy, usually over a period of 1 to 3 weeks. Intensive bimanual approaches to motor rehabilitation in hemiplegic children have also been developed with evidence of similar efficacy. All such interventions should adhere to the principles of the WHO International Classification of Functioning, Disability, and Health, use objective and validated outcome measures, and monitor achievement of child-specific functional goals.

Noninvasive brain stimulation such as transcranial magnetic stimulation (TMS) represents an opportunity for neuro-modulation to enhance function. Safety and tolerability of TMS is well established in children. In adults, many randomized, controlled trials of brain stimulation have demonstrated efficacy for stroke-induced hemiparesis. A trial of repetitive TMS (rTMS) in 19 children with hemiparetic cerebral palsy over 2 weeks demonstrated favorable safety and tolerability with early evidence of efficacy. A recently completed factorial trial of 45 school-aged children with perinatal stroke hemiparesis randomized to inhibitory rTMS or sham and CIMT or not. After an intensive, 2-week, peer-supported, goal-directed motor learning day camp, all children perceived significant functional gains. The chances of achieving significant change doubled with rTMS or CIMT with additive effects.

## Nonmotor Disabilities

Dysfunctional sensation is an understudied but important contributor to disability in perinatal stroke. The sensation of position, motion, and force or proprioception provides afferent input that is essential for integrated limb control. Studies of children with cerebral palsy have suggested proprioceptive dysfunction is common. In adults with stroke, proprioception is a major determinant of upper extremity hemiparesis recovery. New evidence studying robotic position matching suggests marked deficits in position sense in children with perinatal stroke (Kuczynski et al., 2016).

Visuospatial deficits can occur after perinatal stroke. Deficits may parallel patterns in older children and adults such as contralateral quadrantanopsia with visual pathway injuries though robust plasticity in visual cortex often seems to minimize such problems. Right hemisphere lesions may be more likely to impair spatial integration (organizing elements into a unified whole) whereas left-sided injuries may impair processing detail. Using a block-design test, children with perinatal stroke in the right hemisphere made more global errors (overall design shape) whereas children with left-sided lesions tended to make local errors (precise internal pattern). Visuospatial neglect may also occur but without the predilection for right hemisphere lesions seen in adults.

Deficits in higher brain functions occur in more than half of children with PAIS. The study of neuropsychological outcomes faces numerous challenges, including delayed timing of appearance of deficits to later in childhood. Standardized IQ testing studies suggest mean intelligence is usually within the low-normal range but prospective longitudinal studies have demonstrated specific disorders of cognitive function. Age at testing is critical and deficits emerge over time. Verbal abilities may be relatively preserved compared with performance abilities. Children with epilepsy may be particularly at risk (see later in this chapter). Carefully developmental follow up is required with neuropsychological and educational testing over time to define learning needs and optimal educational environments.

Behavioral and emotional self-regulation included in executive functions (e.g., attention, inhibition, mental flexibility, working memory, and metacognitive skills) may be altered after perinatal stroke. Routine cognitive testing may suggest relative sparing of some executive functions. Studies of children with congenital hemiplegia as well as perinatal stroke describe higher rates of attention disorders. Attention deficit hyperactivity disorder (ADHD) is also increased after early childhood stroke. With implications for academic success and readily available treatments, attention disorders should be screened for.

Disorders of language represent a stark contrast from adult stroke. Developmental language disorders may occur in 20% to 25%, but lesion laterality makes little or no difference.

Subtle lateralization effects may include left-sided lesions in school-aged children, leading to increased morphologic errors, less use of complex syntax, and reduced detailed story settings when relaying a personal narrative. Functional MRI (fMRI) studies suggest most children have bilateral language representation for both expressive and receptive functions. This balance may dictate function as preservation of ipsilesional frontal areas, but bilateral representation of temporal-parietal language areas has been associated with better function. Language is a prominent component of preschool developmental assessments in which early speech therapy may be indicated.

Children with PAIS risk later epilepsy though estimates vary from 15% to 54%. Although lesions are unilateral, diffuse epileptic encephalopathies such as infantile spasms can occur. Many children may “outgrow” their epilepsy, only incurring seizures during a window of development.

Anticonvulsant or other treatments specific to perinatal stroke have not been determined though lesion focality makes such children excellent epilepsy surgery candidates. Possible associations between early acute seizures and later epilepsy may emphasize the importance of early management.

Accumulating evidence suggests that epilepsy may adversely influence neuropsychological outcomes. Emerging data from a population-based perinatal stroke study suggests a strong association between continuous discharges in slow-wave sleep and poor neuropsychological outcomes. Such pathological EEG activity may be both a biomarker and potentially modifiable modulator of neuropsychological outcomes. Screening for such abnormalities may be indicated, particularly in children with poor developmental trajectories or regression. Beyond this, treatment is based on best practices for childhood epilepsy.

## Outcome Prediction

Estimating long-term outcomes in the acute setting is important to counsel families and select patients for trials. The ability of early clinical, laboratory, and EEG markers to predict outcomes has been disappointing. Neuroimaging variables, including lesion size and location, have been associated primarily with outcomes. Injury to major components of the motor system (rolandic cortex, posterior limb of internal capsule, basal ganglia) can estimate risk of cerebral palsy. Restricted diffusion in the corticospinal tract or “pre-Wallerian degeneration” also helps predict long-term hemiparesis. Most remaining brain functions are more difficult to estimate. When counseling families, it should be remembered that even for motor outcomes, only approximations can be made. This is particularly true for more complex developmental outcomes in which only years of observation will determine the outcome in most cases.

## Recurrence

The most predictable outcome from perinatal stroke is the lack of recurrence. Lifetime occurrence of ischemic stroke is exceedingly rare, estimated at less than 1% for both the child and future pregnancies. An exception is neonates with congenital heart disease in which recurrence rates approach 14%. In the remaining neonates, secondary stroke prevention is not usually required. With no established maternal risk factors, primary prevention strategies do not exist. This message of extremely low risk of recurrence for child and mother must be repeatedly stated to families to alleviate worry and inform family planning.

## Psychology and Mental Health

Family-centered education, support, and counseling are essential. Quality of life may be underestimated by parents, and

**Figure 20-2. Arterial Presumed Perinatal Stroke.** **A**, Parents noted their 6-month-old was not using the left upper extremity. FLAIR MRI at 9 months demonstrates a large cystic area with surrounding gliosis in the distribution of the right middle cerebral artery (MCA). Sparing of the putamen suggests the site of occlusion was the distal M1 segment. **B**, A 2-month-old with failure to thrive and microcephaly underwent MRI. Well demarcated, cystic areas with surrounding gliosis are shown in the distributions of the entire right MCA and posterior trunk of the left MCA.

inversely related to degree of cognitive dysfunction. Recent interventional clinical trials suggest meaningful psychological and quality-of-life benefits may be realized. Parental psychological morbidity can easily be missed but disabling to the entire family. The Alberta Perinatal Stroke Parental Outcome Measure (POM) was recently developed and validated to screen for parental psychological morbidity. As a definitive cause can usually not be identified, mothers may harbor unjustified feelings of guilt and/or blame with implications for maternal mental health and family life. Simple educational counseling, connecting parents with information, and establishing support resources with the help of best-practice documents now available can have a major influence. Families also require help interpreting the abundance of misinformation currently available to make informed decisions.

### PRESUMED PERINATAL ISCHEMIC STROKE (PPS)

Many perinatal strokes will not manifest clinical signs during newborn period (Kirton et al., 2008). Diagnosis instead occurs retrospectively when congenital hemiparesis, new-onset seizures, or other deficits appear later in infancy. The most common presentation is motor asymmetry or early hand preference at 4 to 6 months. There is often a diagnostic delay up to 2 years as parental concerns may be minimized. Neuroimaging with MRI is the definitive diagnostic test. This scenario is referred to as presumed perinatal ischemic stroke (PPS), defined as a term (longer than 36 weeks) infant older than 28 days with a normal neonatal neurologic history presenting with a neurologic deficit or seizure referable to focal, chronic infarction on neuroimaging. As some lesions involve both ischemic and hemorrhagic mechanisms (see later in this chapter), the more general term of presumed perinatal stroke (PPS) is used here. Precise timing is not possible but is presumed to be either fetal or immediately proximate to delivery with acute signs being absent or missed. The clinical syndrome of PPS has long been recognized, but imaging can now define specific PPS diseases. Late-presenting versions of the arterial PAIS described previously can be differentiated from fetal venous lesions.

### ARTERIAL PRESUMED PERINATAL STROKE

Many PPS are well demarcated, wedge-shaped areas of encephalomalacia within an arterial territory, typically the middle cerebral artery (Fig. 20-2). Lesions are indistinguishable from chronic PAIS imaging. Infants with arterial PPS are more likely to show isolated deep lesions. Pathophysiology of arterial PPS is poorly understood. Categories of risk factors similar to PAIS are suggested, including acute perinatal factors and prothrombotic conditions. These similarities support the suggestion that symptomatic PAIS and arterial PPS are often the same disease, differing only in the timing of clinical presentation. Only limited associations have been suggested between cardiac disease, arterial PPS, and the yield of cardiac evaluations when examination is normal is probably very low. As only those children with deficits will typically be diagnosed, there is a strong selection bias whereby most arterial PPS cases have long-term morbidity. This creates an effect whereby arterial PPS outcomes appear relatively severe compared with the other perinatal stroke syndromes. As hemiparetic cerebral palsy is the most common presenting sign, it is not surprising that more than 70% to 80% have motor deficits. Compared with subcortical venous PPS (see later in this chapter), arterial PPS is associated with risk of seizures and nonmotor developmental delays. Cortical involvement appears to predict nonmotor outcomes, including language and cognitive morbidities, as well as epilepsy.

### PERIVENTRICULAR VENOUS INFARCTION (PVI)

Modern neuroimaging of PPS has defined a specific fetal perinatal stroke. PVI defines term-born children with preterm, in utero germinal matrix hemorrhage, and secondary venous infarction. Germinal matrix hemorrhage obstructs medullary venous drainage of the periventricular white matter with resulting venous infarction damaging the corticospinal tracts. Children are normal at birth but present with hemiparetic cerebral palsy at 4 to 6 months. The same mechanism of injury is well established in delivered preterm infants (see Chapter 22). Modern MRI can confirm such remote germinal matrix hemorrhage using blood-sensitive sequences (Fig. 20-3).

**Figure 20-3. Fetal Periventricular Venous Infarction (PVI).** Parents noted a right hand preference at 4 months and left-sided weakness of arm and leg by 12 months. **A**, T2-weighted MRI at 24 months demonstrates a focal area of encephalomalacia and gliosis in the periventricular white matter with sparing of the basal ganglia. Blood-sensitive imaging shows hemosiderin in the region of the germinal matrix (**B**, Gradient ECHO) and white matter lesion (**C**, Susceptibility-weighted imaging) consistent with PVI.

Validated diagnostic imaging criteria for PVI include isolated, cystic porencephaly of the periventricular white matter with gliosis and ex vacuo ventricular dilatation, sparing of the basal ganglia and subcortical white matter, and increased T2/FLAIR down the posterior limb of the internal capsule. Compared with arterial PPS, the lower extremity is more often affected in PVI. In a PPS series, PVI accounted for 75% of subcortical injuries. Case-control risk factors studies for PVI are limited. With timing removed from the immediate perinatal period, no associations with recognizable clinical factors have been identified. A contribution of thrombophilia has been suggested. Genetic alterations influencing vascular stability such as *COL4A1* and *COL4A2* mutations are increasingly recognized. Risk factors for germinal matrix hemorrhage in preterm infants described elsewhere (see Chapter 22) that often relate to neonatal intensive care are avoided in term-born PVI.

Consistent with the small, subcortical location of PVI, most incur only a “pure,” isolated motor impairment. The lower extremity is more often affected in PVI. Risk of cognitive and behavioral disorders as well as epilepsy is very low. For both arterial PPS and PVI, the general principles of neurorehabilitation outlined previously are applicable.

## NEONATAL CEREBRAL SINOVENOUS THROMBOSIS (CSVT)

### Epidemiology

Cerebral venous drainage occurs through superficial and deep systems of cerebral veins that converge to form dural venous sinuses. CSVT is the pathological formation of thrombus within this venous system which may or may not lead to venous congestion and infarction. The incidence of neonatal CSVT is approximately 0.4 per 100,000 (deVeber et al., 2001).

### Pathophysiology and Risk Factors

With limited prospective or case-control data, evidence for neonatal CSVT pathophysiology is lacking. Reduced flow results in venous congestion progressing to venous infarction, often with prominent hemorrhagic transformation. This process can mimic intracerebral hemorrhage, particularly in term neonates with intraventricular hemorrhage, many of whom have deep CSVT with thalamic injury.

A consistent list of associations includes thrombophilia in which relative risk is highest for antithrombin III, protein C, and protein S deficiencies. Nonspecific perinatal complications and systemic diseases associated with neonatal CSVT include hypoxic-ischemic encephalopathy, sepsis and other infections (including meningitis), disseminated intravascular coagulation, meconium aspiration, and dehydration. Extracorporeal membrane oxygenation—but not cardiac disease alone—may be a risk. Slower flow and stasis within the cerebral veins and dural venous sinuses may contribute to thrombosis. The proximity of the dural sinuses to suture lines may create vulnerability to trauma at the time of birth. Occipital bone compression of the superior sagittal sinus related to supine positioning is associated with neonatal CSVT and may be amendable to simple positioning.

### Clinical Presentation and Diagnosis

Seizures are the most common presentation of neonatal CSVT (Berfelo et al., 2010). Focal signs are uncommon, but diffuse neurologic dysfunction is often evident, including lethargy, hypotonia, feeding difficulties, and apnea. The majority of cases present in the first week of life. Extensive CSVT may result in impaired venous drainage and/or hydrocephalus secondary to arachnoid granulation dysfunction and impaired cerebrospinal fluid resorption. Resulting increased intracranial pressure may manifest with bulging fontanel, splayed sutures, impaired upgaze, and prominent scalp veins.

Neuroimaging is required to confirm CSVT and parenchymal involvement. Cranial ultrasound may detect midline thrombus or unilateral thalamic hemorrhage whereas power Doppler can image sinus flow. Additional imaging is required to exclude CSVT in peripheral locations and confirm the extent of thrombosis and brain tissue involvement. Unenhanced CT is insensitive, but contrast-enhanced CT venography can effectively diagnose CSVT by demonstrating filling defects. CT alone lacks accuracy with the added risk of radiation.

An MRI is the investigation of choice with superior ability to define venous edema, infarction, and hemorrhage (Figs 20-4, 20-5, 20-6). Blood-sensitive sequences may be particularly useful, including specific biomarkers such as the “iris” sign in the frontal white matter of neonates with deep CSVT (Fig. 20-6). MR venography (MRV) can confirm the location,

**Figure 20-4. Neonatal Cerebral Sinovenous Thrombosis (CSVT).** Sagittal T1 MRI shows extensive T1 hyperintense thrombus within the superior sagittal sinus, straight sinus, and the vein of Galen in a 2-week-old neonate who presented with seizure.

**Figure 20-6. Deep system neonatal CSVT with hemorrhage.** A term neonate presented with seizures on day 6. The MRV (not shown) confirmed CSVT involving the straight sinus. **A**, T2 MRI demonstrates hemorrhage in the left thalamus with intraventricular extension and punctate white matter lesions in the frontal white matter. **B**, SWI confirms hemorrhage in the same territory (iris sign).

extent, and degree of occlusion. Gadolinium-based or three-dimensional (3D) MRV may have significant advantages over time-of-flight studies. Imaging signs of deep CSVT can be difficult to interpret but must not be missed for risk of bilateral deep injury and poor outcome.

## Management

Evidence supports the consideration of anticoagulation for neonatal CSVT (Moharir et al., 2010). However, consensus-based guidelines and treatment practices among pediatric stroke experts are inconsistent. The American College of Chest Physicians guidelines suggest anticoagulation for infants without significant intracranial hemorrhage. For those with hemorrhage, they suggest either (1) anticoagulation or (2) supportive care with radiological monitoring at 5 to 7 days with anticoagulation if thrombus extension occurs. The American Heart Association (AHA) guidelines recommend antico-

agulation only with evidence of thrombus propagation. Significant experience supports the safety of anticoagulation in neonates with CSVT.

Without controlled trials, the best evidence for efficacy comes from a large study of 83 neonates with CSVT. All were diagnosed, serially imaged, and treated according to protocol with 35% receiving anticoagulation. Follow-up imaging at 5 to 7 days demonstrated propagation in 28% of untreated newborns compared with 4% of those anticoagulated. Propagation was associated with new infarcts in 10% whereas hemorrhage in 3 of 21 was not associated with outcome. Anticoagulation treatment should therefore be considered, and if not initiated, early repeat imaging to exclude propagation is indicated. Duration of therapy is typically 6 to 12 weeks with 90% demonstrating full recanalization. Additional early management should adhere to the neuroprotective strategies described previously, including correction of dehydration and the treatment of infection and seizures.

## Outcomes

Neonatal CSVT outcomes are abnormal in most survivors. In a systematically evaluated cohort of 90 neonates followed for a median of 2.5 years, most (more than 60%) incurred neurologic morbidity with language and sensorimotor deficits being most common. Predictors of poor outcome include parenchymal injury and bilateral lesions. Hemiparesis and cerebral palsy estimates range from 25% to 67%. Most children will walk unless they have bilateral injuries. Cognitive and neuropsychological deficits are consistently described though long-term outcome studies are limited. The risk of epilepsy after neonatal CSVT is 15% to 40%, and those with thalamic injury may be at high risk of sleep-related epileptic encephalopathy. Rehabilitation strategies are comparable to those outlined previously. Recurrence risk is very low with long-term prevention typically only required for children with chronic high-risk conditions such as severe thrombophilia.

## PERINATAL INTRACEREBRAL HEMORRHAGE

### Definitions and Epidemiology

Inconsistent terms for neonatal brain bleeding include neonatal hemorrhagic stroke, perinatal hemorrhagic stroke, and perinatal intracerebral hemorrhage (ICH). According to the NIH Common Data Elements, perinatal ICH is “a condition in a term (longer than 36 weeks) neonate with encephalopathy, manifest as seizures, altered mental status, and/or neurologic deficit occurring before the 29th postnatal day confirmed by neuroimaging or autopsy showing a focal collection of blood within the brain parenchyma.” This term is distinct from intraventricular hemorrhage in a preterm infant (see Chapter 22), but term-born intraventricular hemorrhage is included here. Pathological bleeding can extend across multiple intracranial compartments, but pure extraaxial hemorrhage is not considered here (see Chapter 19). It should be noted however that modern neuroimaging has shown that mild extraaxial bleeding occurs in up to 50% of term neonates.

Research of perinatal ICH has been limited and complicated by terminology issues with the four largest series reporting different proportions of ICH types. Precise incidence estimates for term ICH are unknown, but one population-based, administrative data set suggested a prevalence of 6.2 per 100,000 (1 in 16,000) live births for intraparenchymal and subarachnoid hemorrhage (Bruno et al., 2014).

## Pathophysiology and Risk Factors

The mechanisms of perinatal ICH are idiopathic in more than 50% of cases. The primary differential diagnoses include vascular malformations (e.g., arteriovenous malformations) and hematological disorders (e.g., thrombocytopenia, hemophilia). Trauma should be considered but not assumed simply due to the presence of blood combined with normal neonatal bruising or assisted delivery as this disassociation has long been established. Clinical variables, including maternal, antenatal, and neonatal factors, have not been consistently associated. Vitamin K-dependent bleeding may be increasing due to refusal of vitamin K at birth but is easily treatable. Hemorrhagic transformation of ischemic injuries can mimic perinatal ICH and is common. Genetic disorders such as *COL4A1* mutations can cause perinatal hemorrhage. Cutaneous vascular lesions or family history may suggest a genetic vascular malformation syndrome such as hereditary hemorrhagic telangiectasia (HHT).

## Clinical Presentation and Diagnosis

The most common presentation for perinatal ICH is seizures within 48 hours of birth. Compared with the ischemic perinatal stroke syndromes discussed previously, prevalence of neonatal encephalopathy, decreased level of consciousness, poor feeding, apnea, and signs of increased intracranial pressure are more common. Electrographic-only seizures often occur, suggesting a role for continuous video EEG monitoring. Accurate diagnosis and assignment of mechanism depend on neuroimaging (Figs. 20-8 and 20-9). MRI is the investigation of choice though an unstable neonate may require urgent cranial ultrasound or CT. An MRI includes sequences with exquisite sensitivity to blood such as susceptibility-weighted imaging. Most perinatal ICH lesions are single and unilateral, and the presence of diffuse bilateral lesions should alter the differential diagnosis (e.g., bleeding diathesis). Routine MRI sequences can help age blood although the rules for doing so are based on adult studies. An MRI avoids radiation and can usually be completed without sedation. Vascular imaging with angiography (MRA) to screen for malformations and venography (MRV) to exclude CSVT are usually indicated. Conventional angiography may eventually be required in some children to exclude or characterize vascular malformations. Additional investigations include blood work to screen for bleeding disorders.

**Figure 20-8. Perinatal intracerebral hemorrhage (ICH).** A term baby presented with seizures and encephalopathy on day 1. **A**, CT demonstrates a large intracerebral hemorrhage in the right frontal lobe with spillage into the ventricles. **B**, T1-weighted MRI confirms the same whereas blooming on SWI MRI (**C**) exaggerates the appearance of hemorrhage.

## Management

The American Heart Association guidelines offer several recommendations for the treatment of perinatal ICH. These include immediate correction of hematological abnormalities, giving Vitamin K to those at risk, replacement of coagulation factors in neonates with known deficiency, and consideration of ventricular drainage for posthemorrhagic hydrocephalus. Larger bleeds require immediate neurosurgical consultation. The general principles of neuroprotection outlined previously apply.

## Outcomes

Studies on outcomes from perinatal ICH are limited with short follow-up durations. They suggest an increased mortality but lower long-term morbidity compared with other perinatal stroke types. The larger series suggest mortality rates of 13% to 25% but no neurologic deficits for most survivors (60% to 80%). Epilepsy occurs, but prevalence and risk factors have not been well described. Recurrence risk for perinatal ICH is very low unless there are persisting risk factors such as a bleeding disorder or vascular malformation. With a low recurrence and such a high proportion of “idiopathic” cases, it has been suggested that many perinatal ICH may be “one-time” events secondary to small vascular malformations that rupture and obliterate during transition to extrauterine life.

## Neonatal Nervous System Trauma

Mary J. Harbert and Andrea C. Pardo

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

### INTRODUCTION

Obstetric and perinatal trauma resulting in neonatal death or severe disability was a very common problem until the late 20th century; these were described at length in classic textbooks and journal articles. Methods to assess the fetus and improved obstetric techniques have significantly decreased birth-related trauma today. Accidental and abusive traumas have now gained more prominence. The neurologist has an important role in the assessment and evaluation of neonates that have suffered central or peripheral nervous system injury caused by trauma.

The neurologist is expected to provide guidance for prognosis as well as to determine the etiology of the suspected injury. As cases of perinatal trauma often become litigious, particularly ones involving labor and delivery management, the neurologist should take care when discussing the causality of an injury. A detailed history and physical examination are critical. The neurologist must note the events of pregnancy, labor, and delivery as this time window is one of high potential for nervous system injury. Gestational age is critical as preterm newborns are more vulnerable to injury than a term newborn and their manifestations of brain injury are often different. Consideration of nontraumatic disorders that clinically manifest similarly to traumatic injury is crucial, particularly if the cause of the injury is unclear. Knowledge of incidental nervous system findings that can be associated with labor and delivery is also vital; not all intracranial hemorrhage seen after delivery is traumatic (Rutherford, 2015; Volpe, 2008).

### INTRAUTERINE TRAUMA

Pregnancies are complicated by trauma in about 5% to 7% of the cases. The most common causes of trauma in pregnant women are motor vehicle accidents (MVAs), accidental falls, and violence.

Blunt trauma to the abdomen during pregnancy is a known trigger of preterm labor and placental abruption, and begets a higher incidence of cesarean delivery. Catastrophic labor events such as maternal trauma, placental abruption, and uterine rupture are considered “sentinel events” for intrapartum asphyxia and these newborns may require evaluation for therapeutic hypothermia.

The incidence of MVAs during pregnancy is high; in a multiyear retrospective study of over 320,000 singleton live births, 2.8% of pregnant mothers had been in a car accident. MVAs during pregnancy significantly increase risk for preterm labor and placental abruption regardless of maternal injury, and women who sustain injury are at higher risk for cesarean delivery and fetal demise. Fetal neurologic trauma as a result of MVAs includes intracranial hemorrhages, skull fractures, and even fetal transection. There are case reports of fetal injury and fatality even when the mother has not sustained significant trauma (ACOG, 2014).

Domestic violence is a frequent cause of blunt trauma sustained during pregnancy and is also associated with

repeated trauma during pregnancy, heightening the risk of injury to both mother and newborn. There is association between physical abuse during gestation and adverse neonatal outcomes such as prematurity, low birth weight, and, possibly, the need for cesarean delivery. There are no large-scale studies that have evaluated neonatal outcomes specifically involving the nervous system in the context of physical abuse during pregnancy. If trauma caused by physical abuse is suspected, the mother should be asked confidentially, as women who are asked about battering are more likely to answer in the affirmative without others present. Engagement of the social work team is paramount.

Penetrating trauma accounts for 10% of all traumas in pregnancy. Up to 6% of all fetal deaths are related to gunshot wounds. The incidence of fetal injury is about 70%, with fetal demise in 65% of the cases of gunshot wound to a pregnant mother. Death results from direct injury, uteroplacental damage, or shock. In cases of uterine injury with a viable fetus, delivery is recommended. Fetal intracranial gunshot wounds are extremely rare and often fatal; with survival, there is risk of encephalopathy, seizures, and long-term developmental impairment.

### PERINATAL TRAUMA BY LOCATION

#### Extracranial Injury

*Caput succedaneum* is a self-limited collection of serosanguineous fluid infiltrating the connective tissue beneath the skin. The position of the caput depends on the presentation of the fetus and is most commonly seen in the occipital midline. The reported prevalence is between 1.8% and 33.6% of all vaginal births, with the most common risk factors being maternal nulliparity and the use of vacuum delivery. *Caput succedaneum* may be an indicator of prolonged labor. It is rarely associated with intracranial injury. No treatment is required because it normally resolves spontaneously within a few days of birth.

*Cephalohematoma* is a relatively common extraaxial injury in the neonate, occurring in up to 2.5% of all births. Instrumented vaginal delivery (with forceps or vacuum) increases the incidence to about 10%, and both nulliparity and prolonged labor are additional risk factors. Cephalohematomas, however, do not usually represent a problem to the neonate. Bleeding occurs because of the rupture of the diploid veins beneath the periosteum. Most cephalohematomas are recognized within 24 hours after birth and are firm, well-demarcated and are bounded by the suture lines given the dense attachment of the periosteum to the bone. Cephalohematomas may calcify and very rarely may become a source of infection if punctured. They may require excision if they are cosmetically deforming or invading. Cephalohematomas may be associated to skull fractures in up to 25% of the cases and a skull radiograph may help determine the presence of a fracture. Further imaging or testing is usually not needed unless other injuries are considered based on the neurologic examination.

Cephalohematomas tend to disappear spontaneously by the first month of age.

*Subgaleal (or subaponeurotic) hemorrhage* is a potentially lethal complication of vacuum delivery. It develops when emissary veins connecting the dural sinuses and scalp veins rupture and bleed into the potential space between the scalp aponeurosis and the periosteum. This space in term newborns may hold up to 260 mL of blood and there are several reports of subgaleal hemorrhage causing exsanguination and hypovolemic shock. This space is not limited by cranial suture lines and can extend from the nape of the neck to the orbits, which differentiates it from cephalohematomas. Subgaleal hematomas may progress over the first 24 hours and usually resolve after 2 to 3 weeks. Problematic subgaleal hematomas may not manifest until significant blood volume has been lost and altered mental status, pallor, hypotonia, apnea, and other symptoms related to hemorrhagic shock develop. Cranial ultrasonography may identify the hematoma as a hypoechoic or hyperechoic collection in the subgaleal space and a skull radiograph may be needed to rule out fractures. Mortality is high and reported in up to 25% of neonates mostly because of hemorrhagic shock, coagulopathy, and multiorgan failure. Management consists of adequate fluid resuscitation, control of the coagulopathy, and supportive care. It is not clear if neurosurgical intervention may be helpful in subgaleal hemorrhage, although there is a case report of a newborn with massive subgaleal hemorrhage and shock who made a good recovery after evacuation of the hematoma through a scalp incision.

*Skull fractures* have a wide-ranging incidence in the neonatal period, being reported in 0.5% to 10% of births. Skull fractures may be caused by compression during instrumented vaginal delivery or by compression from the maternal pelvis, and they are extremely rare when the fetus is delivered by cesarean section. Some skull fractures in the neonatal period present without an inciting event and may be a result of intrauterine mechanical stresses such as fibroids or other pelvic abnormalities. Risk factors for skull fractures include nulliparity, elderly multiparity, and dislodgement of the vacuum cup, and they should be suspected in cases of cephalohematoma and subarachnoid hemorrhage. Skull fractures may be linear or depressed (also known as “ping-pong” fractures). Linear fractures may radiographically present as linear lucencies. Depressed skull fractures may present as linear hyperdensities at the rim of the skull. A “growing skull fracture” is a pathologic splitting along a suture line and can be a result of vacuum- or forceps-aided delivery. The meninges can herniate through this defect, creating a fluid-filled collection known as a leptomenigeal cyst, or “growing fontanelle” when in proximity to a fontanelle. These typically need surgical repair. Nongrowing linear fractures do not require any treatment. Treatment of depressed skull fractures is controversial and may include surgical elevation when deeper than 5 mm. Surgical reduction is recommended when there is radiologic evidence of bone fragments within the parenchyma, neurologic deficits related to the fracture, increased intracranial pressure, or signs of cerebrospinal fluid (CSF) leakage under the galea.

*Spinal cord injuries* associated with birth are uncommon. Although more cord injuries are reported with instrumented delivery, particularly with forceps and rotation of the forceps, spinal cord injury has also been reported in newborns after uneventful deliveries, implicating in utero injury. There are several case reports of intrauterine injury to the spinal cord presumably because of neck hyperextension and breech positioning. Injury to the cervical cord has been documented with breech delivery, mostly when the fetal head is hyperextended (Reichard, 2008).

## Intracranial Hemorrhage

The incidence of intracranial hemorrhage secondary to birth trauma is declining, likely because of improved obstetric care (Werner et al., 2011). Etiologies other than traumatic injury related to birth should be kept in mind when evaluating an infant with intracranial hemorrhage (see section [Trauma mimics](#)). Abusive head trauma should always be considered in the differential diagnosis if the newborn has returned to the hospital (Pollina et al., 2001).

*Epidural hemorrhage* (bleeding between the dura and the skull) is rare in neonates. It is unclear whether the hemorrhage comes from branches of the meningeal arteries or the venous sinuses and this remains a topic of controversy. Epidural hemorrhage can present with seizures and hypotonia, usually within the first 24 hours of life. The most common risk factors are maternal nulliparity and the use of forceps. Skull fractures may be present. Head ultrasonography may not show evidence of epidural hemorrhage unless the bleeding is significant or causes significant midline shift. Computed tomography (CT) and magnetic resonance imaging (MRI) are more accurate in detecting epidural hemorrhage. Treatment is supportive. The need for decompressive surgery is rare, but indicated when there is neurologic deterioration or evidence of significant mass effect or midline shift of brain structures.

*Subdural hemorrhage (SDH)* is present in roughly a quarter of asymptomatic term newborns. The proposed mechanism of the bleeding is tearing of the falx and tentorium or the bridging cortical veins. Associated risk factors include difficult delivery, prolonged labor, and vacuum extraction. The presentation is variable depending on location and extent of the hemorrhage, and symptoms include pallor, lethargy, irritability, tense fontanelle, irregular respiration, apnea, hypotonia, and seizures. Most SDH found in asymptomatic infants secondary to birth trauma are less than 3 mm in diameter and resolve by 4 weeks of age. Asymptomatic SDH has an excellent prognosis. Symptomatic posterior fossa SDH in the term neonate is rare, but is clinically important as it can cause brainstem compression or hydrocephalus, which may require surgery. MRI is superior to CT in identification of posterior fossa SDH in neonates (Figure 21-2); ultrasonography usually fails to identify a posterior fossa hemorrhage but is able to identify hydrocephalus.

*Subarachnoid hemorrhages* are more common in preterm newborns. Suspicion for subarachnoid bleed arises when lumbar puncture reveals blood that fails to reinitiate with drainage and elevated CSF protein. Symptomatic subarachnoid hemorrhage can also present with neonatal seizures, irritability, feeding difficulties, and occasionally hyperthermia because of cortical irritation.

*Intraparenchymal hemorrhages* in the term neonate are rare and usually asymptomatic, unless they are extensive. Intraparenchymal bleeding can arise from small cortical contusions, shear injury, or diffuse axonal injury. When symptomatic, features include seizures, hypotonia, apnea, and altered mental status. Intracranial ultrasonography reveals focal areas of hyperechogenicity that may have mass effect. The presentation of intraparenchymal hemorrhage in term neonates may be associated with coagulopathy, as well as sepsis and hypoxic ischemic injury. Most newborns with intraparenchymal hemorrhage do not require acute neurosurgical intervention (Figure 21-3).

## Peripheral Nerve Injuries

*Facial nerve injury* from perinatal trauma occurs in 0.5 to 7.5 per 1000 live births. Risk factors include fetal macrosomia, nulliparity, and use of forceps. Forceps can directly compress

**Figure 21-2.** Term infant presented with seizures and somnolence. Magnetic resonance imaging T1-weighted image showing hyperintense hemorrhage layering posterior to the cerebellum, along the tentorium bilaterally and the cisterna magna. (Courtesy of Dr. Andrea C. Pardo, MD, Loma Linda University School of Medicine.)

**Figure 21-3.** Coronal T2-weighted and axial T1-weighted magnetic resonance images of a 2-week-old newborn with right temporal intraparenchymal and extra-axial hemorrhage. (Courtesy of Dr. Paggie Kim, MD, Loma Linda University School of Medicine.)

the facial nerve at the stylomastoid foramen, or the nerve can be compressed against the maternal sacral promontory or ischial spines. The typical presentation is hemifacial weakness with inability to close the eye and flattening of the nasolabial fold at rest. Mimics of facial nerve injury include Möbius syndrome, hypoplasia of the anguli oris muscle, and hemifacial microsomia. MRI or high-resolution CT imaging can assist in evaluating neonates in whom the etiology is uncertain. Birth-related facial nerve palsy spontaneously resolves in 90% of infants by 1 month of age, and treatment is usually conservative before 4 weeks of age. Surgery is indicated if there is complete absence of voluntary and evoked motor unit responses in all muscles innervated by the facial nerve, if there is no functional or electrophysiologic recovery present after 5 weeks of age, or if there is hemotympanum with a displaced petrous bone fracture (Bergman et al., 1986).

*Brachial plexus injury* is a common perinatal injury, occurring in 1 to 3 neonates per 1000 live births. The most important risk factor is shoulder dystocia, but other risk factors include malposition, labor induction, prolonged second stage, instrumented vaginal delivery, and fetal macrosomia. Erb's palsy is an injury to the upper plexus and accounts for 80%

of brachial plexus injuries. The newborn displays lack of movement of the affected arm and the classic "waiter's tip" posture because of the loss of wrist extension. During examination, the lack of movement of the upper extremity is confirmed with tactile stimulation, Moro reflex, asymmetric tonic neck reflex, and palmar grasp. Fracture of the clavicle or humerus, subluxation of the shoulder, or cervical spine may be present. Klumpke's paralysis is defined by injury isolated to the C8 and T1 roots and accounts for 1% of brachial plexus injuries. Klumpke's paralysis is recognized by a flaccid hand in an otherwise active arm. Usually, there is evidence of injury to the entire plexus rather than just upper or lower plexus involvement (Abzug and Kozin, 2014).

There are several clinical classifications in the literature, but the Narakas classification may be the most useful for prognosis (Table 21-2).

A common mechanism of perinatal brachial plexus injury is lateral traction of the head at delivery with the anterior shoulder caught behind the maternal symphysis pubis. This may result in bleeding, edema, tearing of the branches of the brachial plexus, or even root avulsion. Avulsion injury is the most severe and should be suspected with complete

**TABLE 21-2** Narakas Classification for Brachial Plexopathy

Group	Nerve Roots	Examination	Recovery
I	C5, C6	Paresis of deltoid and biceps without involvement of the wrist or hand	>90%
II	C5, C6, C7	Paresis of deltoid, biceps, triceps, and wrist extensors. Long flexors and intrinsic hand muscles unaffected	~65%
III	C5, C6, C7, C8, T1	Flail arm (total arm weakness)	<50%
IV	C5, C6, C7, C8, T1 with Horner syndrome	Flail arm in association to Horner syndrome ipsilateral to the affected arm	0%

plexopathy, Horner syndrome, or hemidiaphragm paralysis. Nontraumatic causes of brachial plexus injury, such as cervical ribs, amniotic bands, and congenital aplasia of the brachial plexus, should be considered in the differential diagnosis.

A chest radiograph should be obtained for newborns with plexopathy to rule out fractures, cervical ribs, and investigate concomitant hemidiaphragm paralysis, although hemidiaphragm elevation may not be seen if the baby is receiving positive-pressure ventilation. Visualization of the brachial plexus for perioperative planning can be performed with a CT myelogram, although recent data have shown that high-resolution MRI is equally sensitive and specific, and can spare the infant the radiation exposure and the injection of intrathecal contrast. Electrodiagnostic testing can describe the location and extent of injury, but the clinical utility remains controversial as it may overestimate recovery.

Treatment of neonates with brachial plexus injuries in the absence of a fracture may commence immediately with passive range of motion of the upper extremity in order to avoid contractures. If there is a fracture present, the passive range of motion treatment may commence after 3 weeks, when the fracture has healed. Nonsurgical management is indicated when there is antigravity biceps strength at 3 months of age and a greater likelihood of recovery. Surgical management is indicated when there is absence of biceps function at 3 months of age. Nerve grafting transfer is the most commonly used microsurgical technique for the repair brachial plexus injuries, with good functional outcomes in 60% to 80% of infants.

*Phrenic nerve injury* is rare in the perinatal period, occurring in 1 per 15,000 live births, and it is usually concomitant with brachial plexus palsy in 75% of patients. The mechanism of injury is overextension of the cervical cord during birth. Most commonly, the right phrenic nerve and subsequently the right hemidiaphragm are affected. The diagnosis is usually suspected because of paradoxical chest rise during respiration. Chest x-ray identifies an elevated hemidiaphragm. There may be spontaneous recovery from 1 to 6 months of age, but failure to wean ventilator support and persistent respiratory distress are indications for diaphragmatic plication.

## TRAUMA ASSOCIATED WITH SPECIFIC OBSTETRIC MANEUVERS

Delivery via vacuum extraction has been linked to many types of nervous system trauma. Documentation of delivery via cesarean section does not preclude the use of vacuum extraction. Debate about the safety of vacuum extraction exists in the obstetric literature dating back to the 1960s. In 1998 the U.S. Food and Drug Administration issued a health advisory reporting newborn deaths and injuries in the wake of vacuum delivery. After the advisory was released, reports of adverse events attributed to vacuum delivery increased 22-fold. Overall, rates of instrumented delivery in the United States have recently declined (ACOG, 1994).

Most guidelines recommend against the use of vacuum extraction in neonates of less than 34 weeks' gestation. There are few studies documenting the outcomes of preterm infants delivered via vacuum extraction, and so this recommendation is based upon the reasonable assertion that vacuum extraction is not a good choice for delivering preterm neonates with a tendency toward spontaneous intracranial hemorrhage. A Swedish study compared preterm infants delivered via vacuum against those delivered via cesarean section and noninstrumented vaginal delivery, and found that preterm neonates delivered via vacuum extraction suffered significantly higher rates of intracranial and extracranial bleeding, as well as higher rates of brachial plexus injuries.

Extracranial complications of vacuum extraction include caput succedaneum, cephalohematoma, subgaleal hematoma, and skull fractures. Higher rates of retinal hemorrhages are seen in newborns delivered via vacuum extraction, with one study finding retinal hemorrhages in 75% of vacuum-delivered newborns. Other less common extracranial injuries attributed to vacuum extraction include scalp subcutaneous emphysema, skull lacerations, and corneal injuries. Newborns delivered via vacuum extraction have a higher rate of shoulder dystocia and brachial plexus palsy. Although this could reflect confounding by increased birth weight, this association also has been seen in preterm newborns delivered by vacuum extraction (Doumouchtsis and Arulkumaran, 2008).

Vacuum extraction has been associated with every type of intracranial hemorrhage, although the most commonly observed types of bleeds are extracranial hemorrhages. Subdural hematomas of the posterior fossa are of particular concern because expansion of the hemorrhage can cause brainstem compression and may require surgical evacuation. Dural tears, tentorial laceration, and venous sinus rupture have been reported as a consequence of vacuum extraction as have focal ischemic strokes. Although cerebral herniation is uncommon in newborns that underwent vacuum extraction because of the mobility of the cranial sutures, it can occur; medial herniation of the parietal lobes has been reported in association with vacuum extraction.

Usage of forceps in operative vaginal delivery has been declining in recent years for a number of reasons: the availability of blood products and a wider variety of antibiotics increasing the safety of cesarean delivery; possible increased fetal morbidity with forceps delivery; increased consumer emphasis on natural childbirth; and fear of litigation. Injury to the facial nerve is a well-known complication of forceps utilization. Spinal cord injury, as well as in some cases even transection, has been attributed to forceps delivery, particularly when the forceps are used to rotate the fetal head into the desired occiput anterior position. There are many reports of ocular trauma with forceps; contact between the blade of the forceps and the eye can result in direct trauma to the eye or compression of the globe between the orbit and the forceps blade.

Fetal scalp electrodes have been associated with increased rates of infection and maternofetal transfer of infections such

as herpes. Fetal scalp electrodes have been associated with puncture of the meninges and CSF leaks.

## PERINATAL COUNSELING FOR AVOIDANCE OF BIRTH-ASSOCIATED TRAUMA

Neurologists are increasingly involved in perinatal consultation for fetal neurologic problems, especially as the use of fetal MRI becomes more common. The particular ethics challenges of fetal neurologic diagnosis are beyond the scope of this chapter, and they are important and are discussed in Chapter 33.

Birth-related injuries are not easily predicted based solely on the presence of a fetal brain malformation, although there are some congenital disorders that predispose to birth trauma. The American College of Obstetrics and Gynecology has noted that fetal congenital anomalies are a relative contraindication for vaginal delivery, such as hydrocephalus with increased biparietal diameter and some skeletal dysplasias. Fetal conditions must be considered on an individual basis, as not all fetal anomalies confer the same risk of birth trauma.

## IATROGENIC NEUROTRAUMA DURING THE NEWBORN PERIOD

Infants admitted to the neonatal intensive care unit may be hospitalized for a prolonged time period and undergo multiple interventions, making them susceptible to iatrogenic trauma. Intravascular catheters in the setting of an immature clotting system place infants at risk for venous and arterial clots, which may result in stroke or paraplegia. Intravascular catheters can puncture the ascending lumbar veins, creating a pathway for infusion of nonblood substances into the dural space. Central venous lines can puncture the subarachnoid space. Scalp venous catheters have been associated with venous dural air emboli, which may be prevented by using the supine or Trendelenburg position to avoid the pressure gradients that increase the risk of air embolism. Epidural catheters for regional anesthesia have been implicated in causing epidural bleeding and paraplegia.

Peripheral nerves may also be subject to iatrogenic damage. Internal jugular lines damaging the phrenic nerve can result in respiratory failure and prolonged need for ventilation. Brachial artery puncture has been associated with median nerve injury resulting in pincer grasp impairment in later infancy. Carpal tunnel syndrome secondary to radial artery catheterization has also been reported. Umbilical arterial catheters can migrate into the inferior gluteal artery and cause ischemic necrosis of the gluteal region with subsequent sciatic and peroneal neuropathy.

## TRAUMA MIMICS

Rare disorders that predispose to bone fractures such as osteogenesis imperfecta and Menkes disease can present as fractures and/or intracranial hemorrhages that can be erroneously attributed to perinatal trauma. Bleeding disorders may also be mistaken with trauma in the neonatal population, and 3% to 5% of newborns with hemophilia present around birth with intracranial bleeding, including intraparenchymal hemorrhage, cephalohematoma, and SDHs. Vacuum-assisted delivery and rotational and mid cavity forceps are associated with a higher risk of intracranial hemorrhage in patients with neonatal hemophilia and should be avoided. Other primary bleeding disorders that can present in newborns

with intracranial hemorrhage mimicking birth trauma include congenital afibrinogenemia, von Willebrand disease, and neonatal autoimmune thrombocytopenia. Parental refusal of vitamin K administration for prophylaxis against late vitamin K deficiency bleeding can also result in spontaneous intracranial hemorrhage. Intracranial hemorrhage in the neonate can (rarely) be caused by rupture of an aneurysm or arteriovenous malformation. Normal routine prenatal imaging does not rule out intracranial vascular malformation, as these malformations have been reported to develop relatively late in gestation. There are also reports of arteriovenous malformations of the spinal cord in which the presenting symptom is paralysis caudal to the lesion.

Neonates with nervous system trauma should be followed closely by a child neurologist. Neurologists may become the medical home for providing interventions, referring to physical or occupational therapies, and establishing long-term relationships with the caretakers as they may face challenges during the school years.

## Injury to the Developing Preterm Brain: Intraventricular Hemorrhage and White Matter Injury

Janet S. Soul and Laura R. Ment

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

### INTRODUCTION

Preterm birth represents one of the most important public health problems in the world today. There were an estimated 140 million live births worldwide in 2012, and 11.5% of them were premature, or born at less than 37 completed weeks of gestation (Blencowe et al., 2013). Worldwide, over half of neonates born at younger than 28 weeks' gestation and 24% of those born at 28 to 31 weeks are estimated to have neurodevelopmental impairment. Survival is increasing for neonates of all gestational ages, and thus the prevalence of prematurely born children with cognitive impairments, behavioral disorders, and motor handicaps at school age continues to rise.

Brain injury is common in preterm neonates, and the two most common neuropathologic processes include intraventricular hemorrhage (IVH) and white matter injury (WMI). IVH, or hemorrhage into the germinal matrix tissues of the developing brain, is detected in 10% to 25% of very low birth weight preterm neonates, whereas WMI and the global neuronal and axonal deficits that may accompany it are found in 50% or more of this vulnerable population. Because both processes are unique to preterm neonates and represent a significant burden of disease, the pathophysiology, outcome, and prevention of these injuries will be reviewed separately.

### INTRAVENTRICULAR HEMORRHAGE

IVH is a problem for infants at the lowest limits of viability. Both the incidence and severity of hemorrhage are inversely related to gestational age (GA); the highest grades of hemorrhage occur in 37% of neonates of 22 to 23 weeks' gestation but only 9% of those born at 26 to 28 weeks of gestation. High-grade IVH is more common in males than females, and, although the risk period for IVH is in the first 4 to 5 postnatal days, the timing of IVH is bimodal. Half occur within the first 6 postnatal hours, whereas one third occur after the first postnatal day, suggesting differing etiologies.

Cranial ultrasounds are routinely used to screen preterm neonates for IVH, and the most commonly employed grading systems for hemorrhage are shown in Table 22-1. When associated with grades 1 to 3 IVH, unilateral grade 4 hemorrhages most likely represent periventricular hemorrhagic infarctions (PVHI).

During the first three postnatal days, 75% of infants with IVH suffer seizures detected by amplitude-integrated EEG monitoring. Approximately one third develop posthemorrhagic ventricular dilation (PHVD), defined as ventricular enlargement higher than the 97th percentile for gestational age, and 15% of infants with grades 3 to 4 IVH require permanent CSF diversion. Finally, although preterm neonates with parenchymal involvement of hemorrhage are at high risk for neurodevelopmental handicap, even those with low-grade hemorrhage (i.e., grades 1 to 2 IVH) perform less well at school age than their nonhemorrhagic preterm peers.

### PATHOPHYSIOLOGY

#### Intraventricular Hemorrhage Is a Complex Disorder

IVH is a complex developmental disorder, with contributions from both the environment and the genome of the child. IVH occurs in that critical period of time before week 32 to 33 postconception and has been attributed to changes in cerebral blood flow to the immature germinal matrix microvasculature. Genetic vulnerability and healthcare disparities may also play a role.

Multiple lines of data support the hypothesis that the etiology of IVH is multifactorial. Maternal transport, antenatal steroid administration, and improved resuscitation techniques have become the standard of care worldwide, but the incidence of grade 3 to 4 hemorrhage has remained 14% to 17% for almost 20 years. In addition, the risk period for hemorrhage is independent of GA, suggesting that either the transition to extrauterine life and/or the triggers to which the neonates are exposed contribute to hemorrhage. Twin studies show that 41.3% of the variance in IVH risk is attributable to familial and environmental factors. Finally, candidate gene studies implicate the inflammatory, coagulation, and vascular pathways.

### Clinical Risk Factors

Clinical studies suggest numerous environmental and medical risk factors for IVH, as shown in Box 22-1. In addition, maternal race and healthcare disparities influence the risk for IVH in preterm neonates. Women of African ancestry are at greater risk for preterm delivery compared with white women, and more women of African ancestry who deliver prematurely receive inadequate prenatal care. Further, their neonates are less likely to receive surfactant or assisted ventilation. The rate of IVH-related mortality in neonates of African ancestry is twice that in white neonates, and, relative to white infants, those of African ancestry are at significantly increased risk for hemorrhage.

### Anatomic Factors Are Permissive for Hemorrhage

The germinal matrix remains relatively robust through 32 to 33 weeks' gestation, and its microvessels are the source of hemorrhage in the brain of the prematurely born. Proliferation of glial and neuronal precursors occur in both the germinal matrix and the subventricular zone, and the metabolically active germinal matrix requires a rich blood supply, yet its vessels are neuropathologically immature and thus at risk for hemorrhage. (For review, see Ballabh, 2010).

The blood-brain barrier is composed of basement membrane proteins, endothelial tight junctions, capillary pericytes, and astrocytic endfeet. In comparison to microvessels within

**TABLE 22-1** Grading Systems for Germinal Matrix Intraventricular Hemorrhages

Papile*		Volpe†	
Grade	Description	Grade	Description
Grade 1	Germinal matrix hemorrhage	Grade I	Germinal matrix hemorrhage with no or minimal hemorrhage
Grade 2	Blood within but not distending ventricular system	Grade II	IVH (10–50% of ventricular area)
Grade 3	Blood filling and distending ventricular system	Grade III	IVH (>50% of ventricular area; usually distends ventricle)
Grade 4	Parenchymal involvement of hemorrhage	Severe + periventricular hemorrhagic infarction	Grade III IVH with periventricular hemorrhagic infarction

### BOX 22-1 Clinical Risk Factors for Intraventricular Hemorrhage

#### EARLY ONSET HEMORRHAGE

- Low birth weight, low gestational age
- Maternal fertility treatment
- No prenatal care
- No antenatal steroid exposure
- Maternal antenatal hemorrhage
- No maternal preeclampsia
- Maternal chorioamnionitis and/or infection
- No tertiary care delivery
- Early clamping of the umbilical cord
- Vigorous resuscitation
- No CPAP ventilation
- Neonatal transport after delivery

#### ONSET AFTER 6 TO 8 POSTNATAL HOURS

- Hypotension requiring medical therapy
- Respiratory distress syndrome
- Acidosis
- Hypoxemia
- Extremes of  $PCO_2$  levels (both high and low)
- Sodium bicarbonate exposure
- Pneumothoraces
- Seizures

the gray and white matter, germinal matrix microvessels demonstrate a paucity of fibronectin, fewer pericytes, and decreased perivascular coverage by glial endfeet, consistent with regional vulnerability of the blood-brain barrier. The germinal matrix also has a greater vascular density than other brain regions, suggesting rapid angiogenesis to support its greater metabolic rate requirement. This angiogenesis is induced by high levels of vascular endothelial growth factor (VEGF) and angiopoietin (ANGPT)-2 found selectively in the germinal matrix compared with both cortical and white matter regions. Together, these factors promote sprouting of immature vessels lacking both basement membrane proteins and pericyte investiture, providing further evidence for microvascular vulnerability.

The venous circulation may also contribute to the susceptibility to intraparenchymal hemorrhage. Venous blood from the periventricular white matter flows through a fan-shaped array of medullary veins into the veins of the germinal matrix, and subsequently into the terminal veins. This tortuous anatomy results in venous stasis, permitting periventricular hemorrhagic infarction (PVHI).

## Alterations in Cerebral Blood Flow Contribute to IVH

Alterations in cerebral blood flow (CBF) may also play a role. CBF was reported to be pressure-passive in the asphyxiated preterm infant over four decades ago, yet the physiologic factors that contribute to cerebral autoregulatory systems in the prematurely born are just beginning to be understood. Further, the definition of the cerebral pressure-flow autoregulatory plateau, or that range of cerebral perfusion pressures over which CBF is normally maintained, is poorly defined for the extremely low GA neonate. Nonetheless, preclinical data suggest that at perfusion pressures both higher than and lower than this reportedly relatively narrow plateau, cerebral blood flow becomes pressure-passive.

Changes in perfusion pressure, alterations in circulating oxygen and carbon dioxide levels, and in the magnitude of these fluctuations are important regulators of CBF in the preterm neonate, and CBF remains stable in preterm neonates who do not develop IVH. In contrast, lower systemic perfusion pressure followed by cerebral hyperperfusion, a fluctuating perfusion pattern, and lack of autoregulation are all associated with IVH. In response to these alterations, hemorrhage begins within the germinal matrix, and blood may rupture into the ventricular system. After ventricular distension by an acute hemorrhage event, cerebral blood flow falls. Venous stasis within the periventricular white matter ensues, and periventricular hemorrhagic infarction may soon develop.

Prostaglandins, and particularly the cyclo-oxygenase 2 (COX-2) system, are important modulators of CBF. Hypoxia, hypotension, growth factors, and inflammatory modulators may all induce COX-2. An increase in prostanoids results in release of VEGF, the potent angiogenic factor associated with hemorrhage.

Clinical events associated with increases in cerebral blood flow include vigorous resuscitation, rapid volume reexpansion, endotracheal tube repositioning, recurrent suctioning, complex nursing care procedures, and the administration of sodium bicarbonate, as well as respiratory distress syndrome, hypoxemia, extremes of  $PCO_2$  levels (i.e., both hypocapnia and hypercapnia), and acidosis. Similarly, IVH has been reported after seizures and pneumothoraces in infants with no previous hemorrhage. In contrast, a delay of at least 30 seconds (and to 180 seconds) to clamp the umbilical cord after birth stabilizes blood pressure and decreases the incidence of IVH.

## Candidate Genes for IVH

IVH has been attributed to the interaction of the environment and the genome. Preclinical candidate gene studies implicate

microvascular proteins, whereas clinical data suggest variants in inflammatory, coagulation, and vascular pathways.

Preclinical studies suggest that variants in one or more microvascular proteins confer vulnerability to environmental triggers. Mice with mutations in COL4A1 experience IVH after the stress accompanying vaginal delivery. These are preventable by surgical delivery, suggesting an interaction between an environmental trigger and the genome. Similarly, mice with mutations in activin receptor-like kinase 5, alpha v integrins, annexin 7, CREB binding protein, death receptor, Id proteins 1 and 3, or Tgfb2 also develop hemorrhage mimicking grade 4 IVH. All are implicated in angiogenesis and vascular maturation. (For review, see [Ment et al., 2014](#)). In addition, autoregulation relies on smooth muscle cells, pericytes, and proteins ranging from Ca<sup>++</sup> and K<sup>+</sup> channels, phospholipase A1, arachidonic acid, and adenosine to nitric oxide and cytokines among others. Mice with mutations in annexin 7, a gene encoding a Ca<sup>++</sup>-activated GTPase supporting Ca<sup>++</sup> channel activity, experience IVH, suggesting that variants in genes controlling CBF may also contribute to hemorrhage.

Coagulation factors have long been considered clinical candidate genes for IVH, both because of the pathophysiology of hemorrhage and their putative role in perinatal stroke. The most widely studied include the factor V Leiden (F5) variant, polymorphisms of methylene-tetrahydrofolate reductase (MTHFR) and the prothrombin 20210G>A variant (F2).

The contribution of the F5 polymorphism to IVH has been interrogated in different populations with varying results. A point mutation results in replacement of amino acid 506 arginine to glutamine in an activated protein C cleavage site. Activated protein C cleaves the peptide bonds in activated F5, resulting in inhibition of the coagulation pathway, and the variant presents with hypercoagulability. In four different studies, the F5 variant was reported to be associated with IVH, protect against hemorrhage or show no effect.

MTHFR, a second candidate, catalyzes the reduction of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate and is necessary for conversion of homocysteine to methionine. Hyperhomocysteinemia is associated with polymorphisms at -677 and -1298 and results in endothelial cell injury and alterations in coagulation including stroke, thrombosis and vascular disorders. A recent investigation of these polymorphisms in preterms with atypical PVHI suggested a high incidence of deleterious variants.

Cytokines are also postulated to play a role in IVH. Hypoxia results in the loss of blood-brain barrier function, permitting cytokines from the peripheral circulation direct access to the preterm brain. Cytokines secreted may also be synthesized by CNS glia. Interleukin-1 $\beta$  (IL-1 $\beta$ ) is the major cytokine involved in activation of the hypothalamic-pituitary-adrenal axis. In response to hypoxic ischemic injury, IL-1 $\beta$  increases across the brain, and both the IL-1 $\beta$  -511 T and the IL-1 $\beta$ -31 C allele have been associated with an increased risk for hemorrhage.

Similarly, in a single study the CC genotype of IL-6-174 significantly increased risk for IVH. Finally, TNF- $\alpha$  plays a pivotal role in the acute phase proinflammatory cytokine cascade and the -308 A allele in the TNF- $\alpha$  promoter region has been associated with IVH in preterm neonates.

Proteins contributing to the integrity of the developing CNS vasculature and those mediating cerebral blood flow are also excellent targets. COL4A1 encodes type IV collagen alpha chain 1A, a principal component of basement membranes expressed during development. Mutations in COL4A1 have been reported in infants with congenital porencephaly, fetal IVH, and preterm neonates with hemorrhage. Likewise, nitric oxide (NO) promotes cerebral vasodilation, and variants in the promoter of endothelial NO synthase have also been associated with hemorrhage.

## NEUROPATHOLOGY

Over 90% of all IVH in preterm infants originate in germinal matrix tissues between the caudate nucleus and the thalamus at the level of, or slightly posterior to, the foramen of Monro. A small percentage may also originate from the choroid plexus, a common site of IVH in term infants.

Periventricular hemorrhagic infarction (PVHI), germinal matrix destruction, porencephaly, and posthemorrhagic hydrocephalus (PHH) are the direct neuropathologic consequences of hemorrhage. In contrast, WMI with associated atrophic ventriculomegaly is frequently detected in infants with IVH but is multifactorial in etiology.

Ten percent to 20% of infants with GMH develop intraparenchymal abnormalities, or PVHI. These venous infarctions arise not only from the acute increase in intracranial pressure attributable to the GMH itself, but also from the tortuous anatomy of the periventricular venous system. In addition, some investigators believe that the parenchymal involvement of IVH represents a direct pressure-mediated extension of hemorrhage from either a massive GMH or blood within the ventricular system. These lesions are difficult to distinguish and have been variously named PVHI, parenchymal involvement of hemorrhage, or grade 4 IVH.

Further, whereas germinal matrix hemorrhage may result in the destruction of the germinal matrix and loss of neuronal and glial cells residing there, extension of hemorrhage into the subventricular zone and periventricular white matter is associated with not only the loss of additional precursor cells but also axonal necrosis. After grade 4 IVH, a cavitory lesion, or porencephaly, may result. Porencephalies have hemosiderin in the walls lining them and are freely communicating with the ventricular system.

Finally, PHH represents a not uncommon sequela of IVH. The meninges are thickened and show an infiltration by hemosiderin-laden macrophages, resulting in occlusion of the arachnoid villi, obstruction to flow of CSF through the foramina of Luschka and Magendie, and impairment of flow through the tentorial notch. Occasionally, aqueductal obstruction is caused by an acute blood clot, ependymal disruption, or reactive gliosis.

## NEUROIMAGING

Cranial ultrasonography is the current method of choice for the diagnosis and monitoring of IVH in preterm infants. Many nurseries use the standard grading system found in [Table 22-1](#). Although grades 3 to 4 IVH are easily imaged by ultrasonography, grades 1 to 2 hemorrhage may be more difficult to both diagnose and differentiate, and interobserver agreement is reportedly poor with these lesions. Use of the posterior fontanelle or the appreciation of posthemorrhagic ventricular dilation may facilitate diagnosis of grade 2 IVH, but this distinction may also be made by the use of newer MRI sequences including susceptibility-weighted imaging.

Rarely found without IVH, intraparenchymal echodensities (IPE) are believed to represent PVHI and generally occur in infants of the youngest GAs during the first postnatal week. The ultrasound appearance is an echogenic juxtaventricular white matter lesion, superior and lateral to the lateral ventricle and extending toward the cortex in a flare pattern without evidence for mass effect on the surrounding brain. IPE eventually cavitate or atrophy to form either a porencephaly or adjacent *ex vacuo* ventriculomegaly, and MR studies demonstrate a single hemorrhagic lesion adjacent to or communicating with the lateral ventricle in addition to IVH.

## CLINICAL FINDINGS

The clinical manifestations of IVH are variable, and in one large series, over 75% of hemorrhages were clinically unrecognized. Nonetheless, infants with large hemorrhages may suffer a significant decrease in hematocrit and experience coma, seizures, changes in tone and reflexes, and unremitting metabolic acidosis. Apneic and bradycardic spells may be attributable to either increased intracranial pressure or changes in CBF to brainstem respiratory control centers. In addition, infants with even low-grade IVH may have significantly elevated serum glucose values and evidence for inappropriate secretion of antidiuretic hormone.

Examination of the CSF in preterms undergoing unremarkable sepsis evaluations reveals 0 to 20 WBC, absence of RBC, and protein values of 100 to 200 mg/dL. In patients with new-onset IVH, findings include large numbers of RBC, WBC in direct proportion to the peripheral RBC/WBC ratio, elevations of protein, and low glucose values. Although infants with grade 1 IVH have no CSF abnormalities, for neonates with grade 2 to 4 hemorrhage CSF protein levels and red blood cell counts correlate with grade of IVH. Profound hypoglycorrhachia, with CSF glucose values lower than 10 mg/dL, may be found in infants with all grades of hemorrhage, although this is also more common with high-grade hemorrhage.

Days to weeks after hemorrhage, the CSF demonstrates decreasing red blood cell numbers but elevated white blood cell counts in excess of 500 to 1000/mm<sup>3</sup> and persistent hypoglycorrhachia. The latter two findings may lead to a suspicion of bacterial meningitis, a diagnosis only determined by CSF cultures.

## NEONATAL OUTCOME

In the neonatal period, infants with IVH are at risk for the development of seizures and posthemorrhagic ventricular dilation (PHVD). The incidence of seizures in infants with IVH ranges from 5% to 75%, and diagnosis is facilitated by continuous amplitude-integrated EEG.

Approximately one third of infants with IVH develop PHVD, defined as ventricular enlargement greater than the 97% for GA. In addition, as many as 25% to 50% of infants with grades 3 to 4 IVH experience PHH, or the presence of intraventricular blood, increasing ventriculomegaly, and increased intracranial pressure; 15% of neonates with grades 3 to 4 IVH and PHH require permanent CSF diversion (Mazzola et al., 2014). Infants with IVH may also develop acute obstruction at either the foramen of Monro or the aqueduct; they present with signs of acutely increased intracranial pressure and require immediate neurosurgical attention, as shown in

 Video 20-1. Randomized controlled trials for PHH include intraventricular streptokinase or tissue plasminogen activator, repeated lumbar punctures, and DRIFT (drainage, irrigation and fibrinolytic therapy), but none of these strategies has proven effective.

Infants with IVH and/or PVHI should undergo regular ultrasonographic determinations of ventricular size. If ventricular size and ICP increase, neurosurgical consultation is recommended. Temporizing measures, including subgaleal shunts, ventricular reservoir placement, or third ventriculostomy (Video 20-2) aim to avoid permanent ventriculoperitoneal shunt placement, but future multicenter randomized trials are required to explore these treatment options.

## LONG-TERM OUTCOME

Cerebral palsy has long been recognized as a sequela of IVH, and significant cognitive and neuropsychiatric abnormalities are also being recognized at school age and beyond.

For preterm children, the incidence of CP is reported to increase with the grade of hemorrhage. CP is diagnosed in 30% of children with grade 3 to 4 IVH, 10.4% with grades 1 to 2 IVH, and 6.5% with no hemorrhage. Recent data indicate that CP among preterm infants is almost equally divided among spastic diplegia, hemiplegia, and quadriplegia.

IVH is also a significant cause of disability in the prematurely born. Preterm subjects with grades 3 to 4 IVH have significantly worse cognitive abilities and educational performance compared with those without hemorrhage. They are also at high risk for executive function, memory and behavioral disorders. In a recent large study, over three fourths of subjects with grade 3 to 4 IVH had full scale IQ scores more than 2 SD lower than the mean, compared with 12% of subjects with no hemorrhage. However, even survivors with low-grade IVH experience alterations in cognition and behavior, and recent reports note significantly more deficits in cognitive abilities and executive function in preterm subjects with grade 2 IVH compared with those without hemorrhage at childhood and adolescence.

Finally, gray and white matter volumes are decreased during childhood and adolescence in preterms with IVH. Similarly, diffusion tensor imaging shows impaired cerebral myelination in those with high-grade hemorrhage, suggesting that IVH irreversibly alters corticogenesis in the prematurely born.

## PREVENTION OF INTRAVENTRICULAR HEMORRHAGE

Although the most efficacious means for preventing IVH would be the prevention of preterm birth, environmental and pharmacologic interventions must be considered (Table 22-5).

When preterm birth is certain, transport of the mother and fetus to a tertiary perinatal center specializing in high-risk obstetric care is advisable; infants who are “outborn” and require transport have consistently higher rates of hemorrhage than “inborn” neonates. Blood pressure and transcutaneous oxygen pressure should be continuously monitored to prevent hypoxemia, hypotension, and acidosis. Abrupt changes in

**TABLE 22-5** Prevention of IVH in Preterm Neonates

Etiology	Strategies
Environmental	Universal prenatal care Maternal transport Tertiary care center delivery Delayed cord clamping (when feasible for 30–60 seconds after birth)* Bag and mask ventilation, early CPAP Monitoring of blood gases to prevent hypoxemia, hypocarbia, hypercarbia, and/or acidosis Continuous blood pressure monitoring—prevention of arterial hypotension No routine tracheal suctioning or chest physical therapy No early neonatal transport
Pharmacologic	Complete course of antenatal steroid exposure Early administration of surfactant (within first 30 postnatal minutes) Postnatal indomethacin Avoid sodium bicarbonate exposure

CPAP, continuous positive airways pressure.

\*American College of Obstetricians and Gynecologists (Obstet Gynecol 2012;120:1522–1526)

blood pressure, hypocarbia with PCO<sub>2</sub> levels lower than 30 mm Hg, and sodium bicarbonate administration should be avoided. Finally, delayed cord clamping significantly decreases the incidence of IVH, and the WHO recommends delayed cord clamping, when feasible, for at least 30 to 60 seconds after birth in preterm neonates.

In addition, corticosteroids administered before preterm birth lower the incidence of IVH and decrease mortality. Fetal exposure to antenatal steroids decreases the relative risk of any IVH by half, and the relative risk for severe IVH is approximately 25% compared with preterms without exposure. These benefits extend to a broad range of gestational ages, are not limited by gender or race, and are not associated with adverse side effects.

Likewise, postnatal indomethacin treatment significantly decreases the overall risk for IVH, and particularly that for grade 3 to 4 hemorrhage. Meta-analyses show no increase in necrotizing enterocolitis, excessive bleeding, or renal complications in treated infants compared with controls, and follow-up studies demonstrate no adverse outcomes. Current recommendations suggest that infants of 32 weeks and younger GA who are at high risk for IVH and lack contraindications for therapy be treated with prophylactic indomethacin 0.1 mg/kg/dose beginning at 6 to 12 postnatal hours, with two additional doses 24 and 48 hours thereafter.

Finally, protocols, including both pharmacologic and environment interventions (antenatal steroids), resuscitation by an attending neonatologist to include bag and mask ventilation with air only, early CPAP, administration of surfactant without intubation and avoidance of routine tracheal suctioning, and arterial hypotension significantly decrease hemorrhage.

## CEREBELLAR HEMORRHAGE

Cerebellar hemorrhage (CBH) occurs in 20% or more of preterm neonates, and as many as three-fourths of infants with cerebellar hemorrhages experience IVH. The timing of injury may differ, however, suggesting differences in pathophysiology; the mean age for diagnosis of CBH is 5.2 days, compared with 1.7 days for IVH. Risk factors for CBH include lack of antenatal steroid exposure, emergent cesarean section, hypotension requiring therapy, sepsis, PDA, and acidosis. Finally, infants who experience CBH are at high risk for neurodevelopmental disability.

## WHITE MATTER INJURY OF THE PREMATURE NEWBORN

White matter injury (WMI) is the predominant lesion of the premature newborn brain, resulting in much of the cognitive, behavioral, and motor impairments seen in children born prematurely. The true incidence of this injury is not known, largely because detection of the diffuse, noncystic form of this lesion is difficult using conventional neuroimaging and because a threshold for defining clinically important signal abnormality in the cerebral white matter has not been rigorously defined either by US or MRI. White matter injury is used increasingly in place of the traditional term periventricular leukomalacia (PVL) as it describes better the more common diffuse lesion of the cerebral white matter that extends beyond the periventricular regions. A more encompassing term, "encephalopathy of prematurity," has been proposed by Volpe to include the findings of cortical and subcortical gray matter abnormalities associated with WMI (Volpe, 2009). This term is not yet in widespread use in the literature, but it reflects increasing evidence that premature newborns suffer a diffuse

brain injury that affects many gray matter structures as well as cerebral white matter.

## Neuropathology

The neuropathology of WMI consists of two components: focal necrosis (leading to cyst formation) in the deep periventricular white matter and a diffuse gliosis of the cerebral white matter, often extending well beyond the periventricular region. The acute lesions of WMI are characterized by axonal swellings, microglial activation, and reactive astrocytosis. Older lesions of remote WMI consist of astrogliosis, microgliosis, hypomyelination, and sometimes cysts which may be quite small (less than 1 mm), hence not detectable by conventional imaging studies. Failure of oligodendrocyte maturation results in hypomyelination, which together with axonal loss/injury, causes the decrease in cerebral white matter volume with accompanying increase in ventricular volume (atrophic ventriculomegaly).

Gray matter (neuronal) loss and injury in association with WMI has been demonstrated by quantitative neuroimaging studies showing marked reductions in cortical and subcortical gray matter volume and neuropathologic studies showing significant neuronal loss and gliosis in the thalamus, basal ganglia, and cerebral cortex. In addition, gliosis and neuronal loss were found in the cerebellar white matter, cortex, and nuclei, and selected brainstem nuclei of some infants with WMI. It remains unclear whether the neuronal loss and gliosis are predominantly a consequence of primary injury to axons of the cerebral white matter, or whether there is a separate direct injury to neurons of the cortical, subcortical, and cerebellar gray matter, or both. Volpe elegantly synthesized the neuropathologic findings together with concurrent events in human brain development to present a comprehensive thesis of how the interaction of both destructive and altered developmental processes produces the "encephalopathy of prematurity." He proposed that WMI in the preterm brain involves primary destructive effects as well as widespread disturbances of brain maturation and development, producing a diffuse brain "lesion" (Volpe, 2009). This review is a must read for understanding injury to the developing brain, as he describes how injury and loss of cerebral axons, subplate neurons and migrating cortical GABAergic neurons, and impaired cerebellar growth and injury all may contribute to the diffuse encephalopathy of prematurity that extends beyond the well-recognized white matter pathology.

## Pathogenesis

The distinctive lesion found in the immature white matter of preterm newborns likely results from the interaction of multiple pathogenetic factors whose relative contributions likely differ among individuals and populations of newborns (Volpe, 2008). Numerous risk factors for the development of WMI have been identified, but in most cases three major categories of factors contribute to the pathogenesis of WMI in premature newborns (Box 22-3):

1. Hypoxia-ischemia
2. Inflammation/infection
3. Vulnerability of immature white matter

These three categories, as well as additional risk factors for WMI, are discussed in detail.

### Hypoxia-Ischemia

Neuropathologic studies employing postmortem injections of the vessels demonstrated vascular border and end zones in the

**BOX 22-3** Factors in the Pathogenesis of White Matter Injury**HYPOXIA-ISCHEMIA**

- Arterial watershed zone in periventricular white matter
- Low cerebral blood flow in cerebral white matter
- Impaired autoregulation—pressure-passive cerebral circulation
- Patent ductus arteriosus
- Acute/chronic lung disease, including hypoxia, hypocarbia
- Sepsis/infection causing hypotension, impaired autoregulation

**INFLAMMATION/INFECTION**

- Chorioamnionitis
- Maternal/intrauterine infections (other than chorioamnionitis)
- Neonatal infections (e.g., necrotizing enterocolitis)
- Abundance of activated microglia in immature white matter

**INTRINSIC VULNERABILITY OF IMMATURE WHITE MATTER AND OLIGODENDROCYTES**

- Impaired antioxidant defense in immature oligodendrocytes
- Exuberant production of reactive oxygen and nitrogen species by reactive astrocytes, oligodendroglia, and microglia
- Susceptibility to excitotoxicity through high expression of glutamate transporter and receptors

**ADDITIONAL POTENTIAL RISK FACTORS**

- Intraventricular hemorrhage
- Postnatal corticosteroid use
- Nutritional deficiencies

periventricular white matter in which WMI is typically found, suggesting a major role for hypoxia-ischemia. In addition, cerebral blood flow is quite low in the white matter of preterm newborns, and data show that critically ill premature newborns frequently have pressure-passive circulation at least intermittently, putting them at risk for cerebral ischemia. Notably, the fluctuations in pressure-passivity do not necessarily correlate with periods of hypotension, suggesting that a normal blood pressure does not necessarily indicate adequate cerebral perfusion. In addition to the intrinsic immaturity of the cerebral circulation in preterm newborns, a patent ductus arteriosus, as well as serious perinatal or postnatal infections such as necrotizing enterocolitis (NEC), sepsis, and/or meningitis, can all adversely affect cerebral hemodynamics. Hypoxia and hypocarbia, ventilation strategies, suctioning, medications such as indomethacin or caffeine, infusions, transfusions, and other interventions have all been shown to exert a deleterious effect on cerebral hemodynamics and may contribute to the pathogenesis of WMI.

**Inflammation/Infection**

Both epidemiologic and experimental studies support a role for inflammation and/or infection in the pathogenesis of WMI. Studies show an association between maternal infection, prolonged rupture of membranes, cord blood IL-6 levels, placental inflammation/infection, and WMI, suggesting that maternal infection is an etiologic factor in the pathogenesis of WMI. Similarly, significant postnatal infections such as sepsis or NEC have been associated with WMI. Neuropathologic data show an abundance of activated microglia in the white matter of the preterm brain, suggesting that infection/inflammation is a potential mechanism in the pathogenesis of WMI. Rodent data show involvement of activated microglia and a role of cytokines such as interferon- $\gamma$ , suggesting mechanisms by which inflammation/infection may play a role in the pathogenesis of WMI (Back and Rosenberg, 2014). Additionally, an

interaction or synergism between hypoxia-ischemia and infection/inflammation is likely, as hypoxia-ischemia may result in activation of microglia, and conversely, systemic infection may result in hypoxia-ischemia.

**Vulnerability of Immature White Matter**

WMI occurs much more commonly in the preterm newborn than in the term newborn, and its diffuse gliotic lesion affects the immature (premyelinating) oligodendrocyte predominantly. These findings point to a maturational vulnerability of the immature cerebral white matter in which this cell type is most vulnerable to injury at this age. Immature oligodendrocytes are susceptible to injury and apoptotic cell death by free radical attack, cytokines, and excitotoxicity.

**Additional Risk Factors**

Numerous risk factors for WMI and/or long-term neurologic impairments have been identified in epidemiologic and prospective studies of preterm newborns, although the specific mechanism by which each risk factor exerts its effect is not always clear. Many known risk factors—for example, lower gestational age at birth and chronic ventilation for chronic lung disease in preterm newborns—may mediate their effect through one or more of the three major pathogenetic mechanisms described previously. Additional risk factors deserve mention.

**Intraventricular Hemorrhage.** As described in the previous section on IVH, IVH and WMI are often both present in many neuropathology, imaging, and clinical studies of preterm newborns and are difficult to separate. IVH likely increases the risk of WMI, not only because these two entities share some of the same pathogenetic risk factors (e.g., hypoxia-ischemia) but also because IVH may exacerbate WMI. Given their frequent cooccurrence, it is difficult to differentiate the etiologic factors and separate effects of IVH and PVL on long-term neurologic outcome.

**Postnatal Corticosteroid Use.** Clinical studies of postnatal steroids (particularly dexamethasone) given to treat lung disease have shown an association with worse neurodevelopmental outcome in treated compared with untreated preterm newborns, although the mechanism is unclear. Data showing an adverse effect of dexamethasone on brain development and neurodevelopmental outcome led to a change from frequent use of postnatal steroids to treat lung disease, to a careful weighing of the risks of steroid use against the risk of severe lung disease, and to consideration of using hydrocortisone rather than dexamethasone.

**Nutrition.** Nutritional factors such as total caloric intake, as well as specific vitamins and nutrients, are likely extremely important for optimal brain development and neurologic outcome. Data suggest that undernutrition during a vulnerable period of brain development can result in hypomyelination (rodent) or smaller brain volumes (human). Further work is needed in this critically important field of early life nutrition and its influence on brain development.

**Clinical Presentation**

WMI is typically a clinically silent lesion, evolving over days to weeks with few or no outward neurologic signs, until spasticity is first detected weeks to months later or when children present at an even later age with cognitive difficulties at preschool or school age, sometimes without preceding motor abnormalities. With moderate to severe WMI, some degree of spasticity in the lower extremities may be detected by careful

examination by term age or earlier, and there may be axial flexor and proximal appendicular weakness or feeding difficulties when WMI is severe. Because detection of WMI is not possible by routine clinical examination during the newborn period in most cases, imaging studies are needed to detect WMI (and IVH), as recommended in standard published imaging guidelines (Ment et al., 2002).

## EEG

EEG is useful in the identification of brain injury by demonstrating background abnormalities in the first days after birth or by demonstrating focal abnormalities such as transient positive rolandic sharp waves (a highly specific but not highly sensitive marker of WMI). Serial EEG studies are more useful than a single EEG for the identification of abnormalities that correlate with WMI and long-term neurologic deficits. Interestingly, WMI is associated with early acute EEG changes followed by later chronic abnormalities (coinciding with cyst formation, when that occurs), supporting the idea that the insult resulting in WMI occurs around or very soon after birth.

## Neuroimaging

### Ultrasound

The evolution of echogenic (or hyperechoic) lesions in the periventricular white matter over the first few weeks after birth, with or without cyst formation, is the classic description of WMI detected by serial cranial ultrasound (US) studies (Fig. 22-15). The diagnosis of noncystic WMI is difficult with US, partly because the interobserver variability is high even in rigorous, prospective US studies and partly because there is no general agreement regarding the number, size, location, and persistence of hyperechoic lesions defining WMI by US. Cerebral atrophy (i.e., volume loss) associated with WMI results in eventual atrophic ventriculomegaly and enlarged extraaxial

CSF spaces, which are usually present within weeks after birth (see Fig. 22-15).

### Magnetic Resonance Imaging

MRI is used to detect WMI in newborns and children born prematurely, particularly for research studies but increasingly for clinical purposes. Conventional T1- or T2-weighted (T1w, T2w) MRI sequences easily demonstrate cystic lesions, but noncystic WMI is also detected by MRI, evident as high T2w signal intensity and low T1w signal intensity in the cerebral white matter in newborns (Kwon et al., 2014). Punctate lesions have been reported particularly in the corona radiata and posterior periventricular white matter (and occasionally the gray matter) (Fig. 22-15). Notably, cystic lesions may collapse over time and may appear as punctate lesions or other patterns of signal abnormality in the white matter, highlighting the utility of serial imaging studies. Although MRI is more difficult to obtain than US in the early acute period, it is more sensitive than cranial ultrasound for the detection of WMI in preterm newborns, especially for the noncystic form of WMI and small cerebellar hemorrhage. As for US studies, no universally accepted measure of the severity, pattern, or location of signal abnormality by MRI defines WMI for clinical purposes. Although clearly a greater severity of WMI correlates with a higher incidence of later neurodevelopmental deficits in general, a broad range of neurologic outcome exists for mild, moderate, and severe WMI.

Research MRI studies have been particularly helpful in elucidating the timing, distribution, and clinical correlates of WMI in children born prematurely. For example, volumetric MRI data analysis demonstrated the marked reduction in cortical and subcortical gray matter volumes accompanying WMI that had been underappreciated before the availability of these quantitative measurement techniques. Volumetric, DTI, and functional MRI studies of older children born preterm have been particularly useful in determining the clinical correlates

**Figure 22-15. Ultrasound and MRI correlation of white matter injury.** Sagittal and coronal US at 2 days (A, B) and 1 month (C), and MRI at 2 months (D, Sag T1; E, Ax T1 FLAIR; F, Ax T2) of baby born at 28 weeks, showing PVL with echogenicity in periventricular white matter bilaterally by US (arrows) that evolves to bilateral linear punctate lesions by MRI and enlargement of extraaxial CSF spaces (notched arrowheads).

of MRI findings because the larger, mostly myelinated brain of the older child allows many brain structures to be analyzed in greater detail and more precisely than in the newborn, and cognitive, social, and behavioral outcome measures are also more definitive and specific than at the young ages often used in neonatal outcome studies.

### Recommendations for Imaging the Preterm Neonate and Child Born Preterm

Current recommendations for imaging the preterm neonate state that screening cranial ultrasound should be performed on all infants with gestational ages younger than 30 weeks at 7 to 14 days of age and should be repeated at 36 to 40 weeks' postmenstrual age (Ment et al., 2002). This recommendation by the Quality Standards Subcommittee of the American Academy of Neurology and the Practice Committee of the Child Neurology Society is designed to detect both clinically silent IVH, which may require additional clinical and/or radiologic monitoring and changes in management, and

evidence of PVL +/- ventriculomegaly. Emerging data suggest that cerebral MRI with DTI at term equivalent age may provide important prognostic information about injury not detected by US and may help predict motor outcome and, to a lesser degree, risk of cognitive, social, or sensory impairments. The largest study to date of 480 newborns born at younger than 28 weeks confirmed that severity of WMI and cerebellar injury predicted neurologic outcome at 18 to 22 months of age, and that late US or MRI (35 to 42 weeks) were more predictive than early US (4 to 14 days). Brain MRI may also be performed in an older infant or child born prematurely to confirm clinically suspected WMI when there are cognitive, motor, and/or sensory impairments of unclear etiology (see Fig. 22-16), for example, when neonatal cranial US studies were reportedly normal. MRI studies beyond the newborn period rarely show cysts but may show increased signal intensity on T2w as well as fluid-attenuated inversion-recovery images in areas of gliotic white matter with delayed or decreased myelination, thinning of the corpus callosum, and enlarged ventricles, indicating a decrease in cerebral white (and likely gray) matter

**Figure 22-16.** MRI of mild and severe white matter injury in young children. **A–C,** Axial T2-weighted. **(A)** T2 fluid-attenuated inversion-recovery (FLAIR) **(B)** and sagittal T1-weighted **(C)** images demonstrating mild WMI in a 12-month-old born at 30 weeks' gestational age; at age 3 years this patient had mild spastic diparesis with accompanying gross and fine motor impairments/delays. **D–F,** Axial T2-weighted. **(D),** T2 FLAIR **(E)** and sagittal T1-weighted **(F)** images demonstrating severe WMI in a 2-year-old boy born at 29 weeks' gestational age; this patient had severe diplegia (quadriplegia), infantile spasms, severe cognitive impairment with IQ lower than 70, and cerebral visual impairment. *Arrows* demonstrate areas of signal abnormality in the white matter on axial sequences and thinning of the corpus callosum on the sagittal sequence.

volume (Fig. 22-16). Abnormal signal intensity may be detected in gray matter structures, but volume loss in cortical and subcortical gray matter structures is difficult to detect without quantitative measurement.

## Outcome

WMI is the principal cause of the cognitive, behavioral, motor, and sensory impairments found in children born at younger than 32 weeks' gestational age. Most outcome studies of children born prematurely include children with all types of brain lesions, so it is difficult to determine the specific outcome attributable to WMI alone. That being said, it is likely that WMI and hemorrhagic venous infarction (grade 4 IVH) are the major lesions contributing to neurologic disabilities in children born prematurely. The incidence and severity of neurologic impairments increases with lower gestational age at birth, but many other antenatal, neonatal, and postneonatal risk factors relate to later neurodevelopmental impairments, such as chronic medical illness, socioeconomic status, and parental education.

## Cognitive

Lower overall IQ and specific types of cognitive impairments have been found in children born prematurely compared with term-born children. Lower gestational age and birth weight are major risk factors for cognitive impairments, in addition to identified brain injury. Deficits of attention and organization, math skills, and reading comprehension are much more common in children born extremely preterm than in term-born controls. Most large prospective studies of the cognitive outcome of older children born prematurely do not associate cognitive measures with specific brain lesions (such as WMI), but quantitative imaging data suggest that it is indeed WMI and associated gray matter correlates that underlie most of these cognitive impairments.

## Social/Behavioral

Children born prematurely have higher rates of social and behavioral difficulties than do term-born children, including attention deficit/hyperactivity, emotional, anxiety, autism spectrum, and behavioral disorders. Of these, attention problems are commonly recognized, although anxiety and other social and emotional disorders are increasingly identified. Children born preterm appear to be at higher risk of autism than term-born children, but the reported incidence of autism is highly variable, depending on the population studied, age at assessment and the tool used to identify autistic traits.

## Motor

WMI and lower gestational age at birth are major risk factors for motor disability. The incidence of CP is much higher in children born extremely prematurely, occurring in approximately 20% of children born at 26 weeks or younger gestational age, but in only 4% of children born at 32 weeks' gestational age. Spastic diparesis is the most common form of CP in preterm infants with WMI, which may present as quadriplegia when severe. Some dystonia is frequently part of spastic diparesis caused by PVL, and occasionally hypotonia, ataxia, or some other motor abnormality may be observed. Hemiparesis is found less frequently than spastic diparesis and usually results from periventricular hemorrhagic infarction but may occasionally result from markedly asymmetric WMI. Even in the absence of overt CP, coordination difficulties, and other more subtle abnormalities of motor function or development are often found in children born prematurely.

## Visual

Whereas some children born prematurely have retinopathy of prematurity affecting their vision, WMI and other cerebral lesions can result in strabismus, nystagmus, and other disorders of ocular motility, low acuity, visual field deficits (largely inferior fields), and perceptual difficulties, some of which may not be recognized until school age or later. Children with WMI may have visual perceptual defects or other higher order visual impairments that worsen their cognitive and school function, so these are particularly important to detect and address with therapy.

## Epilepsy

Children with severe WMI occasionally develop epilepsy (e.g., Fig. 22-16), although epilepsy is more commonly related to gray matter lesions, and most long-term studies reporting epilepsy rates do not specify associated brain lesions. Reported rates of epilepsy vary from 2% to 6%, and are associated with lower gestational age at birth.

## Prevention and Management

Preventive efforts should begin antenatally whenever possible, with administration of medications known to reduce morbidity in preterm newborns. Antenatal steroid administration has been associated with approximately 50% decrease in cerebral white matter lesions and a decrease in neonatal death (odds ratio 0.69), with no change or decreased rate of adverse neurodevelopmental outcome, and thus is recommended for women with preterm labor. Meta-analyses of five trials of antenatal magnesium showed a 32% reduction in the risk of CP and improved motor outcome.

## NICU Management

After birth, maintenance of normal cerebral perfusion and oxygenation should be attempted by careful management of systemic hemodynamics and oxygenation, including blood pressure, intravascular volume, oxygenation, and ventilation, and avoidance of treatments or procedures that result in sudden or deleterious changes in hemodynamics or oxygenation. Avoidance and prompt treatment of infection may minimize WMI, although no prospective studies have demonstrated the effect of such interventions on reducing WMI. Adequate nutrition is also important for normal brain development, but the specific type and amount of nutrients also remain an active area of research.

At the time of writing, no specific neuroprotective therapies or medications prevent or minimize WMI during the newborn period, but promising neuroprotective agents shown to prevent or minimize WMI in animal models are currently being tested in clinical trials (Juul SE and Ferriero, 2014). Erythropoietin is being tested in two ongoing trials to determine whether it can improve neurologic outcome in preterm newborns, and melatonin is being tested to determine whether it has neuroprotective effects in IUGR fetuses and preterm newborns. Results of these trials will likely be available after publication of this textbook with further trials of neuroprotective agents in the coming years.

## Management After NICU Discharge

Management of infants with WMI after discharge from the neonatal intensive care unit should include careful monitoring to identify any cognitive, behavioral, sensory, or motor delays or impairments, with implementation of appropriate therapies. Follow up by pediatric neurologists or other

pediatric physicians trained in infant and child development should be provided for children born prematurely, particularly those born at younger than 32 weeks' gestational age. Early intervention services, including physical, occupational, speech and language, behavioral/social, and visual therapies, should be provided as needed to address specific developmental delays or impairments. Auditory and visual evaluations should be performed at older ages to ensure normal specialized sensory function because subtle sensory and perceptual difficulties may not be apparent without specific testing. Similarly, assessment of cognitive and social function of school-age children may be needed even in the absence of early developmental delay or other sensorimotor impairments.

## Perinatal Metabolic Encephalopathies

Rebecca N. Ichord and David R. Bearden

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

### INTRODUCTION

This chapter reviews perinatal metabolic encephalopathies under two categories: (1) correctable disturbances in glucose and ion balance, and (2) genetically determined inborn errors of metabolism (IEMs), grouped according to clinical symptomatology into the following four types (Box 23-1):

- Fulminant metabolic crisis
- Epileptic encephalopathies
- Chronic encephalopathies with multiorgan involvement
- Chronic encephalopathies without multiorgan involvement

A brief synopsis of each condition is provided, emphasizing distinctive clinical features, diagnosis, and management (Hoffman, Zschocke, and Nyhan, 2010; Ficioglu and Bearden, 2011).

### GENERAL APPROACH

Metabolic disease should be considered in any newborn with encephalopathy. Acute reversible metabolic perturbations are monophasic and resolve after metabolic correction, whereas presentation in IEMs is delayed or progressive, often with diffuse nonspecific symptoms evolving to malignant symptoms (seizures, movement disorder). Neonatal-onset chronic static encephalopathies are increasingly linked to genetic metabolic disease, and may have few features distinguishing them as metabolic. Suspicion of IEM should increase with any of the following factors:

- Multiple components of the nervous system affected (brain, peripheral nerves, skeletal muscle)
- Multiple organ systems affected
- Systemic symptoms (vomiting, autonomic instability)

The most common nongenetic acute neonatal metabolic encephalopathies can be identified from history and results of first-stage studies. Encephalopathic newborns often are assumed incorrectly to have suffered asphyxia when, in fact, they have a static disease of prenatal origin or a metabolic disease that decompensated at birth. Perinatal hypoxic-ischemic encephalopathy should be diagnosed only with unequivocal evidence of ischemic or hypoxemic exposure. Without this, the differential diagnosis should remain broad until a comprehensive evaluation is complete. Evaluation involves staged diagnostic testing while simultaneously treating potentially life-threatening conditions (Table 23-2, Fig. 23-1).

### CORRECTABLE DISTURBANCES OF GLUCOSE AND SALT BALANCE

#### Hypoglycemia

Neonatal hypoglycemia falls into five categories: (1) extrauterine maladaptation, (2) hyperinsulinism, (3) increased glucose consumption, (4) congenital endocrinopathies, and (5) IEMs. Clinical presentation is variable and nonspecific, featuring

tachycardia, irritability, and altered consciousness; with blood glucose levels less than 1.0  $\mu\text{M}$ , symptoms may progress to coma and circulatory collapse. Mild symptoms rapidly reverse with glucose administration, whereas severe encephalopathy does not. In severely symptomatic cases, imaging may show acute injury preferentially affecting the parietal-occipital cortex and periventricular white matter. Symptomatic infants should be treated while evaluation proceeds. Poor outcome is associated with severe acute encephalopathy or when the cause is a fatty acid oxidation defect or hyperinsulinism.

### Disturbances of Sodium Balance

Sodium plays a critical role in regulating cell volume, water flux, membrane excitability, and synaptic transmission. Causes of hyponatremia or hypernatremia are numerous.

#### Hyponatremia

Hyponatremia is common in sick neonates, often as a result of excess arginine vasopressin secretion with other organ disease (lung disease, intracranial hemorrhage, surgery), and rarely congenital adrenal insufficiency. Mild symptoms appear at 120 to 130 mEq/L and severe symptoms at less than 120 mEq/L, with somnolence and hypotonia progressing to seizures and coma. Mild subacute chronic hyponatremia is treated by correcting the underlying cause. Treatment of acute severe hyponatremic encephalopathy is challenging. Seizures are resistant to anticonvulsants, and the encephalopathy frequently depresses respiratory function and warrants rapid correction, which can be accomplished with 3% saline, generally without neurologic complications.

#### Hypernatremia

Hypernatremic encephalopathy arises from hypertonic dehydration of neurons and glia, sometimes compounded by hyperviscosity, cerebral venous thrombosis, or intracranial hemorrhage. Hypernatremia is caused by excess sodium intake, excess water losses, or both. Management requires repleting volume deficits with isotonic solutions or plasma expanders, correcting hypernatremia over 48 to 72 hours, and lowering serum sodium approximately 10 to 15 mEq/L/24 hours.

### INBORN ERRORS OF METABOLISM

Perinatal genetic metabolic encephalopathies are divided into the following four groups (Box 23-2):

1. Acute fulminant illnesses with metabolic crisis
2. Subacute epileptic encephalopathies
3. Chronic encephalopathies with multiorgan involvement
4. Chronic encephalopathies without multiorgan involvement

Clinical features, magnetic resonance imaging (MRI) findings, and results of first-stage tests may suggest specific disorders, verified by definitive second- or third-stage tests, including

**BOX 23-1** Predominant Presenting Clinical Features in Neonatal Genetic Metabolic Disorders**ACUTE FULMINANT METABOLIC CRISIS**

- Urea cycle defects
- Maple syrup urine disease (MSUD)
- Organic acidopathies: isovaleric, propionic, methylmalonic
- Oxidative phosphorylation disorders (OxPhos defects): pyruvate dehydrogenase (PDH) deficiency, pyruvate carboxylase (PC) deficiency, electron transport defects
- Fructose-1,6-bisphosphatase deficiency
- Glutamine synthetase deficiency
- Fatty acid oxidation defects: carnitine palmitoyltransferase deficiency type II (CPT II), mitochondrial trifunctional protein deficiency (MTP defects), malonyl-CoA decarboxylase (MCD)

**SUBACUTE PROGRESSIVE EPILEPTIC ENCEPHALOPATHY**

- Glycine cleavage defects
- Pyridoxine and pyridoxal 5'-phosphate (PLP) dependency
- Sulfite oxidase and molybdenum cofactor deficiency (Sulf Ox, Moco)
- Menkes' disease
- Cytochrome oxidase (COX) deficiency
- L-amino acid decarboxylase (L-AAD) deficiency
- Methyl-CpG-binding protein-2 (MECP2)
- Glucose transporter type 1 deficiency syndrome (GLUT1 DS)
- 5-amino-4-imidazolecarboxamide ribosiduria/succinyl-5-amino-4-imidazolecarboxamide ribosiduria (AICAR/SAICAR)
- Serine biosynthesis defects

**CHRONIC ENCEPHALOPATHY WITH MULTIORGAN INVOLVEMENT**

- Mitochondrial disorders
- Congenital defects of glycosylation (CDGs)
- Peroxisomal disorders
- Cholesterol biosynthesis defects

**CHRONIC ENCEPHALOPATHY WITHOUT MULTIORGAN INVOLVEMENT**

- L-amino acid decarboxylase (L-AAD) deficiency
- Glutaric aciduria
- GTP cyclohydrolase deficiency
- Phenylketonuria (PKU)
- Succinic semialdehyde dehydrogenase (SSADH) deficiency

genetic and molecular studies (Xue, Ankala, Wilcox, and Hegde, 2014). See Table 23-2 and Figure 23-1.

**Acute Fulminant Metabolic Diseases****Maple Syrup Urine Disease**

Maple syrup urine disease (MSUD) is an autosomal-recessive defect of branched-chain keto acid dehydrogenase (BCKAD) causing elevated plasma leucine, isoleucine, and valine, and their corresponding keto acids. The severe neonatal form is most common, presenting 4 to 7 days after birth with progressive lethargy, dystonia, and seizures, evolving to coma and decerebrate posturing. MRI features include T2 hyperintensity and restricted diffusion of brainstem, dentate nuclei, deep gray nuclei, and periventricular white matter. Biochemical abnormalities include ketoacidosis, ketonuria, hypoglycemia, and hyponatremia. Elevated plasma leucine, isoleucine, and valine, and elevated urinary 3-hydroxyvaleric acid, should suggest the diagnosis. BCKAD enzyme activity in skin fibroblasts is low. Treatment for severe decompensation requires peritoneal dialysis or hemodialysis, along with supportive

**BOX 23-2** Causes of Hyponatremia and Hypernatremia in Neonates**CAUSES OF HYPONATREMIA****Disorders Causing Positive Water Balance**

- Excessive AVP secretion
  - Systemic hypoxia, ischemia
  - Mechanical ventilation
  - Pneumothorax
  - Intracranial hemorrhage
  - Septic shock
  - Neonatal drug withdrawal
  - Hypothyroidism
- Water intoxication
  - Inappropriately dilute intravenous fluids
  - Inappropriately dilute formula feedings

**Disorders Causing Negative Sodium Balance**

- Abnormal renal salt handling
  - Chronic renal insufficiency
  - Adrenal insufficiency
  - Acute pyelonephritis
  - Acute obstructive uropathy
  - Urinary ascites
- Insufficient salt intake relative to losses
  - High insensible fluid/electrolyte losses
  - Vomiting, diarrhea
  - Low-salt-containing infant formulas

**CAUSES OF HYPERNATREMIA****Disorders Causing Negative Water Balance**

- Deficient AVP secretion (central diabetes insipidus)
  - Meningitis, encephalitis
  - Hypoxic-ischemic encephalopathy
  - Midline CNS malformations with pituitary insufficiency
- Renal unresponsiveness to AVP
  - Obstructive uropathy
  - Renal dysplasia
  - Drugs
- Excess water losses
  - Extensive skin disease
  - Osmotic diuresis

**DISORDERS CAUSING POSITIVE SODIUM BALANCE**

- Administration of hypertonic salt solutions
- Ingestion of hypertonic feedings

AVP, arginine vasopressin; CNS, central nervous system.

and nutritional measures to induce an anabolic state. Long-term management requires dietary restriction of leucine, good nutritional support, and avoidance of catabolic stresses. Long-term outcome is related to the number and severity of metabolic decompensations.

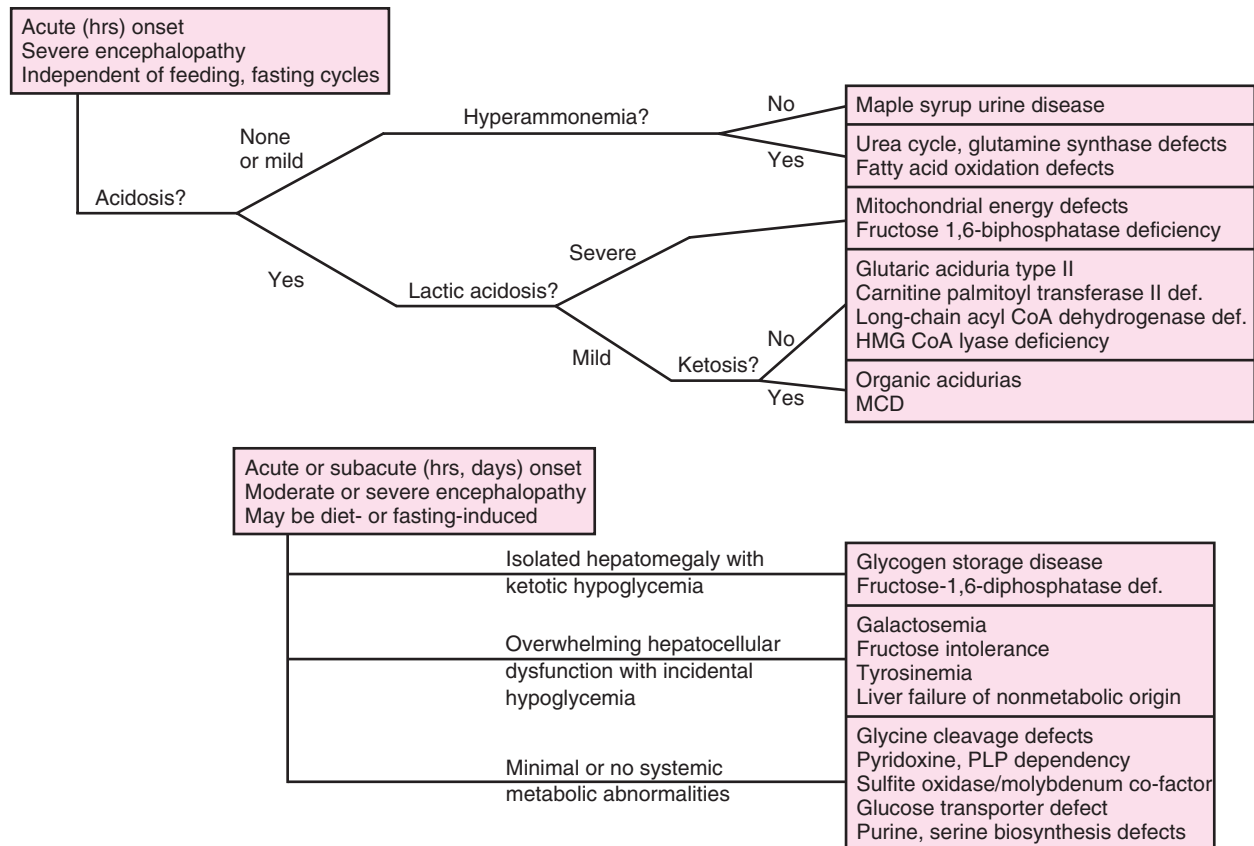

**Other Organic Acidopathies**

Organic acidopathies involve defects in amino acid catabolism resulting in elevated urinary organic acids (Knerl et al., 2012). MSUD is a prominent example, as described in the preceding section. Defective degradation of leucine, valine, and isoleucine causes accumulation of branched-chain organic acid intermediates, most commonly isovaleric (IVA), propionic (PA), and methylmalonic aciduria (MMA). Newborn screening detects many cases. Symptoms in neonates include vomiting and lethargy, progressing to seizures and coma. These disorders should be suspected when first-stage screening reveals ketosis, lactic acidosis, hypoglycemia, and hyperammonemia. Diagnosis rests on urinary organic acid profiles and

measurement of serum amino acids and acylcarnitines, confirmed by enzyme assay and/or genetic testing. Management involves glucose administration and protein restriction. Peritoneal dialysis may be necessary. Cofactor supplementation may be helpful using L-carnitine and N-carbamylglutamate and biotin for PA, glycine for IVA, and cobalamin for MMA. Creatine and ornithine alpha-ketoglutarate replacement has been suggested. Long-term management involves protein-restricted, high-carbohydrate diets and avoidance of catabolic stresses. Long-term outcome can be normal if decompensations are minimized in frequency and treated aggressively.

### Primary Lactic Acidosis Resulting From Defects in Oxidative Phosphorylation

Primary lactic acidosis causes severe encephalopathy in neonates, with defects in pyruvate oxidation involving the pyruvate dehydrogenase (PDH) enzyme complex, pyruvate carboxylase (PC), and the respiratory chain. Secondary lactic acidosis is common in hypoxia or ischemia and in other IEMs secondarily affecting energy metabolism.

Pyruvate oxidation disorders related to PDH deficiency include multiple subtypes. The most common E<sub>1</sub> component defects are X-linked dominants, presenting in newborns with permanent lactic acidosis and fulminant encephalopathy progressing to death. Intrauterine growth retardation, facial and limb anomalies, and minor brain dysgenesis are common. Neuroimaging findings include necrosis and cavitation in cortical white matter, basal ganglia, and brainstem nuclei. Treatment is limited. Some success has been reported with the ketogenic diet and thiamine and carnitine supplements.

Several subtypes of PC deficiency exist, with a spectrum of clinical manifestations. Type B is the severe neonatal form, presenting as fulminant neonatal encephalopathy with permanent lactic acidosis, hypoglycemia, citrullinemia, and hyperammonemia, and is usually fatal in early infancy. Symptoms include depressed mental status, hypotonia, tremors and dystonic movements, and paroxysmal eye-movement abnormalities. Imaging shows cystic periventricular leukomalacia. Diagnosis is challenging because of similarities to other IEMs and hypoxic-ischemic encephalopathy. Treatment involves use of high-carbohydrate diets.

Respiratory chain defects comprise a large spectrum of biochemical and genetic disorders with variable phenotypes. These disorders should be considered in infants with severe intractable lactic acidosis or encephalopathy combined with a cardinal clinical feature (external ophthalmoplegia, myopathy, or cardiomyopathy). Growth failure and other organ dysfunction are common. When lactic acidosis is present, the lactate:pyruvate ratio is increased (>25) in disorders of oxidative phosphorylation as compared with PDH complex disorders, in which the lactate:pyruvate ratio is usually normal. Clinical course may be benign in cases with only skeletal muscle involvement (benign infantile mitochondrial myopathy) or fatal in cases with intractable acidosis. Treatment options are limited and rely on supportive strategies to minimize catabolic stresses, and administration of cofactors (carnitine, nicotinamide, riboflavin).

Diagnosis of primary genetic defects of mitochondrial function involving pyruvate metabolism and respiratory chain is difficult because of the extreme phenotypic and genotypic variability and because histologic and histochemical diagnostic techniques are difficult and not widely available. These conditions should be suspected in infants with persistent severe lactic acidosis combined with other organ disease, especially myopathy and/or cardiomyopathy. Confirmation and further biochemical definition of the diagnosis are complex and may require detailed biochemical studies to isolate the

functional defect, followed by identification of specific pathogenic gene mutations (Honzik et al., 2012).

### Glutamine Synthetase Deficiency

Glutamine synthetase (GS) plays a critical role in the brain to detoxify ammonia and regulate concentration and compartmentalization of neurotransmitter pools of glutamate and gamma-aminobutyric acid (GABA). GS deficiency is a rare autosomal-recessive condition manifest as profound neonatal encephalopathy with coma, quadriplegia, severe bulbar dysfunction, lissencephaly, and death shortly after birth as a result of multiorgan failure. Diagnosis in this clinical setting is suggested by moderate hyperammonemia with very low or absent glutamine concentration in blood, cerebrospinal fluid (CSF), and urine, and is confirmed by deficient enzyme activity in cultured fibroblasts. There are no effective treatments.

### Fructose-1,6-Biphosphatase Deficiency

Fructose-1,6-biphosphatase (FDPase) deficiency is an autosomal-recessive defect in gluconeogenesis. It presents as early infantile-onset severe acute encephalopathy, with fasting-induced lactic acidosis, ketoacidosis, and hypoglycemia, usually without other organ involvement, except hepatomegaly. The clinical and biochemical features should suggest the diagnosis, confirmed by enzyme assay on a liver biopsy specimen. Treatment is similar to that for type I glycogenosis, in addition to restriction of fructose and sucrose intake.

### Fatty Acid Oxidation Defects

Fatty acid oxidation disorders involve several enzymes in the degradation of lipids to fatty acids to acetyl-CoA or ketone-body production. These include carnitine palmitoyl transferase II (CPT II) deficiency, mitochondrial trifunctional protein deficiency (MTP), malonyl-CoA decarboxylase deficiency (MCD), multiple acyl-CoA dehydrogenase deficiency (MADD), and classic acyl-CoA dehydrogenase deficiencies (long-chain, or LCAD; medium-chain, or MCAD; short-chain, or SCAD). Although most of these present beyond the neonatal period, several have distinctive presentations in neonates, involving rapid onset of a fulminant metabolic encephalopathy with hypoglycemia, hyperammonemia, low or moderate ketonuria, and metabolic acidosis. Associated features include hepatomegaly, cardiomyopathy, and myopathy. Patients with MCD and MADD have cortical dysgenesis with pachygyria, white-matter atrophy, and gray-matter heterotopias. Characteristic clinical features should suggest the diagnosis, supported by decreased total plasma carnitine and elevated plasma acylcarnitine intermediates. Definitive diagnosis rests on measuring enzyme activity and genomic sequence analysis. Treatment involves supportive measures, glucose administration, carnitine supplementation, and modification of feeding schedules to minimize fasting states. Long-term outcome depends on the frequency and severity of decompensation.

MTP deficiency predominantly presents in neonates, with rapid onset of depressed consciousness, heart failure, diffuse hypotonia and weakness with absent tendon reflexes, severe lactic acidosis, and death in a majority of patients as a result of heart failure. Multisystem involvement may include retinopathy, peripheral neuropathy, myopathy, cardiomyopathy, and liver disease.

CPT II deficiency has several phenotypes presenting at different ages. The neonatal-onset form is the least common and most severe form and is almost always fatal. Affected infants have prenatally detected cerebral lesions and malformations. Neurologic symptoms appear shortly after birth, including seizures, depressed consciousness, hypotonia with myopathic

features, and cardiomyopathy leading to circulatory failure. Metabolic features are typical of fatty acid oxidation defects. Management is supportive and symptomatic, but ineffective in most cases. Definitive biochemical diagnosis is a prelude to confirmatory genetic testing.

### Urea Cycle Disorders

Neonates with urea cycle defects (UCDs) develop severe hyperammonemia, rapidly progressive lethargy, and vomiting, progressing to coma (Häberle et al., 2012). First-stage testing reveals no other major biochemical abnormalities. Diagnosis rests on plasma amino acid and urine organic acid and urinary orotate excretion profiles. Definitive diagnosis is confirmed by genetic testing. Elevated plasma glutamine levels are common to all of the UCDs. Transient hyperammonemia of the newborn resembles UCDs, featuring severe transient hyperammonemia associated with respiratory distress syndromes or herpes simplex infection. It differs from UCDs in its earlier onset (first 24 hours of life) and association with prematurity and pulmonary disease. Treatment includes discontinuing protein intake and administering intravenous dextrose and ammonia-scavenging drugs—sodium benzoate, phenylacetate, and arginine. Infants unresponsive to these measures or those presenting with coma may require hemodialysis. Long-term outcome is variable, with motor and cognitive deficits dependent on the severity and frequency of hyperammonemic decompensations.

## Subacute Epileptic Encephalopathies

### Glycine Cleavage Defects

Glycine cleavage defects are autosomal-recessive disorders causing glycine accumulation. The most common form is a neonatal-onset progressive encephalopathy with depressed consciousness, apnea, and seizures, usually myoclonic, and burst suppression on electroencephalogram (EEG). Lifelong severe cognitive and motor disabilities and intractable epilepsy are the rule among survivors. Factors predicting poorer outcome include early age of symptom onset, presence of cerebral dysgenesis, and degree of glycine elevation. Neuroimaging abnormalities include cerebral dysgenesis of prenatal origin, compounded by acute new foci of injury in acutely symptomatic neonates appearing as restricted diffusion in the posterior limbs of the internal capsule, lateral thalami, and dorsal midbrain and pontine nuclei, evolving to a progressive vacuolating myelinopathy in the postnatal period. Biochemical abnormalities are limited to elevated glycine levels in plasma and CSF, with CSF:plasma ratio less than 0.06. Definitive diagnosis rests on finding absent or very low activity of the glycine cleavage system enzyme in liver biopsy or autopsy, confirmed by genetic studies. Glycine cleavage defects differ from the hyperglycinemia that accompanies organic acidopathies in the presence of ketosis in the latter, and in characteristic organic acid excretion profiles. There are no proven therapies. Seizures are resistant to standard anticonvulsants. Treatment with dextromethorphan, ketamine, benzoate, and the ketogenic diet has been reported, with limited success.

### Pyridoxine-Dependent and Pyridoxal Phosphate-Dependent Epileptic Encephalopathies

Pyridoxine is the precursor for pyridoxal-5-phosphate (PLP), an essential cofactor for multiple enzymes in brain metabolism. Two enzyme defects with distinct gene mutations cause deficient PLP production: pyridoxine-dependent epilepsy (PDE) and pyridoxal phosphate-dependency disorder

(Plecko, 2013). Pyridoxal phosphate-dependency disorder involves mutations in the gene for pyridox(am)ine-5'-phosphate oxidase (PNPO), which converts pyridoxine to PLP. The spectrum of PDE includes gene mutations leading to partial loss of PNPO activity, presenting as pyridoxine-responsive neonatal-onset epilepsy with normal levels of PDE biomarkers.

Affected infants present with prenatal- or neonatal-onset drug-resistant epilepsy and chronic encephalopathy, with no other metabolic abnormalities. EEG is severely abnormal, with several types of epileptiform patterns (hypsarhythmia, burst suppression, generalized spike-wave). Diagnosis in PDE rests on finding elevated levels of  $\alpha$ -amino adipic semialdehyde and pipercolic acid in urine, blood, and CSF, confirmed by mutation analysis of the *antiquitin* gene. Diagnosis of PNPO deficiency should be considered in infants with the clinical features of PDE, but who are not fully responsive to pyridoxine, lack the confirmatory biochemical markers (elevated urinary  $\alpha$ -amino adipic semialdehyde dehydrogenase [AASA]), and respond to PLP. Genetic testing of the PNPO gene confirms the diagnosis.

Folinic acid-responsive neonatal epileptic encephalopathy (FARNE) resembles PDE clinically and electrographically. Although FARNE is identical biochemically and genetically to PDE, these patients have a better response to either a combination of pyridoxine and folinic acid or folinic acid alone.

Treatment in pyridoxine-dependency disorders includes supplementation with both pyridoxine and folinic acid because there is variable response to either agent alone. Dietary restriction of lysine has been suggested. Infants with clinical features PDE who are unresponsive to pyridoxine and folinic acid may be given pyridoxal supplementation while awaiting genetic testing for PNPO deficiency.

### Sulfite Oxidase and Molybdenum Cofactor Deficiency

Molybdenum cofactor (Moco) deficiency and isolated sulfite oxidase deficiency are related autosomal-recessive diseases affecting xanthine and sulfite metabolism. These defects share a similar clinical presentation that involves severe neonatal-onset epileptic encephalopathy with diffuse severe cavitory leukomalacia (Schwarz, Mendel, and Ribbe, 2009). Infants are born at term uneventfully and develop seizures in the first week, followed by arrested development, acquired microcephaly, and early appearance of generalized hypertonicity. Clinical and radiographic features in the early stages mimic hypoxic-ischemic encephalopathy. Distinctive neuroimaging features include symmetric acute lesions affecting the globus pallidi and subthalamic regions coexisting with chronic-appearing cerebral infarction, pontocerebellar hypoplasia, and severe cavitory leukomalacia. There are no associated malformative anomalies, systemic metabolic perturbations, or abnormalities affecting other organ systems.

Diagnosis is suggested by increased urinary excretion of sulfites, thiosulfate, S-sulfocysteine, and taurine. Patients with Moco deficiency have low serum and urinary uric acid levels and increased urinary xanthine and hypoxanthine levels. Patients with isolated sulfite oxidase deficiency have normal uric acid metabolite levels. Diagnosis may be confirmed by enzyme assay of biopsied liver or cultured skin fibroblasts. Treatment is supportive, with an emphasis on optimizing anti-convulsant therapy.

### Serine Biosynthesis Defects

Serine biosynthesis defects may present as neonatal-onset chronic encephalopathies with prominent refractory epilepsy, and most commonly result from 3-phosphoglycerate dehydrogenase deficiency. Affected infants are neurologically

abnormal at birth, with intrauterine growth retardation, congenital microcephaly, cataracts, seizures, and neurodevelopmental impairment. They have a distinctive leukoencephalopathy with hypomyelination, vacuolar changes, and gliosis, which may improve after treatment with serine and glycine supplementation. Diagnosis rests on finding low CSF concentrations of serine, glycine, and 5-methyltetrahydrofolate. This disorder is treatable with high-dose dietary supplementation of serine (500-700 mg/kg/day) and glycine (200 mg/kg/day).

### Purine Biosynthesis Defects

Purine biosynthesis disorders manifesting in the neonatal period involve adenylosuccinate lyase or riboside transformylase enzyme deficiencies (Jurecka, 2009). Affected infants are born uneventfully at term and develop severe neonatal encephalopathy with hypotonia and seizures. Neuroimaging may be normal initially, followed later by diffuse atrophy. These infants develop severe static encephalopathy with profound mental retardation, blindness as a result of optic atrophy, refractory epilepsy, and growth failure. The cardinal biochemical feature is elevated riboside metabolites 5-amino-4-imidazolecarboxamide ribosiduria (AICA) and succinyl-5-amino-4-imidazolecarboxamide ribosiduria (SAICA) in urine and CSF. Affected infants may have disturbed glucose and lipid metabolism as a result of impaired hepatic gluconeogenesis and fatty acid and cholesterol synthesis. Treatment with D-ribose and uridine supplementation has been shown to be of limited benefit. Management is symptomatic and supportive because there is no definitive or curative treatment.

### L-Amino Acid Decarboxylase Deficiency

L-amino acid decarboxylase deficiency (L-ADD) is a defect of biogenic amine neurotransmitter metabolism that results in deficient brain dopamine, serotonin, norepinephrine, and epinephrine. Patients present in the first weeks of life with lethargy, hypotonia, dysphagia, and seizures, and sometimes with hypoglycemia and acidosis. Autonomic dysfunction leads to ptosis, hypotension, gastric and intestinal dysmotility, and impaired thermoregulation. Movement disorders are common, with dystonia, athetosis, oculogyric crises, and nonepileptic myoclonus. Diagnosis rests on finding increased L-DOPA and 5-hydroxytryptophan and decreased homovanillic acid (HVA) and 5-hydroxy-indole-acetic acid (5-HIAA) levels in CSF. Vanillic acid (VLA) levels are elevated on urine organic acid profile. Management is symptomatic and supportive. Outcome is poor in most patients, who develop mixed severe motor and cognitive disability and chronic movement disorders that are refractory to symptomatic treatment.

### Asparagine Synthetase Deficiency

Asparagine modulates the cell cycle, cell proliferation, and neuronal hyperexcitability. Asparagine synthetase (AS) deficiency causes a progressive neonatal-onset encephalopathy featuring quadriplegia, profound intellectual disability, refractory epilepsy, and progressive diffuse cerebral atrophy. CSF levels of asparagine in affected patients are low compared with normal patients. Diagnosis is confirmed with molecular genetic analysis. Treatment rests on supportive and anticonvulsant therapies. Nutritional supplementation with asparagine has been suggested, with uncertain benefit.

## Chronic Encephalopathies Without Multiorgan Involvement

### Hyperphenylalaninemia

Hyperphenylalaninemia causes a neonatal-onset chronic encephalopathy as a result of defects in phenylalanine metab-

olism, including phenylalanine hydroxylase (PAH) deficiency, tetrahydrobiopterin (BH<sub>4</sub>) synthesis deficiency, and GTP cyclohydrolase (GTPC) deficiency. In classical phenylketonuria (PKU) caused by PAH deficiency, plasma phenylalanine levels exceed 1000 μM, and PAH activity in liver biopsy is severely deficient. Non-PKU hyperphenylalaninemia is a milder form, with plasma phenylalanine less than 1000 μM and less severely deficient PAH activity. Clinical symptoms in untreated classical PKU include irritability, hyperkinesia, acquired microcephaly, and severe cognitive deficiency. Infants with GTPC deficiency have a neonatal-onset chronic encephalopathy with severe hypotonia, bulbar dysfunction, and seizures. Treatment with L-DOPA has been beneficial in some patients. Diagnosis is made through newborn metabolic screening followed by quantitation of plasma phenylalanine and tyrosine and urinary and CSF biopterin metabolites. Treatment involves dietary restriction of phenylalanine, and folate and BH<sub>4</sub> replacement in patients with BH<sub>4</sub> disorders.

### Succinic Semialdehyde Dehydrogenase Deficiency

Succinic semialdehyde dehydrogenase deficiency is a defect of GABA degradation causing elevated brain GABA. Some patients present as neonates with a chronic encephalopathy and later develop diffuse hypotonia, neurodevelopmental impairment, and epilepsy. MRI finding of T2 hyperintensity in the globus pallidus may suggest the diagnosis, which rests on finding high levels of GABA in CSF and urine and elevated urinary 4-hydroxybutyric acid. Treatment with vigabatrin has been suggested, with variable results.

### Glutaric Aciduria

Glutaric aciduria (GA) is an autosomal-recessive defect in degradation of 2-keto-adipic acid, a metabolite in lysine and tryptophan degradation pathways. Neonatal and early infantile presentation occurs in type I GA, caused by glutaryl-CoA dehydrogenase deficiency. Affected infants have chronic progressive encephalopathy of neonatal or early infantile onset with macrocephaly, hypotonia evolving to rigidity and dystonia, developmental regression, and epilepsy. There may be episodic decompensations triggered by intercurrent illness, with vomiting, ketotic hypoglycemia, acidosis, hyperammonemia, hepatomegaly, and depressed consciousness. MRI shows frontotemporal atrophy with prominent extraaxial CSF collections and, in some cases, subdural hemorrhage. Metabolic crises are associated with acute bilaterally symmetric striatal necrosis, leading to permanent neuromotor disability. Diagnosis rests on finding elevated urinary glutaric acid and 3-OH-glutaric acid, confirmed by enzyme assay. Treatment involves dietary protein restriction, in particular L-lysine and tryptophan, and supplementation with L-carnitine and riboflavin. Type II GA involves multiple acyl-CoA dehydrogenase deficiencies, causing elevations of multiple organic acids. The clinical picture in neonatal-onset type II GA is severe, with nonketotic hypoglycemia, metabolic acidosis, vomiting, depressed consciousness, and multiorgan dysfunction.

## Chronic Encephalopathies With Multiorgan Involvement

### Congenital Disorders of Glycosylation

Congenital disorders of glycosylation (CDGs) involve defective protein glycosylation, affecting cotranslational modification of numerous secretory and membrane-bound proteins (Funke et al., 2013). Type I involves oligosaccharide precursor assembly; type II involves oligosaccharide processing. A new classification system based on genetic and molecular features uses the gene symbol followed by the extension "CGD." CDG

type Ia is the most common and has two presentation types: a neurologic and a multisystem pattern. The neurologic presentation involves chronic severe neurologic disability with prominent hypotonia and cerebellar dysfunction, punctuated by episodic acute deterioration resembling stroke. MRI shows cerebellar atrophy. Usually normal at birth, some patients present with hypotonia and oculomotor abnormalities, with later ataxic hypotonic motor impairment and severe cognitive deficiency, retinopathy, epilepsy, acquired microcephaly, thromboembolic strokes, and weakness resulting from polyneuropathy. Associated nonneurologic findings include growth failure, protein-losing enteropathy, obstructive cardiomyopathy, and nephrotic syndrome. Diagnosis rests on the measurement of transferrin isoelectric focusing (TIEF) and molecular genetic testing. Associated biochemical findings include elevated liver transaminases, low serum proteins, anemia, leukopenia, and low serum cholesterol. Treatment includes supplementation of mannose for MPI-CDG, fucose for SLC35C1-CDG, and butyrate for PIBM-CDG, with variable benefit.

### Peroxisomal Disorders

Peroxisomal disorders are progressive neurologic diseases with variable age of onset and severity. Neonatal forms with prominent neurologic involvement are autosomal-recessive disorders, including Zellweger syndrome (ZS) and neonatal adrenoleukodystrophy (NALD). ZS involves multiorgan dysfunction, with typical facial dysmorphism, ocular anomalies (cataracts, glaucoma, pigmentary retinopathy), hepatic fibrosis, cystic kidney disease, subclinical adrenocortical insufficiency, and cardiac anomalies. Neurologic features include seizures, cranial nerve dysfunction, optic atrophy, and diffuse myopathic weakness. Survivors are profoundly handicapped. Neuroimaging and pathological studies reveal cortical and cerebellar migrational abnormalities and central white-matter demyelination. Biochemical studies reveal elevated very-long-chain fatty acids (VLCFAs), phytanic acid, and pipecolic acids, and deficient synthesis of plasmalogens. Diagnosis can be confirmed by gene sequencing. NALD resembles ZS in many respects but is less severe. There are no proven treatments.

### Cholesterol Biosynthesis Defects (Smith–Lemli–Opitz Syndrome)

Smith–Lemli–Opitz syndrome is a disorder of cholesterol biosynthesis and presents in the neonatal period with multiple congenital anomalies and a chronic static encephalopathy, with hypotonia, sensorineural deafness, dysphagia, severe cognitive deficiency, microcephaly. Nonneurologic problems include abnormal facies with ptosis and micrognathia, genital anomalies, growth retardation, cataracts, congenital heart defects, digital anomalies, and cleft palate. Cerebral malformations (holoprosencephaly, agenesis of the corpus callosum, frontal hypoplasia, cerebellar hypoplasia) are common. Diagnosis is suggested by low serum cholesterol, confirmed by finding elevated serum 7-and 8-dehydrocholesterol. Treatment is supportive and symptomatic.

## Overview of Human Brain Malformations

*William B. Dobyns, Renzo Guerrini, and A. James Barkovich*

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

**INTRODUCTION**

This section (Part V) on congenital structural defects reviews a large and growing number of complex developmental disorders of the brain, spinal cord, and skull. They represent the tip of the iceberg of developmental brain disorders more broadly, as they present with many of the same clinical features and involve many of the same molecular pathways—and sometimes the same genes—as more common and less specific disorders such as intellectual disability, early life epilepsy and autism. They collectively encompass a field of knowledge that has expanded dramatically over the past several decades. But the field has not expanded in isolation. Brain malformations:

- Largely represent defects during the earliest stages of brain development, and thus reflect the underlying embryology and developmental genetics of the nervous system;
- Provide an important window into normal brain development and into the genetic regulation of brain development and function;
- Frequently co-occur with other diverse developmental brain disorders both with and without recognized structural defects; and
- Are associated with a wide spectrum of functional deficits including intellectual disability (mental retardation), developmental language disorders, epilepsy, social and behavioral disabilities, numerous other specific learning disabilities, attention deficits, motor deficits associated with abnormal motor tone and posture or dyskinesias, and a host of problems associated with sleep, feeding, mood, hormonal and autonomic dysregulation.

Thus an understanding of brain malformations is important in assessing almost all types of neurologic disorders in children. They are separated into disorders involving defects in development of primary brain stages and regions including neural tube (Chapter 25); forebrain (Chapter 26) and mid-hindbrain (Chapter 27) defects; malformations of cortical development involving brain size (Chapter 28) and other malformations of cortical development (Chapter 29); diverse disorders resulting in hydrocephalus (Chapter 30) or skull development (Chapter 31); and an important new chapter on clinically and genetically overlapping disorders without consistent brain malformations that we designate “developmental encephalopathies” (Chapter 32) with Angelman and Rett syndromes as paradigms. This section ends with a detailed look at prenatal diagnosis for this group of disorders (Chapter 33). In the sections that follow, brain malformations are reviewed including epidemiology, classification, clinical recog-

niton, relationship to other neurologic disorders and selected environmental factors, and genetic counseling.

**EPIDEMIOLOGY**

The incidence of brain malformations has been estimated to be approximately 3.32 per 1000 and the prevalence approximately 2.21 per 1000 at age 14 years from studies of a 1-year birth cohort from northern Finland (Von Wendt and Rantakallio, 1986). These are much higher rates than were recognized in the era before MRI and recent increases in surgical treatment of hydrocephalus and epilepsy. Not surprisingly, the incidence is much higher in studies of children with cerebral palsy. This is an important point. To emphasize this, boy with apparent cerebral palsy attributed to prematurity at approximately 29 weeks gestation had a brain MRI that revealed mild callosal and cerebellar vermis hypoplasia, and chromosome microarray revealed a deletion 22q11.2, which implies either a genetic cause or possibly combined genetic and acquired pathogenesis.

**CLASSIFICATION**

Although the chapters that follow review many different malformations, they are not complete as the number of recognized malformations continues to expand. Presenting these data is also complicated by the tendency for malformations to co-occur in some patients. For example, Figure 24-1 shows a striking example of a boy with malformations of the forebrain (agenesis of the corpus callosum), mid-hindbrain (severe cerebellar hypoplasia and mega-cisterna magna), brain size (megalencephaly), neuronal migration (periventricular nodular heterotopia), and cortical organization (polymicrogyria overlying the heterotopia).

We have from time to time constructed flexible classification schemes for many of these malformations that primarily rely on traditional concepts such as embryology and anatomy with a contribution from genetic discoveries. Whereas recent discoveries lead to genes and gene pathways more than to embryology and anatomy, a more traditional classification scheme is listed in this and the following chapters. Outlines for brainstem and cerebellar (mid-hindbrain) malformations and for cortical malformations are shown in Boxes 24-1 and 24-2. Further details regarding most subgroups of malformations and the basis for the classification are given in the primary references (Barkovich et al., 2005; Barkovich et al., 2009). These schemes rely on—in decreasing order of priority—the underlying genetic basis when known, the

**Figure 24-1.** Brain images from a single patient showing multiple malformations. T1-weighted sagittal images demonstrate severe callosal hypogenesis with a small anterior remnant (angled arrow in **A**), very small cerebellar vermis (horizontal arrow in **A**) in an enlarged posterior fossa, extended Sylvian fissure with cortex connecting the perisylvian and superior parietal regions (angled arrow in **B**), and periventricular nodular heterotopia in the trigone (horizontal arrow in **B**). T2- and T1-weighted axial images show periventricular nodular heterotopia adjacent to the posterior portion of the lateral ventricles (horizontal arrows in **C** and **D**), and infolded gyri with mildly thick cortex overlying the heterotopia (angled arrows in **C** and **D**). ### BOX 24-1 Classification for Mid-Hindbrain Malformations

- I. Malformations secondary to early anteroposterior and dorsoventral patterning defects, or to misspecification of mid-hindbrain germinal zones
  - A. Anteroposterior patterning defects
    1. Gain, loss, or transformation of the diencephalon and midbrain
    2. Gain, loss, or transformation of the midbrain and rhombomere 1
    3. Gain, loss, or transformation of lower hindbrain structures
  - B. Dorsoventral patterning defects
    1. Defects of alar and basal ventricular zones
    2. Defects of alar ventricular zones only
    3. Defects of basal ventricular zones only
- II. Malformations associated with later generalized developmental disorders that significantly affect the brainstem and cerebellum (and have pathogenesis at least partly understood)
  - A. Developmental encephalopathies associated with MHM
  - B. Mesenchymal-neuroepithelial signaling defects associated with MHM
  - C. Malformations of neuronal and glial proliferation that prominently affect the brainstem and cerebellum
  - D. Malformation of neuronal migration that prominently affect the brainstem and cerebellum
    1. Lissencephaly with cerebellar hypoplasia
    2. Neuronal heterotopia with prominent brainstem and cerebellar hypoplasia
    3. Polymicrogyria with cerebellar hypoplasia
  4. Malformations with basement membrane and neuronal migration deficits
  - E. Diffuse molar tooth type dysplasias associated with defects in ciliary proteins
    1. Syndromes affecting the brain with low frequency involvement of the retina and kidney
    2. Syndromes affecting the brain, eyes, kidneys, liver and variable other systems
- III. Localized brain malformations that significantly affect the brainstem and cerebellum (pathogenesis partly or largely understood, includes local proliferation, cell specification, migration and axonal guidance)
  - A. Multiple levels of mid-hindbrain
  - B. Midbrain malformations
  - C. Malformations of rhombomere 1 including cerebellar malformations
  - D. Pons malformations
  - E. Medulla malformations
- IV. Combined hypoplasia and atrophy in putative prenatal onset degenerative disorders
  - A. Pontocerebellar hypoplasia
  - B. Mid-hindbrain malformations with congenital disorders of glycosylation
  - C. Other metabolic disorders with cerebellar or brainstem hypoplasia or disruption
  - D. Cerebellar hemisphere hypoplasia (rare, more commonly acquired than genetic, often associated with clefts or cortical malformation)

relevant embryology, brain imaging features, and miscellaneous other clinical features. Future revisions of these systems will rely more and more on the molecular pathways and genes.

### Brain Imaging Recognition

The improved quality of brain imaging studies, especially advances in MRI technology, has led directly to increased recognition and more accurate classification of brain malformations. Still, several recurrent types of classification errors continue to occur based on studies sent to the authors for review. First, pachgyria appears to be the best known of the severe cortical

malformations, and accordingly, all types of severe cortical malformations are often interpreted as “pachgyria.” The prime examples of malformations mistaken for pachgyria include severe congenital microcephaly (but here the cortex is usually thin rather than thick), tubulinopathies, polymicrogyria, and cobblestone malformations (for these, the cortex is moderately thick, but the surface and cortical-white matter interface are irregular rather than smooth). This unfortunately often leads to testing of the “lissencephaly” genes in patients with other cortical malformations, with negative results. Second, a thin corpus callosum may result from reduced volume of white matter due to abnormal development of white matter,

**BOX 24-2** Classification for Malformations of Cortical Development**MALFORMATIONS OF CORTICAL DEVELOPMENT**

- I. Malformations due to abnormal neuronal and glial proliferation or apoptosis
  - A. Decreased proliferation or increased apoptosis, or increased proliferation or decreased apoptosis
    1. Microcephaly with normal to thin cortex
    2. Microlissencephaly (extreme microcephaly with thick cortex)
    3. Microcephaly with polymicrogyria
    4. Megalencephaly
  - B. Abnormal proliferation (abnormal cell types)
    1. Nonneoplastic
      - a. Cortical hamartomas of tuberous sclerosis
      - b. Cortical dysplasia with balloon cells
      - c. Hemimegalencephaly
    2. Neoplastic (with disordered cortex)
      - a. Dysembryoplastic neuroepithelial tumor
      - b. Ganglioglioma
      - c. Gangliocytoma
- II. Malformations due to abnormal neuronal migration
  - A. Lissencephaly and subcortical band heterotopia spectrum
  - B. Cobblestone malformation syndromes
  - C. Heterotopia
    1. Subependymal (periventricular)
    2. Subcortical (other than band heterotopia)
    3. Marginal glioneuronal
- III. Malformations due to abnormal cortical organization (including late neuronal migration)
  - A. Polymicrogyria and schizencephaly
    1. Bilateral polymicrogyria syndromes
    2. Schizencephaly (polymicrogyria with clefts)
    3. Polymicrogyria as part of multiple congenital anomaly/mental retardation syndromes
  - B. Cortical dysplasia without balloon cells
  - C. Microdysgenesis
- IV. Malformations of cortical development, not otherwise classified
  - A. Malformations secondary to inborn errors of metabolism
    1. Mitochondrial and pyruvate metabolic disorders
    2. Peroxisomal disorders
  - B. Other unclassified malformations
    1. Sublobar dysplasia
    2. Others

progressive white matter dysgenesis, or white matter injury. However, this appearance is sometimes interpreted as agenesis of the corpus callosum. Next, diverse causes of cerebellar hypoplasia are often interpreted as Dandy-Walker malformation (when associated with a large posterior fossa and an enlarged fourth ventricle) or the so-called “Dandy-Walker variant” (equated with isolated cerebellar vermis hypoplasia). The latter is so overused and misapplied that the term should be abandoned. Finally, enlarged fluid collections below and especially behind the cerebellum are interpreted as arachnoid cysts or as “mega-cisterna magna” considering the latter a non-pathogenic variant. In our experience, mega-cisterna magna with fluid both below and behind the cerebellum sometimes represents a developmental disorder that belongs in the Dandy-Walker spectrum, and may be incorrectly interpreted as an arachnoid cyst.

**Relationships to Other Neurologic Disorders**

The close connection between brain malformations and other classes of developmental disorders is conceptually important. A few examples include agenesis of the corpus callosum associated with nonketotic hyperglycinemia; cerebellar vermis hypoplasia or heterotopia with multiple acyl-CoA dehydrogenase deficiency known as glutaric aciduria type 2; cobblestone malformations and cerebellar hypoplasia with congenital disorders of glycosylation; pachygyria variants with severe peroxisomal disorders such as Zellweger syndrome; and cerebellar hypoplasia or agenesis of the corpus callosum with either autism or infantile spasms. Further, most malformations of cortical development are associated with epilepsy, which may be severe. Observations in these and many other disorders suggest that brain malformations represent the most severe expression or “tip of the iceberg” of a host of developmental brain disorders. One of the best examples involves disorders associated with mutations of the ARX gene, which can cause lissencephaly, agenesis of the corpus callosum, hydrocephalus, developmental encephalopathy with epilepsy (i.e., epileptic encephalopathy), or mental retardation with dyskinesia.

**Relationship to Environmental Factors**

The genetic basis for many brain malformations has been known for years, and new genes are constantly being discovered. The question arises: are all brain malformations genetic? Although easy to overlook, substantial data exists to support environmental (extrinsic) causes for several brain malformations. Both microcephaly and hydrocephalus can result from numerous prenatal and early life diseases such as intraventricular hemorrhage in premature infants, other causes of intracranial bleeding, hypoxic-ischemic injury, central nervous system infections, and a host of other disorders reviewed throughout this text. Holoprosencephaly has been associated with pregestational diabetes and with structural analogs of cholesterol that interfere with cholesterol metabolism in humans and animals. Periventricular nodular heterotopia have been seen in mice and rats after prenatal exposure to high-dose ionizing radiation and possibly in humans as well. Schizencephaly and polymicrogyria, usually with microcephaly as well, have been associated with second trimester (13 to 21 weeks gestation) prenatal vascular disruption and with intrauterine cytomegalovirus infections. Numerous reports in the lay press from mid-2015 on, as well as one report of prenatal diagnosis have recently implicated the Zika virus as a cause of microcephaly, sometimes with additional evidence of prenatal brain injury. It has been blamed for a dramatic increase in the frequency of congenital microcephaly in Brazil and is rapidly spreading to other countries and regions.

**GENETIC COUNSELING**

Although the genetic basis for more and more brain malformations and related syndromes are being uncovered, few studies examining the overall contribution of genetic disorders to brain malformations have been reported. Accordingly, only partial and selective information about the genetic recurrence risk for different brain malformations is available. However, some general guidelines are listed in [Table 24-1](#).

For example, the recurrence risk for holoprosencephaly reported in the literature is approximately 6%, but we have become aware of frequent mild expression or “formes frustes” of this malformation and, accordingly, suggest using a higher recurrence risk of 13% for isolated holoprosencephaly without

**TABLE 24-1** Probable Genetic Recurrence Risks for Major Classes of Brain Malformations

Malformation Groups	Pattern of Inheritance					Recurrence Risk Comments
	Sp	Ch	AD	AR	XL	
<b>FOREBRAIN MALFORMATIONS</b>						
Holoprosencephaly	++	++	++	±	±	Risk is variable, may be high
Agenesis of corpus callosum	++	++	±	±	++	Risk is generally low
Septo-optic dysplasia	++	-	-	±	-	Risk is very low, has occurred
<b>MID-HINDBRAIN MALFORMATIONS</b>						
Pontocerebellar hypoplasia	-	-	-	++	-	Risk is 25%, all forms are AR
Cerebellar hypoplasia (diffuse)	++	++	±	++	+	Risk is variable, need diagnosis
Cerebellar hypoplasia (vermis)	++	++	±	+	+	Risk is variable, need diagnosis
Dandy-Walker malformation	++	+	±	±	±	Risk is very low, has occurred
Molar tooth malformation	-	-	-	++	-	Risk is 25%, all forms are AR
Rhombencephalosynapsis	++	-	-	-	-	No recurrences reported
<b>CORTICAL MALFORMATIONS</b>						
Microcephaly, congenital	-	-	-	++	-	Risk is 25%, most forms are AR
Microcephaly, postnatal	++	++	+	+	+	Risk is variable, includes XL
Megalencephaly	++	-	-	-	-	Risk is low (except for PTEN)
Lissencephaly and SBH	++	++	-	+	++	Risk is variable, includes XL
Cobblestone malformation	-	-	-	++	-	Risk is 25%, all forms are AR
Heterotopia, periventricular	++	++	+	±	++	Risk is variable, may be high
Heterotopia, subcortical	++	-	-	-	-	No recurrences reported
Polymicrogyria, perisylvian	++	++	±	±	+	Risk is low, XL may be important
Polymicrogyria, other forms	++	++	±	±	+	Risk is generally low
Schizencephaly	++	-	-	±	-	Risk is very low, has occurred
Focal cortical dysplasias	++	-	-	-	-	No recurrences reported
Hemimegalencephaly	++	-	-	-	-	No recurrences reported

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; Ch, chromosome imbalance; Risk, recurrence risk for siblings or other relatives; Sp, sporadic occurrence; XL, X-linked; ++, commonly observed; +, occasionally observed; ±, rarely observed and often poorly documented; -, never observed

known chromosome imbalances. For several malformations such as agenesis of the corpus callosum and polymicrogyria, single gene inheritance has been reported but only rarely and no formal studies are available. This implies a “generally low” risk and counseling with some uncertainty given that the experience is limited and exceptions occur. For some other malformations such as rhombencephalosynapsis and hemimegalencephaly, no examples of familial recurrence have ever been reported despite clinical recognition for decades. The first reports of familial focal cortical dysplasia have appeared, but this must be very rare, suggesting that the recurrence risk is very low. The most difficult malformations are those with significantly different recurrence risks for different subtypes and syndromes such as diffuse and vermis predominant cerebellar hypoplasia. These estimates are largely anecdotal in origin, so treating physicians and genetic counselors are encouraged to review information on the specific disorder at hand when counseling families.

## INTRODUCTION

Neural tube defects (NTDs) are second only to congenital heart defects as the most common serious birth defect, affecting between 0.3 and 10 per 1000 live births, depending on geographic region. NTDs result from complex interactions of genes and environmental conditions. A significant proportion of NTDs may be preventable with measures such as prenatal maternal folic acid (FA) supplementation or by avoiding prenatal exposure to known teratogenic drugs or toxins. Here we discuss the NTD pathogenesis, risk factors, complications, and management.

## ANATOMY AND EMBRYOLOGY

### Formation of the Neural Tube

Among the earliest morphologic specializations in the embryo is the neural placode, followed by neural plate and then neural tube. In the late second gestational week, the human embryo is a bilaminar disc of epiblast cells overlying hypoblast cells. By the third week, the disc develops a midline groove, the primitive streak, in the caudal third (Fig. 25-1A), which marks the initiation of gastrulation and the formation of three germ layers—ectoderm (giving rise to skin and the nervous system), mesoderm (providing inductive signals to ectoderm and contributing to morphogenesis), and endoderm (giving rise to viscera). The primitive node at the cranial end of the streak contains cells that act to organize the embryonic axes (Fig. 25-1). At the same stage, thickening of the rostral ectoderm by the apical-basal elongation of cells into a pseudostratified columnar shape produces the neural placode that marks the initiation of neurulation (see Fig. 25-1B). Cells migrating through the primitive streak and node displace the hypoblast cells to form endoderm and subsequently middle layer mesoderm. Cells that migrate through the node in the midline form the prechordal plate and notochord, which are important for induction of the ventral CNS structures, starting with the neural plate.

Neural plate formation is actually a default state of the ectoderm, and formation of epidermis involves the inhibition of bone morphogenetic protein (BMP) and the wingless (Wnt) signaling pathway. As the plate begins to emerge, morphogenesis, or shape changes, involving groups of cells in the neuroepithelium and surround, is essential to formation of brain and spinal cord. By 20 days of gestation, the neural plate appears indented in the midline, forming a groove or medial hinge region flanked by ridges—the neural folds. These folds elevate from the plane of the neural plate through the combined influences of proliferation of neural cells and underlying mesenchymal cells. Bending inward of the neural folds at the dorsolateral hinge points occurs through morphologic shape changes of the neural cells, which become radially elongated while their apical (luminal) poles constrict, through a combination of cell-cycle regulation that moves nuclei to the basal end of cells in the hinge region and actin-myosin contraction at the apical poles of cells in the hinge region, to bring the tips of the neural folds to touch. In the head region,

proliferation and movement of epidermis and mesenchyme cells also help to push the neural folds into apposition because at spinal levels, neighboring mesenchyme may be less critical to neural tube closure. In addition to cell elongation and proliferation, the shape changes in the neural plate are affected by cell motility in the form of convergent extension, in which laterally placed cells move to the midline and migrate rostrocaudally in a process that is mediated by noncanonical Wnt signaling (Fig. 25-4). Thus once elevation and bending of the neural folds occur, the lateral margins or tips of the folds join and then fuse in the midline to become the neural tube.

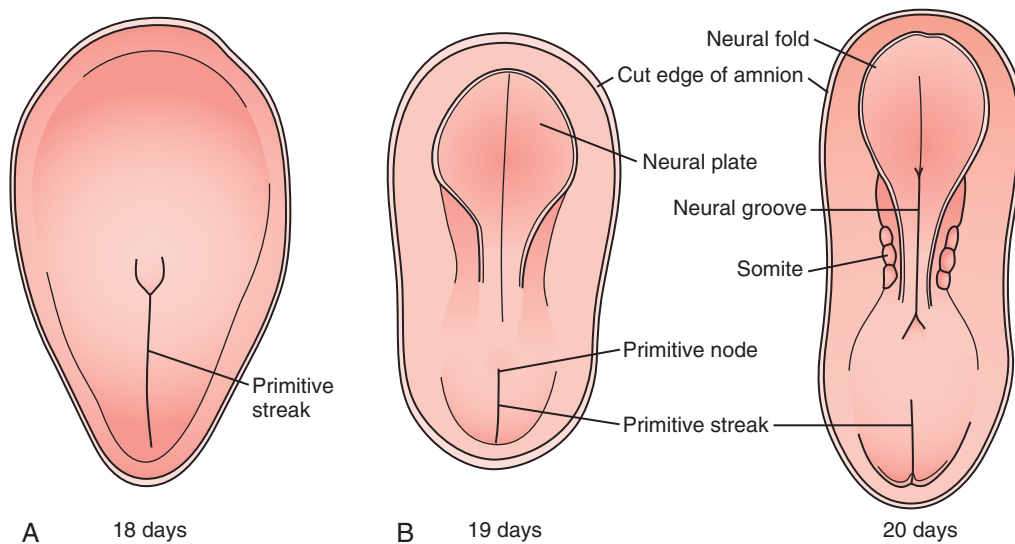

In order to achieve this rising and bending inward of the neural folds, the cells of the neural plate must proliferate in an ordered manner, called interkinetic nuclear migration of progenitors, forming a pseudostratified epithelium in which S-phase occurs at the basal (outer) surface of the neural folds, mitosis (M-phase) occurs at the apical (central or luminal) surface, and G1 and G2 phase nuclei are positioned at intermediate locations. In addition, in the process of convergent extension, cells move medially and through the medial hinge region to migrate rostrocaudally and elongate the neuraxis, narrowing the ventral floor plate. If the floor plate is too wide or the neural folds fail to elevate and bend, the folds will not appose and NTDs will ensue (see Fig. 25-4). When apposition is successful, midline fusion of the neural folds, a process known as neurulation, occurs first at primary closure points and progresses by adding multiple closure points such as the teeth of a zipper to extend rostrally and caudally from each node to complete neural tube closure (Copp et al., 2003).

In humans, the anterior neuropore, the region that will eventually give rise to the brain, closes approximately by day 26 of human gestation. The posterior neuropore, the region that will give rise to the caudal spinal column, closes approximately by day 29 of human embryogenesis. After the neural tube closes, it separates from the overlying ectoderm in a process termed dysjunction. Cells of the somitic mesoderm invade the space between the ectoderm and neural tube to form somites that eventually give rise to the posterior elements of the vertebral bodies and the paraspinal muscles. Specific neural cells at the tips of the folds are excluded from the neural tube; these cells form the neural crest, which is the anlage of the peripheral sensory and autonomic nervous systems and which also contributes the meninges and portions of the skull and face.

### Molecular Patterning of the Neural Tube

Work in animal models has identified a host of factors required for proper neurulation and neural tube closure. A key observation was that a small fragment of nonneural tissue (mesoderm), when transplanted, could duplicate the neural tube, indicating that secreted factors from mesoderm are sufficient to induce neurulation. These factors include chordin, noggin, sonic hedgehog (SHH), and several others, which are both necessary and sufficient for proper neurulation and control of the amount and fate of the neuroectoderm. In mammals, two distinct groups of nonneural cells appear to provide these early patterning signals: axial mesodermal cells of the

**Figure 25-1.** Early stages of gastrulation and neurulation in human embryogenesis: views of the dorsal surface. **A**, The primitive streak emerges as a groove at the caudal pole of the embryo, with the primitive node at the cranial pole. Epiblast cells moving through the primitive streak and node form the three germ layers—ectoderm, mesoderm, and endoderm. **B**, A thickening of the ectoderm forms the neural plate, initiated at the cranial pole, whereas the primitive streak at the caudal end initiates gastrulation. By 20 days' gestation, the neural folds have elevated from the neural plate, and tips of the folds are closing. Somites, comprised of mesoderm cells, support the elevation of the neural folds and are the precursors of vertebrae. (Adapted from Sadler, T.W., 2005. *Embryology of neural tube development*. *Am J Med Genet C Semin Med Genet* 135C, 2–8.)

**Figure 25-4.** Cell movements affecting planar cell polarity (PCP) signaling in the early developing nervous system. **A** and **B**, Schematics showing cell movement toward the midline into the neural groove and longitudinally to narrow and elongate the embryo. **C**, This movement serves to narrow the ventral floor plate (red), facilitating median hinge-point bending and apposition of the neural folds. **D**, When PCP signaling is impaired, as in the looptail mouse-bearing mutation in *Vangl2*, the floor plate is wider (intervening cells remain in the floor plate region), which prevents the folds from meeting in the midline. (A, With permission from Ybot-Gonzalez, P., et al., 2007. *Convergent extension, planar-cell-polarity signaling and initiation of mouse neural tube closure*. *Development* 134, 789–799. B–D, With permission from Copp, A.J., et al., 2003. *Dishevelled: linking convergent extension with neural tube closure*. *Trends Neurosci* 26, 453–455.)

notochord, which underlie the midline of the neural plate; and the cells of the epidermal ectoderm, which flank its lateral edges. The notochord is the source of ventralizing inductive factor, and the epidermal ectoderm is the source of dorsalizing factors. Opposing actions of these two signals establish the identity and pattern of cell types generated along the dorsal-ventral axis of the neural tube.

The nervous system is organized in response to intrinsic patterning genes and critical embryonic signaling pathways involving secreted factors and cell-cell interactions. The homeotic, Hox, transcription factor genes provide a positional “address” or identity of spinal cord and hindbrain neurons. Fate determination along the dorsal-ventral axis also requires the action of three opposing signaling pathways:

1. Sonic hedgehog (SHH), produced ventrally by the notochord
2. Wnt, in which pathway different Wnts define dorsoventral regions of neural tube
3. Bone morphogenetic protein (BMP), in which pathway different BMPs are secreted by dorsally placed cells from the boundary of the neural and nonneural ectoderm

In this model, SHH released by the notochord diffuses toward the ventral neural tube and induces the differentiation of the floor plate. The floor plate then produces additional SHH, which diffuses and establishes a gradient along the dorsal-ventral axis of the neural tube. Differentiation of cells in the dorsal half of the neural tube depends on signals such as BMPs provided by the lateral epidermal ectoderm. BMP4 and BMP7, released by the epidermal ectoderm, diffuse toward the dorsal neural tube and induce the differentiation of the roof plate. Regions of the spinal cord that are exposed to the highest concentrations of SHH and lowest concentrations of BMPs give rise to ventral motor neurons, whereas cells exposed to lowest SHH and highest BMP concentrations give rise to dorsal cells, such as commissural projection neurons. Rostro-caudally, the neural tube is regionalized into four major divisions: forebrain, midbrain, hindbrain, and spinal cord. Actions of FGF, Wnt, and retinoic acid (RA) pathways confer a caudal identity and also influence telencephalic patterning.

## EPIDEMIOLOGY AND PATHOGENESIS

### Incidence

Among live births, females are more affected by NTDs than males by 2 to 1. Additionally, the prevalence of NTDs varies across time, by region, and by ethnicity and approximates 0.5 cases per 1000 in the United States but 10 per 1000 in parts of China and India. FA fortification of the United States food supply and/or the availability of prenatal diagnosis and the elective termination has reduced NTD prevalence in the United States to 0.37 cases per 1000 reported. The twin concordance rate among same-sex twins (presumed monozygotic) is significantly increased (to 6.8%), supporting a genetic contribution. Furthermore, compared with an incidence in the general population of 1 per 1000, the risk of NTD recurrence in a family with one affected child increases to 1.8 per 100 but does not approach the 1 in 4 recurrence risk of an autosomal-recessive mutation with complete penetrance.

### Complex Genetic Contributions

The complexity of the genetic underpinnings of neurulation is reflected in the NTD-prone mouse lines, for which over 250 mutations have been associated with failure of neural tube closure (Harris and Juriloff, 2010). Despite this wealth of information, there is no single-gene polymorphism in the human homologs of these mouse genes that confers a robust, broadly reproducible enhanced risk of developing an NTD. This has led to the supposition that the genesis of NTDs requires the compounding of multiple gene polymorphisms.

The several hundred genes that have been associated with NTDs in mouse models are beginning to provide insights into molecular networks that are critically important for neurulation and may become clinically useful (Ross, 2010). For example, just as mutation in *Vangl2* renders the looptail mouse prone to NTD, polymorphisms in human *Vangl1* and *Vangl2* have been implicated in NTD patients. The complexity of the genetic underpinnings of NTD indicates that meeting the challenge for determining individual risk—and the optimal preventative therapy—will require evaluation of multiple genes (in signaling, metabolic, and transcriptional pathways)

in a single person to detect compounding effects of gene polymorphisms that alone might not be significant. Advanced technologies for high-throughput genomic DNA sequencing and analysis and detection of the epigenome and perhaps the microbiome, as well as untargeted metabolomic screening, will all play a role in the clinical evaluation of individual patient assessments of NTD risk and prevention.

## Gene-Environment Interactions in Neural Tube Defects

The environmental variables that have been implicated as risk factors for nonsyndromic forms of spina bifida are listed in Table 25-1. Risk factors include maternal diabetes, maternal obesity, and prepregnancy weight gain. Moreover, maternal periconceptual elevations in simple sugars that raise the glycemic index have been associated with increased NTD risk, even among nondiabetic women. In animal models, exposing rat embryos to a hyperglycemic environment induces dysmorphisms, accompanied by increases in biomarkers of oxidative stress and inositol depletion.

Studies in the United Kingdom, later corroborated in Eastern Europe and elsewhere, indicated that the prevalence of NTDs could be reduced by 70% or more by prenatal supplementation with FA, even in the absence of maternal folate deficiency. However, some populations demonstrated only a small or no significant reduction in NTD rates with prenatal FA supplementation, suggesting that differences in genetic background, diet, or other environmental exposures could influence the efficacy of folate supplementation. Inadequate intake of natural folate before and during early pregnancy is associated with a 2- to 8-fold increased risk of MMC and anencephaly, as indicated by several series of case-controlled, randomized clinical trials and community-based interventions.

### Teratogens

RA is a well-known teratogen when administered to nonhuman embryos, in which one of its many effects is to induce

**TABLE 25-1** Risk Factors for Spina Bifida

Risk Factor	Relative Risk (-Fold Increase)
<b>ESTABLISHED RISK FACTORS</b>	
History of previous affected pregnancy with same partner	30
Inadequate maternal intake of folic acid	2–8
Pregestational maternal diabetes	2–10
Valproic acid and carbamazepine	10–20
<b>SUSPECTED RISK FACTORS</b>	
Maternal vitamin B <sub>12</sub> status	3
Maternal obesity	1.5–3.5
Maternal hyperthermia	2
Maternal diarrhea	3–4
Gestational diabetes	NE
Fumonisin	NE
Paternal exposure to Agent Orange	NE

NTDs, including spina bifida, exencephaly, and anencephaly in several different species. Most, if not all, antiepileptic drugs (AEDs) are known teratogens. Different AEDs, however, are associated with different constellations of malformations. An increased risk of MMC is associated with in utero exposure to valproic acid or carbamazepine alone, or in combination with other AEDs. In infants exposed to valproic acid or carbamazepine, the risk of MMC can be as high as 1% to 2% (Włodarczyk et al., 2012). The mechanisms by which valproic acid and carbamazepine increase the risk of NTD have not been established, but there is general consensus that genetic predisposition to its teratogenic effect is required for valproate to promote NTDs. Folate administration does not appear to protect against the effects of valproic acid or carbamazepine on neural tube closure.

## CLASSIFICATION OF NEURAL TUBE DEFECTS

### Nomenclature

Broadly speaking, it is useful to separate those anomalies that arise from an early failure of neural tube formation and those that arise from defects in subsequent developmental steps. MMC refers to the commonest form of spina bifida, which comprises a flat neural placode, the unfolded derivative of the neural plate, elevated above a sac containing cerebrospinal fluid and continuous with the skin.

Neural tube closure is required for subsequent steps, including formation of mesodermal structures (e.g., dura, posterior spinal elements, and muscle). Milder NTDs often result in near-normal formation of mesodermal structures and closure of the overlying skin. This basic difference, the presence or absence of skin, has led to the designation of spina bifida into open forms, spina bifida aperta, or closed forms, spina bifida occulta. Spina bifida occulta is a confusing term because it can refer to either a broader group of anomalies that have normal skin overlying the spinal defect or a specific anomaly that indicates a lack of fusion of the spinous processes in the lumbar area and has limited clinical significance

(see later in this chapter). Fortunately, both of these terms are not common in current use.

## Embryologic Classification of Neural Tube Defects

Neurulation is first visible as ectodermal thickening into the neural plate and proceeds in steps outlined previously. The commonly encountered NTDs may be classified on the basis of the embryologic anomalies due to:

- Defects of neural folding and formation—myelomeningocele and anencephaly
- Disordered postneurulation development—encephaloceles
- Incomplete dysjunction—dermal sinus and associated dermoid and epidermoid tumors
- Premature dysjunction—spinal cord lipomas
- Disorders of gastrulation—split cord malformation, neuroenteric cysts
- Disordered secondary neurulation—thickened filum terminale, myelocystocele
- Failure of caudal neuraxial development—sacral agenesis

## MYELOMENINGOCELE

Myelomeningocele (MMC), the most complex of congenital spinal deformities, involves all tissue layers dorsal to and including the neural tube (i.e., spinal cord, nerve roots, meninges, vertebral bodies, skin). The dysplastic neural tube observed in newborns with MMC is a flat, disorganized segment of tissue located at the middle and most superficial portion of a cerebrospinal fluid-containing sac (Fig. 25-14).

## Antenatal Diagnosis

Maternal serum  $\alpha$ -fetoprotein (AFP) determination and ultrasound examination are used to identify fetuses that have or are likely to have spina bifida or anencephaly. Elevated amniotic AFP concentrations correlate with open NTDs, whereas

**Figure 25-14. Lumbar meningocele in a newborn.** **A**, External appearance of the skin. **B**, Midline sagittal view from a fetal T2-weighted MRI study depicts a fluid-filled cystic lesion. Note homogeneous water signal within the lesion, suggesting the diagnosis of meningocele, rather than meningomyelocele. **C**, Midline sagittal T2-weighted image from the postnatal MRI showing the fluid-filled sac and the spinal cord within the spinal canal.

closed lesions usually do not lead to increased AFP concentration. Detection of NTDs correlates with the magnitude of increase in the amniotic fluid AFP level; NTDs are associated in a minority of pregnancies with mildly elevated AFP levels, in a majority of those with moderately elevated levels, and overwhelmingly in those with very elevated AFP levels.

Sonography can differentiate between ventral wall defects and NTDs and can identify additional structural malformations that are characteristic of fetuses with chromosomal abnormalities. It is 60% accurate in low-risk pregnancies, which is equivalent to the accuracy of serum AFP screening (64%), 89% accurate in high-risk pregnancies, and 100% accurate for women referred for confirmation of a suspected spina bifida by another ultrasonographer. The data indicate that neither sonography nor AFP screening alone provides sufficient sensitivity or specificity but that, when these studies are used together, the predictive value is much higher.

## Clinical Features

The mortality rate for MMC is approximately 50% in the absence of therapy. The primary goal of surgery for closure of the lumbosacral defect is to prevent meningitis. The location and extent of the defect determine the nature and degree of neurologic impairment; rating scales attempt to standardize the evaluation of affected children. Lumbosacral involvement is most common. Thoracic defects are the most complex and frequently are associated with serious complications. Cervical cord involvement is different from MMC of the lower spine and can be differentiated into two types:

1. Myelocystocele herniating posteriorly into a meningocele
2. Meningocele with or without an underlying split cord malformation

Varying degrees of leg paresis, usually profound, and sphincter dysfunction are the major clinical manifestations. Congenital dislocation of the hips or deformities of the feet such as clubbing may also occur. Severe sensory loss and accompanying trophic ulcers may complicate the condition. Occasionally, only sphincter disturbances are present.

Hydrocephalus is present in about 70% to 85% of patients with MMC and occurs most frequently with thoracolumbar lesions, which accounts for 90% of patients. Most persons with spina bifida have normal intelligence, but specific cognitive disabilities and language difficulties are common and can adversely affect educational and occupational achievements and the ability to live independently.

## Secondary Abnormalities

### Central Nervous System Complications

Seizures have been reported in up to 17% of patients with MMC and almost always occur in those with shunted hydrocephalus. Additional CNS abnormalities seen in these patients may underlie seizures and include encephalomalacia, previous stroke, malformations, and intracranial calcifications. Seizures may be difficult to control, and frequently, seizure exacerbation is associated with shunt malfunction or ventriculitis.

### Bladder and Bowel Dysfunction

Bladder dysfunction and urinary incontinence pose major management problems and may be present at birth in the form of hydronephrosis. Interruption of sacral nerve roots and fiber connections between the brainstem and sacral cord causes the dysfunction. Loss of sphincter tone, overflow

incontinence, sacral and rectal loss of sensation, and loss of detrusor activity on cystometry are seen. Normal bladder control occurs in 10% of children with MMC. Prevention of bladder infection requires intermittent catheterization to maintain low residual urine volumes and prophylactic antibacterial drugs. Vesicoureteral reflux often develops during the second and third years of life, and assessment for this problem must be ongoing.

## Orthopedic Problems

Orthopedic defects associated with this paralysis, muscle imbalance, and accompanying regional spasticity may be severe and necessitate early intervention. Severe foot deformities afflict 80% of children and are treated with splinting or casting. Sensory deficits of the casted skin areas increase risk of skin ulcers. Physical therapy may help to preserve and extend the range of motion of the joints.

Progressive leg or foot deformity, weakness, pain, or deterioration of gait or bladder function implies restricted growth or tethering of the spinal cord. Cord tethering affects many older children with spina bifida who are neurologically stable. Surgical repair of a worsening tethered spinal cord and shunting or fenestration of syringomyelia can prevent decline of function.

## Chiari II Malformation

**Classification.** Multiple hindbrain malformations are associated with congenital hydrocephalus. Four types of Chiari malformation have been characterized. Chiari I malformation is a downward displacement of the cerebellum and cerebellar tonsils. Chiari II malformation is a complex malformation that includes downward displacement of the cerebellar vermis and tonsils and is encountered almost exclusively in patients with MMC. Chiari III is an encephalocervical meningocele, and Chiari IV refers to hypoplasia of the cerebellum.

The major features of the Chiari II malformation include:

1. Inferior displacement of the medulla and the fourth ventricle into the upper cervical canal
2. Elongation and thinning of the upper medulla and lower pons, persistence of the embryonic flexure of these structures, and the appearance of a "beaking" of the tectum
3. Inferior displacement of the lower cerebellum through the foramen magnum into the upper cervical regions
4. A variety of bone defects of the foramen magnum, occiput, and upper cervical vertebrae

Hydromyelia and syringomyelia of the cervical spinal cord occur in 20% to 50% of patients.

**Clinical Features.** The symptoms associated with Chiari II malformations include apnea, swallowing difficulties, and stridor in the newborn and headache, quadriparesis, scoliosis, and balance and coordination difficulties in the older child; they are present in up to one-third of persons with the disorder (Box 25-1). It is often difficult to differentiate between symptoms related to the hydrocephalus versus cerebellar malformation, but many symptoms are directly referable to cerebellar, brainstem, and cranial nerve dysfunction. More than one-third of affected infants display feeding disturbances with reflux and aspiration. Vocal cord paralysis with stridor and abnormalities of ventilation, including both obstructive and central apnea may occur.

The causes of the clinical abnormalities of brainstem function are threefold. First, they relate in part to the brainstem malformation, which involves cranial nerves and other nuclei, present in most cases. Second, compression and traction of the anomalous caudal brainstem by hydrocephalus and

**BOX 25-1** Clinical Manifestations of Chiari II Malformation

- Apnea
- Tongue fasciculations
- Stridor
- Facial palsy
- Gastroesophageal reflux
- Swallowing difficulties
- Poor feeding
- Ataxia
- Hypotonia
- Upper extremity weakness
- Hydrocephalus
- Syringomyelia
- Attention deficit
- Seizures
- Extraocular movement abnormalities
- Nystagmus
- Increased mortality

(With permission from McLone, D.G., Dias, M.S., 2003. *The Chiari II malformation: cause and impact. Childs Nerv Syst* 19, 540–550.)

increased intracranial pressure also may play a role, especially in the vagal nerve disturbance that results in vocal cord paralysis and stridor. Third, ischemic and hemorrhagic necrosis of the brainstem often is present also and may be secondary to the disturbed arterial architecture of the caudally displaced vertebrobasilar circulation.

## Management

Management of MMC requires multidisciplinary efforts involving many specialists. Treatment includes surgical reduction and other associated defects such as syringomyelia, prevention of infection, covering of the MMC, control of hydrocephalus, management of urinary dysfunction, and treatment of the paralysis and abnormalities of the hips and feet.

### Fetal Repair of Myelomeningocele

Compared with historical controls, infants given treatment in utero have a lower incidence of moderate to severe hindbrain herniation and hydrocephalus requiring shunting. A randomized, prospective clinical trial examined the efficacy of fetal repair of MMC between 22 and 26 weeks gestational age compared with standard postnatal repair. After inclusion of 183 subjects and analysis of 158 children at 12 months of age, the study was closed because of demonstrated benefit in the fetal treatment arm (Adzick et al, 2011; Gupta et al, 2012). In particular, there was a reduced rate of hydrocephalus requiring shunting, an improvement in motor function, and an improvement in hindbrain herniation in the group who underwent fetal repair. These benefits were balanced by the increased risk of preterm delivery and a number of maternal risks. The long-term outcomes are still undefined, but the patients recruited for the study described previously are being evaluated.

### Management in the Newborn Period

Standard treatment includes closure of skin lesions overlying MMCs and treatment of hydrocephalus. The value of immediate correction of the defect within 48 hours of birth is widely

accepted. Even when cerebrospinal fluid leakage occurs, however, a delay in closure for up to 48 hours does not increase the risk of infection or worsen the neurologic deficit. In such cases, the patient is given antibiotics, and the exposed placode is kept clean and moist. Ultrasonography and urodynamic studies should be carried out to assess the status of the urinary tract and provide a baseline for continuing assessment. At this age, bowel function is usually not difficult because affected infants have the gastrocolic reflex and pass stools with most feedings. The decision to give vigorous therapy for the most severely affected infants with MMC is beset by moral and medical considerations; restricted therapy often is associated with survival but poor outcome.

## Treatment of Chiari II Malformation

Evaluation with MRI is the procedure of choice to evaluate a Chiari II malformation. Before considering surgical decompression of the posterior fossa, it is important to treat hydrocephalus if present. A properly functioning ventricular shunt often can obviate the need for decompression of hindbrain herniation. Many patients will resolve brainstem symptomatology with shunting. Significant improvement in the size of an accompanying spinal syrinx may occur after ventriculoperitoneal shunting or shunt revision. Suboccipital craniectomy may be warranted to decompress neural and vascular structures.

## Outcome

Short-term and long-term survival of patients with spina bifida has increased with improvements in medical and surgical management. Patients with MMC are at substantial risk for leg weakness and paralysis, sensory, bowel and bladder dysfunction, and orthopedic abnormalities (e.g., clubfoot, contractures, hip dislocation, scoliosis, kyphosis). In general, the functional level corresponds to the anatomic level of the bony spinal defect. Patients with MMC also develop symptoms from associated malformations of the CNS, including hydrocephalus, syringomyelia, and Chiari II malformations.

## ANENCEPHALY

Anencephaly is a congenital malformation in which both cerebral hemispheres are absent. Most anencephalic infants are stillborn, and those infants born alive die shortly after birth. Epidemiologic studies demonstrate a striking variation in prevalence rates. The highest incidence is in Great Britain and Ireland, and the lowest incidence is in Asia, Africa, and South America.

In the past two decades, prenatal screening with ultrasound examination during the first trimester, which is nearly 100% accurate, and maternal AFP determinations have resulted in earlier detection of anencephaly. Earlier detection has resulted in a dramatic decrease in the average gestational age at birth, from 35.6 weeks in the 1970s to 19.6 weeks in 1988 to 1990, with virtually no term liveborn anencephalic infants born after 1990 in those pregnancies in which a prenatal diagnosis of anencephaly had been made (Drugan, 2001).

## Pathogenesis

The causes of anencephaly remain unknown; however, of importance, they mirror the causes of spina bifida, and similarly, folate has reduced the incidence of disease significantly. Indeed, both spina bifida and anencephaly can occur in the same family, reflecting the stochastic nature of where and

when neural tube closure may fail. Risk factors discussed previously apply to both spina bifida and anencephaly.

## Differential Diagnosis

In anencephaly, the absence of the brain and calvaria can be total or partial. Acrania is defined as congenital partial or total absence of the skull. Craniorachischisis is characterized by anencephaly, accompanied by a contiguous bony defect of the spine and exposure of neural tissue. In iniencephaly, dysraphism in the occipital region is accompanied by severe retroflexion of the neck and trunk, with three cardinal features: deficiency of the occipital bone; cervicothoracic spinal retroflexion; and rachischisis. Iniencephaly differs from anencephaly in that the cranial cavity is present and skin covers the head and retroflexed region. A majority of the patients also have visceral and other severe CNS malformations. In encephalocele, the brain and meninges herniate through a defect in the calvaria.

## Pathology

The cranial vault is defective over the vertex, exposing a soft, angiomatous mass of neural tissue covered by a thin membrane continuous with the skin. The cranial abnormality may extend inferiorly to the cervical region, with formation of a complete spina bifida. The extremely thin and flattened spinal cord is readily observed. The optic globes usually are protuberant because of inadequate bony orbits.

## ENCEPHALOCELE

An encephalocele is a herniation of intracranial contents through a midline skull defect. Also known as cephaloceles, these lesions are classified by their contents and location. Cranial meningoceles contain only leptomeninges and cerebrospinal fluid, whereas encephaloceles also contain brain parenchyma. The incidence of cephaloceles is approximately 0.8 to 5 per 10,000 live births, with encephaloceles being the most common form.

Encephaloceles occur in the occipital (75%) or frontal areas (25%). Basal and transsphenoidal encephaloceles are rare; they may appear between the ethmoid and sphenoid bones and extend into the upper pharynx. Encephaloceles extending from the orbit, nose, or forehead are termed sincipital encephaloceles; those in the occipital region are termed notencephaloceles.

## Etiology

The etiology of encephaloceles is likely multifactorial. Studies have indicated that consumption of FA during the periconceptional period can reduce the risk of anencephaly, as well as spina bifida. A similar protective effect, however, has not been noted for encephalocele.

## Clinical Characteristics

A fluctuant, round, balloon-like mass that protrudes from the cranium, usually posteriorly, is the most typical manifestation of encephaloceles. The mass may pulsate and be covered by an erythematous, translucent, or opaque membrane, or by normal skin. The amount of compromised and deformed neural tissue and the degree of resultant microcephaly determine the extent of cerebral dysfunction. Brain tissue not extending into the encephalocele (i.e., retained within the intracranial cavity) may be deformed and functionally impaired.

Severe intellectual and motor delays typically occur in association with microcephaly; motor delay is accompanied by weakness and spasticity. Intellectual impairment is more prevalent in patients with posterior encephaloceles than in those with anterior encephaloceles. Some patients, however, may have fairly normal development. When the deformity extends into the ventricle, hydrocephalus is almost inevitable.

## Management

Prenatal diagnosis of encephaloceles may be established with determination of increased amniotic AFP content and ultrasound studies. Surgical correction of all but the smallest encephaloceles is necessary. Accompanying hydrocephalus may require ventriculoperitoneal shunting. Associated systemic abnormalities are present in approximately half of the patients, depending on the syndromic nature of the condition. A full battery of endocrinologic screens should be performed to evaluate basal encephaloceles.

## OCCULT FORMS OF SPINAL DYSRAPHISM

The spectrum of occult spinal dysraphism includes anomalies in which the overlying skin is mostly normal and covers the underlying NTD. These anomalies include distortion of the spinal cord or roots by fibrous bands and adhesions, intraspinal lipomas, dermoid or epidermoid cysts, fibrolipomas, spinal cord lipomas, lipomyelomeningocele, and split cord malformations.

Symptoms of occult spinal dysraphism may be absent, minimal, or severe, depending on the degree of neural involvement. The patient may exhibit static or slowly progressive weakness, spasticity, or sensory loss in the legs or feet, gait difficulty, and foot deformity. Bowel and bladder dysfunction such as incontinence, repeated bladder infection, and enuresis also may occur. Common findings include diminished Achilles tendon reflexes, contracted heel cords, high arches, equinovarus deformity of the feet, decreased rectal sphincter tone, unequal leg or foot length, scattered sensory loss, Babinski signs, and trophic ulcers. Ultrasonography and MRI have greatly facilitated the diagnosis and management of these occult lesions. A tethered spinal cord, lipoma, or fatty filum terminale can be detected without invasive myelography. Ultrasonography can demonstrate a poorly pulsatile, low-lying, or thickened conus medullaris in infants. The decision to proceed to surgery is based on progressive symptomatology.

## Spinal Cord Lipoma

Spinal cord lipomas are developmental anomalies that range from a small fatty mass attached to the distal spinal cord to very complex anomalies that involve all spinal structures. In some cases, the lipoma is entirely intraspinal and extends through a limited defect in the posterior elements of the spine into the subcutaneous tissues. When involving subcutaneous tissues along with a cerebrospinal fluid-containing space, this is usually referred to as a lipomyelomeningocele.

Spinal cord lipomas are considered more complex forms of spinal dysraphism. Despite this, they can present with either no symptoms or symptoms over long periods of time. If untethering of the spinal cord can be accomplished with low morbidity, then a surgical procedure should be considered early in life. For large and complex lesions, particularly in patients with normal function, serious consideration should be given to observation, as deficits can evolve slowly.

## Dermal Sinus Tract

Recurrent meningitis from external contamination of cerebrospinal fluid may result from occult congenital malformations along the spinal canal and neuraxis such as dermal sinus tracts. From an embryologic perspective, sinus tracts consist of epithelial-lined canals that probably represent persistence of an ectodermal-derived pathway from the skin to the CNS. In most cases, the spinal cord appears largely normal, implying that neural tube formation is complete but a persistent communication is still present. Dermal sinus tracts are seen in approximately 1 in 2500 live births. An MRI scan should be obtained, followed by surgical treatment to eliminate this connection and remove the risk of meningitis.

## Spina Bifida Occulta

Spina bifida occulta, a confusing term, is defined as a defect in the posterior bony components of the vertebral column without involvement of the cord or meninges. It occurs in at least 5% of the population but most often is asymptomatic. The presence of a cutaneous lesion, tuft of hair, or a cutaneous angioma or lipoma in the midline of the back, is associated with spina bifida occulta in only approximately 10% of cases, although the percentage increases to approximately 50% when two or more skin lesions are present.

## Meningocele

Meningocele, a protrusion of meninges without accompanying nervous tissue, is not associated with neurologic deficit. The mass usually is evident as a fluid-filled protrusion covered by skin or membrane in the midline. An MRI is essential to determine the contents of a mass along the spine and in differentiating meningocele from MMC (Fig. 22-14). Very small subcutaneous lesions may remain undetected for prolonged periods and typically require no specific treatment.

When careful examination of patients with suspected meningocele reveals significant neurologic abnormality (e.g., equinovarus deformity, gait disturbance, abnormal bladder function), the diagnosis of MMC is appropriate. These patients likely have entrapped nerve roots within the defect that can be identified during surgery.

## Split Cord Malformations

### Embryology

In split cord malformations, previously known as diastematomyelia, a midline septum divides the spinal cord longitudinally into two, usually unequal portions extending up to 10 thoracolumbar segments. The septum may span the entire width of the spinal canal and is anchored to the ventral dura mater on the posterior aspect of the vertebral bodies. Split cord malformations can be divided into two different types. In type I, present in 50% of cases, a split spinal cord is surrounded by a normal undivided arachnoid-dural sleeve without a septum. In type II, present in the other 50%, each hemicord is invested by a separate dural sleeve, divided by a fibrous, cartilaginous, or bony septum.

### Clinical Characteristics

Patients with split cord malformations present with a congenital scoliosis, hydrocephalus, or cutaneous lesion such

as hairy patch, dimple, hemangioma, subcutaneous mass, or teratoma. A progressive myelopathy with deformities of the feet, scoliosis, kyphosis, or discrepancy in leg length may develop. The intervening mesenchymal elements appear to contribute to progressive neurologic, urologic, and orthopedic deterioration from spinal cord tethering. Resection of the spur should be performed in patients who have progressive neurologic manifestations; those without worsening symptoms should be observed until progression occurs and then resection performed.

## DISORDERS OF SECONDARY NEURULATION

### Fibrofatty Filum Terminale

The filum terminale is the nonfunctional continuation of the end of the spinal cord. It usually consists of fibrous tissue without functional nervous tissue. Although its embryologic origin is unclear, it probably represents the termination of the neural tube and its most caudal link to the rest of the embryonic tissues. The filum can be enlarged either with fibrous tissue only or with fat. A thickened or fatty filum terminale may be associated with a low conus and a spectrum of clinical findings, including bladder dysfunction, leg numbness and weakness, and scoliosis. In the presence of neurologic findings and a fatty filum, an untethering procedure may be considered.

### Sacral Agenesis

Sacral agenesis is a congenital absence of all or part of the sacrum. In its classic form, often described as the caudal regression syndrome, malformations of most or all structures derived from the caudal region of the embryo, including the urogenital system, the hindgut, caudal spine, spinal cord, and the lower limbs, may be seen. Approximately 15% to 25% of mothers of these children have insulin-dependent diabetes mellitus.

## INTRODUCTION

The prosencephalon forms at the end of primary neurulation as one of three principal vesicles: the hindbrain, the midbrain, and the forebrain (prosencephalon). The major disorders of prosencephalic formation, holoprosencephaly, agenesis of the corpus callosum, and septooptic dysplasia, are discussed in the next sections, after a brief introduction to prosencephalic development.

## Prosencephalon Patterning

Prosencephalic development occurs by inductive interactions from the prechordal mesoderm. The peak time period of development is the second and third months of gestation. Prosencephalon development occurs as three sequential events: prosencephalic formation, prosencephalic cleavage, and midline prosencephalic development (Fig. 26-1). Prosencephalic formation segments this structure into three prosomeres (P1–P3). P1 becomes the pretectum, P2 the thalamus, and P3 the prethalamus. More rostral brain regions, including the telencephalon, are also divided into prosomeric boundaries. The neocortex itself exhibits regionally restricted gene expression; however, data argue against anatomically and regionally restricted boundaries because cell lineage experiments demonstrate that sibling cells can occupy multiple nuclei throughout the anteroposterior axis.

## Prosencephalic Cleavage

Prosencephalic cleavage occurs in the fifth and sixth weeks of gestation and includes three basic cleavages:

1. Horizontal, to form the paired optic vesicles, and olfactory bulbs and tracts
2. Transverse, to separate the telencephalon from the diencephalons
3. Sagittal, to form the paired cerebral hemispheres, lateral ventricles, and the basal ganglia from the telencephalon

Three crucial thickenings or plates of tissue become apparent around the end of the second month; these are the commissural, the chiasmatic, and the hypothalamic plates. These structures are important in the formation, respectively, of the corpus callosum, anterior commissure and septum pellucidum, the optic nerve chiasm, and the hypothalamic structures. Disorders associated with abnormal development of the prosencephalon are outlined in Table 26-1.

## HOLOPROSENCEPHALY

Holoprosencephaly (HPE) is a complex brain malformation characterized by a failure of the forebrain (prosencephalon) to separate completely into two distinct cerebral hemispheres,

a process normally complete by the fifth week of gestation. HPE is typically associated with midline facial anomalies.

## Epidemiology

HPE is the most common developmental defect of the forebrain and midface in humans and occurs in 1 in 250 pregnancies, but because only 3% of the fetuses with HPE survive to delivery, the incidence in live births is only approximately 1 in 10,000. There also appears to be a slight female preponderance in some case series. A few studies of limited size suggest a higher than average prevalence of HPE in Far East Asians and Filipinos.

## Definition and Subtypes of Holoprosencephaly

The sine qua non of HPE is incomplete cleavage of midline structures involving the telencephalon and diencephalon. HPE typically is divided into three main subtypes and distinguished by the degree of separation of the cerebral hemispheres (Fig. 26-2).

In the most severe type, *alobar HPE*, nearly complete lack of separation of the cerebral hemispheres is characteristic, with a single midline ventricle very often communicating with a dorsal cyst. The interhemispheric fissure and corpus callosum are completely absent. In the intermediate form, *semilobar HPE*, the anterior hemispheres are not separated, but some degree of separation of the posterior hemispheres is seen. Similarly, the genu and body of the corpus callosum are absent, but the splenium is present. The frontal horns of the lateral ventricles are not developed, but the posterior horns are present. The mildest form, *lobar HPE*, is characterized by lack of separation of the most rostral and ventral aspects of the cerebral hemispheres. The splenium and body of the corpus callosum are present, but the genu is absent. Rudimentary frontal horns may be present.

In addition to these types, another subtype is identifiable: the *middle interhemispheric variant*. In this variant, the midportion of the cerebral hemispheres is continuous across the midline, with absence of the corpus callosum seen only in this region. There is separation of the anterior frontal lobes, basal forebrain, and occipital lobes. Evidence for this malformation being a subtype of HPE is bolstered by mutation of the *ZIC2* gene, which has been implicated in causing the classic forms of HPE.

Failure of separation also is common in the hypothalamic, caudate, lentiform, and thalamic nuclei. About one fourth of patients have some degree of midbrain nonseparation. Occasionally, isolated neuronal heterotopias are seen, particularly in the middle interhemispheric variant. The gyri often are normally developed, although in alobar and semilobar HPE, the gyri may be excessively smooth or broad. Although for discussion HPE is divided into subtypes, the degree of

**Figure 26-1. Prosencephalic midline development.** The prosencephalic midline is presented by a series of independent but closely related segments. Note particularly the commissural, chiasmatic, and hypothalamic primordia or plates. The proximity of these structures in the developing brain and their derivation from a common primordium explain the spectrum of midline defects associated with septooptic dysplasia, which include optic nerve hypoplasia and hypothalamic and corpus callosum defects. (With permission from Leech RW, Shuman RM. *Holoprosencephaly and related midline cerebral anomalies: A review. J Child Neurol* 1986;1:3.)

malformation occurs along a spectrum, and individual patients do not fall neatly into categories.

## Etiology

Multiple environmental and genetic factors have been implicated in causing HPE. Prenatal exposures to a variety of toxins, medications, and infections also have been reported. The strongest teratogenic evidence exists for maternal diabetes and exposure to alcohol and retinoic acid. A diabetic mother's risk of having a child with HPE is approximately 1%, a greater than 100-fold increase over the general population. A recent population study confirmed the risks of preexisting maternal diabetes and salicylates (aspirin) but also noted an increased risk with artificial reproductive therapy. Some teratogens are thought to produce HPE via interference with the sonic hedgehog gene signaling pathways, or cholesterol biosynthesis.

Approximately 30% to 50% of live births with HPE have chromosomal abnormalities, but this is likely an overestimation based on underreporting of milder cases. HPE can be seen in association with trisomy 13, trisomy 18, or triploidy. Various deletions or duplications of chromosomal regions have also been associated with HPE. HPE is also seen in single gene syndromes, such as Pallister-Hall syndrome, Rubinstein-Taybi syndrome, Smith-Lemli-Opitz, and Goldenhar syndromes. An updated list of genetic disorders associated with HPE can be found on the online Mendelian Inheritance in Man (OMIM) website (<http://www.ncbi.nlm.nih.gov/omim>).

In nonsyndromic and nonchromosomal HPE, autosomal-dominant and autosomal-recessive pedigrees have been reported. At least nine genes have been associated with HPE, including: SHH (7q36); ZIC2 (13q32); SIX3 (2p21); TGIF (18p11.3); PATCHED-1 (9q22); GLI2 (2q14); DISP1 (1q24); NODAL (10q); and FOXH1 (8q24.3). Of these genes, the four most commonly affected (SHH, ZIC2, SIX3, and TGIF) account for only 25% of the cases of HPE with normal chromosomes and approximately 5% to 10% of all HPE patients (Roessler and Muenke, 2010).

SHH (sonic hedgehog) was the first identified HPE-associated mutated gene, and the SHH protein is a secreted

intercellular signaling molecule involved in establishing cell fates at several points during development. SHH is expressed early in development in the ventral forebrain and is critical for ventral patterning of the developing neural tube. Disruption of SHH signaling in animal models mimics the brain and facial malformations in HPE.

The SHH signaling network is the common pathway through which multiple environmental and genetic influences interact to cause HPE. For example, PTCH is a receptor for SHH, and GLI2 is a mediator of SHH target gene transcription. Environmental influences link the SHH signaling network with hypocholesterolemia. For example, maternal hypocholesterolemia has been implicated in HPE. Also, HPE is seen in Smith-Lemli-Opitz syndrome, which is due to a defect in 7-dehydrocholesterol reductase, the final enzyme in cholesterol synthesis.

## Clinical Manifestations and Outcomes

Along with the midline brain malformation seen in HPE, a corresponding midline facial malformation may be present. In its most severe and usually lethal form, cyclopia with the presence of a single midline eye and a proboscis (rudimentary single-nostril nose) above the eye can be present. Survivors may have hypotelorism, a flattened nasal bridge, median cleft lip and palate, or a single median maxillary central incisor. The oft-quoted statement "the face predicts the brain" refers to the observation that the degree of facial malformation frequently reflects the degree of brain malformation. This was amended later to "the face predicts the brain approximately 80% of the time," in recognition of individuals with alobar HPE with a normal facial appearance, as well as cases of milder brain malformation associated with abnormal facies.

Previous studies indicated that children with HPE do not survive beyond early infancy. This may have been due to the identification of only the most severe cases. Early death is typical for most cytogenetically abnormal children and those individuals with the most severe facial features (cyclopia or ethmocephaly). In children without these risk factors, more

recent studies have indicated that long-term survival is not uncommon. In one series of 104 HPE patients, the mean age at the time of study was 4 years, and 15% were between 10 and 19 years of age. When death did occur, causes included brainstem dysfunction, pneumonia, dehydration from diabetes insipidus, and rarely, intractable seizures.

Children with HPE may experience a variety of medical and neurologic problems. A significant proportion develops hydrocephalus, with 60% of alobar and 8% of semilobar requiring a VP shunt. As in children with other midline brain defects, endocrinologic problems are very common. Diabetes insipidus is particularly frequent, growth hormone deficiency, hypocortisolism, and hypothyroidism also may occur. The endocrinopathies may be due to midline defects involving the hypothalamus and are rarely due to a dysgenetic (e.g., hypoplastic or ectopic) pituitary gland.

Approximately half of the children with HPE have epilepsy, and the likelihood of developing seizures does not correlate with the severity of the brain malformation. The most common seizure type is complex partial seizures, with or without secondary generalization, but seizures can include generalized tonic-clonic, tonic, atonic, myoclonic, or infantile spasms. In 50% of affected children, the seizures are relatively easy to control with antiepileptic medication but with increased risk associated with cortical dysplasia.

Feeding problems and swallowing dysfunction are common in children with HPE and are correlated with the severity of the brain malformation. Two thirds of patients with alobar and semilobar HPE require gastrostomy tubes.

Developmental disability affects nearly all patients with HPE. The severity of the brain malformation determines the degree of delay and neurologic impairments (including hypotonia and spasticity). Severe developmental delay is present in alobar HPE. There is no reported case of a child with alobar HPE who is able to sit independently. In lobar HPE, approximately 50% of children ambulate (with or without assistance), use their hands functionally, and have some verbal communication. Neuropsychologic evaluation in HPE demonstrates relative strengths in receptive language and socialization and weaknesses in visual reasoning and nonverbal problem skills.

In the middle interhemispheric variant, the incidence of endocrinopathies is much lower than has been attributed to the more normally separated hypothalamus seen on MRI. The degree of motor complications (hypotonia evolving into spasticity and dystonia) and developmental dysfunction is similar to that seen in lobar HPE.

## Management

Children with alobar HPE, a dorsal cyst, or normocephaly or macrocephaly should be closely observed for the development of hydrocephalus and perhaps shunting early given the high risk, as hydrocephalus can lead to progressive head enlargement and greater difficulty in caring for the child. Electrolyte screening should be performed for diabetes insipidus surveillance. Screening for other endocrine abnormalities should be considered, including assays of cortisol, thyroid-stimulating hormone, free thyroxine, and insulin-like growth factor-1 (IGF-1). If seizures develop, the possibility of acute reactive seizures should be evaluated for and a serum sodium level checked. MRI also should be considered to evaluate for focal heterotopia. Gastrostomy tubes often are necessary to address the complex management issues of ensuring adequate calories related to feeding dysfunction and delivery of adequate free water necessary for management of diabetes insipidus. Motor difficulties and dystonia may be partially responsive to trihexyphenidyl. This agent may improve upper extremity and

oromotor function. Motor dysfunction, including hypertonia and dystonia, is common and may require physical, pharmacologic, or surgical therapies.

## Prenatal Diagnosis and Imaging

The first-trimester ultrasound can detect alobar HPE but may be much less sensitive in detecting milder cases. The presence of large dorsal cysts, hydrocephalus, or midline craniofacial defects may provide clues that eventually lead to the recognition of the associated HPE. Fetal MRI has been used to diagnosis a range of HPE. Other midline anomalies, such as agenesis of the corpus callosum, absence of the septum pellucidum, and hydrocephalus with communication of the lateral ventricles, are sometimes misdiagnosed prenatally as HPE (Fig. 26-3).

## Genetic Counseling and Testing

The recurrence risk of isolated HPE is estimated to be 6%. Special attention should be given to the family history to identify "microforms" such as anosmia or a single central incisor. Such a finding indicates higher recurrence risk. Genetic sequence analysis is commercially available and should be considered. Prenatal testing for HPE risk genes is possible by means of amniocentesis or chorionic villus sampling. The gene tests, in conjunction with fetal MRI, have been found to be helpful in prenatal diagnosis and counseling in a series of pregnancies. High-resolution cytogenetic analysis can detect abnormalities in 24% to 45% of all individuals with HPE. Chromosomal microarray has a higher yield in detecting chromosomal deletions, duplications, and unbalanced rearrangements and is the preferred chromosomal test in fetuses and newborns suspected of having HPE.

## AGENESIS OF THE CORPUS CALLOSUM

The corpus callosum forms between the 8th and 14th weeks of fetal development. Nearly 200 million axons course through this structure and innervate opposing hemispheres in a homotopic manner; that is, each axon innervates structures in the mirror location in the opposing hemisphere. Absence or diminution of this structure is found in 1 in 3000 live births and is the most common birth defect of the central nervous system after spina bifida. Callosal abnormalities are frequently seen with other malformations of brain development but can present in an isolated manner (Fig. 26-4). Many cases are also associated with birth defects in other organ systems and can be caused by chromosomal disorders. There is also recognition that subtle chromosomal copy number variants (CNVs) play a critical role in the etiology of ACC (Sajan et al., 2013). Single-gene mutations and metabolic disorders can also disrupt callosal development. Fetal alcohol syndrome, the best-known and most studied environmental cause of ACC, can also result in a significant reduction in white-matter volume. There is a great diversity of clinical outcomes for patients with ACC. Many individuals with ACC have deficits in social cognition, even with a normal IQ. Many of these individuals carry clinical diagnoses that place their phenotype on the autism spectrum. In children with ACC and associated brain anomalies, many have seizures and more significant developmental impairment, including intellectual disability and cerebral palsy. In some individuals with ACC due to chromosomal, metabolic, or single-gene disorders, the outcome can be quite severe, including a significantly shortened life expectancy.

**Figure 26-3. Fetal magnetic resonance imaging in holoprosencephaly.** **A** and **B**, Fetal MRI (single-shot fast spin echo) of a 21-week- and 5-day-old fetus with alobar HPE. The thalami, basal ganglia, and midbrain structures are incompletely delineated on the midline sagittal image (**A**). A large dorsal cyst (dc) communicates with the monoventricle (asterisk). The hemispheres are not separated, resulting in a holosphere (**B**). **C** and **D**, Fetal MRI of a 26-week gestational age fetus with trisomy 13 and semilobar HPE. The HASTE fetal sequence in the midsagittal plane (**C**) shows a monoventricle (asterisk), a moderate size dorsal cyst (dc), and inferior cerebellar vermis hypoplasia (Dandy-Walker complex). On the axial image (**D**), the thalami and basal ganglia appear fused, whereas the posterior hemispheres are separated. (With permission from Hahn JS, Barnes PD. *Neuroimaging advances in holoprosencephaly: refining the spectrum of the midline malformation*. *Am J Med Genet Part C* 2010;154C:120–132.)

## Epidemiology

Population studies suggest a birth incidence for ACC of 1 in 3000 (Glass et al., 2008). Like many birth defects, the incidence rate of ACC is higher in births from mothers over age 40, with a nearly three-fold increased risk compared with women in their 20s. There is also a slightly higher prevalence in children born to older fathers, as has also been reported recently for autism. Babies with ACC are nearly four times more likely to be born prematurely than the general population. It should be noted that detection of ACC occurs more commonly with better ultrasound surveillance, and its detection in utero may alert physicians to the increased probability of premature birth (Glass et al., 2008). In addition, identifying ACC should also alert the clinician to screen for other

organ malformations, including musculoskeletal, renal, and gastrointestinal.

## Prenatal Diagnosis and Prediction of Outcomes

The majority of information on the epidemiology of callosal agenesis comes from studies of postnatally diagnosed cases. However, in the studies that investigated all types of ACC in large fetal cohorts, approximately 70% of individuals had other associated anomalies in the central nervous system, including white matter deficits, cortical malformations, cysts, and posterior fossa abnormalities (Hetts et al., 2006). Isolated ACC only accounted for approximately 30% of the total number of cases. In these cases of prenatally detected, isolated ACC, approximately 50% show neurologic impairment in the

first few years of life, and many of the remainder show cognitive and behavioral deficits during school years. Current standard ultrasonography can reliably detect callosal agenesis at 22 weeks' gestation; however, many pregnant women receive a single ultrasound at 18 weeks to evaluate fetal anatomy as part of standard prenatal care. There are recommendations within the obstetric community to perform two ultrasounds, one transvaginally at 14 weeks to assess nuchal translucency and other early visible anatomic changes and a second study at 20 to 22 weeks to better visualize later-developing structures, such as the corpus callosum.

## Development of the Corpus Callosum

The corpus callosum is the largest white-matter tract in the brain, with over 190 million axons crossing the midline to innervate principally homotopic structures. The disproportionate increase in white-matter volume in mammalian and, specifically, in primate evolution points to the importance of long-range connectivity (particularly of the frontal lobes) in brain evolution and function. The first callosal fibers can be seen crossing the midline around the 14th week of gestation. The midline is composed of a number of structures that likely assist in guiding these callosal fibers, including the glial wedge, midline zipper glia, glial sling, and indusium griseum glia (Fig. 26-5). The full complexity of molecular and cellular events necessary for callosal development is not yet known, but these events can be seen within a general framework of developmental steps that include: birth and specification of commissural neurons; guidance of these neurons to the midline; midline fusion and development of key midline structures (as outlined in Fig. 26-5); and axonal crossing of the midline with guidance of crossed neurons to the final site of connectivity. In patients with ACC, it can be difficult to determine which one of these steps is altered. However, in one group, patients with microcephaly and absent Probst bundles, there are likely defects in the initial birth and specification of commissural neurons. In contrast, it is more likely that patients who have Probst bundles (and normal or near-normal cerebral white-matter volume) have deficits in axonal guidance or midline fusion.

## Imaging and the Corpus Callosum

Imaging of children and adults with ACC has shown that the missing corpus callosum is frequently only one component of the spectrum of brain malformations found in an individual patient. In a retrospective study of 142 cases of callosal agenesis, only five had truly "isolated" ACC, whereas over half had malformations of cortical development, one third had cerebellar malformations, and one fourth had brainstem anomalies. Advanced techniques such as diffusion tensor imaging (DTI) have demonstrated that the ventral cingulum bundle (CB) is smaller and has lower fractional anisotropy in ACC patients, which may explain the behavioral deficits observed in ACC.

## Etiology

### Genetic

Many molecular and cellular processes are necessary for normal callosal formation. As such, many single-gene recessive disorders can be associated with callosal agenesis (Table 26-2). Whole exome sequencing has accelerated this discovery and new genes such EPG5 for Vici syndrome, C12orf57 for Temtamy syndrome, and GPSM2 for Chudley-McCullough syndrome were recently discovered. Autosomal dominant disorders associated with callosal agenesis and dysgenesis,

such as mutations in the DEAD-box gene DDX3X were also recently identified (Snijders Blok et al., 2015). In many disorders, the degree of callosal dysgenesis can be quite variable as in Sotos syndrome, in which complete ACC is present in a minority of cases, but other versions of callosal dysgenesis are prevalent in these patients (Schaefer et al., 1997).

There is also evidence that de novo chromosomal disorders play a significant role in callosal dysgenesis. A recent publication cataloged de novo deletions and duplications at recurrent genetic loci from nearly 400 ACC patients. These include regions in 1p36, 1q4, 6p25, 6q2, 8p, 13q, and 14q. A subsequent publication suggested that over 15% of ACC patients have a large de novo CNV that may be causative. Although the initial presumption has been that most cases of ACC have a genetic etiology, it is possible that nongenetic causes may play an important etiologic role.

### Nongenetic

The best example of environmental causes of ACC is fetal alcohol syndrome (FAS). Despite this linkage, there is clearly variability in the expression of callosal deficits in fetal alcohol syndrome. The cell surface molecule L1, which is involved in both axon guidance and fasciculation, is a proposed target for alcohol toxicity and signaling through this pathway may explain the variable expressivity of fetal EtOH exposure. There are a few reports of heavy metal toxicity and ACC, but without many reports, it is difficult to attribute a significant percentage of ACC cases to these causes.

## Clinical Manifestations

### Association of Agenesis of the Corpus Callosum With Autism and Related Neurodevelopmental Disorders

A wide range of clinical deficits can be seen in individuals with callosal agenesis including autism, intellectual disability, epilepsy, and cerebral palsy. However, it is difficult to know the precise prevalence of these associated features because most individuals with ACC are evaluated specifically because of their clinical difficulties, introducing ascertainment bias. With that limitation in mind, many studies have reported that patients with ACC have significant cognitive and neuromotor impairment. Epilepsy is common and is more prevalent in patients who have other associated brain malformations. Autistic features are present in approximately 40% of patients with ACC who have normal IQs, and a more detailed analysis shows that high-functioning ACC individuals also have problems with social cognition, paralinguistic communication, and executive function skills. Thus they have difficulties holding down jobs, finding partners, and living independently, even though they may have normal intelligence.

## Management

Currently, the mainstay of management for patients with ACC includes symptomatic measures that may include use of antiepileptic drugs for epilepsy, physical and occupational therapy for hypotonia and cerebral palsy, and speech therapy. Patients with ACC, including apparently high-functioning individuals, often have difficulty with more complex cognitive and behavioral tasks and need explicit behavioral training and education, which is often lacking in school settings. Anecdotal reports suggest that these individuals do better with therapy targeted at simplifying these tasks, providing repetition, and supporting a slower learning pace. Although many individuals with ACC have social deficits, they generally desire social

**Figure 26-8. Septo-optic dysplasia.** In this brain of a newborn, note corpus callosum thinning (*short arrow*), absent septum pellucidum (*long arrow*), hypothalamic hypoplasia (*double arrows*), and optic nerve hypoplasia (*asterisk*).

interactions. With recent reports of the potential benefits of intranasal oxytocin treatment for autistic individuals with social deficits, some have hypothesized that similar approaches may have long-lasting benefits in ACC patients. This approach remains to be formally tested.

## SEPTO-OPTIC DYSPLASIA

The constellation of symptoms that comprise septo-optic dysplasia (SOD) is presumed to result from failure of formation of the optic nerves, septum pellucidum, pituitary gland, and all midline structures within the prosencephalon (Fig. 26-8). Patients typically present with pituitary hormone abnormalities that can result in hypoglycemia or microphallus at birth or growth failure and other endocrine manifestations throughout childhood. It is a rare condition, with an estimated incidence of 1 to 10 in 100,000; known genetic etiologies contribute to only a small percentage of cases. Also, data suggest that young maternal age contributes to the risk of developing SOD. SOD is better viewed as a complex (SOD complex), with variable etiology and clinical presentation.

## Definition and Subtypes

There are three cardinal features of SOD: optic nerve hypoplasia, pituitary abnormalities, and midline brain defects (involving primarily the septum pellucidum and, at times, the corpus callosum). The diagnosis of SOD is typically made when two of the three features are present; however, given the heterogeneity intrinsic to this constellation of symptoms, most investigators have initiated their analysis by ascertaining patients with optic nerve hypoplasia (ONH) and then grouping those that had both pituitary dysfunction and absence of the septum pellucidum. From a clinical perspective, those that had ONH and pituitary anomalies but a normal septum pellucidum will have similar management issues. In contrast, those that have ONH and an absent septum pellucidum without pituitary abnormalities often have other brain malformations and likely represent a separate group.

## Etiology

SOD and ONH have been associated with primiparous birth and young maternal age. Additional risk factors that have been

consistently reported include maternal smoking and low socioeconomic status. Two genes were initially found in association with SOD, the homeobox gene, HESX1, and the transcription factor gene, SOX2. Chromosomal changes also have rarely been reported in SOD cases. More recently, data suggested an overlap between Kallmann syndrome and SOD. Thus most patients with SOD are hypothesized to result from a combination of genetic and environmental factors, recognizing that other mechanisms are yet to be discovered.

## Clinical Manifestations

SOD can present at birth with manifestations of pituitary insufficiency, including hypoglycemia, hypogonadotropic hypogonadism, and midline birth defects, including cleft lip and palate, as well as other brain malformations such as a thin corpus callosum. SOD patients are also at risk for adrenocorticotropic hormone, thyroid-stimulating hormone, and growth hormone deficiency. As with HPE and ACC, many patients with SOD have developmental delay and cerebral palsy.

## Management

Symptom management is essential in individuals with SOD, and careful attention should be paid to the heterogeneity of this complex disorder. Any child presenting with nystagmus should be evaluated for optic nerve involvement, and if ONH is detected, the patient should be assessed for anterior pituitary hormone deficiency. Additionally, many children with SOD can have developmental delay and seizures and should be evaluated for these possible concerns. Because children are at risk for adrenocorticotropic hormone, thyroid-stimulating hormone, and growth hormone deficiency (as well as hypothalamic dysfunction and poor production of the posterior pituitary hormones, antidiuretic hormone and oxytocin), they can present with hypoglycemia, diabetes insipidus, and poor thermoregulation. Multiple case reports of sudden death in SOD patients have described these complications (Kauvar and Muenke, 2010).

## INTRODUCTION

Advances in brain imaging, neuropathology, clinical phenotyping, genetics, and developmental biology have markedly improved the diagnosis of patients with structural disorders of the cerebellum and brainstem (SDCB) (Barkovich et al., 2009; Doherty et al., 2013; Robinson et al., 2014). It is now possible to recognize dozens of specific conditions by their clinical and imaging features, facilitating the identification of genetic and environmental (nongenetic) causes (Table 27-1).

SDCB include malformations (genetic) and disruptions (acquired due to prenatal infection, hemorrhage, or ischemia). The differentiation between a malformation (genetic) and a disruption (acquired) implies a huge difference in the recurrence risk with implications for genetic counseling and family planning (Poretti et al., 2009). The majority of disruptions are acquired lesions without recurrence risk; however, a genetic predisposition to disruptive lesions may be present in some cases, such as dominant mutations in *COL4A1*.

In addition to specifying recurrence risk, precise diagnosis is essential for providing accurate prognostic information and guiding surveillance for associated medical issues, supportive therapies, genetic testing, and emerging gene-specific therapies. Furthermore, a specific diagnosis can relieve parental guilt and allow families affected by rare disorders to connect with each other for support.

## CLINICAL FEATURES

The clinical features of SDCB are usually nonspecific and include hypotonia, motor delay, ataxia, and abnormal eye movements (Table 27-2). Cognitive impairment is common, but the range is broad (Bolduc et al., 2011). Although characteristic clinical features help identify patients with posterior fossa abnormalities, clinical features point to a specific diagnosis only in a minority (e.g., “figure-of-eight” head-shaking pattern for rhombencephalosynapsis). In the majority of patients, identifying the final diagnosis requires integration of history, clinical examination, neuroimaging, and laboratory testing.

## APPROACH TO NEUROIMAGING

Magnetic resonance imaging (MRI) is the neuroimaging tool of choice (Jissendi-Tchofo et al., 2015). Evaluation in multiple imaging planes and familiarity with the normal age-dependent anatomy of the pediatric mid-hindbrain is essential (Table 27-3).

Advanced neuroimaging techniques may be useful in selected cases. Susceptibility-weighted imaging (SWI) is highly sensitive for blood products and calcifications and is helpful in disruptive lesions. <sup>1</sup>H-MR spectroscopy can be useful in the diagnosis of mitochondrial and other metabolic disorders. Diffusion tensor imaging (DTI) provides information about the microarchitecture of cerebellar structures, the course of cerebellar white matter tracts, and their connections with other brain structures. In addition, DTI may reveal new diseases due to axon guidance defects that are not detectable by

conventional structural MRI. Functional MRI (task-based and resting state) remains largely a research tool but shows promise for improving diagnostic specificity, guiding treatment, and monitoring treatment response.

## APPROACH TO GENETIC TESTING

Given the incredible advances in sequencing technologies and other methods for identifying mutations across the entire genome, clinical genetic testing is very much a moving target. The different SDCB can be caused by large chromosome abnormalities, as well as recessive and dominant simple nucleotide variants. The importance of *de novo* and mosaic dominant mutations has only recently been appreciated. Repeat expansion has only been described in the spinocerebellar ataxias (rare in children), and imprinting defects have not been shown to cause SDCB.

## DISORDERS PRIMARILY AFFECTING CEREBELLUM

### Cerebellar Hypoplasias Primarily Affecting Vermis

#### Dandy-Walker Malformation

*Clinical characteristics:* Dandy-Walker malformation (DWM, OMIM 220200) is the most prevalent human cerebellar malformation (about 1 in 30,000 live births). The majority of children present prenatally or during the first year. Macrocephaly affects 90% to 100% of children during infancy. The outcome is variable and at least one third of patients have normal cognitive function, but the risk of abnormal neurodevelopmental outcome is increased in patients with extra-CNS abnormalities.

*Differential diagnosis and evaluation:* The diagnosis of DWM is based on the neuroimaging findings: 1) hypoplasia and anticlockwise rotation of the cerebellar vermis on sagittal view; and 2) cystic dilation of the fourth ventricle, filling nearly the entire posterior fossa. In most patients, the tentorium is elevated, the posterior fossa is enlarged, and the cerebellar hemispheres are hypoplastic and splayed. Frequently, hydrocephalus is also present, whereas brainstem hypoplasia and other malformations (e.g., callosal dysgenesis and migrational abnormalities) are less common. Abnormal vermian lobulation and additional brain malformations may be associated with poorer cognitive outcome.

Additional terms such as “Dandy-Walker variant,” “Dandy-Walker complex,” or “Dandy-Walker spectrum” have been variably used to refer to related constellations of imaging findings. If full criteria for DWM are not met, a detailed anatomic description (e.g., inferior cerebellar vermis hypoplasia or global CH) should be used, and nonspecific terms such as Dandy-Walker variant should be abandoned.

DWM can be distinguished from other posterior fossa cystic malformations through detailed neuroimaging assessment. Blake’s pouch cyst (BPC) is characterized by an infratentorial cyst that communicates with an enlarged fourth

**TABLE 27-1** Typical Clinical, Imaging, and Genetic Characteristics of Midbrain and Hindbrain Malformations Involving the Cerebellum

Disease	Clinical Features	Neuroimaging Features	Causes (genes)	Inheritance
<b>DISORDERS PRIMARILY AFFECTING THE CEREBELLUM</b>				
Dandy-Walker malformation	Macrocephaly common, variable intellectual disability, systemic involvement possible	Hypoplastic upwardly rotated vermis, fourth ventricle dilatation, large posterior fossa, hydrocephalus	<i>ZIC1</i> , <i>ZIC4</i> , <i>FOXC1</i> , <i>FGF17</i> , <i>LAMC1</i> , <i>NID1</i> (rare), most unknown	Sporadic (recurrence risk <5%)
Joubert syndrome	Hypotonia, ataxia, alternating apnea and tachypnea (improves with age), intellectual disability, retinal dystrophy, coloboma, nephronophthisis, liver fibrosis, polydactyly	Molar tooth sign, vermis hypoplasia, encephalocele (rare), foramen magnum cephalocele (occasional), anterior midbrain and dorsal medulla heterotopia (occasional), polymicrogyria, agenesis of the corpus callosum (rare)	More than 30 genes including <i>AHI1</i> , <i>ARL13B</i> , <i>C2CD3</i> , <i>C5ORF42</i> , <i>CC2D2A</i> , <i>CEP41</i> , <i>CEP290</i> , <i>HYLS1</i> , <i>INPP5E</i> , <i>KIAA0586</i> , <i>KIF7</i> , <i>MKS1</i> , <i>NPHP1</i> , <i>NPHP4</i> , <i>OFD1</i> , <i>RPGRIP1L</i> , <i>TCTN1</i> , <i>TCTN2</i> , <i>TCTN3</i> , <i>TMEM67</i> , <i>TMEM138</i> , <i>TMEM216</i> , <i>TMEM237</i>	AR, X-linked ( <i>OFD1</i> only)
Rhombencephalosynapsis	Alopecia, trigeminal anesthesia (GLH), head shaking (figure-of-eight pattern), hyperactivity and impulsivity, VACTERL features (<50%), variable ataxia, variable cognitive function	Continuity of cerebellar hemispheres, absence of the cerebellar vermis, absent septum pellucidum, aqueductal stenosis, fused colliculi, holoprosencephaly (rare), absent olfactory bulbs (<50%)	Unknown	Sporadic
X-linked intellectual disability with cerebellar hypoplasia	Moderate intellectual disability	Mild vermis hypoplasia, mild cerebellar hemisphere hypoplasia, variable ventriculomegaly	<i>OPHN1</i>	X-linked
Oculocerebrocutaneous syndrome	Orbital cysts, microphthalmia or anophthalmia, focal skin defects and appendages	Severely hypoplastic vermis, normal or hypoplastic cerebellar hemispheres, enlarged dysplastic tectum, thick, vertical superior cerebellar peduncles, agenesis of the corpus callosum, frontal polymicrogyria	Unknown	Sporadic
Unilateral cerebellar hypoplasia	Developmental and speech delay, hypotonia, ataxia, abnormal ocular movements, variable cognitive outcome, segmental head and neck hemangioma in PHACE syndrome	Hypoplasia of one cerebellar hemisphere, vermis may be involved, affected hemisphere may be dysplastic, variable volume of the posterior fossa, brainstem asymmetry, supratentorial disruptive lesions possible	Prenatal hemorrhage	Sporadic
Cerebellar hyperplasia	Highly variable features of Alexander disease, fucosidosis, Sotos syndrome, Williams syndrome, Costello syndrome, MCAP syndrome, MPPH syndrome	Large cerebellum, cerebellum wrapped around brainstem	Genes for associated disorders	Various depending on specific disorder
<i>GPR56</i> -related bilateral frontoparietal polymicrogyria	Seizures, moderate-severe intellectual disability, ataxia	Frontoparietal or generalized polymicrogyria, patchy or diffuse white matter signal changes, cerebellar dysplasia with cerebellar cysts	<i>GPR56</i>	AR
Chudley-McCullough syndrome	Hearing loss, mild or no ataxia, mild neurodevelopmental impairment	Cerebellar hemisphere dysplasia, inferior cerebellar vermis hypoplasia, partial agenesis of the corpus callosum, frontal subcortical heterotopia, frontal polymicrogyria, arachnoid cysts	<i>GPSM2</i>	AR
Poretti-Boltshauser syndrome	Ataxia, ocular motor apraxia, strabismus, speech delay, intellectual disability, high myopia, non-progressive retinal dystrophy	Cerebellar dysplasia with cysts (may be absent), vermis hypoplasia, abnormal configuration of the fourth ventricle	<i>LAMA1</i>	AR

**TABLE 27-1** Typical Clinical, Imaging, and Genetic Characteristics of Midbrain and Hindbrain Malformations Involving the Cerebellum (Continued)

Disease	Clinical Features	Neuroimaging Features	Causes (genes)	Inheritance
PHACE syndrome	Segmental hemangioma (usually head and neck), intracranial and great vessel abnormalities, variable intellectual disability in <50% of patients (usually mild)	Unilateral cerebellar hypoplasia with or without vermis involvement, Dandy-Walker malformation, dysmorphic or absent major vessels, occasional heterotopia, polymicrogyria	Unknown	Sporadic
Lissencephaly-related midbrain and hindbrain malformations	Spasticity, seizures, severe cognitive impairment in patients with <i>RELN</i> mutations, broad range of cognitive outcomes in patients with tubulinopathies and <i>ARX</i> mutations	Heterogeneous: pachygyria with mildly thickened cortex ( <i>RELN</i> ); variable spectrum, lissencephaly with moderately thick cortex (more severe posteriorly), small or absent basal ganglia, agenesis of the corpus callosum, small pons with normal cerebellum ( <i>ARX</i> ); highly variable range of polymicrogyria to lissencephaly, enlarged tectum, dysmorphic basal ganglia, thin or absent corpus callosum (tubulinopathies)	<i>RELN</i> , <i>ARX</i> , <i>TUBA1A</i> , <i>TUBB2B</i> , <i>TUBB3</i>	AR ( <i>RELN</i> ), X-linked ( <i>ARX</i> ), de novo AD ( <i>TUBA1A</i> , <i>TUBB2B</i> , <i>TUBB3</i> )
<b>DISORDERS AFFECTING CEREBELLUM AND BRAINSTEM</b>				
<i>VLDLR</i> -related cerebellar hypoplasia	Ataxia, moderate-severe intellectual disability, quadripedal locomotion in some patients	Cerebellar hypoplasia with decreased foliation (vermis more severe than hemispheres), pontine hypoplasia, simplified cortical gyral pattern	<i>VLDLR</i>	AR
Pontocerebellar hypoplasia type 1	Spinal muscular atrophy	Hypoplastic pons, proportional hypoplasia of vermis and hemispheres	<i>EXOSC3</i> , <i>VRK1</i> , <i>RARS2</i>	AR
<i>TSEN</i> -related pontocerebellar hypoplasia (types 2, 4, and 5)	Neonatal encephalopathy, severe progressive microcephaly, increased tone, dyskinesia, seizures, cortical visual impairment, usually severe intellectual disability	Postmigrational microcephaly, small pons and cerebellum, seemingly atrophic cortex, thin corpus callosum, vermis less hypoplastic than hemispheres (dragonfly appearance)	<i>TSEN54</i> , <i>TSEN2</i> , <i>TSEN34</i>	AR
Pontocerebellar hypoplasia type 6	Increased lactate concentration in CSF	Small pons and cerebellum, vermis more severely hypoplastic than hemispheres	<i>RARS2</i>	AR
<i>CASK</i> -related pontocerebellar hypoplasia	Typically female (rarely male), progressive microcephaly, variable hearing loss, intellectual disability	Small pons and cerebellum (can be mild), proportionate cerebellar vermis and hemisphere hypoplasia	<i>CASK</i>	X-linked
<i>CHMP1A</i> -related pontocerebellar hypoplasia	Acquired microcephaly, increased extremity tone and contractures, moderate-severe intellectual disability	Small pons and cerebellum, proportionate vermis and hemisphere hypoplasia	<i>CHMP1A</i>	AR
Congenital disorders of glycosylation type 1a	Abnormal fat distribution, retinitis pigmentosa, failure to thrive, increased transaminase, coagulopathy, hypothyroidism, hypogonadism, seizures, stroke-like episodes, ataxia, mild-severe intellectual disability	Pontocerebellar hypoplasia with progressive atrophy, T2-hyperintense cerebellar cortex and cortical atrophy in some patients	<i>PMM2</i>	AR
Dystroglycanopathies (Walker-Warburg syndrome, muscle-eye-brain disease, Fukuyama muscular dystrophy)	Seizures, severe intellectual disability, eye involvement (cataracts, coloboma, high myopia), muscle involvement (weakness, contractures, variably increased creatine kinase)	Kinked brainstem, large tectum, cerebellar hypoplasia, subcortical cerebellar cysts, cobblestone cortex, abnormal myelination, ventriculomegaly	15 genes including <i>POMT</i> , <i>POMGnT1</i> , <i>FKRP</i> , <i>POMT1</i> , <i>POMT2</i> , <i>FKTN</i> , <i>LARGE</i> , <i>ISPD</i> , <i>GTDC2</i>	AR

Continued on following page

**TABLE 27-1** Typical Clinical, Imaging, and Genetic Characteristics of Midbrain and Hindbrain Malformations Involving the Cerebellum (*Continued*)

Disease	Clinical Features	Neuroimaging Features	Causes (genes)	Inheritance
Pontine tegmental cap dysplasia	Hearing loss, trigeminal anesthesia, corneal scarring, dysphagia, variable cardiac, vertebral, and rib defects, substantial ataxia, moderate-severe intellectual disability	Hypoplastic pons, mildly hypoplastic cerebellum, cap of white matter on dorsum of pons, hypoplastic middle and inferior cerebellar peduncles	Unknown	Sporadic
Cerebellar agenesis	Ataxia, dysarthria, hypotonia, variable degree of intellectual disability, neonatal diabetes mellitus ( <i>PTF1A</i> mutation)	Small to absent cerebellum, small pons	Variable, including malformations ( <i>PTF1A</i> mutation) and prenatal disruptions	Variable, AR ( <i>PTF1A</i> mutation) or sporadic
<b>DISORDERS PRIMARILY AFFECTING THE BRAINSTEM</b>				
Brainstem disconnection	Absent or weak suck and swallowing, central respiratory insufficiency, increased or decreased muscle tone, poor visual fixation, seizures, unstable body temperature	Nearly complete absence of a brainstem segment with intact rostral and caudal portions connected only by a thin cord of tissue, cerebellar hypoplasia, basilar artery may be absent	Unknown	Sporadic

AD, autosomal dominant; AR, autosomal recessive; CSF, cerebrospinal fluid; GLH, Gómez-López-Hernández syndrome; MCAP, megalencephaly capillary malformation-polymicrogyria; MPPH, megalencephaly polydactyly polymicrogyria-hydrocephalus; PHACE, posterior fossa brain malformations, hemangioma, arterial lesions, cardiac defects, and eye abnormalities; VACTERL, vertebral defects, anal atresia, cardiac defects, tracheo-oesophageal fistula, renal defects, and limb defects.

**TABLE 27-3** Role of the MRI Planes for the Evaluation of Cerebellar Hypoplasia

MRI Planes	Key Points
<b>Coronal</b>	<ol style="list-style-type: none"> <li>Excellent overview of vermis and hemispheres (severity of vermis vs. hemispheric involvement, hemispheric asymmetry).</li> <li>Normally, cerebellar fissures radiate from the cerebellar nuclei to the surface.</li> <li>The orientation and curvature of the cerebellar fissures is abnormal in cerebellar dysplasia.</li> </ol>
<b>Sagittal</b>	<ol style="list-style-type: none"> <li>Assess vermis, brainstem and fourth ventricle morphology, posterior fossa size, and supratentorial midline structures.</li> <li>The dorsal margin of the brainstem should be almost straight.</li> <li>The fastigium of the fourth ventricle should be just below the midpoint of the ventral pons.</li> <li>The rostrocaudal height of the vermis should be almost equal to the distance from the caudal tectum to the obex.</li> <li>In cerebellar hypoplasia, the fastigium is upwardly displaced and the rostrocaudal height of the vermis is reduced.</li> <li>Major vermis fissures are less prominent or absent in rhombencephalosynapsis.</li> </ol>
<b>Axial</b>	<ol style="list-style-type: none"> <li>Assess the morphology of vermis and hemispheres.</li> <li>Essential to assess the supratentorial structures.</li> <li>Normally, the cerebellar fissures have an “onion-like” orientation parallel to the calvarium.</li> </ol>

(Modified with permission from Poretti, A., Boltshauser, E., Doherty, D., 2014. Cerebellar hypoplasia: differential diagnosis and diagnostic approach. *Am J Med Genet C Semin Med Genet* 166C(2), 211–26. PMID: 24839100.)

ventricle. A normal cerebellar vermis differentiates BPC from DWM, whereas an enlarged fourth ventricle differentiates BPC from arachnoid cysts and mega cisterna magna (MCM). Arachnoid cysts do not communicate with the fourth ventricle and may cause obstructive hydrocephalus. MCM is an enlarged cisterna magna with otherwise normal vermis, fourth ventricle, and posterior fossa.

**Pathophysiology:** In most patients, the cause of DWM remains unknown; however, DWM may occur as part of a Mendelian syndrome (e.g., Ritscher-Schinzel or Ellis-van Creveld syndromes), aneuploidies (e.g., trisomy 9, 13, 18), or other chromosome abnormalities. In small subsets of patients, mutations in *ZIC1*, *ZIC4*, *FOXG1*, *FGF17*, *LAMC1*, and *NID1* have been identified. The function of these genes suggests that DWM may result from defects in the interaction between the developing cerebellum and the surrounding mesenchyme. DWM occurs mostly sporadically and overall the recurrence risk is low (1% to 5%); however, in a given family with a specific genetic disorder, the recurrence risk may be substantially higher.

**Management:** Correction of hydrocephalus is the main treatment in DWM. Considerable debate still exists regarding the best CSF diversion strategy. Options include shunt placement and endoscopic third ventriculostomy with or without choroid plexus cauterization.

## Joubert Syndrome

Joubert syndrome (JS) was first described in 1969, and the pathognomonic “molar tooth sign” was identified in 1997 (Romani et al., 2013). We favor using the terms JS or Molar Tooth Malformation disorder for all patients who have the molar tooth malformation (MTM) and describing any additional features present in each patient.

**Clinical characteristics:** Patients with JS are often identified prenatally with vermis hypoplasia and diagnosed with DWM or DWV. After birth, hypotonia is uniformly present, whereas the characteristic abnormal breathing pattern (episodes of

tachypnea followed by apnea) and abnormal eye movements (ocular motor apraxia) are common. Ataxia develops later, and intellectual disability of varying degrees is present in the majority of the patients. Polydactyly, cystic or echogenic kidneys, chorioretinal coloboma, encephalocele, and other features are less common but can be helpful clues to the diagnosis.

*Differential diagnosis and evaluation:* The MTM on brain MRI is pathognomonic, comprising vermis hypoplasia, long, thick and horizontally oriented superior cerebellar peduncles (SCP), and a deep interpeduncular fossa; however, the components of the MTM can be present without an obvious molar tooth appearance on MRI due to the plane of section (Fig. 27-1). In addition, superior cerebellar dysplasia is often present and can be very helpful for diagnosis. Patients may also have other brain abnormalities, including polymicrogyria, agenesis of the corpus callosum, as well as cortical and brainstem heterotopia (Fig. 27-1D).

Other disorders associated with neonatal hypotonia (Prader Willi syndrome, spinal muscular atrophy, myopathies) or cerebellar ataxia can be distinguished from JS by the features listed previously when they are present. Polydactyly, retinal dystrophy, cystic kidney disease, and liver fibrosis result in clinical overlap with other ciliopathies. Infrequently, mildly affected patients can also present with “isolated” ocular motor apraxia or retinal dystrophy.

*Pathophysiology:* The distinctive MTM imaging phenotype has facilitated the identification of mutations in more than 30 genes, all of which encode proteins that function in and around a subcellular organelle called the primary cilium. Primary cilia are membrane-enclosed microtubule-based “antennae” that project from most cells. They are decorated with receptor proteins that detect light, mechanical, and chemical inputs, including ligands for sonic hedgehog, G-protein coupled receptor, and other signaling pathways. Based on these diverse functions in many cell types, the wide variety of phenotypes observed in JS patients is not surprising.

*Management:* Diagnosing JS is essential because of the progressive retinal, kidney, and liver involvement. Identifying the genetic cause facilitates prognostic and reproductive counseling, and guides the frequency of medical monitoring. Early diagnosis of extra-CNS involvement ensures early treatment to avoid secondary complications such as anemia, malnutrition, osteoporosis, and catastrophic gastrointestinal bleeding. Many patients have sleep disordered breathing, requiring careful monitoring and in some cases tonsillectomy and adenoidectomy or positive airway pressure support during sleep.

## Global CH with Involvement of Both Vermis and Hemispheres

Global CH refers to involvement of both vermis and cerebellar hemispheres (Poretti et al., 2014). The clinical and neuroimaging findings associated with CH may suggest a specific disease (such as prenatal infection or neurometabolic disease) or help to plan further investigations and interpret their results (Table 27-4). Chromosome array and whole-exome sequencing are indicated if dysmorphic signs or other features suggest a genetic disorder.

Global CH may be the neuroimaging feature of nonprogressive cerebellar ataxia (NPCA). Patients present with hypotonia and motor and language delays that often evolve into ataxia and intellectual disability. The brain MRI may be normal or reveal widened interfolial spaces, giving the impression of cerebellar atrophy. An increasing number of genes (e.g., *CA8*, *ZNF592*, *WDR81*, *ATP8A2*, and *WWOX*) have been associated with NPCA.

## Unilateral Cerebellar Hypoplasia

Unilateral cerebellar hypoplasia (UCH) ranges from complete aplasia to mild asymmetry in cerebellar hemisphere size. UCH may be an incidental finding or occur in patients with developmental delay and cerebellar signs. Generally, UCH represents a residual change after a disruptive prenatal cerebellar insult, most likely a hemorrhage, so recurrence is rare. The role for thrombophilia workup in these patients is controversial but should be considered. UCH is the most common posterior fossa feature of PHACE(S) (OMIM 606519), usually associated with an abnormal ipsilateral internal carotid artery.

## Cerebellar Atrophy

Cerebellar atrophy (CA) is defined as enlarged fissures (interfolial spaces) in comparison to the folia (Poretti et al., 2008). This pattern implies loss of cerebellar parenchyma caused by a progressive disease or a single severe insult (infection or toxic exposure). Distinguishing CA from CH can be problematic or impossible based on a single imaging study. In addition, atrophy can be superimposed on hypoplasia, as documented in pontocerebellar hypoplasia and congenital disorders of glycosylation type 1a.

Typically, CA is more pronounced in the vermis, but the cerebellar hemispheres can be more affected in some pontocerebellar hypoplasias and extremely premature infants. In contrast to prenatal-onset conditions, the pons is preserved in CA.

A pattern-recognition approach based on neuroimaging findings (Table 27-5) may allow the diagnosis in some patients, whereas CA can be isolated or associated with other infratentorial or supratentorial findings such as hypomyelination, progressive white matter abnormalities (e.g., diffuse, multifocal, with cerebellar, brainstem, or periventricular predominance), involvement of the basal ganglia (e.g., calcifications, atrophy, and signal changes), signal changes of the dentate nuclei, and hyperintense T2-signal in the cerebellar cortex (Fig. 27-2).

## Cerebellar Dysplasias

Cerebellar dysplasia is defined by abnormal cerebellar foliation, white matter arborization, and gray-white matter junction. For specific diagnosis, it is important to determine the pattern of dysplasia, whether cysts are present, and whether the patient has other clinical features (Table 27-6). Diagnosing cerebellar dysplasia is important because most of the genetic causes are autosomal recessive with 25% recurrence risk.

*Clinical Characteristics:* The clinical presentation of cerebellar dysplasia is similar to other SDCB, although frequently more subtle.

*Differential diagnosis and evaluation:* Cerebellar dysplasia disorders have distinguishing features such as frequent seizures, polymicrogyria, and white matter signal changes (Fig. 27-3A) with *GPR56* mutations (OMIM 606854), high myopia, retinal abnormalities, and cerebellar cysts (Fig. 27-3B), without cortical involvement or elevated creatine kinase in Poretti-Boltshauser syndrome (OMIM 615960), and sensorineural hearing loss, partial or complete callosal agenesis, frontal subcortical heterotopia, and frontal polymicrogyria (Fig. 27-3C) in Chudley-McCullough syndrome (OMIM 604213).

*Pathophysiology:* Multiple mechanisms underlie cerebellar dysplasia including abnormal precursor cell division and neuronal migration. In particular, the  $\alpha$ -dystroglycanopathies, Poretti-Boltshauser syndrome (*LAMA1* mutations), and

GPR56-associated cerebellar dysplasia are thought to be due to basement membrane defects that result in abnormal neuronal migration. Chudley-McCullough syndrome is caused by recessive mutations in *GPSM2*, which encodes a GTPase regulator needed for correct orientation of stem cell division.

**Management:** As with other diagnostic categories, patients with cerebellar dysplasia disorders should be monitored for associated medical issues. This is most pertinent to patients with JS as described previously, Poretti-Boltshauser syndrome (high myopia and abnormal retinal development), and Chudley-McCullough syndrome (sensorineural hearing loss).

## Cerebellar Hyperplasia and Chiari Type I Malformation

### Cerebellar Hyperplasia

Cerebellar hyperplasia (macrocerbellum) is rare and characterized by excessive cerebellar volume with preserved shape. The cerebellar hemispheres are usually more affected than the vermis and may expand into adjacent anatomic regions by wrapping around the brainstem.

**Clinical characteristics:** Ataxia, hypotonia, intellectual disability, and ocular movement disorders are common, but other clinical features depend on the underlying disease.

**Differential diagnosis and evaluation:** Macrocerbellum may be isolated or part of well-defined syndromes (e.g., Costello, Sotos, Proteus, megalencephaly syndromes) or neurometabolic diseases (e.g., fucosidosis, Alexander disease, and mucopolysaccharidoses).

**Pathophysiology:** Macrocerbellum is not a nosologic entity but represents the shared structural manifestation resulting from a variety of biological disturbances. The recurrence risk depends on the underlying disorder but is low in children with isolated macrocerbellum.

**Management:** Treatment depends on the underlying disease. In isolated, idiopathic macrocerbellum, treatment is symptomatic.

### Chiari I Malformation

**Clinical characteristics:** Chiari I malformation (CIM) is defined by ectopia/herniation of at least one cerebellar tonsil 5 mm or more below the foramen magnum, although this can be seen in a substantial number of asymptomatic individuals. Children may present with a variety of symptoms ranging from headache to severe myelopathy and brainstem dysfunction. Headache affects approximately 80% of patients and is usually occipital in location and induced or exacerbated by Valsalva maneuvers. Other common symptoms include neck pain, weakness, numbness, and loss of temperature sensation. Ocular (e.g., downbeat nystagmus) and otological signs and symptoms are reported in approximately 70% of patients. Lower cranial nerve dysfunction (e.g., dysphagia and stridor) is typical in children younger than 3 years of age. Progressive scoliosis associated with syringohydromyelia is relatively common.

**Differential diagnosis and evaluation:** CIM is diagnosed by measuring the position of the cerebellar tonsils relative to the line from the basion to the opisthion on midsagittal images. Tonsillar herniation has been shown to be larger than 5 mm in more than 90% of symptomatic children (Fig. 27-4). Tonsillar compression, increased movement of the brainstem and tonsils due to abnormal CSF pulsation, effaced cerebrospinal fluid (CSF) spaces, and decreased flow at the foramen magnum may help identify symptomatic patients. Syringohydromyelia occurs in 30% to 70% of patients and should be assessed by spine MRI. CIM is also seen in a subset of patients

with rhombencephalosynapsis, requiring specific evaluation of imaging for this malformation.

**Pathophysiology:** Pediatric CIM is due to a mismatch between the size of the cerebellum and posterior fossa, that may result from abnormal skull base (e.g. short clivus) or premature closure of cranial sutures such as in Crouzon syndrome.

**Management:** Surgical decompression is the only effective therapeutic approach for CIM and is usually offered if syringohydromyelia, severe characteristic headache, or bulbar symptoms are present. Hydrocephalus should be resolved before decompression is considered. Minimal tonsillar herniation, lack of objective neurologic findings, and mild headache support a conservative approach.

## Rhombencephalosynapsis

Rhombencephalosynapsis (RES) is defined by continuity of the cerebellar hemispheres across the midline with partial or complete absence of the cerebellar vermis (Fig. 27-5).

**Clinical characteristics:** Patients with RES most often present with ventriculomegaly, hydrocephalus, motor delays, and/or ataxia during childhood. Side-to-side or figure-of-eight headshaking, typical facial features (flat midface, prominent forehead, hypertelorism, low set, posteriorly rotated ears), congenital scalp alopecia, towering skull shape, trigeminal anesthesia, and short stature can be clues to the diagnosis. RES can be also associated with features of VACTERL association (vertebral anomalies, anal atresia, cardiac malformations, tracheoesophageal fistula, renal anomalies, and limb defects) or an unusual form of posterior holoprosencephaly. The triad of RES, trigeminal anesthesia, and congenital scalp alopecia, often with abnormal towering head shape, has been named Gómez-López-Hernández syndrome.

**Differential diagnosis and evaluation:** When not immediately recognized, RES should be suspected in patients with ventriculomegaly and a small cerebellum, aqueductal stenosis, or CIM.

**Pathophysiology:** RES is sporadic, and no genetic causes have been identified; therefore, the recurrence risk is considered to be very low. Disruption of dorsal-ventral patterning is a proposed mechanism underlying RES; however, no animal model has been identified, limiting the understanding of underlying mechanisms.

**Management:** Once diagnosed, patients should be evaluated for the features described above, particularly hydrocephalus and trigeminal anesthesia, which can result in blindness from corneal scarring. Evaluation for cardiac and renal abnormalities is also indicated. ADHD symptoms and behavioral issues can be challenging and may respond atypically to medications.

## DISORDERS AFFECTING CEREBELLUM AND BRAINSTEM

### Pontocerebellar Hypoplasias

The term pontocerebellar hypoplasia (PCH) can be used descriptively for reduced volume of both cerebellum and pons; however, PCH has also been used as a diagnostic category, encompassing numbered subtypes with clinical and genetic overlap (Fig. 27-6 and Table 27-1).

**Clinical characteristics:** Patients with PCH can present prenatally with polyhydramnios, microcephaly, ventriculomegaly, or posterior fossa fluid collection, or in the newborn period with abnormal tone, poor feeding, respiratory difficulties, or seizures. Many patients have severe neurodevelopmental disability, with a few notable exceptions. Congenital or postnatal microcephaly is common. Anterior horn cell

**Figure 27-6. Pontocerebellar hypoplasias.** **A**, Midsagittal T1-weighted image of a 6-year-old girl with headache shows normal morphology of the brainstem and cerebellum. **B**, Midsagittal T1-weighted image of a 1-year-old child with postnatal progressive microcephaly, dyskinetic movement disorders, and mutations in *TSEN54* reveals hypoplasia of the pons and cerebellar vermis, as well as a thin corpus callosum and cortical atrophy. **C**, Midsagittal T2-weighted image of a 2.5-year-old girl with developmental delay, seizures, and *CASK* mutation reveals hypoplasia of the pons and cerebellar vermis. **D**, Midsagittal T1-weighted image of an infant with hypotonia and severe developmental delay due to *RELN* mutations reveals hypoplasia of the pons and cerebellar vermis, unfoliated vermis, thickened and simplified gyral pattern in the frontal and parietal lobes, and more normal gyral pattern of the occipital lobe. **E**, Midsagittal T1-weighted image of a 3-year-old boy born at 25 weeks of gestation reveals a small posterior fossa, small cerebellar vermis, small pons, and thin corpus callosum. **F**, Midsagittal T2-weighted image of a 9-month-old girl with congenital disorder of glycosylation type 1a, developmental delay, microcephaly, strabismus, nystagmus, increased liver enzymes, and *PMM2* mutations reveals cerebellar atrophy that is more prominent in the anterior part of the vermis. **G**, Midsagittal T2-weighted image of a 5-month-old child with muscle-eye-brain disease and *POMGnT1* mutations, who presented with developmental delay, seizures, and proximal weakness. Cerebellar hypoplasia, flattening of ventral pons, dysmorphic tectum and midbrain, abnormally concave dorsal brainstem, enlarged fourth ventricle, and supratentorial ventriculomegaly are apparent. **H**, Midsagittal T1-weighted image of a 3-year-old girl with pontine tegmental cap dysplasia, sensorineural hearing loss, and global developmental delay, reveals a flat ventral pons, a cap protruding from the dorsal pons into the fourth ventricle, and mild vermis hypoplasia. (**A** and **B**, With permission from Lee, R.W., et al. *A diagnostic approach for cerebral palsy in the genomic era. Am J Med Genet C Semin Med Genet* 2014;166(2):211–26.)

involvement with weakness and areflexia favors *EXOSC3* and *VRK164* mutations. Increased CSF lactate suggests *RARS2* mutations, whereas sensorineural hearing loss in girls suggests X-linked *CASK* mutations.

**Differential diagnosis and evaluation:** PCHs are difficult to distinguish by neuroimaging features alone, and mutations in the same gene have been reported in different numbered PCH types; therefore, we favor referring to the PCHs by the associated gene rather than by number. A relatively preserved vermis compared with hemispheres (“dragonfly pattern” on coronal view) is typically associated with mutations in *TSEN54*. Simplified cortical gyral pattern and vermis without folia are characteristic features of *RELN*- and *VLDLR*-related PCHs.

PCH may be also seen in patients with tubulinopathies,  $\alpha$ -dystroglycanopathies, congenital disorders of glycosylation type 1, and pontine tegmental cap dysplasia, as well as with severe prematurity.

**Pathophysiology:** Multiple mechanisms lead to the appearance of PCH on imaging. The *TSEN* and *RARS2* genes are involved in tRNA production, and the rapidly developing hindbrain may be particularly sensitive to the resulting impaired protein synthesis. *CASK*, *RELN*, and *VLDLR* (a coreceptor for the *RELN* pathway) may function with *TBR1* to regulate cerebellar neuronal migration and lamination.

**Management:** Patients with PCH are particularly prone to feeding problems, seizures, and tone abnormalities. As yet, PCH-specific treatments have not been developed.

## Congenital Muscular Dystrophies Due to Defective $\alpha$ -Dystroglycan Glycosylation

The “ $\alpha$ -dystroglycanopathies” are a group of congenital muscular dystrophies.

**Clinical characteristics:** The phenotype is characterized by muscle (weakness, hypotonia, and increased CK), brain (intellectual disability, seizures, and tetraspasticity), and eye (microphthalmia, chorioretinal coloboma, cataract, glaucoma, or high myopia) involvement. Based on the severity of the findings, overlapping phenotypes have been described including Fukuyama disease, muscle-eye-brain disease, and Walker-Warburg syndrome.

**Differential diagnosis and evaluation:** Neuroimaging findings may include PCH, cerebellar dysplasia with cysts, dysplastic tectum, pontomesencephalic kinking, ventriculomegaly, white matter signal changes, and cobblestone cortex. The diagnosis can be confirmed by muscle biopsy and genetic testing.

**Pathophysiology:** Mutations in 15 genes responsible for the O- and rarely N-glycosylation of  $\alpha$ -dystroglycan, an extracellular protein required for basement membrane integrity without which neurons overmigrate, have been associated with  $\alpha$ -dystroglycanopathies.

**Management:** Treatment is symptomatic.

## Tubulinopathies

Tubulinopathies are a recently reported group of brain malformations caused by mutations in tubulin genes (Bahi-Buisson et al., 2014).

**Clinical characteristics:** The clinical phenotype is wide and includes variable intellectual disability, spastic cerebral palsy, postnatal microcephaly, and early onset of therapy resistant seizures. Dysmorphic features are rare, and other organs are not affected.

**Differential diagnosis and evaluation:** Neuroimaging findings include malformations of cortical development (lissencephaly and polymicrogyria), dysmorphic basal ganglia with abnormal anterior limb of the internal capsule, ventriculomegaly, agenesis/dysgenesis of the corpus callosum and anterior

commissure, PCH, and dysplasia of the cerebellum, tectum, and brainstem.

**Pathophysiology:** Tubulinopathies are caused by mutations in neuron-expressed tubulin genes (*TUBA1A*, *TUBA8*, *TUBB2B*, *TUBB3*, and *TUBB5*). The majority of mutations are *de novo*, but germline mosaicism and autosomal recessive inheritance have been observed.

**Management:** Treatment is symptomatic.

## Pontine Tegmental Cap Dysplasia

**Clinical characteristics:** Pontine tegmental cap dysplasia (PTCD, OMIM 614688) is sporadic and characterized by bilateral sensorineural deafness, trigeminal anesthesia, facial paralysis, and difficulty swallowing. Ataxia, nystagmus, developmental delay, and intellectual disability are ubiquitous. Trigeminal anesthesia can result in corneal scarring with severe visual impairment. Vertebral segmentation anomalies, rib malformations, congenital heart defects, and cyclic vomiting have been reported.

**Differential diagnosis and evaluation:** Diagnosis is based on a flattened ventral pons, abnormal transverse white matter (“cap”) on the pontine tegmentum, very thin middle cerebellar peduncles (MCP), and absent inferior cerebellar peduncles. Hypoplastic or absent facial and cochlear nerves and duplicated internal auditory canals may be present.

**Pathophysiology:** The (presumed genetic) cause of PTCD is unknown, and the lack of familial recurrence supports *de novo* dominant or complex causes. The absent transverse pontine fibers and SCP decussation, ectopic transverse fibers on the dorsal pons, and ectopic prepontine arcuate fibers are highly suggestive of an underlying axon guidance defect.

**Management:** Treatment is symptomatic. Based on limited experience, the prognosis for cochlear implantation is poor. Keratoplasty may be considered for corneal opacities, but due to the lack of sensation, corneal transplantation should be approached with caution.

## Cerebellar Agenesis

Cerebellar agenesis implies near complete absence of cerebellar structures; pontine hypoplasia is consistently present. The diagnosis is made by neuroimaging showing only a tiny remnant of cerebellar tissue that likely corresponds to the MCPs, anterior vermian lobules, or flocculi. Cerebellar agenesis may be due to a primary malformation (mostly *PTF1A* mutation) or a disruption. Symptoms include ataxia, dysarthria, hypotonia, and variable cognitive impairment. A small subset of patients with myelomeningocele has cerebellar agenesis thought to be due to vascular insufficiency associated with Chiari II malformation.

## DISORDERS PRIMARILY AFFECTING BRAINSTEM Horizontal Gaze Palsy and Progressive Scoliosis

**Clinical characteristics:** Horizontal gaze palsy and progressive scoliosis (HGPPS, OMIM 607313) is an autosomal recessive disorder characterized by congenital absence of horizontal eye movements, preservation of vertical gaze, and progressive scoliosis.

**Differential diagnosis and evaluation:** The diagnosis is based on characteristic neuroimaging findings including a “butterfly”-shaped medulla and a dorsal midline pontine cleft. DTI typically shows absence decussation of the corticospinal tracts, pontine sensory tracts, and SCP.

**Pathophysiology:** HGPPS is caused by mutations in *ROBO3*, which encodes a receptor required for axonal guidance.

*Management:* Scoliosis progresses when children begin to walk and almost all patients require early surgical correction.

## Brainstem Disconnection

Brainstem disconnection (BD) is defined by nearly complete absence of a brainstem segment with intact rostral and caudal portions connected only by a thin cord of tissue.

*Clinical characteristics:* All children are symptomatic at birth, with absent or weak suck and swallowing, central respiratory insufficiency, increased or decreased muscle tone, and reduced visual fixation. Seizures and unstable body temperature may also occur. The majority of children die before 2 months of age and do not achieve any developmental milestones. Extracerebral involvement (congenital cardiac abnormalities, hydronephrosis, and vertebral body anomalies) may occur.

*Differential diagnosis and evaluation:* The diagnosis is based on the characteristic neuroimaging findings, and the basilar artery is absent in most patients. Supratentorial abnormalities are unusual.

*Pathophysiology:* The pathogenesis is unknown. Both malformative and disruptive pathomechanisms have been proposed.

*Management:* Parents should be counseled about the grave prognosis in clear lay terms and given a range of treatment options including comfort care. Invasive treatments should be carefully considered and offered with caution because they will not improve brain function and may not improve quality of life.

## Other Disorders with Predominantly Brainstem Involvement

Athabaskan brainstem dysgenesis syndrome (ABDS, OMIM 601536) and Bosley-Salih-Alorainy syndrome (BSAS, OMIM 601536) are brainstem patterning disorders with normal brain MRI caused by loss of *HOXA1* function. In mouse models, *HOXA1* is needed for correct specification of hindbrain rhombomeres 4 and 5, as well as inner ear and heart development. ABDS and BSAS share the same phenotype including cranial nerve palsies, sensorineural hearing loss, abnormal intracranial blood vessels, and cardiac outflow tract defects.

*CHN1*-related Duane retraction syndrome (OMIM 604356), *SALL4*-related Duane radial ray syndrome (OMIM 607323), and congenital fibrosis of the extraocular muscles types 1 to 3 (OMIM 135700, 602078, 600638, 609384) caused by mutations in *KIF21A*, *PHOX2A*, *TUBB3*, and *TUBB2B* are other cranial dysinnervation disorders characterized by abnormal eye movements.

Moebius syndrome (OMIM 157900) is mostly sporadic and defined by the combination of congenital nonprogressive abducens and facial nerve palsies. It is a heterogeneous disorder presumably caused by malformative and disruptive etiologies and has been associated with prenatal exposure to misoprostol.

## INTRODUCTION

Disorders of abnormal brain size—microcephaly (too small) and macrocephaly (too large)—are very common or relatively common disorders. Microcephaly and macrocephaly are traditionally defined as head circumference—or more formally “occipitofrontal circumference” (OFC)—two or more standard deviations (SD) lower than or higher than the mean for age and gender, respectively. However, this criterion includes many developmentally normal individuals and a host of underlying causes. Researchers studying both usually define severe microcephaly or macrocephaly as OFC 3 SD or 4 SD (or more) lower than or higher than the mean, respectively. In this chapter, microcephaly, and megalencephaly will be discussed separately.

## MICROCEPHALY

Microcephaly (MIC) refers to a cranium significantly smaller than the standard for the individual’s age and sex. It is considered a neurologic sign rather than a disorder per se, as it may result from many different causes that affect several stages of brain development, and occurs in isolation as well as in association with other features in numerous genetic syndromes (Ashwal et al., 2009). Approximately 1% of referrals to child neurologists are specifically for evaluation of microcephaly, and approximately 15% of children referred to child neurologists for evaluation of developmental disabilities have MIC.

Historically, a confusing plethora of terms have been used to describe and classify various types of microcephaly. When severe congenital microcephaly is seen without other major brain or somatic malformations, the term *primary microcephaly* has been used in the literature. However, primary microcephaly is not a distinct etiologic category in and of itself, but rather a term that describes an increasingly broad group of disorders, many with etiologies not yet well understood. The most clinically useful classification of microcephaly from the clinical and molecular diagnostic perspectives is by age of onset into *congenital* and *postnatal onset* microcephaly. Table 28-1 summarizes the common disorders associated with these two groups of microcephaly.

Advances in neuroimaging and molecular genetic technologies, particularly the increasing use of next generation sequencing (NGS), have resulted in dramatically better understanding of the types and causes of microcephaly, suggesting that a reappraisal of schemes for classification and diagnostic testing is warranted. NGS methods in particular, including whole exome sequencing, have uncovered a large number of novel genes associated with microcephaly (Alcantara and O’Driscoll, 2014).

## Pathology

Microcephaly broadly results from decreased neuronal proliferation or increased programmed cell death (apoptosis). However, the pathologic changes described in various types of

microcephaly are diverse, which is not surprising given the genetic heterogeneity of microcephaly and large number of associated conditions. This section is confined to the description to severe congenital microcephaly. The macroscopic changes described in most pathologic reports include a very small cerebral volume, normal or minimally altered pattern of convolutions, and normal size of the third and lateral ventricles. However, our brain imaging experience shows that this is not consistently true as in many forms the frontal lobes are disproportionately small, and the number and complexity of the gyral pattern and the depth of sulci are generally reduced. The microscopic changes, especially involving the cerebral cortex, are also heterogeneous.

In one group, the cortex has normal thickness and lamination, but the number of neurons is dramatically reduced. In several other types of microcephaly, the cortex appears abnormally thin, presumably resulting from premature exhaustion of the germinal zone (Barkovich et al., 1992). In the latter, abnormalities of cellular architecture predominate in the first two layers of the cortex, referred to as “type I familial microcephaly.” Layer 2 is almost devoid of granule neurons and may be fragmented into small nests (sometimes called “glomeruli”) or small columns that protrude into the molecular layer. In a few individuals, the vertical bands of neurons arising in layer 2 cross the molecular layer to protrude into the meninges. Neurons may be seen in the molecular layer, either as scattered large pyramidal or stellate neurons, or as persistence of a fetal monolayer of granule neurons found just beneath the pia. The lower cortical layers are less affected but have abnormal distribution of cells in some areas. In some brains, persistence of fetal wavy or “combed” monolayer bands in the middle of the cortex has been seen. In these types of microcephaly, the cerebellum is typically small but proportionate to the reduced size of the cerebrum or relatively larger.

Severe congenital microcephaly has been observed with several other types of brain malformations including holoprosencephaly, disproportionate brainstem and cerebellar hypoplasia, abnormalities of neuronal migration including true lissencephaly, periventricular nodular heterotopia, and polymicrogyria (Table 28-2). Agenesis of the corpus callosum is commonly seen in different types of microcephaly. We therefore suspect that it is a nonspecific feature of decreased brain growth in most individuals, as the growing cerebral hemispheres must be apposed closely enough for the precallosal sling to cross the gap, which requires growth. We have therefore not included microcephaly and agenesis of the corpus callosum as a category in its own right, although this may need to be added in the future as our delineation and classification of microcephaly syndromes evolve.

## Neuroimaging

In most patients with isolated congenital microcephaly, brain magnetic resonance imaging (MRI) reveals characteristic abnormalities that are collectively designated “microcephaly with simplified gyral pattern” (Basel-Vanagaite and Dobyns,

2010). This pattern consists of a reduced number of gyri separated by abnormally shallow sulci. Commonly associated abnormalities include foreshortened frontal lobes, mildly enlarged lateral ventricles, and a thin corpus callosum or even partial agenesis of the corpus callosum in some individuals. Although interpretation of brain imaging studies in microcephaly would seem straightforward, this has proved challenging in clinical practice, primarily for severe congenital microcephaly, due to a number of factors. First, brain MRI scans of children with microcephaly are often interpreted as normal other than for the small size. However, close inspection of MRI scans will invariably show some of the features noted previously. Although these changes can be subtle, they are not normal and can be of diagnostic importance. Further, brain imaging in individuals with more severe forms of microcephaly may show fewer convolutions, some broader than 2 cm, leading to the misinterpretation of “pachygyria.” But imaging in the large majority of these patients shows a normal or thin cortex, whereas true lissencephaly (agyria and pachygyria) is always associated with an abnormally thick cortex. In these situations, misdiagnoses may result as clinicians often respond to such reports by ordering tests for lissencephaly disorders (such as LIS1 gene analysis, for example), which are almost always negative. There are few disorders that are associated with true microlissencephaly, including the tubulinopathies (such as the TUBA1A-related disorders, for example) and NDE1-related microcephaly.

Whereas most of the genes associated with severe congenital microcephaly are associated with nonspecific brain imaging patterns that can be collectively grouped under the category of microcephaly with simplified gyral pattern, there are numerous microcephaly syndromes associated with recognizable patterns of abnormalities. These additional abnormalities can be broadly divided into the following groups: (1) microcephaly with simplified gyri and pontocerebellar hypoplasia; (2) microcephaly with simplified gyri and enlarged extraaxial space; (3) microcephaly with simplified gyri and both pontocerebellar hypoplasia and enlarged extraaxial space; and (4) microcephaly with additional cortical malformations. Table 28-3, lists the most common genetic causes of various forms of microcephaly.

## Clinical Features

The clinical manifestations associated with microcephaly are heterogeneous, partly depending on the underlying cause. Most individuals with severe congenital microcephaly have an obviously small head, often with a low, sloping forehead and a flat occiput. The face and ears are normal but may appear disproportionately large due to small head size. Intellectual disability is moderate in some types but severe to profound in others. In moderately affected patients, hyperactivity may dominate the patient's behavior even though tone is typically normal. In severely affected children, spasticity, and epilepsy predominate. In children with milder forms of syndromic microcephaly, a variety of dysmorphic features may be present and may be helpful in identifying a specific underlying syndrome.

*Cognitive impairment and intellectual disability.* A correlation between microcephaly and intellectual disability (ID) has been recognized since studies in the late 1800s and subsequent research has explored the strength of this correlation in a number of ways, although rarely in a prospective manner among a broad cohort of subjects. The incidence of microcephaly has varied in studies depending on the population studied. Prevalence estimates of microcephaly in institutionalized patients reported a rate of microcephaly from 6.5% to 53%. In contrast, the prevalence of microcephaly

in children seen in neurodevelopmental clinics averaged 24.7% (range 6%-40.4%). Other studies have looked at the incidence and significance of microcephaly in children who were functioning normally or had normal intelligence. One report of 1006 students in mainstream classrooms found that 1.9% had mild (2 to 3 SD lower than the mean) and none had severe microcephaly (greater than 3 SD lower than the mean). The microcephalic subjects had similar mean IQ (99.5) to the normocephalic group (105) but lower mean academic achievement scores (49 versus 70). Another report looking at the records of 1775 normally intelligent patients aged 11 to 21 years followed in adolescent medicine clinics found 11 (0.6%) with severe microcephaly (greater than 3 SD lower than the mean).

Numerous studies underscore the fact that microcephaly is common in developmentally delayed children with the incidence greater in those with more severe ID. Even in low risk populations (e.g., children with normal school placement), 1.9% has microcephaly and in many of these children, subtle cognitive deficits are detected. In addition, there is a 50% increased risk for being developmentally delayed in children with microcephaly compared with children without microcephaly (e.g., 15.3% versus 7%) and a strong correlation between the severity of microcephaly and developmental outcome (i.e., ID occurs in 10.5% of children with mild microcephaly (less than 2 SD) and in 51.2% of children with severe microcephaly (greater than 3 SD lower than the mean). Given these observations, serial developmental screening should be performed in children with microcephaly.

*Epilepsy.* The relation between microcephaly and epilepsy is of great clinical importance: (a) the incidence of epilepsy is much higher in microcephalic children; (b) a greater number of children with epilepsy are likely to be microcephalic; (c) microcephaly is a significant risk factor for medically refractory epilepsy; and (d) the presence of microcephaly (whether congenital or postnatal) may help determine the underlying etiology of a child's epilepsy.

One study involving 66 microcephalic children (greater than 2 SD lower than the mean) found an overall prevalence of epilepsy of 40.9%. It has also been suggested that epilepsy is more common in postnatal onset than in congenital microcephaly. In one study, epilepsy occurred in 50% of children with postnatal compared with only 35.7% with congenital microcephaly. Microcephaly also is a significant risk factor for medically refractory epilepsy.

In one study of 30 children, microcephaly was found in 58% of those with medically refractory epilepsy compared with 2% in whom seizures were well controlled.

Although children with microcephaly are generally at greater risk for epilepsy, many do not have epilepsy. There are, however, certain microcephaly syndromes in which epilepsy is a prominent feature (Table 28-4). Knowledge of these disorders and their genetic basis can help establish a diagnosis and determine prognosis.

Overall, it is important to be aware that epilepsy is more common in children with microcephaly and when it occurs, it is more difficult to treat. Certain microcephaly syndromes are associated with a much higher incidence of epilepsy. Increasingly, genetic etiologies defining the relation between microcephaly and epilepsy are being identified. In addition, there are no systematic studies regarding EEG findings in children with microcephaly who have or do not have epilepsy.

*Ophthalmologic abnormalities.* Limited studies have surveyed the incidence of vision loss or specific ophthalmologic disorders in children with microcephaly. One study found an incidence of 145 cases of congenital eye malformations (microphthalmia, anophthalmia, cataracts, coloboma, etc.) in 212,479 consecutive births. Microcephaly was among the

malformations in 56% of these children. Another study of 360 children with severe microcephaly (greater than 3 SD lower than the mean) found eye abnormalities in 6.4% but in only 0.2% of 3600 age-matched normocephalic controls. Other reported eye abnormalities in microcephalic children include anophthalmia-microphthalmia, blindness or visual loss, cataracts, colobomas, nystagmus, optic atrophy, ptosis, and retinal disorders. Table 28-5 lists some of the more common microcephaly syndromes associated with ophthalmologic involvement.

**Audiological abnormalities.** No studies have surveyed the incidence of hearing loss or audiological disorders in children with microcephaly broadly. One study of 100 children with complex ear anomalies reported that 85 had neurologic involvement and 13 children were microcephalic. Hearing loss is likely the most common audiological disorder associated with microcephaly. Table 28-6 summarizes the most common microcephaly syndromes listed in OMIM in which prominent audiological involvement is reported.

## Etiology

Mild MIC, which we define as OFC 2 to 3 SD lower than the mean, is associated with a variety of maternal and other prenatal disorders, prenatal and postnatal brain injuries, familial forms, chromosomal disorders, and numerous genetic syndromes. Among the chromosomal disorders, the most commonly associated with microcephaly are trisomies (trisomies 13, 18, and 21) and structural rearrangements such as Cri du Chat syndrome (deletion 5p15). For most individuals, this presents as mild congenital microcephaly that is often followed by more severe postnatal microcephaly. An OMIM search for “microcephaly” lists more than 400 syndromic associations, making this a nonspecific search term. Among the rapidly growing list of disorders, some of the best known include Angelman syndrome, MECP2-related disorders, and Cornelia de Lange syndrome. Here we will review only a small selection of the more common causes of microcephaly.

**Extrinsic causes.** Extrinsic (acquired) injuries before birth or early in life can lead to microcephaly. The developing nervous system is highly vulnerable to infections, including cytomegalovirus, toxoplasmosis, rubella, herpes simplex, and group B coxsackievirus. Intrauterine infections of any of these can result in microcephaly (Norman et al., 1995). Most recently, infections of the Zika virus have been reported in association with severe congenital microcephaly in Brazil and other countries in South America.

Maternal metabolic disorders during pregnancy such as diabetes mellitus, uremia, and undiagnosed or inadequately treated phenylketonuria may result in neonatal microcephaly. These complications are now generally seen less frequently due to improved early detection and treatment of these disorders. Malnutrition, hypertension, and placental insufficiency may also result in intrauterine growth retardation and microcephaly.

Maternal alcoholism during pregnancy has also been linked with microcephaly as part of fetal alcohol syndrome (FAS). The clinical features of FAS include growth and mental retardation, midface hypoplasia, short palpebral fissures, epicanthal folds, and behavioral problems. Neuropathologic findings include microcephaly, heterotopia, widespread cortical and white matter dysplasias, and defects of neuronal and glial migration. MIC has also been reported with maternal exposure to cocaine.

**Isolated congenital (previously termed “primary”) microcephaly.** When congenital MIC is the only abnormality on evaluation, the disorder has been designated “primary microcephaly.” As

discussed previously, this designation becomes much more useful when restricted to children with birth OFC lower than 3 SD. Most patients with primary microcephaly also have mild growth deficiency with statures typically 2 to 3 SD lower than the mean, which may be part of the syndrome or due to nutritional factors. The body growth profile is much less striking than head size, the latter of which is typically 4 to 8 SD lower than the mean after early childhood. Most affected individuals fall into one of two somewhat heterogeneous, clinical subgroups (Dobyns, 2002).

The first group is composed of children with extreme microcephaly but only moderate neurologic problems, usually with only moderate ID and no spasticity or epilepsy. Neonatal examinations are usually normal except for microcephaly, but many children initially have poor feeding and weight gain. They may have normal tone or mild distal spasticity but typically do not have moderate or severe spasticity. Seizures are uncommon and are easily controlled, if present. Febrile seizures occur and should be managed as in any other child. Early development is only mildly delayed and many infants progress to walking between 1 and 2 years of age and develop limited language skills. This group is genetically very heterogeneous (Table 28-3).

The second group consists of congenital microcephaly with a severe neurologic phenotype that includes severe spasticity and epilepsy. Neonatal examination demonstrates abnormal neonatal reflexes and generalized spasticity, and these children subsequently develop impaired feeding and recurrent vomiting leading to poor weight gain, profound ID, and severe spastic quadriplegia. Most of these infants have early-onset intractable epilepsy. In addition to a simplified gyral pattern, brain MRI may demonstrate other abnormalities as summarized previously (Fig. 28-1). Children with Amish lethal microcephaly, for example, fall within this group, except that hypotonia predominates rather than spasticity, and seizures are generally not prominent.

The wide clinical spectrum suggests pathogenetically heterogeneous conditions, and several syndromes and genes have been identified (Table 28-3).

**Severe microcephaly with cortical brain malformations.** Severe microcephaly has been reported in association with several other types of brain malformation. Severe microcephaly and true lissencephaly (with an abnormally thick cortex) have been reported with at least three different patterns. The most common of these very rare syndromes is probably the Barth microlissencephaly syndrome, which consists of severe microcephaly, diffuse complete agyria, and severe brainstem and cerebellar hypoplasia. Severe microcephaly with diffuse periventricular nodular heterotopia has been described and clearly differs from other forms of heterotopia. Other subsets of patients with severe microcephaly also have diffuse polymicrogyria.

With the advent of next generation sequencing, a rapidly growing number of syndromes with microcephaly and additional, often severe, brain malformations, are now known such as the tubulin-related disorders and microcephaly with cortical malformations due to mutations of RTTN, WDR62, KATNB1, to name a few.

**Severe microcephaly with proportionate growth deficiency.** Several syndromes with severe intrauterine and postnatal growth deficiency and proportionate microcephaly have been described, although the head size does not keep up with slow body growth, leading to disproportionate microcephaly in childhood and later on in most affected children. The best known of these disorders are Seckel syndrome, Majewski syndrome, microcephalic osteodysplastic primordial dwarfism type 1 (MOPD1), also known as Taybi-Linder syndrome, and microcephalic osteodysplastic primordial dwarfism type

**Figure 28-1.** Representative magnetic resonance imaging from each microcephaly subgroup. **A–D** Microcephaly with simplified gyral pattern only. **E–F** Microcephaly with simplified gyri and pontocerebellar hypoplasia. **G–H** Microcephaly with simplified gyri and enlarged extraaxial space and proportionate cerebellum. **I–L** Microcephaly with simplified gyri, enlarged extraaxial space, and marked pontocerebellar hypoplasia. **K–L** Normal brain magnetic resonance images for comparison purposes. Asterisks indicate enlarged extraaxial space. (Adapted from: Basel-Vanagaite, L., Dobyns, W.B., 2010. Clinical and brain imaging heterogeneity of severe microcephaly. *Pediatr Neurol* 43, 7–16.)

2 (MOPD2). Several other syndromes with severe growth deficiency and microcephaly have been described in a few patients. In some children, the skeletal changes may be absent or less prominent than in Seckel syndrome or the MOPD syndromes.

Seckel syndrome consists of severe intrauterine and postnatal growth deficiency and abnormal facial features, including large eyes, beaklike protrusion of the nose, narrow face, and receding lower jaw. All affected individuals have severe ID, although severity varies considerably. Abnormalities of the brain seen on postmortem examination or brain imaging demonstrate pure microcephaly with deficient production of neurons and other cell types in some patients, whereas other patients have severe brain malformations including lissencephaly. Some patients have various hematological abnormalities such as pancytopenia or acute myeloid leukemia.

MOPD1, or Taybi-Linder syndrome, consists of similar severe intrauterine and postnatal growth deficiency, combined

with abnormal body proportions and short limbs. Typical skeletal changes consist of low and broad pelvis with poor formation of the acetabulum, short and bowed humerus and femur, dislocated hips and elbows, retarded epiphyseal maturation, cleft vertebral arches, platyspondyly, horizontal acetabular roofs, and short long bones with enlarged metaphyses. Patients with MOPD1 may also have skin abnormalities, including hyperkeratosis and sparsity of hair and eyebrows. Brain malformations are common and include lissencephaly, heterotopia, callosal agenesis, and cerebellar vermis hypoplasia.

MOPD2 consists of similar severe intrauterine and postnatal growth deficiency, proportionate microcephaly at birth that progresses to disproportionate microcephaly, shortening of the middle and distal segments of the limbs, progressive bony dysplasia, abnormal facial appearance—including prominent nose and malformed ears—and a high-pitched voice. Patients may have dilated arteries in the brain that resemble aneurysms or moyamoya disease.

*Microlissencephaly (MLIS) MOPD1-type.* MLIS occurs in some patients with microcephalic osteodysplastic primordial dwarfism type 1 (MOPD1), a syndrome that is difficult to distinguish from severe forms of Seckel syndrome. The phenotype consists of severe prenatal growth deficiency, microcephaly, sparse hair, dry scaling skin, skeletal anomalies such as platyspondyly, slender ribs, short and bowed proximal humeri and femurs, small iliac wings, dysplastic acetabulum and small hands and feet, and profound ID. A few have aplastic anemia, another overlap with Seckel syndrome. The neuropathology consists of a variant form of LIS-3L with frontal predominance.

## Genetics

Microcephaly is genetically very heterogeneous, and the rate of identification of novel microcephaly genes has increased dramatically with the advent of clinical next generation sequencing (NGS). The majority of microcephaly genes are key regulators of critical cellular processes, including mitotic spindle assembly and structure, centrosome formation and function, cilia function, and DNA repair and damage response (DDR) pathways. The most common genes are listed in Table 28-3.

## Antenatal Diagnosis

Microcephaly can often be diagnosed by second trimester fetal ultrasonography. This is likely due to variable onset of deceleration of head growth. When this occurs early, as it often does in severe microcephaly, ultrasound examination should be able to detect the abnormality but not when it begins in the late second or third trimester. The diagnosis of more complex microcephaly syndromes associated with malformations of cortical development is difficult prenatally, as the resolution of fetal MRI scans is often inadequate to fully delineate the nature and extent of cerebral malformations.

## Genetic Counseling

Most forms of severe congenital microcephaly (with or without intrauterine growth retardation [IUGR]) are genetic, and the majority of these disorders are inherited in an autosomal recessive manner, with a 25% recurrence risk. Disorders associated with postnatal microcephaly are much more genetically heterogeneous, with some inherited in de novo/autosomal dominant (familial or sporadic), autosomal recessive, and X-linked inheritance (Table 28-3).

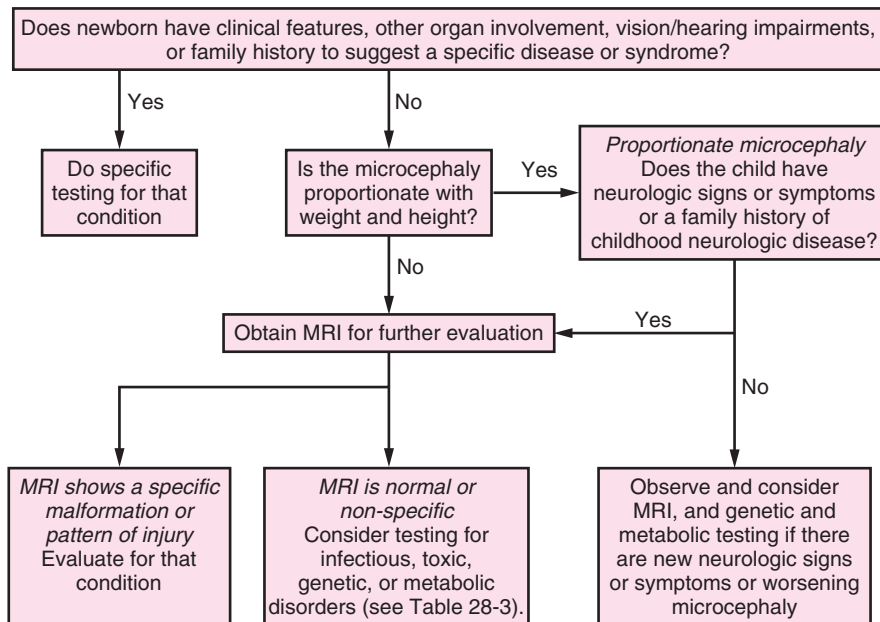

## Summary

With potentially hundreds of causes of microcephaly, including prenatal and postnatal onset disorders, as well as genetic and acquired etiologies, diagnostic evaluations of affected children are often complex. Investigations of patients with microcephaly include evaluation for prenatal exposure to teratogens, especially alcohol, drugs, and isotretinoin (a vitamin A analog), assessment of the family history, birth history, and associated malformations. Laboratory studies should include: titers for toxoplasmosis, syphilis, rubella virus, cytomegalovirus, and herpes simplex virus; neuroimaging; evaluation for maternal and childhood metabolic disorders; and genetic testing, including chromosome analysis and testing for small deletions or duplications, followed by single gene disorders. Algorithms for the evaluation of the infant and child with congenital (Fig. 28-2) and postnatal (Fig. 28-3) microcephaly are available to serve as a generalized approach to the diagnostic evaluation.

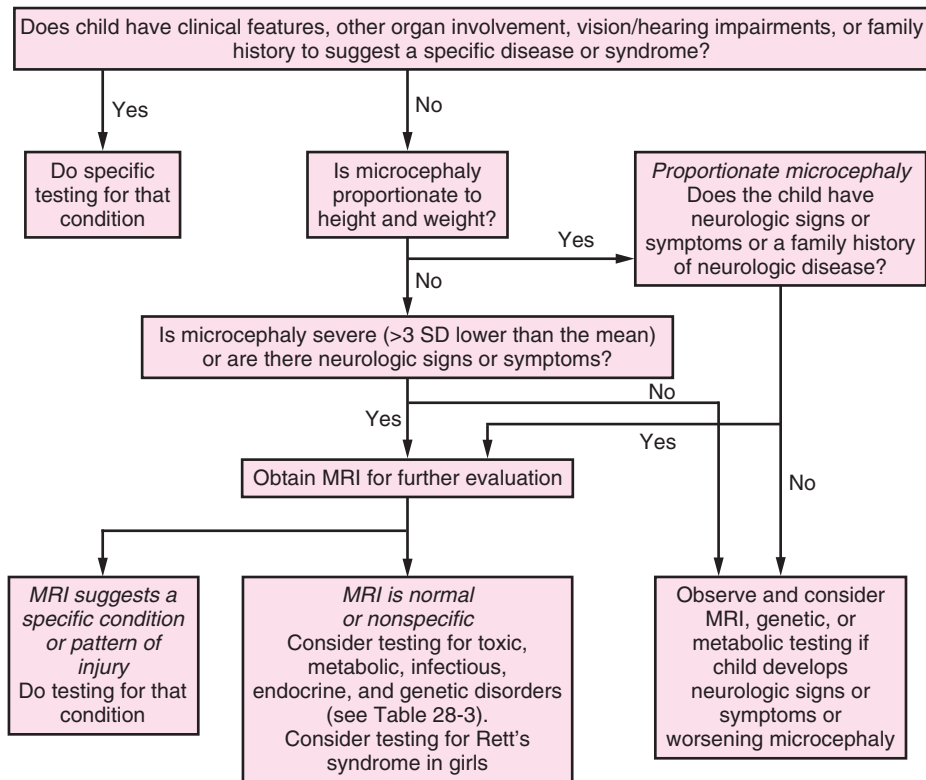

## MEGALENCEPHALY (AND MACROCEPHALY)

### Definition and Classification

*Macrocephaly* is defined as an occipitofrontal circumference (OFC) 2 SD or more higher than the mean for age, gender, and ethnicity measured over the greatest frontal circumference.

**Figure 28-2.** Algorithm for the diagnostic evaluation of the infant or child with congenital microcephaly. (Adapted from: Ashwal, S., Michelson, D., Plawner, L., Dobyns, W.B., 2009. Practice parameter: evaluation of the child with microcephaly (an evidence-based review): report of the Quality Standards Subcommittee of the American Academy of Neurology and the Practice Committee of the Child Neurology Society. *Neurology* 73, 887–897.)

**Figure 28-3.** Algorithm for the diagnostic evaluation of the infant or child with postnatal onset microcephaly. (Adapted from: Ashwal, S., Michelson, D., Plawner, L., Dobyns, W.B., 2009. Practice parameter: evaluation of the child with microcephaly (an evidence-based review): report of the Quality Standards Subcommittee of the American Academy of Neurology and the Practice Committee of the Child Neurology Society. *Neurology* 73, 887–897.)

Macrocephaly is caused by a myriad of conditions, including hydrocephalus, cerebral edema, space-occupying lesions, subdural fluid collection, thickening or enlargement of the skull (or hyperostosis), and a truly enlarged brain or megalencephaly (Box 28-1). The classic definition of *megalencephaly* first proposed by DeMyer in 1986 stands as an oversized and overweight brain (or an increased brain mass) that exceeds the mean by 2 SD or more for age, gender, and ethnicity.

Megalencephaly is associated with diverse syndromes and etiologies. DeMyer first divided it in 1972 into anatomic and metabolic subtypes. *Metabolic megalencephalies* result from cellular edema or abnormal accumulation of metabolic substrates within the neurons and glia secondary to an underlying biochemical defect (most commonly an enzyme deficiency), without an increase in cell number. The most common causes of metabolic megalencephalies are listed in Table 28-7 and include cerebral organic acid disorders such as Canavan disease, glutaric aciduria type I, lysosomal storage disorders, such as generalized gangliosidosis, Tay-Sachs disease, Krabbe disease, some mucopolysaccharidoses, among others. Canavan, Krabbe, Alexander diseases, and megalencephalic leukoencephalopathy with subcortical cysts are leukoencephalopathies—that is, demyelinating disorders whereby the underlying biochemical or genetic defect alters myelin formation and function. The metabolic megalencephalies are not true cortical malformations per se and will therefore not be discussed further in this chapter but are discussed in Chapter 99.

Anatomic megalencephalies, on the other hand, are secondary to an increase in the size or number of cells, or both, and are disorders of neuronal development resulting from

either increased neuronal proliferation or failure of programmed cell death, or apoptosis. These disorders are quite numerous and will be the focus of the remainder of this chapter. Anatomic megalencephaly varies by distribution or degree of involvement from diffuse to focal megalencephaly. This latter group includes classic unilateral megalencephaly or hemimegalencephaly (Table 28-8). The presence of true megalencephaly (versus absolute or relative macrocephaly) is indicated in the table. Focal forms of brain overgrowth, including classic hemimegalencephaly, are characterized by segmental brain overgrowth with unique clinical and neuroimaging characteristics and syndromic associations. The recent molecular discoveries of megalencephaly, hemimegalencephaly, and other segmental forms of cortical dysplasia, including focal cortical dysplasia, highlight that these disorders constitute a continuum or spectrum with shared etiologies, as will be discussed later in this chapter.

## Pathology and Pathogenesis

Numerous animal models of syndromic and nonsyndromic megalencephaly display neuronal and glial hypertrophy, increased neuronal proliferation, and decreased apoptosis. Most of the animal models and studies of human tissues studying megalencephaly have involved important growth signaling pathways, most prominently the phosphatidylinositol-4,5-bisphosphate-3-kinase (PI3K)-protein kinase B (AKT)-mammalian target of rapamycin (mTOR) pathway (PI3K-AKT-MTOR), and Ras/mitogen-activated protein kinase (MAPK) pathways.

Pten (phosphatase and tensin homolog on chromosome ten) mutant mice were found to develop macrocephaly and

behavioral abnormalities reminiscent of human autism spectrum disorders such as reduced social activity, increased anxiety and sporadic seizures. These closely resemble the human phenotype of Pten-related disorders described in this chapter. At the cellular level, *in vivo* effects of loss of Pten include loss of neuronal polarity, neuronal hypertrophy, and, in one study, increased astrocyte proliferation and hypertrophy.

The mammalian target of rapamycin (mTOR) is a serine/threonine kinase that has well-known functions in regulation of cellular proliferation and growth and crucial roles in neuronal development and synaptic plasticity. It also contributes to Pten-mediated growth regulation in the mammalian nervous system. In studies, mTOR inhibition reversed neuronal hypertrophy in Pten-deficient mice and also resulted in amelioration of a subset of Pten-associated abnormal behaviors, thereby substantiating evidence that the mTOR pathway downstream of Pten is critical for its complex phenotype.

Loss of Tsc1 and Tsc2, two downstream negative regulators of the mTOR pathway, has been shown to cause neuronal hypertrophy *in vitro* and *in vivo*, supporting a role of TSC1 and TSC2 in neuronal growth regulation and synaptic function. Interruptions of TSC1 and TSC2 cause tuberous sclerosis complex, known to be associated with megalencephaly, hemimegalencephaly, and focal megalencephaly.

Most recently, studies of other components of the PI3K-AKT-MTOR pathway have been identified in association with megalencephaly, including PIK3CA, PIK3R2, AKT3, and CCND2. CCND2 is one of the D-group of cyclins responsible for regulation the G1-S transition of the cell cycle. *In utero* electroporation of mutant CCND2 in mouse demonstrated increased proliferation of neuroprogenitor cells, as well as decreased cell cycle exit. A mouse model of an Akt3 gain of function mutation has electrographic seizures and showed abnormal hemispheric architecture. Another recent mouse model of a Pik3ca gain of function mutation demonstrates megalencephaly, hydrocephalus, and increased predisposition to epilepsy. In these animal models, treatment with PI3K-AKT-MTOR pathway inhibitors partially rescued several aspects of the phenotypes, including acutely treating epilepsy in the latter model. Further, the Nf1 knockout mouse was found to have increased neuroglial progenitor/stem cells (NSC) proliferation and gliogenesis in the brainstem, also driven by mTOR-mediated activation. All of these studies and many others clearly implicate aberrations of the PI3K-AKT-MTOR signaling pathway as the most critical mediators of brain growth dysregulation.

Other animal models of megalencephaly include mouse mutants with loss-of-function mutations in genes regulating programmed cell death, or apoptosis, such as Caspase-3, Caspase-9, and Apaf-1, which were found to have gross brain malformations and neuronal hyperplasia. These mutations are embryonically lethal when germline. Transgenic mice overexpressing insulin-like growth factor (IGF-1) exhibit brain overgrowth characterized by increased numbers of neurons and oligodendrocytes, as well as excessive myelin formation. IGF-1 stimulates: (1) proliferation of neural progenitors and possibly pluripotent neural stem cells (NSCs); (2) survival of neurons and oligodendrocytes; and (3) differentiation of neurons, including neuritic outgrowth and synaptogenesis, and of oligodendrocytes, including expression of myelin gene proteins and myelination. As a result of these events, brain growth is increased with IGF-1 overexpression and reduced with decreased IGF-1 signaling. Although much less information is available in man, individuals with IGF1 gene deletions or mutations that result in severe deficits in IGF-1 expression are microcephalic and intellectually disabled.

## Etiology

The most common megalencephaly/macrocephaly syndromes are listed in Table 28-8 with a brief overview of their clinical features, MRI findings, and genetic causes. These include classic overgrowth syndromes such as Sotos, Weaver, and Simpson-Golabi-Behmel syndromes, *PTEN*-related disorders, the macrocephaly capillary malformation (MCAP) syndrome, skeletal dysplasias, as well as chromosomal disorders. The majority of these disorders are inherited in a *de novo*/autosomal dominant fashion. Their clinical features and neurodevelopmental outcome are quite variable and dependent on the ensuing neuronal dysfunction caused by the specific underlying disorder. The most notable megalencephaly/macrocephaly disorders are discussed briefly here.

**Overgrowth Syndromes.** Macrocephaly frequently occurs in conjunction with body overgrowth (height and weight more than 2 SD higher than the mean for age) as in Sotos, Weaver, and Simpson-Golabi-Behmel syndromes. Many of these overgrowth disorders are characterized by excessive growth in fetal life and infancy with subsequent decline in growth rate and normalization of growth in adulthood. Partial (or focal) and unilateral overgrowth (or hemihypertrophy) is occasionally seen in other megalencephaly syndromes such as MCAP, *PTEN*-related disorders, among others. Children who are macrocephalic at birth may become normocephalic or relatively microcephalic when older if body overgrowth supersedes brain growth, as typically occurs in Beckwith-Wiedemann syndrome.

Sotos syndrome is an autosomal dominant disorder caused by heterozygous mutations or deletions of *NSD1*. Macrocephaly is usually present at all ages in more than 90% of children and is considered to be a cardinal feature. In some series, macrocephaly was present at birth in 50% of children, with birth OFCs as high as 4 SD higher than the mean and later OFCs ranging between 2 and 7 SD. Most patients have a non-progressive neurologic dysfunction characterized by clumsiness and poor coordination. Delays in expressive language and motor development during infancy are particularly common, and in some instances, may be followed by attainment of normal or near-normal intelligence. Several patients with Sotos and autistic features have been reported. Seizures and tone abnormalities are occasionally present. Brain MRI abnormalities present in patients with Sotos and *NSD1* mutations include enlarged extraaxial fluid and lateral ventricles in 70% and 60% of patients, respectively. It has been suggested that these increased CSF spaces are primarily responsible for macrocephaly in Sotos syndrome rather than true brain overgrowth. Eighty percent to 90% of patients have a demonstrable *NSD1* abnormality. *NSD1* (nuclear receptor-binding SET domain protein-1) is involved in an intricate regulatory network of genes that appear to have a concerted role in various processes including cell growth and tumorigenesis.

Weaver syndrome (WS) is a rare overgrowth disorder characterized by macrocephaly, dysmorphic facial features (especially prominent hypertelorism), metaphyseal flaring of the femurs, camptodactyly, deep-set nails, and hoarse low-pitched cry. Heterozygous mutations of *EZH2* have been identified in WS. *EZH2* catalyzes the methylation of lysine residue 27 of histone 3 (H3K27) as part of the polycomb repressive complex 2 (PCR2), resulting in chromatin compaction and repression of transcription. *EZH2* activity is inhibited by AKT (v-akt murine thymoma viral oncogene homolog 1), a key component of the PI3K-AKT-MTOR pathway, which blocks binding of *EZH2* to histone 3.

Simpson-Golabi-Behmel syndrome (SGBS) is an X-linked disorder characterized by congenital overgrowth, macroglossia, renal and skeletal abnormalities, and an increased risk of

**Figure 28-4. Subtypes of megalencephaly and hemimegalencephaly.** Right parasagittal (left column except midsagittal in **D**), left parasagittal (middle column), and axial (right column) magnetic resonance images from four patients with megalencephaly (MEG) or hemimegalencephaly (HMEG) variants. **A** The top row images depict symmetric MEG and perisylvian polymicrogyria with normal white matter. The patient was a female with the originally described “megalencephaly polymicrogyria-polydactyly hydrocephalus” (MPPH) syndrome (Mirzaa et al., 2004). The symmetry and normal white matter distinguish this malformation from HMEG. **B** The second row images show partial HMEG, with enlargement of the posterior frontal, temporal, and parietal lobes on the right. The abnormal white matter typical of HMEG is seen circling the back of the right lateral ventricle. **C** The third row images demonstrate severe HMEG involving the entire right hemisphere, but sparing the left. The central and deep white matter has diffusely bright signal, sparing only the superficial U fibers. **D** The bottom row images show a very rare malformation consisting of bilateral HMEG that is more severe on the left side. (Courtesy of Dr. Ghayda Mirzaa, William B. Dobyns, Center for Integrative Brain Research, Seattle Children’s Research Institute, Seattle, WA.)

embryonal tumors. Macrocephaly is often congenital. Patients may have hypotonia and mild developmental delay, although most have normal intelligence. Most cases of SGBS are due to mutations or deletions of the glypican-3 (GPC3) gene at Xq26, a member of a multigene family encoding at least six distinct glycosylphosphatidylinositol-linked cell surface heparan sulfate proteoglycans (HSPGs) that act as coreceptors for multiple families of growth factors that have been shown to regulate cell proliferation, differentiation, and patterning, including that of the brain. In support of the glypicans' role in development, mice with null mutations in glypican-1 (Gpc1) have a severely reduced brain size and an abnormally small-sized cerebellum. Therefore Gpc1 may have a role in early neurogenesis, possibly through regulation of fibroblast growth factor (FGF) signaling.

*The megalencephaly capillary malformation syndrome (MCAP).* MCAP is a distinct syndrome characterized by megalencephaly, vascular malformations (most often cutis marmorata), hemihypertrophy, digit anomalies, and skin and connective tissue laxity. Its neuroimaging findings have been thoroughly reviewed in the literature and include cortical malformations (polymicrogyria), ventriculomegaly leading to hydrocephalus, and cerebellar tonsillar ectopia. Vascular anomalies are characteristic features, and most commonly consist of cutis marmorata, the cutaneous marbled appearance frequently seen in Caucasian newborns that tends to fade with time but often persists. Other vascular anomalies include a midline nevus flammeus, vascular rings, and telangiectasias. Digital anomalies include the common 2 to 3 toe syndactyly (greater than 25% syndactyly), 2 to 3 to 4 finger syndactyly, and postaxial polydactyly. MCAP is predominantly caused by mosaic (or postzygotic) mutations of the catalytic subunit of the PI3K enzymatic complex, PIK3CA. Mosaic mutations of the same gene are now known to be associated with segmental cortical malformations, including focal cortical dysplasia and hemimegalencephaly, as well as a spectrum of somatic overgrowth disorders, including CLOVES syndrome, isolated macrodactyly, and isolated lymphatic malformations.

*The megalencephaly perisylvian polymicrogyria-postaxial polydactyly hydrocephalus syndrome (MPPH).* MPPH is a megalencephaly disorder that resembles MCAP. Megalencephaly is most often congenital, with OFCs ranging from 2 to 4 SD higher than the mean at birth, reaching up to 8 SD later in life. Variable degrees of ID, hypotonia, and seizures occur. MRI abnormalities common to both MCAP and MPPH include diffuse megalencephaly that is symmetric or mildly asymmetric, a high rate of hydrocephalus that is often shunted, or ventriculomegaly, progressive posterior fossa crowding with cerebellar tonsillar herniation that may require decompression, polymicrogyria that is by far bilateral perisylvian in distribution, and white matter abnormalities (Fig. 28-4A). A distinct subset of patients has a very thick (or mega-) corpus callosum. All reported cases to date appear sporadic. MPPH is caused by mutations in three core components of the PI3K-AKT-MTOR pathway including PIK3R2, AKT3, and CCND2.

*PTEN-related disorders.* PTEN is a tumor suppressor gene, somatic mutations of which have been reported to varying degrees in multiple sporadic malignancies (such as glioblastoma multiforme). De novo or inherited constitutional mutations of PTEN have been found in a set of disorders of macrocephaly and hamartomatous overgrowth, namely Cowden (CS) and Bannayan-Riley-Ruvalcaba (BRRS). Cowden and Bannayan-Riley-Ruvalcaba syndromes have a high degree of clinical overlap and are believed to constitute a single clinical spectrum called the PTEN-hamartoma tumor syndrome (PHTS). Macrocephaly is a prominent and progressive feature with OFCs typically 4.5 SD or more higher than the mean and reaching up to 8 SD. Hypotonia and delayed gross motor

skills are common findings. Sixty percent of patients have a mild proximal myopathy, and 25% have seizures. Additional features include hamartomas, lipomas, intestinal polyps, and various types of cutaneous vascular malformations. PTEN mutation carriers are at an increased risk of various tumors (most notably of the breast, thyroid, and endometrium). PTEN mediates cell cycle arrest and/or apoptosis by negatively regulating the phosphoinositide-3-kinase-Akt serine/threonine protein kinase (PI3K/Akt) pathway. Accumulating evidence suggests that PTEN also regulates cell survival pathways such as the MAPK pathway. PTEN mutations have recently been identified in patients with isolated macrocephaly and autism spectrum disorders (ASD) and/or ID, with an overall estimated PTEN mutation frequency in macrocephaly autism of 20%.

*RASopathies.* The Ras/mitogen-activated protein kinase (MAPK) pathway is essential in the regulation of the cell cycle, cell differentiation, growth, and cell senescence, each of which are critical to normal development. The "RASopathies" are a class of developmental disorders caused by germline mutations in genes that encode protein components of the Ras/MAPK pathway, which result in dysregulation of the pathway and profound deleterious effects on development. These disorders include neurofibromatosis type 1 (NF1), Costello syndrome (HRAS), cardio-facio-cutaneous (CFC) syndrome (KRAS, BRAF, and MEK1), Noonan syndrome (PTPN11, KRAS, SOS1, RAF1, NRAS, BRAF, SHOC2), and others. Costello syndrome is a unique combination of failure to thrive, cardiac abnormalities, and a predisposition to papillomata and malignant tumors. In a systematic review of 28 patients, absolute or relative macrocephaly was found in 100% of patients and, more specifically, an evolving megalencephaly and cerebellar enlargement, overlapping with MCAP syndrome. Neurologic abnormalities include developmental delay/ID, nystagmus and hypotonia.

Neurofibromatosis type 1 (NF1) shares features of other overgrowth syndromes such as the presence of macrocephaly, various types of tumors, and, occasionally, hemihyperplasia of a limb or digit, despite an increased incidence of short stature. Macrocephaly in the absence of hydrocephalus occurs in 50% of individuals with NF1. Quantitative MRI studies have demonstrated the presence of true megalencephaly, largely secondary to increased white matter volume. Learning disabilities have been reported in up to 70% of individuals, and 3% have severe developmental delay. Their neurocognitive profile may also include easy distractibility, impulsiveness, and deficient visual-motor coordination. Seizures occur in approximately 6% to 7% of patients. Frank hydrocephalus with aqueductal stenosis, as well as asymptomatic ventricular dilation, has been observed in approximately 4% of patients. NF1 is a tumor suppressor gene expressed in neurons and glial cells and encodes neurofibromin, one of the earliest identified regulators of the RAS-MAPK pathway, and thus it has important roles in cellular proliferation and differentiation.

Other syndromes, including skeletal dysplasia, as well as chromosomal abnormalities, associated with megalencephaly are listed in Table 28-8.

## INTRODUCTION

Development of the human cerebral cortex is a complex and tightly regulated process that can be divided into three broad and overlapping steps, including (I) neural stem cell proliferation and cell type differentiation, (II) neuronal migration, and (III) final neuronal positioning, further cortical organization, and connectivity. Disruption of any one of these processes may result in a wide range of developmental disorders in humans. Many of these are recognized as malformations on brain imaging studies or visual inspection at autopsy and, collectively, comprise a class of disorders that we designate as malformations of cortical development (MCD).

Barkovich and associates developed a classification scheme for MCD based on the developmental steps at which the process was first disturbed, the underlying genes and biological pathways disrupted, and—when more objective data was not available—on brain imaging features (Barkovich et al., 2012). This system classifies MCD into three major groups as noted previously. Disorders presenting with abnormal brain size—microcephaly and megalencephaly—were reviewed in the previous chapter (see Chapter 28). Here we consider the subset of developmental disorders of the cortex in which alterations in brain size are not the dominant or only feature. These include several well-known cortical malformations—lissencephaly (LIS) and related tubulinopathies (with features intermediate between LIS and polymicrogyria), cobblestone cortical malformations (COB), classic four-layer (or unlayered) polymicrogyria (PMG) as described in schizencephaly and other conditions, as well as periventricular nodular heterotopia (PNH) and a growing number of predominately subcortical malformations. Although this classification system has proven helpful for recognizing specific MCD and sending appropriate diagnostic testing in affected individuals, it has not consistently fit with new gene discoveries. This has led us to take the first steps in developing a parallel system based on the underlying biological pathways.

## EMBRYOLOGY

The online summary touches on several of the advances made over the past decade; here we include a summary of the key pathways of migration and their primary neurotransmitters in Figure 29-1. Many reviews are available, including a recent collection of papers in a symposium on “Patterning and Evolving the Vertebrate Forebrain” (Retaux, 2009).

## BIOLOGIC PATHWAYS

By last count, at least 20 different biological pathways have been associated with MCD. Several are obvious candidates. For example, several MCD-associated genes function in early forebrain patterning, regulation of the cell cycle (neurogenesis and likely gliogenesis as well), intracellular structural changes necessary for cell movement (i.e., neuronal migration), and central pathways that regulate these processes. But for others the connection with MCD was initially less obvious, such as

defects in messenger RNA splicing, intracellular trafficking, and protein glycosylation. Even as the underlying mechanisms are defined, it often remains unclear why some of these pathways have a disproportionate effect on the brain and why they result in a particular type of MCD. As a first step in developing a parallel classification system for MCD based on biologic pathways, we have organized many of the best understood mechanisms into groups based loosely on head size, a surrogate for control of the cell cycle, and apoptosis (Table 29-1).

## LISSENCEPHALY AND SUBCORTICAL BAND HETEROTOPIA

Lissencephaly (LIS) or “smooth brain” and the related malformation known as subcortical band heterotopia (SBH) are the classic malformations associated with deficient neuronal migration. LIS is recognized based on an abnormal gyral pattern consisting of absent or abnormally wide gyri and an abnormally thick cortex. SBH is less obvious, consisting of a normal or mildly “simplified” gyral pattern associated with a variably thick layer of gray matter replacing the central and upper portions of white matter.

## Brain Imaging

Most of the distinguishing features seen on the macroscopic pathologic examination can be seen by brain imaging as well (Fig. 29-2). The different types of LIS and SBH may be distinguished by both the pattern and severity of the malformation. Recognition of these patterns has become essential for syndrome and molecular diagnosis and for assessing prognosis and genetic risk.

For all forms of true LIS, the brain surface appears smooth, with areas of absent (agyria) and abnormally wide gyri (pachygyria) and abnormally thick cerebral cortex. In normal brains, most gyri are approximately 1 to 1.5 cm wide and the normal cortex 3 to 4 mm thick, but thicker in the primary motor cortex and thinner in the primary visual cortex. In most types of LIS, gyri are typically 3 cm wide or more, and the cortex 8 to 20 mm thick. The exceptions are some tubulinopathies, three-layered LIS, and uncommon variants with an unusual undulating gyral pattern and mildly thick cortex (5 to 10 mm). This pattern can occur with severe cerebellar hypoplasia in the reelinopathies or with normal cerebellar size. Several distinct types of LIS are associated with agenesis of the corpus callosum, moderate to severe cerebellar hypoplasia (designated lissencephaly with cerebellar hypoplasia, LCH), or both.

In SBH, the brain surface appears superficially normal, except that the sulci or crevices between gyri tend to be very shallow, and the cortex is normal and not thick. But just beneath the cortex, often separated from it by just a few millimeters of white matter, lies a smooth band of neurons that never reached the true cortex. The inner margin of the band is usually smooth, whereas the outer margin may appear smooth (with thick bands) or follow interdigitations of the overlying cortex (with thin bands). Both LIS and SBH may be

seen with anterior or posterior predominant distribution. Thus the gradient of LIS and SBH can be anterior equal to posterior ( $a = p$ ), anterior more severe than posterior ( $a > p$ ), or posterior more severe than anterior ( $p > a$ ). In four-layered LIS, the cortex is usually 12 to 20 mm thick, whereas in other variants it may be only 8 to 12 mm thick. Common associated malformations include thick, under rotated and rounded hippocampi, enlarged posterior portions of the lateral ventricles, and flat anterior portion of the corpus callosum. Several other types of LCH may be differentiated based on brain imaging.

## Clinical Features

The clinical features in children with common and severe forms of LIS are similar and can be helpful in differentiating LIS from other cortical malformations (Guerrini and Dobyns, 2014). Children with the most common types of LIS (or SBH) typically appear normal as newborns, although a few have a history of polyhydramnios, apnea, hypotonia, poor feeding, and mildly elevated newborn bilirubin levels that may reflect poor swallowing. With most types of LIS, seizures are uncommon during the first days of life. Most affected children come to medical attention during the first year of life due to (1) neurologic deficits in the first weeks or months consisting of poor feeding, mild hypotonia, and abnormal arching behavior or opisthotonus, (2) delayed motor milestones later in the first year of life, or (3) onset of seizures during the first year of life, which is by far the most common. In all affected children, the major medical problems encountered are feeding problems and gastroesophageal reflux, epilepsy of many different types, and recurrent aspiration and pneumonia due to the feeding problems.

A few children feed poorly from the first weeks of life, but this often improves unless they have one of the severe LIS variants. Most feed reasonably well for the first several years, except that many have difficulty during intercurrent illnesses. Feeding often worsens later, especially after about 3 years, with increased aspiration, decreased feeding tolerance, and recurrent pneumonia. These problems are frequently related to worsening epilepsy, use of some antiepileptic drugs (especially benzodiazepines), and gastroesophageal reflux, whether obviously symptomatic or not. They lead to placement of gastrostomy tubes and operations to reduce reflux (fundal plications) in many affected children, although the age varies widely within the first decade. Other clinical features seen with LIS include minimal pyramidal signs and dysarthria.

## Epilepsy

Most and probably all children with LIS have seizures (Christian et al., 2015). The onset is usually between three and 12 months but may be later. Between 35% and 85% of children with classic LIS develop infantile spasms in the first year of life, although hypsarrhythmia is usually absent. After 1 year, they typically have continued mixed seizure types including epileptic spasms, typically presenting on awakening, myoclonic, tonic, and tonic-clonic seizures. Many meet criteria for Lennox-Gastaut syndrome, which can be associated with a decline in skills with poor seizure control. In general, the same treatment strategies used for Lennox-Gastaut syndrome generally may be used in patients with LIS or SBH. In children with XLAG, epilepsy is nearly continuous. In both classic LIS and XLAG, studies in mouse mutants have shown deficiencies in cortical interneurons that use gamma-aminobutyric acid (GABA) as their primary neurotransmitter. Thus GABAergic medications have some theoretical basis for use in these children. Early diagnosis of seizure disorders and aggressive attempts to control seizures and abate severe

**Figure 29-1.** Representation of a coronal section of the brain from an embryonic day 14 mouse (equivalent to a week 15 human embryo). **Right half,** The major subdivisions of the telencephalic proliferative zones, with the probable regions of origin of neurons expressing specific neurotransmitters, including glutamate, GABA, and acetylcholine. **Left half,** The migration pathways followed by neurons from the various proliferative zones, with straight arrows representing radial migration in all three major zones and curved arrows representing nonradial migration. Most projection neurons follow radial migration, whereas most interneurons follow nonradial pathways. Ach, acetylcholine; aep, anterior entopeduncular area; bmc, basal magnocellular complex; ctx, cortex; gaba,  $\gamma$ -aminobutyric acid; glu, glutamate; gp, globus pallidus; hip, hippocampus; lge, lateral ganglionic eminence; mge, medial ganglionic eminence; poa, anterior preoptic area; str, striatum. See also color plate. (Modified from Wilson, S.W., Rubenstein, J.L.R., 2000. *Induction and dorsoventral patterning of the telencephalon. Neuron* 28, 641–651. Reprinted with permission from Elsevier.)

EEG abnormalities usually prove helpful in maintaining function.

## Survival

For children with the most common forms of classic LIS, the mortality rate is 50% or higher by 10 years, and few live past 20 years. Children with the most severe LIS syndromes, especially MDS, severe forms of LCH, XLAG, MOPD1, or Barth microlissencephaly syndrome, have an even more severe course and higher mortality rate. However, these rates do not apply to children with less severe forms including partial (partial frontal or partial posterior) LIS or pachygyria, SBH, Baraitser-Winter syndrome, or variants with only mildly thick cortex (reelinopathies and the new “thin” LIS variants), as these subtypes all have better cognitive function and much longer survival.

These last several groups, including SBH, have mild to moderate cognitive impairment, although both normal intelligence and severe cognitive impairment have been seen in some individuals. Cognitive development may slow after onset of seizures. The frequency and severity vary greatly. EEG investigations usually demonstrate generalized spike-and-wave discharges or multifocal abnormalities. Neurologic outcome usually correlates with the thickness of the subcortical band heterotopia and severity of the gyral pattern as seen on MRI.

## TUBULINOPATHIES

Mutations of tubulin genes were first reported as causing LIS (for TUBA1A) or PMG with several other genes. Mutations

of TUBA1A were subsequently associated with both classic four-layered LIS and LCH, and mutations of TUBB2B rarely with LCH. With further experience however, the cortical malformations seen in most individuals with mutations of tubulin or tubulin motor genes comprise a recognizable spectrum of malformations that can be distinguished from both LIS and PMG by brain imaging and neuropathology. Thus we have begun to classify them as a group that overlaps with LIS but is distinct from PMG.

## Brain Imaging

The most severe tubulinopathies present with severe LCH that corresponds to two-layered LIS, and some mutations of tubulin or tubulin motor genes cause classic LIS that likely corresponds to four-layered (posterior predominant) LIS. The most common pattern was first described as a form of polymicrogyria, but with further experience, tubulinopathies have features intermediate between LIS and PMG and can be distinguished from both. The gyral pattern is abnormal with patchy and mildly asymmetric abnormalities in gyral size and orientation and varying sulcal depth. A pattern involving a cluster of multiple shallow sulci was frequently observed, especially in the frontal lobes. We will define this as “tubulinopathy-associated dysgyria” until a clearer terminology emerges. This pattern differs from simplified gyral pattern, in which the gyri are too few in number. Cortical thickness varies and can be mildly thin, normal, or mildly thick. The basal ganglia and thalami are dysplastic and mildly asymmetric with a bulbous appearance and diffuse, branched, or absent anterior limb of the internal capsule. The lateral ventricles have an irregular contour and abnormal rounding of the frontal horns, likely related to the basal ganglia dysplasia. The corpus callosum is variably affected from almost complete agenesis to normal. Most have brainstem dysplasia although the severity varies. The most typical features are a mildly enlarged midbrain tectum, flat pons, and globular medulla with indistinct demarcation between the pyramids and olives. Most patients have a striking dysplasia of the anterior (superior) cerebellum that consists of “diagonal” folia on axial views. The vermis, especially the anterior vermis, is usually small with normal or mildly small cerebellar hemispheres.

## Clinical Features

The clinical features of tubulinopathies are generally comparable to LIS. Children with severe LCH with two-layered LIS have profound handicaps and short survival. Children with obvious cortical malformations (the typical appearance described previously that resembles PMG) have severe handicaps. Children with subtle gyral malformations usually have better development, but still with moderate handicaps. Further details are lacking as this group is just now being separated from LIS and PMG.

## COBBLESTONE MALFORMATIONS

Cobblestone malformation or lissencephaly is a severe brain malformation associated with abnormal migration from the brain into the leptomeninges, and frequently with eye anomalies and congenital muscular dystrophy (CMD). The older term “type 2” lissencephaly should be abandoned. These malformations comprise the severe end of a graded series of disorders associated with defective glycosylation of alpha-dystroglycan, that include—from most to least severe—Walker-Warburg syndrome (WWS), muscle-eye-brain disease (MEB), Fukuyama congenital muscular dystrophy (FCMD), CMD with mental retardation and isolated cerebellar hypoplasia

and dysplasia, CMD with mental retardation but no recognized cortical malformation, and limb girdle muscular dystrophy. These are referred to as dystroglycanopathies. Although neuropathological confirmation is sparse, cobblestone or cobblestone-like malformations also occur in a growing group of other disorders, including isolated bilateral frontoparietal cobblestone malformation (previously called bilateral frontoparietal polymicrogyria) associated with mutations of the GPR56 gene, at least two congenital disorders of glycosylation—Debré type autosomal recessive cutis laxa and CHIME-like syndrome—and a small group of disorders associated with mutations of laminin-coding genes.

## Brain Imaging

The brain imaging changes of CMD-associated cobblestone malformation present a continuous series of malformations that begins with the severe changes of WWS and ends with normal brain imaging. But most patients cluster into one of the defined syndromes, which consist of WWS, an intermediate group classified as MEB, and progressively less severe forms ending with normal brain imaging. The key imaging features are most easily recognized for WWS and are collectively pathognomonic for this spectrum of disorders.

The imaging abnormalities seen in WWS, shown in an online figure, begin with macrocephaly and prominent forehead, resulting from existing or prior hydrocephalus, and reduced size and partial obliteration of extraaxial spaces, which is especially prominent between the cerebral hemispheres. The cerebral surface is undersulcated, usually with diffuse apparent agyria. The cerebral cortex is moderately thick, usually about 7 to 10 mm unless thinned by hydrocephalus. The cortical-white matter border is jagged with frequent vertical (perpendicular to the cortical-white matter border) striations, which differs from lissencephaly and from the chaotic striations seen in classic polymicrogyria. Just beneath the cortex, streaks of laminar subcortical heterotopia are seen that differ from typical subcortical band heterotopia based on their beaded and discontinuous appearance. The white matter has very abnormal signal (bright on T2 and dark on T1 MRI sequences; dark on CT scan) and may have small cysts. The white matter volume may be normal or thinned by hydrocephalus. The third and lateral ventricles are enlarged and may be very large and rounded reflecting active hydrocephalus. Very rarely, the ventricles may be small. The corpus callosum is present, although frequently thin.

The brainstem and cerebellum in WWS are remarkably dysplastic with a kink at the midbrain-pons junction in which the midbrain is angled dorsally with respect to the pons. The lower brainstem appears small with moderate to severe hypoplasia of the medulla and pons, near absence of the basis points, and ventral midline clefts of the ventral pons. But the midbrain and especially the tectum are abnormally large. The cerebellum is small with the vermis more severely involved than the hemispheres, a dysplastic foliar pattern, and often small cysts within or near the cerebellar cortex. The posterior fossa may be enlarged and a few patients have small occipital meningoceles.

The imaging abnormalities in MEB are similar but consistently less severe than in WWS. The macrocephaly and hydrocephalus are common in MEB as well, although partial obliteration of extraaxial spaces is less extensive. The cerebral surface is again undersulcated but with frontal predominant cobblestone-type dysgyria that resembles pachygyria but with the intracortical striations noted for WWS. Some areas resembling classic polymicrogyria may be seen. The jagged cortical-white matter border and vertical striations are similar to WWS, although fewer streaks of subcortical heterotopia are seen. The

white matter has a very abnormal signal similar to WWS in infants, but over time, this evolves from diffuse to patchy to minimal signal changes. The frequency of hydrocephalus and thinning of the white matter and corpus callosum is probably similar.

The brainstem and cerebellum in MEB are also dysplastic but less severe than WWS. The brainstem lacks the kink, but the lower brainstem, especially the pons, appears small, whereas the midbrain and tectum are enlarged. The cerebellar changes are similar but on average less severe than in WWS, except that cerebellar cortical cysts may be more common. This may be due to a high frequency of cerebellar cysts in MEB patients with mutations of the *POMGnT1* gene.

The imaging abnormalities in FCMD are similar to MEB but overall less severe. Hydrocephalus is uncommon. The dysgyria is less severe but still frontal predominant, although some patients have severe temporal lobe near agyria. The brainstem and cerebellum most often appear normal. Next on the spectrum, patients with mental retardation and cerebellar cysts have relatively normal forebrain structures and cerebral cortex; however, review of some published images shows that the cortex is mildly abnormal. The cerebellum mimics the appearance seen in MEB.

The brain imaging abnormalities in other cobblestone disorders, especially GPR56-associated brain malformation, are similar to MEB, including moderate frontal-predominant cobblestone-type dysgyria, moderately thick cortex with vertical striations, patchy white matter abnormalities, hydrocephalus, and brainstem and vermis predominant cerebellar hypoplasia and dysplasia. The brainstem is usually not as thin as seen in MEB. Similar imaging features with a posterior predominant (parietooccipital) distribution, including the beaded subcortical heterotopia, have been described with mutations of several laminin genes defining a new "lamininopathy" group of MCD.

## Clinical Features

Cobblestone malformations occur in a graded series of congenital muscular dystrophies with brain involvement associated with reduced glycosylation of alpha-dystroglycan that include—from least to most severe—CMD with mental retardation without obvious cortical malformation, CMD with mental retardation and isolated cerebellar hypoplasia and dysplasia, Fukuyama congenital muscular dystrophy (FCMD), muscle-eye-brain disease (MEB), and Walker-Warburg syndrome (WWS). In all of the cobblestone malformation syndromes associated with CMD, the phenotype consists of moderate to profound mental retardation, severe hypotonia, mild distal spasticity, and poor vision.

## Prognosis and Management

Children with most of these syndromes have both cobblestone brain malformation and progressive muscle disease, which lead to combined hypotonia (from the brain and muscle disease) and spasticity (from the brain malformation). The combination makes orthopedic and rehabilitation management difficult. Although the causative genes may be the same, it is important to distinguish between the various clinical syndromes, as the prognosis and management differ. WWS is a severe disorder associated with profound mental retardation and congenital hypotonia. Few children with WWS survive past 3 years. MEB and FCMD are less severe with variable survival from later in the first decade into the teens and beyond; some patients have survived into the fifth decade. Some children with WWS reported to live longer than 3 years may be better classified as having MEB.

Optimal management begins with early recognition and accurate counseling regarding the prognosis, as some parents of children with WWS choose to limit life-sustaining interventions. Most children with WWS and some with MEB have congenital hydrocephalus that can only be managed with a shunt. Children with WWS who have occipital cephaloceles may not have hydrocephalus at birth, but excision of the cephaloceles may be followed by hydrocephalus. Thus placement of a shunt should be considered at the time of cephalocele removal. Seizures occur but are rarely as severe as those seen in patients with lissencephaly or subcortical band heterotopia. In WWS and MEB, congenital glaucoma and buphthalmos require care by an ophthalmologist. Treatment of other eye anomalies that can interfere with vision, such as retinal nonattachment or detachment, cataracts and corneal opacities, should be assessed on an individual basis in view of the poor prognosis. Children with FCMD and other cobblestone syndromes have no or only minor eye anomalies.

The muscle disease progresses slowly, so that frequent evaluations to assess orthopedic and other rehabilitation needs are important. Careful seating is essential owing to severe hypotonia, and contractures need to be managed with physical therapy and splinting as needed. In WWS, the CMD probably progresses slowly over time, but this is not apparent clinically owing to the severe hypotonia and short survival period. Children with FCMD who learn to walk typically lose this skill several years later.

Individuals with GPR56-associated "frontoparietal" cobblestone malformation have global developmental delay, later moderate to severe intellectual disability, dysconjugate gaze, and bilateral pyramidal and cerebellar signs. Seizures have been reported in more than 90% of patients, most often generalized epilepsy.

## NEURONAL HETEROTOPIA

Neuronal heterotopia consists of groups of neurons in an abnormal location. The most common subtype is periventricular nodular heterotopia (PNH) lining the lateral ventricles. Other less frequent forms include many types of subcortical heterotopia, in which the major portion of the malformation is located in the subcortical white matter, and glioneuronal heterotopia found over the surface of the brain, often described as leptomenigeal. These are also known as brain warts. Examples of several types are shown in the online version.

**Periventricular Nodular Heterotopia.** PNH consist of nodular masses of gray matter that line the ventricular walls and protrude into the lumen, resulting in an irregular outline. They are recognized as a relatively common malformation that may occur as a single nodule or heterotopion or as multiple contiguous or noncontiguous nodules or heterotopia. When the nodules are single or few in number, they may be associated with seizures or learning problems but are unlikely to help with diagnosis. When the lesions are bilateral and numerous, a genetic basis is likely. When the nodules are diffuse and contiguous, they may be associated with other brain malformations, especially hypogenesis of the corpus callosum, cerebellar hypoplasia or polymicrogyria.

## Brain Imaging

Brain imaging using MRI demonstrates typical nodules along the ventricular walls, with different patterns of involvement that can be used to help to distinguish different syndromes. Patients with the classic X-linked form typically have bilateral contiguous or nearly contiguous periventricular nodular

heterotopia that spare the temporal horns, associated with mildly thin corpus callosum, cerebellar vermis hypoplasia, and megacisterna magna. Patients with autosomal recessive severe congenital microcephaly and periventricular nodular heterotopia have symmetric nodular heterotopia lining the ventricles, thin overlying cortex with abnormal gyri, mildly enlarged lateral ventricles and delayed myelination. In the frontal predominant form, heterotopias are limited to the frontal horns and bodies of the lateral ventricles. They may occur alone or with overlying polymicrogyria. In the more common and usually syndromic posterior predominant forms, heterotopias are limited to the trigones, temporal, and occipital horns. Posterior heterotopia may be associated with overlying polymicrogyria and cerebellar hypoplasia, hippocampal and cerebellar hypoplasia, or hydrocephalus.

## Clinical Features

The clinical presentation and course found in patients with PNH varies among the recognized syndromes. In individuals with PNH but no other brain malformations, seizures and learning problems are common, whereas more severe developmental problems are not, although exceptions certainly occur. When microcephaly or any other brain malformations is found, the likelihood of mental retardation increases greatly. Patients with BPNH and severe cerebellar hypoplasia often are brought to medical attention due to developmental ataxia.

Among all forms of PNH, the most common and often the presenting symptom is epilepsy, which has been reported in 80% to 90% of patients, although an ascertainment bias appears likely. The age at seizure onset is variable but at times delayed until early adulthood. Most patients have one or more types of partial seizures, which may be easily controlled or refractory. There is no clear relationship between the epilepsy severity and extent of nodular heterotopia. The associated EEG abnormalities are not specific, consisting of infrequent interictal discharges that may be generalized, multifocal, or focal. Pseudotemporal lobe localization has also been reported. Studies using depth electrodes in patients with periventricular nodular heterotopia and epilepsy have found the nodules to be intrinsically epileptogenic. However, seizure onset most often begins within a complex epileptogenic zone that includes both the heterotopia and overlying cortex. Intractable seizures associated with heterotopia should be treated aggressively. Temporal lobe surgery for patients with periventricular nodular heterotopia and associated hippocampal sclerosis has not generally been successful.

## POLYMICROGYRIA AND SCHIZENCEPHALY

The term "polymicrogyria (PMG)" was first used to describe a cerebral or cerebellar cortex with multiple excessive small convolutions, which may or may not be appreciated macroscopically. Synonymous terms in the literature include status verrucosus deformis, micropolygyria, and microgyria. As most often used in practice, the definition of PMG does not encompass a specific histologic cortical abnormality, but it is generally accepted that PMG is both an abnormality of excessive gyration and a microscopic abnormality of cortical structure. The most recognized and specific pattern of PMG occurs in schizencephaly (SCH), a term first used by Yakovlev and Wadsworth to describe full thickness clefts in the brain that are lined by PMG. The presence of gray matter lining the cleft and usually surrounding the opening on the cortical surface is one of the main distinguishing features between SCH and porencephalic cysts, the latter being lined by white matter or gliosis. SCH often occurs in the same central and perisylvian regions

as other forms of PMG, and many reports in the imaging and pathology literature have described unilateral SCH and contralateral PMG. SCH should be considered a subtype of PMG, and therefore it is presented in this section.

## Brain Imaging

Using CT and low field strength MRI, PMG is difficult to discern and may only appear as mildly thickened cortex. For this reason, PMG is frequently misdiagnosed as pachygyria or lissencephaly. The only current role for CT in the evaluation of PMG is to assess for evidence of intracerebral calcifications, which are seen in PMG resulting from congenital cytomegalovirus infection and a few rare disorders. Using high-quality MRI at 1.5T or greater with appropriate age-specific protocols, it is now possible to reliably differentiate PMG from other malformations of cortical development (MCDs), provided that the individual interpreting the MRI has knowledge of the imaging features of MCDs. Sagittal imaging extending laterally to involve the Sylvian fissures is of great value, as PMG often affects the opercular regions. Examples of several types are shown in the online version.

Polymicrogyric cortex often appears mildly thickened (usually 6 to 10 mm) on imaging due to cortical overfolding rather than true cortical thickening. This compares with lissencephaly in which the cortex is usually 10 to 20 mm thick. With thick slices, the cortex may appear mildly thickened with an irregular or "stippled" gray-white junction and with better imaging (such as inversion recovery) using thin contiguous slices microgyri and microsulci may be appreciated. In younger children with PMG, the cortex may not appear particularly thickened. This is thought due to the immature state of myelination in subcortical and intracortical fibers. T2 signal within the cortex is usually normal, although delayed myelination or high T2 signal in the underlying white matter may be seen. Diffusely abnormal white matter signal should raise the question of an in utero infection such as cytomegalovirus, or a peroxisomal disorder. The subarachnoid space may be enlarged over PMG and may contain excessive or anomalous venous drainage, especially in the Sylvian regions. Other developmental anomalies may include gray matter heterotopia, ventricular enlargement or dysmorphism, and abnormalities of the corpus callosum and cerebellum.

CT or MRI scanning is usually sufficient to diagnose SCH and determine whether the SCH is associated with an open-lip or closed-lip, although MRI is the modality of choice. The gray matter lining the cleft has the imaging appearance of PMG with apparent mild cortical thickening, an irregular surface and stippling of the gray-white interface. Subtle SCH may be recognizable by a "puckering" or "dimple" outwards of the lateral ventricle at the point at which the cleft reaches the ventricular margin. By definition, SCH clefts are always lined by gray matter. SCH is frequently asymmetric, and the contralateral hemisphere should be closely evaluated for the presence of a milder SCH or PMG without a cleft. Agenesis of the septum pellucidum and hypoplasia of the optic nerves are common and are present in as many as 30% of patients with SCH.

Several types of white matter abnormalities can be seen with PMG or PMG-like malformations. In typical PMG and SCH, prominent perivascular spaces are common. Extensive white matter signal changes characteristic of gliosis lining a cleft suggest that the lesion is porencephaly rather than SCH. More extensive white matter signal changes are seen in cobblestone cortical malformations. Abnormal vascular drainage is an extremely common finding, which is detected using MRI imaging sequences for depiction of cerebral veins such as susceptibility-weighted angiography.

PMG has been described in a number of topographic patterns. Most of these are bilateral and symmetric, the most common of which is bilateral perisylvian PMG, although the perisylvian form may be asymmetric or unilateral. Other bilateral symmetric forms are generalized, bilateral frontal, and parasagittal parietooccipital PMG, although little or no neuropathologic data is available to support the classification. PMG has also been described in association with periventricular nodular heterotopia.

## Clinical Features

The clinical sequelae of PMG are highly variable, and depend on several factors. The most consistent predictors of a poor developmental outcome include: microcephaly, especially severe microcephaly of  $-3$  standard deviations or smaller; abnormal neurologic examination, especially spasticity; widespread distribution of PMG, especially when bilateral and frontal; and additional brain malformations such as heterotopia or cerebellar hypoplasia.

PMG is reported as an occasional component in many different conditions, including metabolic disorders, chromosome deletion syndromes, and multiple congenital anomaly syndromes. These patients may have a variety of clinical problems other than those attributable to the PMG. Some patients with PMG or SCH have fewer clinical problems than would be expected for the location and extent of cortex involved (for example, perisylvian PMG with deletion 22q11.2), whereas others have more severe problems (for example, perisylvian PMG with deletion 1p36.3). PMG may involve eloquent cortical areas representing language or primary motor functions, yet these functions may occasionally be retained with minimal or no disability. This is especially true with lesions such as unilateral perisylvian PMG.

**Perisylvian Polymicrogyria.** The most common form of PMG involves the perisylvian regions in a bilateral and relatively symmetric pattern. The combination of bilateral perisylvian PMG, oromotor dysfunction, and seizure disorder has been called the “congenital bilateral perisylvian syndrome” and is the best described syndrome of PMG. Patients with perisylvian PMG typically have oromotor dysfunction, including difficulties with tongue (tongue protrusion and side to side movement), facial and pharyngeal motor function resulting in problems with speech production, sucking and swallowing, excessive drooling, and facial diplegia. They may also have dysarthria and an expressive dysphasia. More severely affected patients have minimal or no expressive speech, necessitating the use of alternate methods of communication such as signing or language assistive devices such as picture boards or computer-assisted devices. Examination demonstrates facial diplegia, limited tongue movements, brisk jaw jerk, and frequent absence of the gag reflex. Patients presenting in childhood may have other abnormalities including arthrogryposis, hemiplegia, and hearing loss, although the data available on children is limited. Up to 75% of affected individuals have mild to moderate intellectual disability. Motor dysfunction may include limb spasticity, although this is rarely severe if present. A smaller group of patients have unilateral perisylvian PMG and present with hemiparesis or seizures. Their developmental and neurologic deficits are typically less severe.

**Other Patterns.** Several other patterns of PMG have been described, including bilateral frontal, bilateral parasagittal parietooccipital, bilateral parietooccipital, multilobar, and bilateral generalized PMG, as well as PMG associated with periventricular gray matter heterotopia. The clinical features of these less common forms of PMG vary from BPP, although

epilepsy, developmental delay, and spasticity are common accompaniments. Unsurprisingly, spasticity appears to be more frequent when the frontal lobes are involved. Note that the subtype described as “bilateral frontoparietal PMG” is in our view better classified as bilateral frontoparietal cobblestone malformation, and was discussed in a previous section.

**Epilepsy.** The data regarding epilepsy in PMG is largely based on the study of patients with perisylvian PMG. The frequency of epilepsy in these patients is 60% to 85%, although seizure onset may not occur until the second decade, usually between 4 and 12 years of age. Seizure types include atypical absence, atonic and tonic drop attacks, generalized tonic-clonic, and partial. It is rare for partial seizures to secondarily generalize. Occasionally patients may develop bilateral facial motor seizures with retained awareness. The occurrence of infantile spasms is uncommon in PMG, in contrast to patients with lissencephaly, tubulinopathies, tuberous sclerosis, or focal cortical dysplasia in which the frequency of spasms is much higher. Seizures may be daily and intractable in at least 50% of patients, and EEG typically shows generalized spike and wave or multifocal discharges with a centroparietal emphasis. Polymicrogyria is a frequent cause of epilepsy with continuous spikes and waves during sleep, a form of age related epileptic encephalopathy.

**Schizencephaly.** Patients with closed-lip SCH typically present with hemiparesis or motor delay, whereas patients with open-lip SCH typically present with hydrocephalus, seizures, and intellectual disability, which can be severe. Seizure types include complex partial seizures, as well as infantile spasms, tonic, atonic, and tonic-clonic seizures, although these are less common. The severity and type of seizures do not appear to correlate with topography of the SCH. The outcome is worst for those with bilateral open-lipped SCH and best for those with unilateral closed-lip SC. Many patients have associated brain abnormalities such as agenesis of the septum pellucidum that probably contribute to the disability in some patients.

## FOCAL CORTICAL DYSPLASIA AND HEMIMEGALENCEPHALY

Hemimegalencephaly (HMEG) and focal cortical dysplasia (FCD) constitute a spectrum of malformations of cortical development with shared neuropathology features. The former is primarily defined by macroscopic enlargement of (more or less) one hemisphere, whereas FCD is primarily defined by histopathology. FCD was first described as a histologic abnormality seen in surgical specimens from 10 patients with epilepsy that is now referred to as FCD type 2b, but use of the term has gradually expanded. As currently classified (Blumcke et al., 2011), FCD encompasses a wide spectrum of cortical malformations with variable features including microscopic neuronal heterotopia, dyslamination, and abnormal cell types. It has been divided into three major types and nine subtypes based on histopathological features. Type 1 consists of abnormal cortical lamination without large or dysmorphic neurons or any other primary pathologic process. Type 2 consists of abnormal cortical lamination with large, dysmorphic neurons and several other features. Type 3 consists of abnormal cortical lamination without large or dysmorphic neurons that occurs immediately adjacent to another principal pathologic process such as hippocampal sclerosis, glial or neuroglial tumor, or vascular malformations. The histopathology in HMEG is essentially the same as FCD type 2, both discussed with megalencephaly in a previous chapter.

## Brain Imaging

FCD is rarely visible by CT and may not be visible even with high quality MRI, especially FCD type 1. Subtle abnormalities in the gyral pattern, cortical thickness, and gray-white junction are best seen using thin slice T1-weighted images. Some forms of FCD may show increased signal on FLAIR and T2-weighted images. White matter signal may be abnormal in the region of FCD, producing intractable seizures, but it is not clear whether this represents dysplastic white matter, or a consequence of abnormal or advanced myelination secondary to frequent seizure activity.

In FCD type 1, typical features consist of subtle cortical thickening and irregular sulcation or gyration. Other features may include lobar hypoplasia or atrophy and hippocampal sclerosis. The most striking imaging features of FCD are seen in FCD type 2. The lesions in these patients typically show increased cortical thickness, blurring of the gray-white junction, abnormal sulcal and gyral patterns, and high signal at the base of the lesion and in the underlying white matter on T2 and FLAIR sequences.

Several specific named patterns of FCD have been described based primarily on brain imaging features. FCD has also been shown to occur at the base of a sulcus with cortical thickening and poor gray-white differentiation, often with a linear band of high signal from the base of the lesion to the lateral ventricle, known as the “transmantle sign,” shown for FCD types Ib and IIb. In focal transmantle dysplasia, a wedge of dysplastic tissue extends from the lateral ventricle up to the cortical surface. Histology shows features of FCD with balloon cells plus white matter astrogliosis, and MRI shows a wedge of disorganized tissue with increased T2 signal. These lesions have collectively been called “bottom of the sulcus” dysplasias. Sublobar dysplasia is characterised by a deep infolding of the cortex with a thickened cortex and possible poor gray-white differentiation in the malformed region. Associated brain abnormalities include ventricular dysmorphism and callosal and cerebellar dysgenesis. Another form of FCD affecting one posterior quadrant of the brain has been designated posterior quadrant dysplasia.

Presurgical localization of these lesions often requires advanced MRI imaging techniques and analysis such as the use of surface coils, volume averaging, curvilinear reformatting, or 3T imaging. Functional studies, including SPECT and FDG-PET scanning, are also often required to maximise the likelihood of identifying and defining the boundaries of FCD. New MRI methods for lesion detection are being evaluated including multichannel coils, high field strength (greater than 3T), arterial spin labeling, susceptibility-weighted imaging, and diffusion tensor/spectrum imaging.

## Clinical Features

Apart from tuberous sclerosis, the cortical malformation typically occurs as an isolated feature with no particular dysmorphic, neurocutaneous, or congenital anomalies. However, HMEG and FCD can occur with several well-known syndromes. These include the linear nevus sebaceous (Schimmelpennin) syndrome, Sturge-Weber syndrome, the PTEN hamartoma tumor (Cowden) syndrome, and pigmentary mosaicism sometimes designated as “hypomelanosis of Ito.”

The most common clinical sequelae of FCD are seizures. Developmental delay, cognitive disability, and focal neurologic deficits are only observed with extensive dysplasias. Seizures from FCD may arise at any age from *in utero* seizures until adulthood, although most patients present in childhood. Some studies have shown consistent clinical differences between patients with FCD types 1 and 2. FCD type 2 usually

has extratemporal location and is manifested with a younger age of seizure onset and higher seizure frequencies. Seizure semiology varies, depending on the location of the FCD and age of the patient. Younger children often present with asymmetric infantile spasms. The seizure disorder may be intractable and life threatening so that surgical resection may be appropriate. Much of the developmental delay and cognitive disabilities associated with FCD may be due to the effects of repeated seizure activity. As complete as possible surgical resection of the FCD is consistently the most important variable for long-term seizure control in epilepsy secondary to FCD that is unresponsive to anticonvulsants; accordingly, surgery is being performed at increasingly younger ages in an attempt to protect the child against the deleterious effect of uncontrolled epilepsy and multiple medications.

## Etiology, Genetic, and Molecular Basis

Since the last edition of this text, substantial progress has been made in understanding the pathogenesis for FCD. In FCD type 1, not much is known. In one large study, prenatal and perinatal brain injuries, especially prematurity, intraventricular hemorrhage with hydrocephalus, and perinatal asphyxia, were found in 25 of 200 (12.5%) of children with FCD, mostly FCD1a and FCD1b. Much more progress has been made for FCD type 2. The PI3K-AKT-MTOR pathway is involved in the control of cell proliferation and growth, protein synthesis, synaptic plasticity, and other key cellular functions. Several studies have shown upregulation of this pathway (especially of MTOR and AKT) in resected brain tissue from patients with FCD type 2, as well as in tuberous sclerosis, hemimegalencephaly, and some low-grade, epilepsy-associated tumors (Jansen et al., 2015). Subsequent genetic analysis has demonstrated germline or mosaic mutations in several genes in the PI3K-AKT-MTOR pathway in both FCD2a and FCD2b, as well as in hemimegalencephaly with FCD type 2 histopathology. The genes implicated to date include PIK3CA, PTEN, MTOR, DEPDC5, and BRAF, as well as AKT3 in hemimegalencephaly (Jansen et al., 2015; D’Gama et al., 2015).

## Treatment

Most patients with epilepsy due to FCD do not respond to conventional antiepileptic drugs, and many remain either surgically inaccessible or surgical failures. A subset of patients are treated surgically with rates of success that can reach up to around 80%, depending on the extent and location of the lesion, its histologic subtype, presurgical assessment, and completeness of resection. The most successful operations are conducted in children with infantile spasms and FCD in whom remission of spasms is often accompanied by overall clinical improvement or in children with FCD of the anterior temporal pole in whom rates of postoperative seizure freedom are very high. High resolution imaging, multimodal fusion imaging, and novel neurophysiological approaches, such as the study of high frequency oscillations, as well as a more precise characterization of eloquent cortical regions, have provided in recent years considerable improvements for less invasive and more precise surgical planning (Guerrini et al., 2015). Although many patients with refractory epilepsy caused by FCD cannot be adequately treated, novel therapeutic avenues based on mTOR inhibitors are opening new perspectives.

## SUMMARY

Researchers in the field of human MCD have made assumptions as to the likely timing of the etiologies of different malformations based on their appearance using both

pathologic and neuroimaging techniques. For example, heterotopic gray matter is assumed to result from disordered neuronal migration, as the heterotopic neurons appear to have arrested their migration to the cortex prematurely. Assumptions such as these were proposed well before a basic understanding of the genetic and molecular mechanisms of normal cortical development were established. In many instances, these assumptions have proved correct, yet it is now appreciated that many cortical malformations are likely secondary to abnormalities occurring at stages other than that of neuroblast migration. Our understanding of the genetic and molecular basis of cortical development is advancing rapidly, with new genes or new roles for known genes being discovered. A more complete understanding of the key genes involved in human cortical development will be required in order to understand the possible timing and molecular basis of many malformations of cortical development.

## HYDROCEPHALUS

### Definition

Hydrocephalus is most simply defined as an increase in the fluid containing spaces of the brain at increased pressure, resulting from an imbalance between cerebrospinal fluid (CSF) production and absorption or flow (Rekate, 2009). This definition excludes other abnormalities of CSF dynamics such as benign intracranial hypertension in which the ventricles are not enlarged, or “hydrocephalus ex-vacuo,” where cerebral atrophy and focal destructive lesions also lead to an abnormal increase of CSF passively.

### Classification

There is no universally accepted classification system, and a number of classification systems for hydrocephalus have been suggested (Boaz and Edwards-Brown, 1999). These include

- Communicating versus noncommunicating
- Obstructive versus absorptive
- Acquired versus congenital
- Genetic or central nervous system (CNS) malformation-associated versus isolated
- Intraventricular-obstructive versus extraventricular
- Simple versus complicated

The terms *compensated hydrocephalus* and *uncompensated hydrocephalus* generally refer to whether an increase in ventricular size is associated with evidence of raised intracranial pressure. In some cases a gradual increase in ventricular size stabilizes by reaching a new equilibrium and the patient has no symptoms or signs of raised intracranial pressure. However, patients with apparently arrested hydrocephalus may still develop symptoms and signs at a later date, and so the process is not entirely static.

In communicating hydrocephalus, the flow is not obstructed but CSF is inadequately reabsorbed in the subarachnoid space, whereas in noncommunicating or obstructive hydrocephalus, the flow of CSF from the ventricles to the subarachnoid space is obstructed.

Congenital hydrocephalus is present at birth and often associated with developmental defects, whereas acquired hydrocephalus occurs after the development of the brain and ventricles. Hydrocephalus also has been classified based on the stage of development at the time that the ventricles became dilated. The various subtypes of fetal hydrocephalus are classified according to the mechanism of obstruction to the flow of CSF. These include: primary or simple hydrocephalus with a single point of obstruction to flow; dysgenetic hydrocephalus with complex abnormalities of the CNS, such as the Arnold–Chiari malformation; and secondary hydrocephalus from tumor or bleeding. This classification is cross-referenced to the stage of fetal development (e.g., neuronal maturation, cell migration) and may prove useful in deciding when treatment may be futile if beyond the legal period for terminating a pregnancy, and in identifying potential candidates for early delivery or fetal surgery.

Extraventricular obstructive hydrocephalus is now recognized to represent, almost universally, benign pericerebral collections of infancy that are usually familial, resolve with time, and almost never require treatment (Drake, 2008). Exceptions include genetic conditions, such as certain mucopolysaccharidoses, achondroplasia, Sotos syndrome, and glutaric aciduria type I, often associated with developmental delay. In these cases, identification is important as therapeutic options exist for many forms of mucopolysaccharidoses and for glutaric aciduria type I.

### Epidemiology

In newborns, cited incidence of hydrocephalus ranges from 0.3 to 4 per 1000 live births. Occurring as a single congenital disorder, the incidence of hydrocephalus has been reported as 0.9 to 1.5 per 1000 births. The incidence of pediatric hydrocephalus has declined in many developed countries as antenatal screening, genetic testing, and pregnancy termination have reduced the incidence of congenital malformations of the brain that cause hydrocephalus. The incidence of open neural tube defects also has decreased precipitously as a result of maternal folate supplementation, antenatal screening, and termination of pregnancy based on superior antenatal imaging with ultrasound and magnetic resonance imaging (MRI) (Chakraborty et al., 2008). The incidence of intraventricular hemorrhage (IVH) also has decreased as a result of better perinatal management of prematurity.

### Cerebrospinal Fluid Production, Circulation, and Absorption

CSF is produced by two mechanisms: Most of the CSF is thought to be secreted by the choroid plexus within the cerebral ventricles. Extrachoroidal CSF production in subarachnoid sites and by way of a transependymal route also has been documented. About 20% or more of CSF is derived from brain extracellular fluid created as a byproduct of cerebral metabolism. Normally, rates of production (0.35 mL/min or approximately 400 to 500 mL/day) and absorption of CSF are equal. Total CSF volume is 65 to 140 mL in children, and 90 to 150 mL in adults.

CSF production has been reported to remain constant across the normal intracranial pressure range and to decrease when intracranial pressure approaches mean arterial pressure. There have been reports, however, of downregulation of CSF production in patients with chronic hydrocephalus.

Information gained from MRI analysis of CSF movement demonstrates pulsatile to-and-fro motion of CSF within the lateral ventricles, produced from a brain-pumping motion that ejects the CSF and causes a net downward flow.

Historically, it has been held that CSF is absorbed into the vascular system mainly through the arachnoid villi within the arachnoid granulations covering the brain and spinal cord leptomeninges. There is normally 5- to 7-mm Hg difference in pressure between the dural venous sinuses and the

subarachnoid space, which is presumed to be the hydrostatic force behind the absorption of CSF. Newborn infants do not have visible arachnoid granulations, suggesting that the maximum capacity for reabsorption is less than that in the adult, or that CSF is absorbed by different mechanisms in the neonate.

More recently, olfactory nerves, the cribriform plate, and nasal lymphatics have been identified as important sites for CSF absorption. Absorption of CSF across brain tissue into capillaries also has been proposed (Greitz, 2004).

## Etiology and Pathophysiology

Hydrocephalus can be a symptom of a large number of disorders (Greitz, 2004), and a list of conditions in which it has been reported is summarized in Box 30-1. It is associated with tumors and infections, and may be a complication of prematurity and trauma (Renier et al., 1988). It is also seen in apparent isolation. High-resolution MRI of postnatal life has provided clues to the etiology of hydrocephalus, which in the past would have been labeled as idiopathic; some of these include IVH, aqueductal stenosis (Figure 30-3), and migrational abnormalities.

Hydrocephalus is caused by either abnormal CSF reabsorption, or flow, or, rarely, overproduction. Its etiology depends on the age of the child. During the neonatal to late infancy period (0 to 2 years), hydrocephalus is usually caused by a perinatal hemorrhage, meningitis, and developmental abnormalities, the most common being aqueductal stenosis. The hydrocephalus seen in babies with spina bifida usually results from an associated Chiari malformation. In early to late childhood (2 to 10 years), the most common causes of hydrocephalus are posterior fossa tumors and aqueductal stenosis.

### Congenital Causes in Infants and Children

Approximately 55% of all cases of hydrocephalus are congenital. Primary aqueductal stenosis accounts for approxi-

**Figure 30-3. Aqueductal stenosis.** Occlusion of the aqueduct of Sylvius results in enlargement of the lateral and third ventricles (proximal to the aqueduct), with relative normalcy of the fourth ventricle (distal to the aqueduct).

mately 5% of congenital hydrocephalus, whereas aqueductal stenosis secondary to neoplasm, infection, or hemorrhage accounts for another 5%. Primary aqueductal stenosis usually presents in infancy. Its morphology may be that of “forking” of the aqueduct, an aqueductal septum, “true” narrowing of the aqueduct, or X-linked aqueductal stenosis. Secondary aqueductal stenosis is caused by gliosis secondary to intrauterine infection or germinal matrix hemorrhage.

Anatomic malformations frequently observed with idiopathic congenital hydrocephalus are associated with abnormalities of hindbrain development, and include Chiari malformations, Dandy–Walker malformation (DWM), and others. DWM is associated with atresia of the foramen of Luschka and Magendie, and affects 2% to 4% of newborns with hydrocephalus. About 50% of all patients with DWM develop hydrocephalus. The dilated fourth ventricle does not communicate effectively with the subarachnoid space. In patients with Chiari malformations, hydrocephalus may occur, with fourth ventricle outlet obstruction in Chiari type 1 malformation; it is commonly associated with myelomeningocele in the Chiari type 2 malformation. Hydrocephalus occurs in approximately 80% to 90% of patients with myelomeningocele; of these cases, 50% are obvious at birth (Tuli et al., 2003).

Neonatal hydrocephalus can also be part of a major cerebral malformation, such as an encephalocele or holoprosencephaly, or can be associated with inherited metabolic diseases, such as achondroplasia and Hurler disease. Other causes of congenital hydrocephalus include agenesis of the foramen of Monro, congenital tumors, arachnoid cysts, vascular malformations (vein of Galen), and intrauterine toxoplasmosis.

### Acquired Causes in Infants and Children

Infective causes of hydrocephalus include meningitis, especially bacterial, which can lead to hydrocephalus by either inflammatory aqueductal stenosis or leptomeningeal fibrosis. In some geographic areas, parasitic disease, such as intraventricular cysticercosis, can cause hydrocephalus by mechanical obstruction.

Posthemorrhagic hydrocephalus (PHH) occurs after IVH and can be related to prematurity, head injury, or rupture of a vascular malformation. Approximately one third of extremely low-birth-weight infants with an IVH develop PHH.

Mass lesions account for 20% of all cases of hydrocephalus in children. These are usually tumors, such as medulloblastoma, astrocytoma, and ependymoma, but cysts, abscesses, vascular malformations, or hematomas also can be the cause. Approximately 20% of children develop hydrocephalus requiring shunting after posterior fossa tumor removal.

Increased venous sinus pressure can also lead to hydrocephalus. This can be related to achondroplasia, some craniosynostosis, or venous sinus thrombosis.

Iatrogenic causes of hydrocephalus include hypervitaminosis A, which can lead to hydrocephalus by increasing secretion of CSF or by increasing permeability of the blood-brain barrier. Hypervitaminosis A is a more common cause of idiopathic intracranial hypertension.

## Clinical Characteristics

The clinical features of hydrocephalus depend on the age of the child at presentation and the time of onset in relation to closure of the cranial sutures. With the current advances in antenatal monitoring, the majority of congenital cases of hydrocephalus are diagnosed early (Figure 30-4), allowing for planned cesarean delivery in the moderate to severe cases in which cephalopelvic disproportion is expected.

**Figure 30-4.** Antenatal magnetic resonance imaging showing fetal hydrocephalus. Asymmetric enlargement of the ventricular system is readily seen in the brain of this fetus.

### Symptoms and Signs in Infants

Hydrocephalus can present as acute raised intracranial pressure but, because of the relative distensibility of the infant skull, the presentation may be more subtle, with symptoms of failure to thrive or delayed development. Infants with hydrocephalus may be drowsy and irritable. Poor feeding and vomiting are common. These infants may have apneic spells, episodes of bradycardia, and a bulging, tense anterior fontanel. Head circumference increases abnormally across centiles, and the head circumference is at or above the 98th percentile for age. Scalp veins may be distended, scalp skin thin and shiny, and cranial sutures splayed. In most children, the hydrocephalus only gradually becomes obvious. In advanced cases, clinical examination reveals a significant craniofacial disproportion, with expansion of the dome and low-set ears and eyes. In very severe cases, where the cerebral cortex is thinned, transillumination of the cranial cavity may be possible. Epileptic seizures are rarely seen as a result of hydrocephalus alone.

Papilledema is rare in this age group, although funduscopy may reveal retinal venous engorgement. Oculomotor abnormalities may include abducens nerve palsy. Upgaze palsy, from third ventricular pressure on the midbrain tectum producing a “setting-sun” sign, can be observed, although this is usually absent in premature infants. Some infants with definite hydrocephalus exhibit no such signs, as hydrocephalus may have developed slowly and the splaying of the sutures may have prevented the intracranial pressure from rising considerably.

### Symptoms and Signs in Older Children

In children older than 2 years, the head circumference is usually within normal limits if hydrocephalus develops after closure of the cranial sutures, or may be increased in children with preexisting (infantile) but unrecognized progressive hydrocephalus.

Learning problems and reduced intellectual function are common, and neurologic development may be delayed. School-aged children may have deteriorating school performance as a result of headaches, failing mental function, memory loss, or behavioral disturbances. More acutely, these

children present with symptoms and signs of increased intracranial pressure, such as headache, nausea, vomiting, drowsiness, gait changes, papilledema, or impaired upward or lateral gaze. Failure of upward gaze is caused by pressure on the tectal plate through the suprapineal recess. When intracranial pressure is significantly increased, other elements of the dorsal midbrain syndrome (Parinaud syndrome) may be observed.

Abnormal hypothalamic functions (e.g., short stature, gigantism, obesity, delayed puberty, primary amenorrhea, menstrual irregularity, and diabetes insipidus) may occur secondary to increased intracranial pressure or dilatation of the third ventricle. Difficulty in walking may develop secondary to truncal and limb ataxia or limb spasticity. This affects the lower limbs preferentially because the periventricular pyramidal tracts are stretched by the enlarged ventricles. Neck pain may indicate associated tonsillar herniation; blurred vision may be present as a consequence of papilledema, which, if left untreated, leads to optic atrophy.

### Genetics

Although commonly considered a single disorder, hydrocephalus is a collection of heterogeneous complex and multifactorial disorders. A growing body of evidence suggests that genetic factors play a major role in its pathogenesis.

Congenital hydrocephalus may occur alone (nonsyndromic) or as part of a syndrome with other anomalies (syndromic). It is estimated that about 40% of individuals with hydrocephalus have a genetic etiology. The isolated (nonsyndromic) form of congenital hydrocephalus is a primary and major phenotype caused by a specific faulty gene. In syndromic forms, it is difficult to define the defective gene because of the association with other anomalies.

Autosomal-recessive, autosomal-dominant, X-linked recessive, and X-linked dominant forms of hydrocephalus are recognized.

At least 43 gene mutations linked to hereditary hydrocephalus have been identified in animal models and humans. To date, nine genes associated with hydrocephalus have been identified in animal models, whereas only one such gene has been identified in humans: the hydrocephalus (X-linked) gene. X-linked hydrocephalus (HSAS1, OMIM) occurs in approximately 5% to 15% of congenital cases in which a genetic etiology is determined. The gene responsible for X-linked human congenital hydrocephalus is at Xq28, encoding for L1CAM (L1 cell adhesion molecule). Congenital aqueductal stenosis can also be inherited as an autosomal-recessive disorder (OMIM 236635).

In general, the recurrence risk for congenital hydrocephalus excluding X-linked hydrocephalus is low. Empiric risk rates range from less than 1% to 4%, indicating the rarity of autosomal-recessive congenital hydrocephalus.

### Neuroimaging

#### Cranial Ultrasound

Ultrasound is by far the quickest, cheapest, and most convenient method to demonstrate ventricular enlargement in infants with an open fontanel, particularly for posthemorrhagic hydrocephalus in premature infants and as serial imaging in follow-up. Ventricular width measured from the midline to the lateral border of the lateral ventricle in the midcoronal view is the measurement with the least interobserver variability, and centiles for gestational age have been compiled. Sedation is not required for acquiring ultrasound images, and the procedure can be repeated frequently without

any adverse effects. It may not visualize the posterior fossa well, and may not always establish an etiologic diagnosis.

### Computed Tomography

Computed tomography (CT) demonstrates ventricular size and morphology and periventricular lucency, and can reveal underlying pathologies, such as hemorrhage or posterior fossa tumors. Imaging of asymptomatic patients (especially after shunt revision) may serve as a reliable baseline study for comparison with subsequent imaging studies when patients become symptomatic. CT is widely available and often does not require sedation of the child. The limitations of CT are exposure to radiation, particularly with serial CT imaging so that alternative imaging such as ultrasound or rapid sequence MRI is frequently preferred.

### Magnetic Resonance Imaging

MRI provides better morphologic definition and etiologic diagnosis, such as the presence of low-grade gliomas or colloid cysts, which may not be demonstrated on CT. It is better for evaluating Chiari malformations or cerebellar or periaqueductal tumors. Cine MRI is an MRI technique to measure CSF stroke volume in the cerebral aqueduct and can be used for demonstrating patency of third ventriculostomy fenestration. Limitations of MRI are that children often require general anesthesia and programmable shunt valves require reprogramming after MRI.

In patients with acute hydrocephalus characterized by ventricular enlargement and transependymal edema, with loss of sulci, the diagnosis is usually very obvious. Serial imaging demonstrating an increase in ventricular size may be required in equivocal cases. Conversely, an apparently normal ventricular size cannot exclude active hydrocephalus in a patient with a preexisting shunt, for example. Hydrostatic hydrocephalus is suggested when either the size of both temporal horns is 2 mm or greater in width, and the sylvian and interhemispheric fissures are not visible, or when both temporal horns are 2 mm or greater, and the ratio of the largest width of the frontal horns to the internal diameter from inner table to inner table at this level is greater than 0.5 mm.

The Evans ratio is the ratio of largest width of the frontal horns to the maximal biparietal diameter. A ratio greater than 30% is suggestive of hydrostatic hydrocephalus. A modification of Evans ratio, the frontal occipital horn ratio, may be more accurate and has been used in a number of prospective studies to quantify the degree of hydrocephalus and the response to treatment.

In communicating hydrocephalus, all ventricles are dilated. If the lateral and third ventricles are dilated and the fourth ventricle is small, it is likely that the obstruction is at the level of the aqueduct of Sylvius.

### Diagnosis

Modern ultrasonography and, since the late 1980s, fetal MRI have significantly improved the ability to detect ventricular enlargement as a result of hydrocephalus in utero. Antenatal ultrasound and MRI provide reasonably detailed fetal brain anatomy, and can detect malformations and fetal ventriculomegaly as early as 17 to 21 weeks and 8 to 21 weeks, respectively. Anatomic ventriculomegaly is not sufficient to diagnose hydrocephalus. When diagnosing hydrocephalus in neonates or infants, it is essential to establish that there is a truly abnormal rate of skull growth. Records of head circumference measurements and its comparison with body weight and length centile charts are an integral part of postnatal follow-up of any child. Head circumference must be recorded and plotted on

an accepted growth curve chart, with the patient's exact age. In the presence of hydrocephalus, any of the following may be observed: head circumference more than 2 standard deviations above normal or disproportionate to body length or weight, accelerated growth crossing centile curves, or continued head growth of more than 1.25 cm/week.

Evaluation of the patient with an enlarged head entails consideration of the many causes of macrocephaly, including hydrocephalus. Evaluation should include a history of trauma or CNS infection. The family history may demonstrate X-linked hydrocephalus caused by stenosis of the aqueduct of Sylvius or may reveal familial macrocephaly.

After a full review of the pregnancy, delivery, and neonatal history, as well as the clinical examination and ultrasound examination, it is usually possible to classify hydrocephalus into an etiologic group. If no obvious explanation can be determined, then the possibility of an intrauterine infection should be investigated. Coagulation factor deficiencies, as well as thrombocytopenia, should be excluded, as isoimmune thrombocytopenia and coagulation factor V deficiency can present as congenital hydrocephalus resulting from congenital IVH.

### Differential Diagnosis

Besides hydrocephalus, causes of increasing head size include chronic subdural effusions or hematomas, pseudotumor cerebri, neurofibromatosis, metabolic abnormalities of bone or brain, cerebral gigantism (Sotos syndrome), and benign familial forms.

Benign extracranial hydrocephalus is a condition in infants and children with enlarged subarachnoid spaces accompanied by increasing head circumference with normal or mildly dilated ventricles. This condition is also known as "benign subdural collections of infancy," "pericerebral CSF collections," or "benign macrocrania." This has been postulated by some to be a variant of communicating hydrocephalus, but tends to run a benign course and stabilize by 12 to 18 months of age. Close serial monitoring of head circumference and serial imaging with CT or MRI are recommended to monitor for ventriculomegaly. Shunting is rarely, if ever, required.

A rare but striking condition that can mimic hydrocephalus is hydranencephaly or anencephaly, a postneurulation defect that results in total or near-total absence of the cerebral tissue, with the intracranial cavity being filled with CSF. This is usually caused by fetal bilateral internal carotid artery infarction or infection.

Hydrocephalus ex-vacuo is caused by atrophy rather than altered CSF dynamics. Certain metabolic and degenerative disorders, such as glycogen storage and Alexander disease, can cause macrocephaly. Finally, there may be a family history of large heads.

### Pathology

The precise pathologic features of hydrocephalus vary, depending on the age of onset, the rate of ventricular enlargement, and the degree of ventriculomegaly. Typically, elevated CSF pressure initially enlarges the frontal horns of the lateral ventricles, followed by enlargement of the entire ventricular system above the site of obstruction. Hydrocephalus is associated with flattening and destruction of the ventricular ependymal lining, as well as edema and necrosis of the periventricular white matter. Periventricular glial cells proliferate, resulting in a layer of reactive gliosis. The pathologic findings may be a result of reduced blood flow to the white matter, causing hypoxic injury or toxicity to the white matter as a

result of build-up of waste products not removed appropriately because of changes in the extracellular matrix.

Separation of the ependymal lining of the ventricles enhances permeability, which increases edema formation in adjacent white matter (transependymal fluid absorption). The expanding ventricles flatten the cerebral gyri and obliterate the sulci over the cortical surface. Unless the acute obstruction is relieved, increasing pressure may hinder cerebral blood flow, cause cerebral herniation, and compromise brainstem function.

Increasing pressure and ventricular enlargement are associated with necrosis of brain parenchyma. White matter is more vulnerable to destruction than gray matter in the presence of progressive hydrocephalus.

## Management

The management of hydrocephalus is the most common problem in pediatric neurosurgery. In infants and children with symptomatic or progressive ventriculomegaly, the decision to treat with a CSF diversion procedure poses no therapeutic dilemma. However, not all patients with enlarged ventricles require treatment.

In patients with obstructive hydrocephalus secondary to a mass that is surgically accessible, resection of the mass may lead to resolution of the hydrocephalus and a shunt might not be necessary. This situation occurs infrequently in comparison with communicating hydrocephalus. If no documented obstruction or operable lesion is present and the hydrocephalus is mild and slowly progressive, a trial period of observation or medical management may be indicated, especially in preterm infants.

Another situation in which observation is reasonable is arrested hydrocephalus, which is an uncommon state of chronic hydrocephalus in which the CSF pressure has returned to normal and there is no pressure gradient between the cerebral ventricles and the brain parenchyma. Patients should be followed carefully, with neurologic examinations, neuropsychological assessments, and careful assessment of their development. A shunt will be necessary if there is any deterioration of those parameters (Figure 30-5).

Rapid-onset hydrocephalus with increased intracranial pressure is an emergency. Depending on the specific patient, any of the following procedures can be performed: Ventricular tap in infants, external ventricular drainage, lumbar puncture in posthemorrhagic and postmeningitic hydrocephalus, endoscopic third ventriculostomy, or placement of a ventriculoperitoneal shunt.

## Prognosis

Before the 1950s, the outlook of untreated hydrocephalus was extremely poor. The development of satisfactory shunting substantially improved the outlook of children with hydrocephalus but brought its own set of problems and complications. Most children with hydrocephalus will require multiple shunt revisions. Shunt dependence carries a 1% per year mortality. Another series of 907 patients reported a mortality rate of 12% at 10 years from the time of initial shunt insertion, with the main risk factor for death being a history of shunt infection. Shunt-related complications, including death, have been reported to be greater in patients with myelomeningocele than in those who required shunt placement for the treatment of other conditions.

The neurologic and intellectual disabilities among patients with hydrocephalus depend on many factors, including etiology and degree of hydrocephalus, thickness of the cortical mantle and corpus callosum, requirement for a shunt, and

**Figure 30-5. Slit ventricle syndrome.** Patients who have undergone ventricular shunting for hydrocephalus and develop severe headache may have normal or small (as seen in this figure) ventricles on imaging studies. The etiology of this syndrome is best determined in the individual patient by intracranial pressure measurement and can include severe intracranial hypotension analogous to spinal headaches, intermittent obstruction of the ventricular catheter, intracranial hypertension with small ventricles and a failed shunt (normal-volume hydrocephalus), intracranial hypertension with a working shunt (cephalocranial hypertension), or shunt-related migraine.

presence of other brain anomalies. Associated conditions, such as IVH, CNS infection, and hypoxia, may dictate the ultimate prognosis more than the hydrocephalus.

A series of 233 patients with congenital hydrocephalus evaluated for longer than 20 years reported a mortality rate of 13.7%. In this series, 115 patients underwent psychological evaluation; approximately 63% showed normal performance, whereas 30% had mild retardation, and 7% had severe retardation. Another study found that children with congenital hydrocephalus were less likely to require special education placement (29%) than those in whom hydrocephalus was caused by meningitis (52%) or IVH (60%) (Kestle et al, 2000).

Intellectual sequelae include significant scatter among Wechsler Intelligence Scale for Children—Revised (WISC-R) subtest scores, often with greater impairment of performance and motor tasks, as well as of nonverbal compared with verbal skills. Normal intellectual function is present in 40% to 65% of patients who received appropriate treatment. The probability of normal intelligence is enhanced if shunts are placed early and proper function is maintained.

## INTRACRANIAL ARACHNOID CYSTS

### Definition

Intracranial arachnoid cysts are benign, nongenetic developmental cysts that contain spinal fluid and occur within the arachnoid membrane (Gosalakkal, 2002). The mechanism of formation during embryogenesis is uncertain. Several mechanisms could account for the enlargement of these cysts, including secretion by the cells forming the cyst walls, a unidirectional valve, or liquid movements secondary to pulsations

**Figure 30-6. Arachnoid cyst.** **A**, A cystic mass with signal intensity suggestive of cerebrospinal fluid is seen to deform the right temporal lobe (arrows) on this parasagittal image from a T1-weighted magnetic resonance imaging (MRI) study. **B**, Note the eroded appearance of the greater sphenoid wing (arrows) from the arachnoid cyst on this axial image from a spin density-weighted MRI study. (Courtesy of Joseph R. Thompson, Department of Radiation Sciences, Loma Linda University School of Medicine, Loma Linda, California.)

of the veins. The cysts occur in proximity to arachnoid cisterns, most often in the sylvian fissure. Common neurologic features are headache, seizures, hydrocephalus, focal enlargement of the skull, and signs and symptoms of elevated intracranial pressure and developmental delay, as well as specific signs or symptoms resulting from neural compression. Some arachnoid cysts remain asymptomatic. Progressive enlargement and intracystic or subdural hemorrhage are potential complications. Suprasellar arachnoid cysts may produce neuroendocrine dysfunction, hydrocephalus, and optic nerve compression. Posterior fossa cysts are now more frequently recognized with the use of MRI and CT, and frequently require surgical treatment.

In a series of 61 children with arachnoid cysts, 42% were supratentorial and 46% infratentorial. Macrocephaly was the presenting symptom in 72%, and associated features included cranial asymmetry in 39%, aqueductal stenosis in 16%, and agenesis of the corpus callosum in 13%. Developmental delay was a common finding. Skull radiographs may suggest the diagnosis; CT or MRI is the definitive diagnostic procedure (Figure 30-6).

### Clinical Characteristics

Symptoms vary, depending on the size of the cyst and its location. Several common locations have been well described in the literature.

#### Sylvian Fissure/Middle Cranial Fossa

Nearly two thirds of pediatric arachnoid cysts are located in the sylvian fissure/middle cranial fossa. They may increase in volume, opening the fissure and exposing the middle cerebral artery. This exposure may result in compression and underdevelopment of the anterior superior surface of the temporal lobe. Controversy remains concerning whether they originate directly from the meninges adjacent to the temporal pole, or whether partial agenesis of the temporal lobe favors secondary formation of the cyst. Headaches are the most common presenting symptom; proptosis, contralateral motor weakness,

and seizures also may occur. In 10% of children, developmental delay may be present. Treatment depends on clinical symptoms. Recent studies have suggested some cognitive improvement after surgical treatment. Children with bitemporal arachnoid cysts also should be evaluated for the possibility of glutaricaciduria type 1 or neurofibromatosis.

#### Sellar Region

Both suprasellar and intrasellar cysts can occur in children. Suprasellar cysts can cause third ventricular obstructive hydrocephalus at the level of the foramen of Monro, and may be associated with visual impairment and endocrine dysfunction. Progressive head enlargement, growth retardation, developmental delay, and bitemporal hemianopsia have all been described. A bobble-head doll syndrome, with involuntary head movements secondary to increased pressure on the third ventricle and dorsomedial thalamic nuclei, is responsible. Endoscopic surgical approaches are now preferred.

#### Posterior Fossa

Arachnoid cysts of the posterior fossa are uncommon and must be differentiated from other cystic malformations of the posterior fossa, such as the DWM. Macrocrania and raised intracranial pressure are frequently observed. Cerebellar cysts demonstrate nystagmus and other cerebellar signs. Other rare manifestations reported include cervical spinal cord compression, which may improve after posterior fossa cystoperitoneal shunting or endoscopic surgery. In such patients, gait disturbances and headache are commonly seen.

### Complications

Several clinical complications are believed to be associated with arachnoid cysts, although the relation between cyst presence and development of symptoms remains controversial; thus, the decision to operate is difficult and must be made on a patient-by-patient basis. Surgery is indicated when the cyst is causing obstructive hydrocephalus or if neuroimaging

demonstrates mass effect, with compression of normal brain or brainstem structures. The relation between symptoms such as attention-deficit disorder, aphasia, or migraine-like headaches is uncertain, and correlation between cyst location and specific symptoms or congruent electroencephalogram (EEG) abnormalities is necessary before symptoms can be attributed to the cyst.

### Epilepsy

Anecdotal studies suggest a relation between seizure reduction and removal of arachnoid cysts. The relation between the presence of arachnoid cysts and occurrence of seizures when the intracranial pressure is normal is uncertain, however, and outcomes, whether patients are managed medically or surgically, are similar. In addition, interictal and ictal EEG may not correspond to the site of the arachnoid cyst, raising the question whether the presence of an EEG abnormality is incidental.

### Subdural Hematoma and Hygroma

Subdural hematomas and hygromas are infrequently encountered complications of arachnoid cysts of the middle cranial fossa and are particularly rare with cysts in other regions. Minor head trauma has been suggested to be a precipitating factor. Arachnoid cysts of the middle cranial fossa were found in 2.4% of patients with chronic subdural hematomas or hygromas in one report.

### Neuropsychiatric Disorders

Attention-deficit/hyperactivity disorder, speech delay, and developmental delay have been found in association with arachnoid cysts, particularly in the temporal lobe, but a causal relation remains uncertain. Mental impairment and developmental delay have been associated with large arachnoid cysts, and the presence of cysts and developmental delay may be part of a common developmental process. Recent studies have suggested improvements in cognition after surgical treatment. The increased incidence of arachnoid cysts in conditions such as Down syndrome, mucopolysaccharidoses, schizencephaly, and neurofibromatosis suggests a higher incidence in children with underlying abnormalities of the brain. Aphasia, including that of Landau-Kleffner syndrome, also has been associated with the presence of left sylvian arachnoid cysts. Even in patients in whom CT and MRI failed to reveal mass effect, positron emission tomography (PET) has demonstrated hypometabolism in speech areas. Postoperative improvement in PET studies corresponded to improvement in vocabulary.

### Management

When symptoms warrant, surgical intervention to decompress the cyst, including endoscopic management or shunting procedures, is required. Arachnoid cysts may occur with or without hydrocephalus. The success rate of fenestration is higher in those patients without hydrocephalus (i.e., 73% required no additional treatment) than in hydrocephalus patients (32%). About 12% of patients with hydrocephalus treated with fenestration alone may require a cystoperitoneal

shunt. In general, cyst fenestration should be the primary procedure in patients without hydrocephalus. If hydrocephalus is present, cyst fenestration is still recommended, but a ventriculoperitoneal (VP) shunt should be placed if hydrocephalus is marked or after fenestration if the hydrocephalus is progressive.

### CONCLUSIONS

Pediatric hydrocephalus, arachnoid cysts, and benign extra-axial collections are common, complex, and, in many ways, poorly understood disorders. Whereas persistent efforts over the last century to improve understanding and, where required, treatment of these disorders have had modest success, recent advances in imaging, neurophysiology, and molecular biology have led to important discoveries, suggesting that significant advances are imminent.

### E-BOOK FIGURES AND TABLES

The following figures and tables are available in the e-book at [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Fig. 30-1 Cerebrospinal fluid pathway.

Fig. 30-2 Posthemorrhagic hydrocephalus.

Box 30-1 Differential diagnosis of hydrocephalus.

Table 30-1 Causes of hydrocephalus.

Table 30-2 Summary of Current Known Loci of Hydrocephalus in Humans

Table 30-3 Distribution of Arachnoid Cysts

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Congenital anomalies of the skull can arise any time during gestation. During the first 4 to 6 weeks of development from conception, neural crest cells in the fetal head region migrate and differentiate into mesenchymal cells that form the bones of the face, whereas the cranial base and base of the skull are derived from the occipital somitomeres. The viscerocranium is derived from neural crest and it forms the cartilaginous bones of the face (Sadler and Langman, 2009). The neurocranium develops directly from mesenchyme derived from the occipital somitomeres through membranous ossification and is divided into the membranous part, forming the flat bones of the cranial vault, and the chondrocranium, forming the cartilaginous bones of the base of the skull.

There are six fibrous areas where two or more cranial bones meet (fontanels). The five major sutures are the metopic, sagittal, coronal, squamosal, and lambdoid sutures; the six fontanels are the anterior (one), anteriolateral (sphenoidal) (two), posterolateral (two), and posterior (one) fontanels (Figure 31-1). The presence of the sutures and fontanels allows the bones of the skull to overlap each other (termed *molding*) during the birth process. Different sutures become ossified at different times, with the metopic suture being the first to ossify at 4 to 7 months and the remaining sutures not completely ossifying until adulthood.

## CRANIOSYNOSTOSIS VERSUS DEFORMATIONAL PLAGIOCEPHALY

Craniosynostosis is the process of premature sutural fusion that results in craniostenosis (literally “cranial narrowing”). *Plagiocephaly* is a nonspecific term used to describe an asymmetric head shape, which can result from either craniosynostosis or positional cranial deformation, and differentiation between these two causes is critical to determining the proper mode of treatment (i.e., surgery vs. physical or molding techniques). Craniosynostosis is usually treated with a neurosurgical procedure involving partial calvariectomy, whereas deformational plagiocephaly usually responds to early physical therapy, repositioning, and/or cranial orthotic therapy if those measures are unsuccessful.

In an otherwise structurally normal fetus, prenatal relaxation of normal growth-stretch tensile forces in the underlying dura across a suture for a significant period during late fetal life can result in craniosynostosis. This may also occur when the lack of growth stretch is caused by a deficit in brain growth, as in severe primary microcephaly. The most common cause of craniosynostosis in otherwise normal infants is constraint of the fetal head in utero. Factors that influence fetal constraint may include multiple birth gestation, macrosomia, oligohydramnios, and maternal uterine malformations (e.g., uterine fibroids, bicornuate uterus). When external fetal head constraint limits growth stretch parallel to a cranial suture, it may lead to craniosynostosis of an intervening suture between the constraining points. Sagittal craniosynostosis (the most common type of craniosynostosis) usually is isolated

and occurs in an otherwise normal child. The constrained suture tends to develop a bony ridge, especially at the point of maximal constraint between the biparietal eminences. Such ridging can easily be palpated or visualized on skull radiographs, and three-dimensional cranial computed tomography (3D-CT) allows the ridge to be seen even more clearly (Figure 31-2).

Craniosynostosis is usually recognized shortly after birth from the abnormal shape of the head and lack of molding resolving to normal. Early closure of a fontanel, head asymmetry, and/or palpable ridging along a closed suture can be presenting features. If there is uncertainty whether sutures are truly synostotic, 3D-CT can provide a more accurate appraisal (see Figure 31-2).

Synostosis prevents future expansion at that site, and the rapidly growing brain then distorts the calvarium into an aberrant shape, depending on which sutures have become synostotic (Figure 31-2). The earlier the synostosis takes place, the greater the effect on skull shape. Craniosynostosis may be caused by many different mechanisms, such as mutant genes, chromosome disorders, storage disorders, hyperthyroidism, or failure of normal brain growth (Table 31-1). The entire topic of craniosynostosis has been comprehensively reviewed (Cohen and MacLean (2000).

## Sutural Anatomy and Head Shape

Different terms have been used to describe the varying head shape alterations caused by craniosynostosis, with the resultant head shape dependent on the suture involved. An elongated keel-shaped skull with prominent forehead and occiput is termed *dolichocephaly* or *scaphocephaly*. This head shape is usually associated with premature sagittal suture closure and a palpable ridge toward the posterior end of the suture (see Figure 31-2).

Premature fusion of both coronal sutures produces a high, wide forehead with a short skull, resulting in brachycephaly, whereas fusion of one coronal suture produces an asymmetric head shape. When coronal craniosynostosis occurs, it is important to examine the patient carefully for associated anomalies that might suggest a recognizable genetic syndrome such as thumb anomalies in Pfeiffer syndrome, ambiguous genitalia in Antley-Bixler syndrome, or polysyndactyly in Apert syndrome. Synostosis of multiple cranial sutures is more likely to result in elevated intracranial pressure and to require shunting for hydrocephalus. In extreme cases, a cloverleaf head shape can result from multiple suture synostosis, usually with signs of increased intracranial pressure and a “beaten copper” radiographic appearance of the inner table of the skull.

A triangle-shaped skull (trigonocephaly) is caused by premature fusion of the metopic suture (see Figure 31-2). Syndromic metopic synostosis can also occur, and trigonocephaly is seen in a variety of syndromes, some of which are associated with mental retardation or chromosome anomalies.

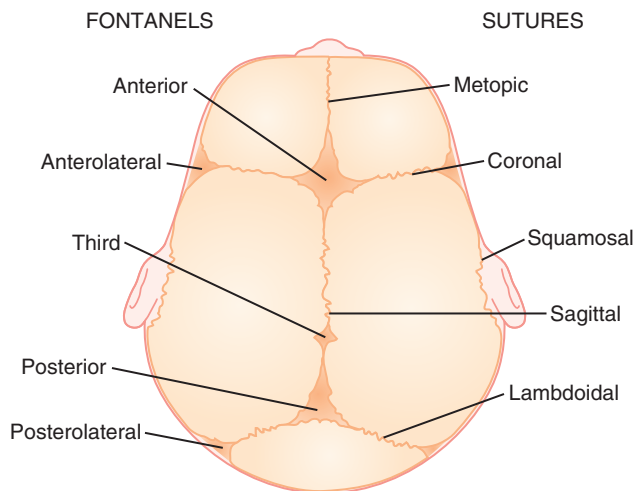

Unilateral lambdoid synostosis results in trapezoidal plagiocephaly, which differs from deformational posterior

plagiocephaly because of supine positioning and torticollis, and from synostotic anterior plagiocephaly because of unicoronal synostosis (see Figure 31-2). Radiographic signs include trapezoidal cranial asymmetry, small posterior fossa, and sutural sclerosis with ridging; however, sole reliance on skull radiographs and clinical signs can lead to misdiagnosis, so it is best to confirm the diagnosis of suspected lambdoid synostosis with a 3D-CT scan.

*Plagiocephaly* (which translates literally from the Greek term *plagio kephale* as “oblique head”) is a term used to describe asymmetry of the head shape, when viewed from the top (Graham and Sanchez-Lara, 2016). The term *deformational plagiocephaly* should suffice to distinguish this type of defect and its proper type of management. The side of the plagiocephaly is usually indicated by the bone that has been most flattened by the deforming forces (usually the occiput for infants who sleep on their backs). Deformational plagio-

cephaly is usually not associated with premature closure of a cranial suture, but because craniosynostosis can also be caused by fetal head constraint, when both deformational plagiocephaly and craniosynostosis occur together, the diagnosis can be difficult, requiring complex management.

Infants with limited mobility because of hypotonia, hydrocephalus, macrocephaly, or limb anomalies are also more likely to develop deformational plagiocephaly, which can complicate syndromes with these features. Predisposing factors resulting in excessive or asymmetric head deformation include restrictive intrauterine environments, poor muscle tone, torticollis, clavicular fracture, cervical-vertebral abnormalities, sleeping position, multiple gestation, and incomplete bone mineralization. The development of excessive positional brachycephaly, with or without plagiocephaly, can be an early indication of hypotonia or that parents are not providing their infants with adequate “tummy time.”

### Epidemiology of Craniosynostosis

The incidence of craniosynostosis is 3.4 per 10,000 births, and it is usually an isolated, sporadic anomaly in an otherwise normal child. A specific genetic etiology can be identified in approximately 21% of cases. About 8% of all craniosynostosis cases are familial. Familial types of craniosynostosis are seen frequently in coronal synostosis, accounting for 14.4% of coronal synostosis, 6% of sagittal synostosis, and 5.6% of metopic synostosis, whereas lambdoidal synostosis is almost never familial. The frequency of associated twinning is increased, and most twin pairs are discordant, especially with sagittal and metopic synostosis, which would tend to support fetal crowding as a cause for these types of synostosis; concordance for coronal synostosis is much higher for monozygotic twins than for dizygotic twins, suggesting that many cases of coronal synostosis have a genetic basis.

Sagittal synostosis is the most common type of craniosynostosis, accounting for 50% to 60% of cases and occurring in 1.9 per 10,000 births, with a 3.5:1 male-to-female sex ratio.

Only 6% of cases are familial, with 72% of cases sporadic and no paternal or maternal age effects noted. Twinning occurred in 4.8% of 366 cases, with only one monozygotic twin pair being concordant.

Coronal craniosynostosis is the second most frequent type of craniosynostosis (accounting for 20% to 30% of cases). Unilateral coronal craniosynostosis can be either genetic or caused by fetal head constraint from an aberrant fetal lie, multiple gestation, or small uterine cavity. Approximately 71% of unilateral coronal craniosynostosis is right-sided, and 67% of vertex presentations are in the left occiput transverse position, possibly explaining the prevalence of right-sided, unilateral, coronal craniosynostosis. Nonsyndromic coronal craniosynostosis occurs 0.94 per 10,000 births, with 61% of cases sporadic, and 14.4% of 180 pedigrees familial. Bilateral cases occur much more frequently than unilateral cases, and coronal synostosis is more frequent in females (male-to-female ratio 1:2). The paternal age is statistically older than average (32.7 years), and these data have been interpreted as being consistent with fresh dominant mutation and autosomal-dominant inheritance with 60% penetrance, when the synostosis has a genetic basis.

Metopic synostosis occurs in about 0.67 per 10,000 births, making it the third most frequent type of craniosynostosis (accounting for 10% to 20% of patients). Like sagittal synostosis, metopic synostosis is more frequent in males (3.3:1

male-to-female ratio) and seldom familial (5.6% of cases). There is no maternal or paternal age effect, and the frequency of associated twinning was 7.8% of 179 pedigrees studied, with only 2 twin monozygotic pairs concordant.

Familial craniosynostosis is usually transmitted as an autosomal-dominant trait with incomplete penetrance and variable expressivity. A wide variety of chromosomal anomalies have also been associated with craniosynostosis with microdeletions and duplications detected by karyotype or chromosome microarray analysis. Deletions of 9p and 11q, microdeletions, and translocations disrupting *TWIST1* on chromosome 7p have all been described. In addition, craniosynostosis can also occur as a feature of several genetic syndromes, many of which manifest phenotypic overlap and genetic heterogeneity. Single-gene disorders associated with craniosynostosis include Apert syndrome, Crouzon syndrome, Pfeiffer syndrome, Saethre-Chotzen syndrome, Jackson-Weiss syndrome, Boston craniosynostosis, Beare-Stevenson cutis gyrate syndrome, and Muenke syndrome.

Secondary craniosynostosis can occur with certain primary metabolic disorders (e.g., hyperthyroidism, rickets), storage disorders (e.g., mucopolysaccharidosis), hematological disorders (thalassemia, sickle cell anemia, polycythemia vera), brain malformations, and selected teratogenic exposures (e.g., diphenylhydantoin, retinoic acid, valproic acid, aminopterin, fluconazole, cyclophosphamide) (Cohen and MacLean, 2000).

Bilateral coronal synostosis often lacks sutural ridging and usually has a genetic pathogenesis. Some have suggested that all patients should be screened for mutations in one or more of the following genes: *CD96*, *EFNB1*, *ERF*, *FGFR1*, *FGFR2*, *FGFR3*, *GLI3*, *IFT122*, *MEGF8*, *MSX2*, *POR*, *RAB23*, *RECQL4*, *RUNX2*, *SKI*, *TCF12*, and *TWIST1*. In 2010 Wilkie et al. established a genetic diagnosis in 21% of cases (86% monogenic disorders, and 14% chromosomal disorders), with the most frequently involved genes *FGFR2* (32%), *FGFR3* (25%), *TWIST1* (19%), and *EFNB1* (7%) (Wilkie et al., 2010). Inability to demonstrate a mutation does not rule out a genetic basis for the craniosynostosis, and not every person with a pathogenic mutation manifests craniosynostosis.

### Kleeblattschädel (Cloverleaf Skull)

*Kleeblattschädel* is a term used to describe a cloverleaf skull configuration consisting of protrusion of each of the cranial bones, with broadening of the temporal region and face. These cranial protrusions are separated into focal bulges by furrows along the suture lines. The eyes often protrude, leading to corneal ulceration, scarring, and subsequent blindness, if the corneal surface remains unprotected. Occipital encephaloceles can occur, and associated hydrocephalus is common. The presence of *kleeblattschädel* indicates that multiple sutural fusions occurred during early prenatal life. Increased thickening of the base of the occipital bone prevents lengthening of the skull, thus yielding the typical shape.

Multiple sutural synostosis is much more likely to result from genetic mutations in *FGFR* genes, *TWIST*, or *MSX2*, all of which result in syndromes that can present with cloverleaf skull (Cohen and MacLean, 2000).

Patients with *kleeblattschädel* need to be followed carefully for hydrocephalus, which may be part of the syndrome, rather than attributable to the multiple suture synostosis. The purpose of surgery should be to decompress the brain, expand the bony orbits to accommodate the globes, and open airway passages.

### Treatment and Outcomes of Craniosynostosis

Mild degrees of craniosynostosis may not always require surgery. The usual indication for surgery is to restore normal craniofacial shape and growth. When both the coronal and sagittal sutures are synostotic, impairing brain growth early in infancy, surgery is indicated to prevent neurologic and ophthalmologic complications associated with increased intracranial pressure and inadequate orbital volume. Several neurosurgical techniques have been developed for the treatment of craniosynostosis. Most of these techniques involve removing the aberrant portion of the bony calvarium from its underlying dura, including the area surrounding the synostotic suture(s). Newer endoscopic repair techniques have been developed, followed by postoperative orthotic molding. Such procedures are most effective if performed relatively early in infancy. These techniques are most effective in normal infants without a syndromic type of craniosynostosis.

One comorbidity of synostosis is hydrocephalus, which may occur secondarily, or be a part of a genetic craniosynostosis syndrome. This occurs in 4% to 10% of patients with craniosynostosis and is more frequent with syndromic and multiple sutural craniosynostosis. In nonsyndromic patients, the rate of cerebral ventricular dilatation is the same as that observed in the general population. Such dilatation usually stabilizes spontaneously and rarely requires shunting. Some cases of progressive hydrocephalus in syndromic craniosynostosis cases were related to multiple sutural involvement, thereby constricting cranial volume, constricting the skull

base, crowding the posterior fossa, and causing jugular foramen stenosis. These findings were most frequent among patients with Crouzon, Pfeiffer, or Apert syndrome, especially in association with cloverleaf skull abnormalities. A diffuse beaten copper pattern on skull radiographs, along with obliteration of anterior sulci or narrowing of basal cisterns in children under the age of 18 months, is predictive of increased intracranial pressure in over 95% of cases.

### Nonsyndromic Craniosynostosis Neurocognitive Development

There is a growing body of evidence that single-suture craniosynostosis is associated with neurobehavioral problems. Syndromes with multiple-suture fusions have more commonly been associated with elevated rates for intellectual disability and learning disabilities. Most studies have found adverse neurocognitive outcomes in about 35% to 40% of assessed cases, with an occasional study finding this number to be as high as 50%. A few studies have reported a 3- to 5-times higher-than-average risk of poor neurobehavioral outcome. In studies that directly measured the IQs of children with sagittal synostosis, a discrepancy of greater than 20 standard score points between language and nonverbal IQ scores was found.

Sagittal synostosis has not been found to affect the neurologic function of the infant or toddler significantly (Kapp-Simon et al., 1993). However, some studies conducted in older children have found moderate to severe speech and language difficulties in up to 37% of cases, and the tendency toward such problems is associated with a positive family history for such difficulties and later age of surgical correction.

In a long-term neurodevelopmental outcome study of nonsyndromic cases, correlation was found between outcomes and timing of surgery, with 22.6% of those operated on before 12 months showing impaired mental development versus 52.2% impaired mental development in those who underwent surgery after age 12 months. Overall, 31% of cases of trigonocephaly were observed to have delayed development, and this appeared to be related to the severity of the malformation and the presence of associated malformations. There is preliminary evidence that surgical management with whole-vault cranioplasty performed before 6 months of age provides the most favorable long-term intellectual outcomes in patients with isolated sagittal synostosis.

### WIDE CRANIAL SUTURES

Cranial sutures are considered to be widened when the sutural separation is more than 2 SD above the mean sutural width for age. Wide cranial sutures in themselves cause no impairment, but they can be an indication of increased intracranial pressure or caused by craniosynostosis in another part of the skull. The younger an infant begins to have increased intracranial pressure, the earlier sutural diastasis will appear. If the wide cranial sutures are caused by defective or delayed ossification, no treatment is generally indicated as the ossification will improve and sutural width will decrease with age.

### ANOMALIES OF FONTANELS

A fontanel measuring either 2 SD above or 2 SD below the mean for age is termed large or small, respectively. Closure of the anterior fontanel before 6 months is considered early, whereas closure after 18 months is considered late. The other fontanelles are normally closed at term gestation.

The anterior fontanel is the largest of the fontanelles and normally closes by 18 months. A small or absent anterior

fontanel usually indicates some type of underlying pathology, with the most common etiologies including any cause of congenital microcephaly, craniosynostosis (particularly involving the metopic suture), or accelerated bone maturation such as that occurs in hyperthyroidism.

Large fontanels may be noted at birth by palpation and confirmed by measurement. Causes of both large fontanels and delayed closure include increased intracranial pressure or delayed ossification of the cranium caused by an underlying genetic, nutritional, or metabolic etiology. Cleidocranial dysplasia typically results in delayed closure of the anterior fontanel with widened cranial sutures and hypoplastic clavicles. Although early or late closure of the fontanel is reasonably common, care must be taken to rule out underlying pathology.

### CRANIAL DERMAL SINUS

A cranial dermal sinus is a midline depression or tract lined by stratified squamous epithelium that extends from the skin toward the central nervous system or its coverings. Cranial dermal sinuses are most common in the occipital region, but can be found anywhere. Clinical presentation is often as a cutaneous localized swelling that presents an infection or cystic expansion of the sinus tract beneath the skin surface, occasionally with drainage. Occasionally, cystic expansion occurs within the cranial cavity, which obstructs cerebrospinal fluid flow, compresses the adjacent neural structures, and/or ruptures to cause sterile meningitis, which can be recurrent.

In the facial region, the most frequent congenital midline mass is a nasal dermoid sinus cyst, which can have intracranial extension and be associated with other anomalies. Nasal dermoid sinus cysts usually arise sporadically, although reports of familial occurrence have been documented. Nasal pits are present in 50% of patients with nasal dermoids and intracranial extension noted in 36% to 45% of cases. Associated anomalies were present in 41% of one series examined by a multidisciplinary team, and they were associated with many different syndromes and chromosome anomalies. Complications can result from enlargement of the cyst, skeletal distortion, and recurrent infection. The recommended treatment of the tract and any associated dermoid tumor or cyst is surgery.

### PARIETAL FORAMINA (INCLUDING CRANIUM BIFIDUM)

Parietal foramina are small defects in the superoposterior angles of the parietal bones through which emissary veins may pass through the calvarium (Figure 31-5). Usually, parietal foramina present as symmetric oval defects situated on each side of the sagittal suture, and their size diminishes with age. They are covered with normal scalp and hair, and are detected through palpation and radiography. Occasionally, brain covered by dura and intact scalp can bulge through extensive lesions, suggesting the possibility of an encephalocele, but the location of these lesions off the midline differentiates them from neural tube closure defects (Epstein and Epstein, 1967).

Parietal foramina are usually small and only detectable radiographically; however, 10% are 5 mm or more and can be as large as 50 mm in diameter. Small parietal foramina are found in 60% to 70% of all adults, whereas large parietal foramina are present in less than 1% of adults. Small unilateral defects are more common than bilateral defects. When the defect is unilateral, it more often involves the right side, and males are more commonly affected than females, with a ratio of 5:3. Parietal foramina themselves cause no impairment, usually manifest autosomal-dominant inheritance with

**Figure 31-5. Parietal foramina.** A and B, Large parietal defects at birth detected by MRI. C, Partial closure by age 16 months on skull radiograph.

variable expression, and can occur as part of the phenotype in a few syndromes.

### WORMIAN BONES

Wormian bones were named after Dr. Worm, who initially described them as accessory bones that occur within cranial suture lines or fontanels. They can occur singly, or in large numbers, and are diagnosed radiographically. Wormian bones could be mistaken for a skull fracture, but experienced radiographic interpretation should resolve this error. They can occur within any suture but are rare in coronal or sagittal sutures. Although they do not cause any impairment themselves, their significance is variable.

The pathogenesis of Wormian bones is thought to be related to intracranial strain along with open sutures causing ossification defects. Although the prevalence of Wormian bones in the general population is as high as 17%, the prevalence varies with age. Males are more often affected than

females, and differences between ethnic groups have been noted. Wormian bones are commonly seen in osteogenesis imperfecta and other disorders resulting in defective cranial bone mineralization. The more severe the defective mineralization, the more numerous the Wormian bones, and such infants can also become quite brachycephalic as a consequence of postnatal supine positioning with soft cranial bones.

### SCALP VERTEX APLASIA

Scalp vertex aplasia, or aplasia cutis congenita (ACC), is a relatively common congenital defect resulting in localized absence of skin, usually occurring on the scalp as an isolated finding not associated with other abnormalities. Scalp vertex aplasia begins as multiple or solitary, sharply marginated, raw areas with absence of skin. These lesions mature into atrophic scars devoid of adnexal structures, usually in the vertex area or midline superior occipital region. The cause of these lesions is heterogeneous and includes vascular disruption, trauma, teratogens, and genetic factors. The frequency is 1 per 3000 live births, and a classification system of subtypes for ACC has been suggested by Frieden. With prompt closure and a healthy underlying dura, cranial bone growth will occur after prompt early wound closure, and the risk of fatal hemorrhage or meningitis is greatly lessened.

### THIN CRANIAL BONES

Thin cranial bones have little or no diploë, which is the spongy intervening bone separating the outer and inner layers. The diagnosis of thin cranial bones is made radiographically and is usually subjective. Thin calvarial bones can be secondary to craniosynostosis (particularly adjacent to the ridging in sagittal synostosis) and hydrocephalus, or can occur as part of several syndromes in which undermineralization is a feature. Areas of radiolucency are called craniolacunae (luckenschadel) and are often secondary to spinal dysraphism. These generally disappear by age 1 year. Regionally thinned areas can also occur in association with porencephaly, subdural hygroma, arachnoid cyst, and some tumors. Craniolacunae probably do not occur as isolated traits. Prognosis depends on the underlying etiology, and lacunar skull defects themselves have no direct effects on the infant.

### UNDERMINERALIZATION OF THE SKULL

Undermineralization of the skull results in increased radiolucency of the cranial bones and is attributable to decreased calcium deposition. Congenital under mineralization occurs in several syndromes, particularly osteogenesis imperfecta and hypophosphatasia. Hypophosphatasia occurs in at least three forms, including infantile, childhood, and adult forms. Undermineralization is most pronounced in the infantile form and is least evident in the adult form. The infantile form can usually be diagnosed by fetal ultrasonography, whereas the other forms are often diagnosed after birth by radiographs and measurement of serum alkaline phosphatase levels (Goodman and Gorlin, 1983). Fluorosis and vitamin D-dependent rickets can also produce postnatal undermineralization of the skull, but areas of sclerosis are also present in fluorosis. The incidence of undermineralization is low, and prognosis is dependent on cause, varying widely from stillbirth or death during infancy to little effect at all.

### CRANIOTABES

Prolonged forceful pressure on the fetal vertex may result in diminished cranial mineralization affecting the superior

portions of the parietal bones. Such craniotabes is more likely to occur in first-born infants, especially with early fetal head descent into a vertex presentation for a prolonged period. Mild degrees of craniotabes occur in about 2% of newborn babies, and more extensive degrees of craniotabes are less common. Craniotabes was first described in congenital syphilis, and it can also be seen with subclinical rickets because of vitamin D deficiency. Rickets should be considered in any infant with a nonvertex presentation, whose mother might be at risk for nutritional deficiency, and such infants usually manifest generalized craniotabes with osteomalacia.

With compression-related craniotabes, the prognosis is excellent, and the calvarium usually mineralizes in a normal fashion within 2 to 3 months after birth. If the mother has vitamin D-deficient rickets and there is more generalized craniotabes and osteomalacia, this condition usually manifests a prompt response to vitamin D therapy over the next few months. As in other defects of skeletal mineralization, such as osteogenesis imperfecta and hypophosphatasia, initial care must be taken to avoid fractures. Infants with osteogenesis imperfecta or hypophosphatasia usually show generalized osteomalacia, brittle bones, and Wormian bones.

### THICK CRANIAL BONES

Increased thickness of cranial bones is detected on radiographic examination, and there may be normal or increased cranial density. The diagnosis of a thickened cranium is made radiographically, although no formal criteria have been established for determining whether cranial bones are thick. Although there is wide variability among different individuals, the thickest part of a normal cranium is not, in general, any greater than 1 cm. There are both ethnic- and sex-related variations in skull thickness. Women have thicker skulls than men, and blacks have thicker skulls than whites.

Several syndromes with thick calvarial bones have been described, including Pyle disease, Robinow syndrome, Fountain syndrome, autosomal-dominant osteopetrosis, and pseudohypoparathyroidism. It is unknown whether thick cranial bones can occur as an isolated trait, and the prognosis depends on the underlying condition. In hemolytic diseases, such as thalassemia, vertical striations ("hair-on-end" appearance) occur, whereas in bone diseases such as osteopetrosis, sclerosis occurs. Overgrowth of the middle table can also occur in microcephaly. In situations in which a shunt has been placed to relieve hydrocephalus, thickening of both inner and middle tables can occur.

### SCLEROSIS AND HYPEROSTOSIS OF THE SKULL

Increased density or overmineralization of the cranial bones can be generalized or localized, and this is termed *sclerosis* or *hyperostosis of the skull*. Sclerosis generally refers to an increase in bone density without an alteration in width, whereas hyperostosis is caused by bone overgrowth that leads to an increase in density and width, though not all cases fit cleanly into one category or the other (Kozlowski and Beighton, 1995). Hyperostosis is distinct from thick cranial bones, although hyperostosis and occasionally sclerosis can also cause thick cranial bones. Most of the sclerosing bone dysplasias manifest generalized changes, which are classified on the basis of the distribution and configuration of these abnormalities (Kozlowski and Beighton, 1995).

The presence of sclerosis or hyperostosis can be diagnosed radiographically or by CT, and scintigraphy may provide information on disease progression (Figure 31-8). Radiologic changes are age related, and definitive diagnosis may be difficult in early childhood (Kozlowski and Beighton, 1995). All

Figure 31-8. Craniometaphyseal dysplasia presenting with progressive craniofacial changes and hearing loss.

conditions that cause generalized osteosclerosis affect the skull (Kozłowski and Beighton, 1995). Localized sclerosis of the base of the skull can occur in polyostotic fibrous dysplasia, Jansen-type metaphyseal dysplasia, severe anemia, hypercalciuria, and Paget's disease. It may also be seen with a meningioma or inflammation (Kozłowski and Beighton, 1995). Symptoms include narrowing of cranial nerve foramina, which in turn can cause nerve palsy, deafness, or vision defects. Increased intracranial pressure is not uncommon, and papilledema can also occur as a complication. Two primary pathologic processes can lead to sclerosis: overproduction of bone and failure of osteoclastic absorption of bone. The prognosis depends on the underlying cause and varies from individuals being asymptomatic to sudden death from medullary compression. In addition, facial palsy, as well as hearing and vision loss, may occur because of cranial nerve compression within stenotic foramina, which may require surgical decompression. Craniotomy to relieve increased intracranial pressure may also be indicated.

### ANOMALIES OF THE SELLA TURCICA

Anomalies include abnormal size and/or shape of the sella turcica, which is the central depression within the sphenoid bone that contains the pituitary gland. Assessment of the sella turcica can be best established radiographically using a lateral skull x-ray or by CT scan using the "bone window" setting. It is a critical landmark for orthodontics and craniofacial morphology, and variants in shape should be noted in orthodontic planning. A small or absent sella has been described in patients with hypopituitarism and myotonic dystrophy, whereas a large sella occurs in patients with storage disorders, pituitary tumors, empty sella syndrome, craniopharyngioma, intrasellar aneurysm, untreated hypogonadism, and hypothyroidism.

A J-shaped sella describes the lateral profile of the sella turcica, in which the sella resembles a "J" lying on its side. A J-shaped sella can occur as a normal variant, but may also occur in individuals with calvarial enlargement or optic nerve gliomas (Swischuk, 1972). Bridged sella is caused by bony bridging between anterior and posterior clinoids and can be a normal variant. It can also be seen in neurofibromatosis type 1 (NF1), neurofibrosarcoma, craniofaciocaudal syndrome, geophysic dysplasia, and lysosomal storage disorders.

### ANOMALIES OF TEMPORAL BONE

Congenital anomalies of the temporal bone (including external, middle, and inner ear abnormalities) can cause significant morbidity in children such as hearing loss and balance problems. A complete discussion of the myriad of congenital temporal bone anomalies is beyond the scope of this chapter. Jackler et al. proposed the most commonly used classification of inner ear abnormalities. Inner ear malformations consist of complete labyrinthine aplasia, cochlear aplasia, common cavity, incomplete partition type I & II, cochlea hypoplasia, semicircular canal abnormalities, and enlarged vestibular aqueduct (Yiin et al., 2011).

### ANOMALIES OF FORAMEN MAGNUM

The foramen magnum is an oval-shaped opening in the occipital bone bound by the basiocciput anteriorly, the occipital condyles laterally, and the supraocciput posteriorly. If premature suture fusion occurs and/or endochondral ossification is abnormal, a small foramen magnum is the result. Anomalies of the foramen magnum include either small or large size, or a keyhole shape. In a retrospective review of

3D-CT on 101 patients, Göçmez ranked their frequency. MRI best achieves diagnostic assessment of foramen magnum size or shape, although x-ray or CT may also be used. Reference tables have been published indicating normal foramen magnum size. The clinical effects of a small foramen magnum vary from asymptomatic individuals to those with weakness, apneic spells, hyperreflexia, hydrocephalus, and abnormal somatosensory-evoked potentials and/or polysomnograms. Achondroplasia is the most common syndrome with a small foramen magnum, but other skeletal dysplasias and disorders associated with sclerosis of the skull can also lead to a small foramen magnum. A large foramen magnum usually results from chronic increased intracranial pressure or from direct effects of an expanding process within the foramen magnum (syringomyelia, Arnold-Chiari malformation). Asymmetry of the foramen magnum occurs with craniovertebral anomalies or premature synostosis of one or more of the occipital synchondroses. Children with the latter may tend to hold their heads obliquely. A keyhole-shaped foramen magnum has been described in the hydrolethalus syndrome.

Prognosis for a small foramen magnum is variable, but the most serious outcome of brainstem compression may be sudden death. Recommended treatment is suboccipital craniectomy. The prognosis for a large or abnormally shaped foramen magnum is dependent on the underlying cause.

### ANOMALIES OF THE OTHER BASAL FORAMINA AND CANALS

There are at least 11 foramina and canals in the base of the cranium through which blood vessels and nerves enter or leave the intracranial space. Congenital anomalies include asymmetry of paired foramina, communication with other foramina, and absence if the transmitted structure is absent. Anomalies of any of these foramina can include abnormal opening size or configuration and are typically incidental findings discovered on scans obtained for other purposes.

### BASILAR IMPRESSION

Basilar impression is a malformation or deformation of the cranial base consisting of indentation of the base of the skull at the craniospinal junction. Basilar impression may be suspected when there is limited movement and shortening of the neck, but definitive diagnosis requires radiography, CT scan, or MRI scan. In basilar impression, the odontoid moves cephalad and can protrude into the foramen magnum, thus compromising function of the spinal cord, brainstem, and cerebellum, as well as impeding the flow of cerebrospinal fluid. Symptoms include pain, limitation of movement, increased intracranial pressure, hydrocephalus, and cranial nerve symptoms. Symptoms may appear suddenly or develop over several months.

Primary basilar impression is caused by a congenital defect of osseous structures in the cervico-occipital region, and can occur as an autosomal-dominant trait. Secondary basilar impression is related to disease of the skull and has been reported in association with osteogenesis imperfecta, Hajdu-Cheney syndrome, and several endocrine disorders.

Affected individuals may be asymptomatic, develop sudden or progressive symptoms, or die suddenly. Treatment consists of immobilization or, in severe cases, decompression of the foramen magnum, laminectomy of the first and second cervical vertebrae, and cervico-occipital fusion. Shunting for hydrocephalus may also be indicated. Cranial base pathology is a serious complication of osteogenesis imperfecta, and early bisphosphonate treatment may delay development of cranio-cervical junction pathology.

## Bathrocephaly

Bathrocephaly is a skull deformation that appears as a step-like deformity at the back of the skull, and it is also termed *an occipital shelf*. It is not associated with craniosynostosis, but can occur secondary to breech position in utero and has been associated with a persistent mendosal suture. In general, this anomaly is of no significance, and spontaneous improvement usually occurs. Prognosis is poor only if breech position is secondary to malformation or neurologic dysfunction.

## Occipital Horns

Occipital horns are bony protuberances situated on both sides of the foramen magnum and pointing caudad. They have been described only in individuals with an X-linked syndrome, Ehlers-Danlos type IX, or a mild form of Menkes disease caused by mutation in the gene encoding Cu(2+)-transporting ATPase, alpha polypeptide (*ATP7A*).

## DEFINITION OF DEVELOPMENTAL ENCEPHALOPATHIES

This chapter addresses a group of disorders that share a common constellation of features. These are disorders that have not fit neatly into the traditional classifications of autism spectrum disorder, perhaps because of concomitant severe intellectual disability, or have not quite been captured by the category of “intellectual disability” because of the obvious and profound abnormalities of social interaction, language development, and repetitive behaviors more consistent with a diagnosis of autism. Many of these disorders also may present with a severe early-life epileptic encephalopathy—yet on follow-up at a later age, the epilepsy is not a prominent part of the phenotype. A common feature is also that, aside from hypotonia, many of these disorders are not overly apparent at birth. Head size at birth is frequently normal, but in many of these disorders, microcephaly emerges over time. Brain magnetic resonance imaging (MRI) usually does not show classic malformations, but subtle features typically involving the corpus callosum and cerebellum can be seen. During infancy, these disorders may resemble one another, making clinical diagnosis difficult. Sentinel features then emerge over time. All of these disorders commonly include the development of multiple elements of dysfunction in the neurologic axis, and they can include breathing dysfunction, gastrointestinal motility disorders, mood disorders, and other severe impairments that are in excess of those usually seen in individuals with intellectual disability alone or autism alone. These affected domains are illustrated in [Figure 32-1](#). We therefore introduce the term *developmental encephalopathy* to more effectively describe the severe patterns of disabilities seen in these individuals ([Table 32-1](#)).

## RELATIONSHIP TO EPILEPTIC ENCEPHALOPATHIES

Epileptic encephalopathies were originally defined as disorders with prominent seizures, in which neurologic function deteriorates as a consequence of epileptic activity, usually combined with a severe signature interictal pattern ([Dulac, 2001](#)). Canonical examples of epileptic encephalopathies include early myoclonic encephalopathy, Ohtahara syndrome, malignant migrating partial seizures of infancy, infantile spasms, and Lennox-Gastaut syndrome. More recently, epileptic encephalopathies have been defined as electroclinical syndromes associated with a high probability of encephalopathic features that present or worsen after the onset of epilepsy ([Berg et al., 2010](#)). The implication in these disorders is that the epileptic activity itself may contribute to severe impairment beyond what might be expected, and this impairment may worsen over time. However, the discovery of mutations in numerous genes for epileptic encephalopathies has led to the hypothesis that the overall disorder may be the product of the underlying genetic cause or a combination of the genetic cause and the epileptic process itself. An example of this phenomenon is individuals with duplications of 14q12 that

include the gene *FOXG1*, who typically present with infantile spasms, respond to adrenocorticotrophic hormone with cessation of spasms and resolution of hypsarrhythmia, do not develop subsequent epilepsy, yet on follow-up have severe intellectual disability, impaired language, socialization, and repetitive movements. The case of duplications of *FOXG1* suggests the epilepsy course is not the primary determinant of the natural history of the disorder, and what may begin as an epileptic encephalopathy can emerge in later childhood as a developmental encephalopathy. Therefore most epileptic encephalopathies are best understood to be a subset of developmental encephalopathies that present with prominent seizure symptoms.

## RELATIONSHIP TO DISORDERS WITH PROMINENT BRAIN MALFORMATIONS

Polyalanine expansion mutations in *ARX* were the first genetic cause of epileptic encephalopathy to be described, and these mutations are one of the best-understood causes of a spectrum of developmental brain disorders that includes intellectual disability, dystonia, infantile spasms, and agenesis of the corpus callosum, with individuals with null mutations having the brain malformation–multiple congenital anomaly syndrome X-linked lissencephaly with abnormal genitalia. The milder mutations found in individuals with polyalanine expansions in *ARX* fit the diagnostic criteria for a developmental encephalopathy (with an emphasis on the subgroup of epileptic encephalopathy), illustrating how different mutations within the same gene can result in different classes of developmental brain disorders. However, individuals with developmental encephalopathies do not typically have major brain malformations but much more commonly have disorders of head size, such as postnatal microcephaly, agenesis of the corpus callosum, and cerebellar vermian hypoplasia.

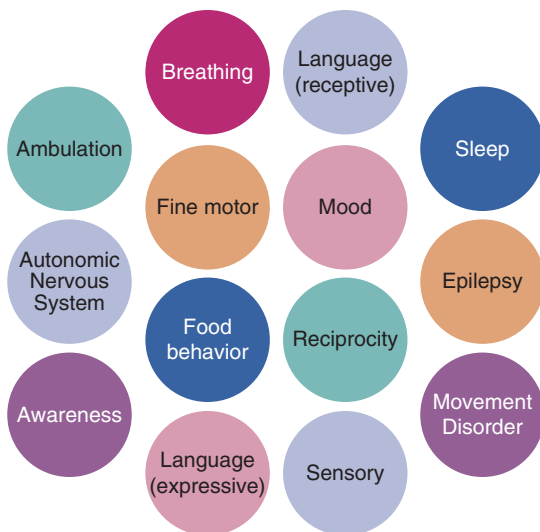

## RELATIONSHIP TO AUTISM SPECTRUM DISORDERS

Angelman syndrome and Rett syndrome, two classical examples of developmental encephalopathies, were previously termed “genetic forms of autism.” However, as our knowledge of the natural history of both Angelman and Rett syndromes has advanced we are now aware of additional features, such as characteristic breathing rhythm abnormalities and cardiac complications seen in girls and women with *MECP2* mutations and characteristic electroencephalogram and epilepsy findings in individuals with Angelman syndrome that are not seen in individuals with more typical autism spectrum disorders. Furthermore, aspects of the standardized autism diagnostic tools, such as the Autism Diagnostic Observation Schedule (ADOS) and the Autism Diagnostic Interview (ADI-R), are difficult to test in children with Angelman or Rett syndrome as a result of the concomitant cognitive impairment. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-V) removed genetic causes from the diagnostic definition of autism spectrum disorders in an attempt to less

**TABLE 32-1** Neurofunctional Domains That Are Commonly Disordered in Individuals With Developmental Encephalopathies

Many of the Domains That Are More Severely Impaired in Developmental Encephalopathies, When Milder, Are Core Features of Autism Spectrum Disorders

Neurofunctional Domain	Severe Examples	More Common Examples
Ambulation	Inability to attain walking in several disorders	Abnormal gait in Angelman syndrome
Autonomic nervous system	Cardiac rhythm disturbances in Rett syndrome; severe constipation in Mowat-Wilson syndrome	Difficulties with temperature regulation in many disorders
Awareness of self and environment	Inability to respond when name is called or to orient toward a caregiver in several disorders	May also be a common feature of autism
Breathing	Hyperventilation in Pitt-Hopkins syndrome; breathing dysrhythmia in Rett syndrome	
Epilepsy	Epileptic encephalopathy in <i>CDKL5</i> disorder; infantile spasms in <i>FOXG1</i> duplications	Nonspecific epilepsy in many disorders
Fine motor	Absence of functional hand use in <i>FOXG1</i> -related disorder	Fine motor development impeded by frequent hand stereotypies
Food behavior	Hyperphagia in Prader-Willi syndrome	Anorexic symptoms in many disorders
Language (expressive)	Absence of verbal language in many disorders	Core feature of autism spectrum disorders
Language (receptive)	Delays in receptive language in many disorders, although many caregivers report receptive language skills are stronger than expressive language skills	Impairment also seen in autism spectrum disorders
Mood	Persistent irritability may be a feature of many disorders and can affect activities of daily living	Inappropriate laughter in Angelman syndrome
Movement disorder	Chorea/dystonia in <i>FOXG1</i> disorder; parkinsonism in Rett syndrome	Hyperkinesia in <i>MEF2C</i> -disorder
Reciprocity	Impairment of social "give-and-take" in many disorders	Core feature of autism spectrum disorders
Sensory	Increased pain threshold in many disorders may lead to injuries	
Sleep	Abnormal sleep-wake cycles in Angelman syndrome	

**Figure 32-1.** Fourteen neurobehavioral and neurofunctional domains that may be affected with disability in individuals with developmental encephalopathies.

the confusion about overlap among these developmental conditions. We now see a hypothesis emerging that genetic mutation class can influence where on the spectrum a patient falls between autism spectrum disorder and developmental encephalopathy; for example, such a spectrum of disability has been observed in individuals with mutations in *CNTNAP2* ranging from classic autistic features to a more severe Pitt-Hopkins syndrome phenotype.

**TABLE 32-2** Genes and Biological Pathways Associated With Developmental Encephalopathies

Gene	Protein Function	Syndrome(s)
<b>TRANSCRIPTIONAL REGULATORS</b>		
<i>ARX</i>	Transcription factor	X-linked infantile spasms syndrome; X-linked lissencephaly with abnormal genitalia; Partington syndrome
<i>FOXG1</i>	Transcription factor	<i>FOXG1</i> disorders
<i>MEF2C</i>	Transcription factor	<i>MEF2C</i> disorder
<i>MECP2</i>	Methyl-CpG-binding domain protein	Rett syndrome
<i>PURA</i>	Transcription factor	<i>PURA</i> disorder
<i>TCF4</i>	Transcription factor	Pitt-Hopkins syndrome
<i>ZEB2</i>	Transcription factor	Mowat-Wilson syndrome
<b>SYNAPTIC STRUCTURAL SUPPORT</b>		
<i>CDKL5</i>	Serine-threonine protein kinase	<i>CDKL5</i> disorder
<i>CNTNAP2</i>	Cell adhesion, ion channel localization	<i>CNTNAP2</i> disorder
<i>NRXN1</i>	Cell adhesion	<i>NRXN1</i> disorder
<b>UNKNOWN BIOLOGICAL PATHWAY</b>		
<i>UBE3A</i>	Ubiquitin-protein ligase	Angelman syndrome

## BIOLOGICAL PATHWAYS INVOLVED

Mutations in numerous novel genes have been discovered recently in individuals with all forms of developmental brain disorders, including developmental encephalopathies, providing an emerging landscape of the biological pathways involved in the pathogenesis of these disorders. [Table 32-2](#) summarizes

some of the key genes, biological pathways, and the syndromes with which they are associated. This is an area of active research and new genes are being added to this list with high frequency. One observation is the prominence of transcription factors (genes that encode proteins that bind DNA and regulate the expression of other genes) or regulators of transcription factors among these pathways. Several of these transcription factors have known critical roles in forebrain development, suggesting that mutations in these genes lead to abnormal patterning, and specific impairments of neuronal development such as migration, neurite outgrowth, and synapse development and function. Other biological pathways clearly involved in the pathogenesis of this class of disorders include synapse structural support (i.e., *CDKL5*) and synaptic function (i.e., *SCN1A*, *SCN2A*, *STXBP1*), and it is not surprising that these pathways also overlap with disorders that often present as epileptic encephalopathies.

## SPECIFIC DEVELOPMENTAL ENCEPHALOPATHIES

### Rett Syndrome

Rett syndrome, initially described by Andreas Rett in 1966 but not widely recognized until several decades later, is in many respects the prototypical developmental encephalopathy. Caused by loss-of-function mutations in *MECP2* (Amir et al., 1999), Rett syndrome manifests as a combination of intellectual disability, autistic features, abnormal movements, and a spectrum of additional neurofunctional deficits. Affected individuals often have a period of normal development, although hypotonia can be present early on. Deceleration in head growth, loss of verbal language, and stereotypic hand movements usually start in toddlerhood, but may be present as early as 6 months of age. Other distinguishing features include breathing abnormalities, bruxism, abnormal sleep patterns, abnormal muscle tone (including spasticity), and scoliosis. The associated movement disorder appears to be complex, and has a natural history of hyperkinesia in younger individuals, with bradykinesia with parkinsonian features emerging in older patients. The breathing abnormalities are also distinctive, and include both hyperventilation and breath holding. Cardiac rhythm abnormalities, dysautonomia, and biventricular myocardial dysfunction can also occur in patients with Rett syndrome, and affected individuals have a 300-fold increased risk of sudden cardiac death.

Multiple forms of epilepsy have been reported in individuals with Rett syndrome, and up to 60% can be affected with seizures. Complex partial, generalized tonic-clonic, atypical absence, atonic, tonic, and myoclonic seizures have all been described. Epilepsy usually develops at a mean age of 4.7 years. Four characteristic stages of electroencephalogram (EEG) abnormalities that reflect the progression of epilepsy and encephalopathy have been described. One challenge in the care of individuals with Rett syndrome and seizures is the common prevalence of nonepileptic behavioral spells.

### *CDKL5* Disorder

During the characterization of Rett syndrome, a group of girls were identified with epileptic encephalopathy, usually infantile spasms, who went on to have some symptoms reminiscent of Rett syndrome. Mutations in *CDKL5* were subsequently discovered in these patients (Weaving et al., 2004). Since then, much has been learned about the natural history that departs from the clinical course of Rett syndrome, and it is no longer appropriate to refer to *CDKL5* disorder as a “Rett variant” or “congenital Rett syndrome.”

Unlike in Rett syndrome, infantile spasms and early infantile myoclonic seizures are common in individuals with mutations in *CDKL5*. Infants show developmental delays early that are associated with their epileptic encephalopathy and do not have a period of normal development followed by regression as can be seen in Rett syndrome. Deceleration of head growth is common, with 55% of individuals in one study manifesting postnatal microcephaly. Similar to Rett syndrome, those with mutations in *CDKL5* also have severely delayed motor development and poor functional hand use, and most are nonambulatory. Many have disordered breathing and sleep disturbance. Mutations of *CDKL5* do occur in surviving males, and in one cohort of boys presenting with epileptic encephalopathy 3% had mutations in *CDKL5*.

### *FOXP1* Disorders

*FOXP1* found on chromosome 14q12 is a transcription factor that regulates dorsal-ventral brain patterning. It is necessary for the development of Cajal-Retzius cells and inhibits gliogenesis and promotes neurogenesis. Disorders involving *FOXP1* were first described in 2005 in a female patient with agenesis of the corpus callosum, severe cognitive impairment, and microcephaly. Children with mutations of *FOXP1* are often thought to have a variant of Rett syndrome; however, it has become increasingly clear that individuals with mutations of *FOXP1* have a clearly distinct phenotype.

There are two clinical syndromes recognized in *FOXP1*, deletions/intragenic loss-of-function mutations and duplications. Each of these has distinct developmental and behavioral characteristics. Individuals with deletions or intragenic mutations of *FOXP1* have global developmental delay and cognitive impairment starting early in infancy. These individuals are typically nonverbal with little expressive or receptive language, have severely impaired motor development, and do not attain ambulation. Oftentimes a chorea-dystonia movement disorder is evident. Sleep dysfunction is common as a result of frequent awakenings and GI disturbances such as gastroesophageal reflux can be severe, even requiring surgical treatment with a fundoplication and feeding tube placement. Individuals with deletions/intragenic mutations of *FOXP1* have low to borderline normal head circumferences at birth and often develop postnatal microcephaly by 2 years old. Epilepsy is very common in these children, with seizures developing early in childhood, and they have a variety of seizure types, including complex partial seizures, myoclonic seizures, and generalized tonic-clonic seizures. The patterns of seizures and epileptiform activity do not fit a typical epilepsy syndrome, and the seizures are often refractory to treatment. On MRI, individuals with deletions or intragenic mutations of *FOXP1* often have abnormalities of the corpus callosum, ranging from hypoplasia of the genu to agenesis of the corpus callosum, which are associated with larger deletions. Also evident are foreshortened frontal lobes and reduced white-matter volumes.

Duplications of *FOXP1* have different clinical features. These children also have developmental delay but are not always as impaired as seen in the deletions/intragenic mutations. Individuals with duplications of *FOXP1* frequently have language delay, but they are more likely to attain ambulation compared with the deletions/intragenic mutations. Fine motor skills are not as severely affected in the duplications *FOXP1* group. These individuals do not have the same choreiform movement disorder and are normocephalic. MRI scans are typically normal. Children with duplications of *FOXP1* have epilepsy but it is distinctive from the mutations/intragenic mutations. Duplications of *FOXP1* are associated with a younger age of onset of epilepsy and more specifically with

infantile spasms. What is perhaps most interesting about this subgroup with infantile spasms and duplications of *FOXP1* is that the spasms typically respond to adrenocorticotrophic hormone (ACTH), and the children do not go on to develop other types of epilepsy.

### **MEF2C Disorder**

Deletions and loss-of-function mutations in *MEF2C* on chromosome 5q14.3 are associated with intellectual disability and epilepsy with additional autistic features such as absent speech and impaired social interactions. Several observers have commented on the abnormal tone and movement patterns that emerge during infancy in individuals with *MEF2C* disorder, with profound hypotonia being common, coupled with the emergence of a hyperkinetic (“always in motion”) pattern prevalent with frequent hand stereotypies that can be accompanied by dystonia and/or chorea. Available data on the natural history of the *MEF2C* movement disorder are sparse, but one 46 year-old individual was described with hypokinesia, spasticity, and intermittent hand-wringing stereotypies.

Just over half of individuals with *MEF2C* disorder are diagnosed with epilepsy during infancy, with myoclonic seizures and infantile spasms being the most common semiology. The remainder of individuals will usually develop epilepsy later in childhood, although several individuals have been described without seizures, and these tend to be those with partial deletions of *MEF2C*. *MEF2C* disorder is therefore another developmental encephalopathy where many (but not all) patients present with an epileptic encephalopathy, but the epilepsy is ultimately variable and not a distinctive feature of the phenotype.

Children with *MEF2C* disorder have a range of other neurofunctional and behavioral impairments that describe the class of developmental encephalopathies. Individuals are usually nonverbal with severe impairment of language and reciprocal communication. Visual tracking is usually poor, and some individuals have avoidance of eye contact. Most manifest inappropriate laughter. Gastrointestinal motility is often abnormal, with clinically significant reflux disease, dysphagia, and constipation. Many parents report their children had high pain tolerance, for example not crying during immunizations or after injuries. Two subjects have been reported with persistent episodes of breathing dysrhythmia, but this behavior does not appear to be a widespread phenomenon.

Brain MRI findings are usually nonspecific in *MEF2C* disorder, with patients generally having normal head size and no cortical malformations. One report documented periventricular nodular heterotopia in three patients with chromosome 5q14.3q15 deletions, but *MEF2C* was considered outside the heterotopia critical region, and this association has not been reported in other patients. Other nonspecific findings on MRI, such as corpus callosum dysmorphology, increased extraaxial spaces, enlarged lateral ventricles, white-matter hyperintensities, and mild cerebellar vermis hypoplasia, have also been described.

### **Pitt-Hopkins Syndrome**

Pitt-Hopkins syndrome is characterized by intellectual disability, postnatal microcephaly, and a characteristic respiratory dysrhythmia (Pitt and Hopkins, 1978). The breathing pattern is usually a combination of hyperventilation mixed with breath-holding behavior that can worsen with excitement, usually appears during early childhood but may not emerge until after the second half of the first decade.

Pitt-Hopkins syndrome is caused by *de novo* loss-of-function mutations in the transcription factor *TCF4*. *TCF4* protein

forms heterodimers with *HASH1*, another helix-loop-helix transcription factor important in the development of noradrenergic neurons that control respiratory drive in the brainstem, possibly explaining the prominent breathing dysrhythmia associated with this syndrome.

Most individuals with Pitt-Hopkins syndrome develop epilepsy after 2 years of age, although seizures during infancy are not uncommon. Seizure types described are nonspecific, but can be intractable. Brain MRI findings are nonspecific and can include hypoplasia of the corpus callosum, mild-moderate dilation of the lateral ventricles, and cerebellar hypoplasia with the only really characteristic observation in some patients being an unusual “bulging” of the caudate nuclei into the lateral ventricles.

### **Mowat-Wilson Syndrome**

Mowat-Wilson syndrome is a multiple congenital anomaly syndrome with prominent intellectual disability, agenesis of the corpus callosum, microcephaly, and seizures (Mowat et al., 1998). Affected individuals have characteristic facial dysmorphology including hypertelorism, medially flared and broad eyebrows, prominent columella, (i.e., tissue linking nasal tip to nasal base) pointed chin and uplifted, cupped earlobes. Congenital heart defects and Hirschsprung disease are also core features of the phenotype. *De novo* mutations in *ZEB2* (previously known as *ZFH1B* and *SIP1*) and deletions of chromosome 2q22 cause Mowat-Wilson syndrome.

Between 70% and 75% of individuals with Mowat-Wilson syndrome have epilepsy, with onset of seizures occurring at a median age of 14.5 months. Atypical absence seizures were common, as were focal seizures, and status epilepticus also reported. Frequent additional neurofunctional deficits included oral and repetitive behaviors, pain insensitivity, and emotional disturbances.

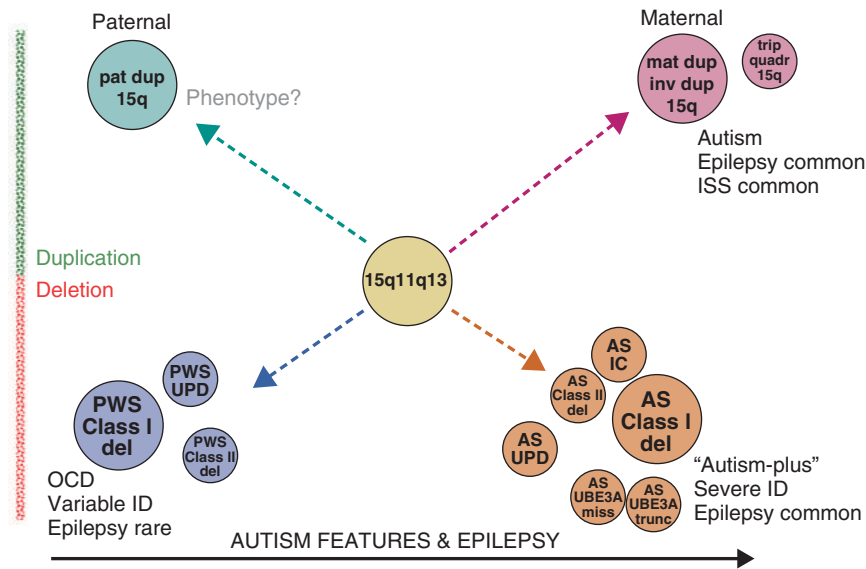

*ZEB2* is a transcriptional inhibitor that mediates axonal growth and plays a role in ipsilateral intracortical brain formation. Mice deficient in *Sip1* lack a corpus callosum, anterior commissure, and corticospinal tracts. The protein is highly expressed in pyramidal neurons in the hippocampus and dentate gyrus and in postmitotic neurons in the cerebral cortex, and it also controls a feedback signaling mechanism promoting fate switch in cortical progenitors from neurogenesis to gliogenesis. Finally, *Zeb2* appears to be positioned downstream of *Dlx1/2* in a pathway required to generate cortical GABAergic interneurons, which may play a role in the frequent epilepsy seen in Mowat-Wilson syndrome.

### **Chromosome 15q Disorders**

Three distinct disorders are mediated by mutations or structural rearrangements occurring on chromosome 15q11q13, providing a fascinating window into the pathogenesis and differential symptomatology of developmental encephalopathies. The proximal chromosome 15q is subject to unequal crossover, resulting in rearrangements, and there are several well-described breakpoint regions. The scope of abnormalities seen in the chromosome 15q disorders is illustrated in Figure 32-3.

#### **Angelman Syndrome**

Angelman syndrome was first described in 1965 and the associated phenotypes of inappropriate laughter, developmental disability, and ataxic gait are well recognized (Angelman, 2008). Although four mechanisms can lead to Angelman syndrome (Table 32-3), the common genetic etiology is the loss of expression of the maternally inherited copy of the

**Figure 32-3.** Interrelationships among the disorders associated with chromosome 15q11q13. Duplications of chromosome 15q from paternal origin (top left) are not described, and it is not known if they manifest a phenotype. Duplications of 15q from maternal origin (top right) are associated with autism and epilepsy, including frequent infantile spasms (ISS). Deletions of 15q from paternal origin (lower left) are associated with Prader-Willi syndrome (PWS), with frequent obsessive-compulsive disorder (OCD) symptoms, variable intellectual disability (ID), and, rarely, epilepsy. Deletions of 15q from maternal origin (lower right) and mutations in *UBE3A* cause Angelman syndrome (AS), which is associated with autism features, severe ID, and, commonly, epilepsy. There is overall a trend toward more severe autism features and epilepsy in maternal duplication of 15q11q13 and Angelman syndrome and less of these phenotypic features in Prader-Willi syndrome. Mat dup, maternal duplication; inv dup, inverted duplication; trip, triplication; quad, quadruplication.

Class	Genetic Event	Angelman Syndrome Cases, %
I	De novo deletion in maternally inherited chromosome 15q11q13	70–75
II	Uniparental disomy chromosome 15	2–3
III	Imprinting center defects	3–5
IV	<i>UBE3A</i> mutations	5–10

imprinted gene *UBE3A* on chromosome 15q11q13. This may occur through de novo deletion in the maternally inherited chromosome 15q11q13 (70%–75% of individuals with Angelman syndrome), uniparental disomy of chromosome 15 with a failure to inherit the maternal copy of *UBE3A* (2%–3% of individuals with Angelman syndrome), abnormal 15q11q13 methylation resulting from mutations in the imprinting center (3%–5% of individuals with Angelman syndrome), and mutations in *UBE3A* itself (5%–10% of individuals with Angelman syndrome).

Physical and behavioral features that include intellectual disability and absent language characterize Angelman Syndrome. Individuals with Angelman syndrome typically have a happy demeanor with inappropriate laughter, but hyperactivity and aggression are frequent behavioral complications. Several abnormal movement patterns have been described in Angelman syndrome, including ataxic gait and jerk-like limb movements. Tremor has been commonly reported, and may represent semirhythmic cortical myoclonus. One individual has been reported with paroxysmal tonic upward gaze. Sleep disturbance is also a significant clinical finding in 72% of

individuals with Angelman syndrome, with abnormal sleep-wake cycle impairment. There are data suggesting that behavioral therapy may be helpful in addressing disordered sleep. Intractable epilepsy is common in Angelman syndrome, with 80% to 90% of individuals affected. The average age of seizure onset was 1 year old, with a range of 4 months to 2 years 11 months. Multiple seizure types have been observed, including atypical absence, myoclonic, partial, complex partial, generalized tonic-clonic, and status epilepticus. Angelman syndrome therefore is an example of a developmental encephalopathy in which seizures can be prominent, although no single electroclinical epilepsy syndrome is dominant in the phenotype. The natural history of epilepsy in Angelman syndrome has been studied, and seizures usually persist into adulthood.

### Prader-Willi Syndrome

The inclusion of Prader-Willi syndrome within the category of developmental encephalopathy may appear at first glance to be surprising. Yet when one contemplates the phenotype of this disorder mediated by abnormal imprinting of the paternal copy of 15q11q13, it is evident that the criteria for developmental encephalopathy are met. Individuals with Prader-Willi syndrome can present in infancy with marked hypotonia and failure to thrive. Characteristic dysmorphic findings of eye shape, small hands, and small feet are usually seen. However, many affected children are not diagnosed at this stage although the importance of recognizing this disorder early is paramount for the option of growth hormone therapy to be offered to the family. Growth hormone therapy has resulted in a dramatic change in the outcome of Prader-Will syndrome, and in many cases, the morbid obesity is a consequence of unchecked hyperphagia that can be avoided. Older individuals have a characteristic neurobehavioral phenotype that includes frequent ritualistic obsessive-compulsive behaviors. Affective

psychiatric disorders are common, and individuals with the maternal uniparental disomy genetic subtype appeared to be especially vulnerable to these behavioral complications.

Epilepsy is a rare complication of Prader-Willi syndrome, which is remarkable given the high density of GABAergic genes (*GABRA5*, *GABRB3*, and *GABRG3*) on chromosome 15q11q13 and the high prevalence of epilepsy in Angelman and duplication of maternal 15q11q13 syndromes. It appears likely that the effect of loss of paternal imprinting on these genes is not epileptogenic.

### Duplication of Maternal 15q11q13

Duplications of the maternally inherited copy of chromosome 15q11q13 region are the most frequently reported chromosomal aberration in individuals with autism spectrum disorders (0.5%-3%) (Bolton et al., 2001; Depienne et al., 2009). Epilepsy is common, with infantile spasms having a high incidence, and Lennox-Gastaut syndrome reported as well. Some individuals have been described with tetrasomy and pentasomy 15q11q13, severe intellectual disability with autism, and mild dysmorphism.

### *CNTNAP2* and *NRXN1* Disorders

Autosomal recessive mutations in *CNTNAP2* and *NRXN1* have been described in individuals with intellectual disability, severely limited verbal language, and respiratory dysrhythmia similar to Pitt-Hopkins syndrome. Both of these genes have emerged as candidates for autism spectrum disorders, although the evidence supporting pathogenicity of variants in autism is not very strong. *CNTNAP2* variants have also segregated with learning disability and dyslexia in some families. Others have identified heterozygous variants in both *CNTNAP2* and *NRXN1*; however, in most cases, the variant was inherited from a normal parent and no second mutation in the gene was identified. Therefore the full spectrum of *CNTNAP2* and *NRXN1* disorders and their relationship to Pitt-Hopkins syndrome, autism spectrum disorders, or other learning disabilities remain unclear.

### *DYRK1A* Disorder

*DYRK1A* is a tyrosine-(Y)-phosphorylation regulated kinase encoded on chromosome 21 that has been implicated as responsible for the cognitive abnormalities common in Down syndrome. Recently de novo loss-of-function mutations in *DYRK1A* and chromosome 21q22.13 microdeletions have been identified in individuals with congenital microcephaly, intellectual disability, and autistic features. Additional clinical findings include ataxia, intrauterine growth restriction, and characteristic facial features. Impaired speech and stereotyped behaviors were common findings. Mutations in *DYRK1A* were found recurrently in a series of individuals with intellectual disability, suggesting the disorder may be more frequent than currently recognized.

### *PURA* Disorder

*PURA* disorder is one of the most recent diagnoses discovered that fits within the definition of developmental encephalopathy. De novo loss-of-function mutations in this transcriptional regulator have been found in individuals presenting with neonatal hypotonia, poor feeding, and epilepsy. Affected individuals with deletions of chromosome 5q31.3 including *PURA* were previously described. Initial genotype-phenotype correlations suggest that mutations disrupting the Pur repeat III result in a more severe phenotype. Brain MRI findings

appear to include nonspecific white matter dysmaturation and increased extraaxial spaces.

## Conclusions

We use the term *developmental encephalopathy* to capture the full spectrum of phenotypes in conditions where intellectual disability coexists with autistic features and other abnormalities of the autonomic nervous system, changes in gastrointestinal motility and breathing rhythm, specific types of epilepsy, and movement disorders. This new conceptual framework is necessary to differentiate these conditions from neurodevelopmental disorders that primarily present with global developmental delay, isolated intellectual disability, and epilepsy syndromes. When initially described, the clinical features of affected individuals may be complex and overlap with intellectual disability, autism spectrum disorders, and other neurobehavioral characteristics such that one disorder is superficially difficult to distinguish from another. For this reason, close attention to differentiating signs and symptoms is important. Some of these disorders have specific abnormalities seen on brain imaging. In some cases, specific epilepsy types or movement disorder patterns are common.

As more genetic causes of developmental encephalopathies are discovered, we can begin to understand the associated underlying biological mechanisms. An emerging common theme is that of abnormal transcriptional regulation at the critical early stages of brain development; many of the causative genes are transcription factors that bind specific DNA sequences and regulate the expression of other genes. Synapse structural support is another biological grouping that appears to be important in the causation of developmental encephalopathies. Ultimately, the molecular circuitry underlying these disorders may create common features among various disorders, offering the potential that common novel therapeutic strategies may be applied to multiple disorders. It is interesting that both of these pathways overlap with the emerging biological mechanisms for epilepsy and autism spectrum disorders, which certainly share similar phenotypic features. A better understanding of the specific pathophysiological mechanisms by which the mutations cause the developmental encephalopathies outlined in this chapter will likely provide insight into the pathologic mechanisms underlying these common disorders.

As advanced genetic technologies are increasingly being used to make diagnoses in the child neurology clinic, it is not surprising that these approaches are helpful in making a molecular diagnosis in children with developmental encephalopathies as well. Identification of a genetic cause for an individual's disorder may allow recommendations to be made for surveillance for known medical complications and affect decisions about choice of medications. Identification of a genetic diagnosis may also open the door for affected individuals to participate in clinical trials and/or natural history studies available for that disorder.

Appropriate genetic evaluation of a patient with a developmental encephalopathy will include specific genetic studies for clinically identifiable disorders. For example, for girls with developmental regression with loss of hand skills and language, Rett Syndrome should be considered and mutation analysis of *MECP2* performed. Rett Syndrome-like features with early seizures suggest mutation testing in *CDKL5* and DNA methylation studies of chromosome 15q to evaluate for Angelman and Prader-Willi syndromes if clinical features suggest these disorders. Chromosomal microarray (CMA) tests for pathogenic microdeletions or microduplications, such as duplication 15q11q13 syndrome. Also, CMA may detect microdeletions involving any of the single-gene disorders discussed in this chapter. Should methylation studies and

CMA be negative, a clinician can either proceed to an appropriate next-generation sequencing gene panel, if it includes the likely genes of interest, or whole-exome sequencing. The use and interpretation of these technologies are discussed in Chapter 30.

### INTRODUCTION

The fetal brain develops during the course of pregnancy, from its primitive three-vesicle stage into a complex structure with an array of sulci and gyri resembling the adult brain by the end of gestation. Fetal brain development can be studied by ultrasound (US), starting from gestational weeks 6 to 7 until delivery. Fetal magnetic resonance imaging (MRI) further enables demonstration of anatomy, particularly of cortical development and diverse anomalies, starting at around 18 to 20 weeks of pregnancy.

Sonography is the most important imaging method for prenatal malformation screening. The use of a comprehensive, multiplanar approach, in which coronal and sagittal planes are added to the classical axial planes, and addition of a transvaginal approach enable depiction of the cortex, midline brain structures, and the posterior fossa.

Fetal MRI is complementary to US and is used primarily to confirm and characterize brain abnormalities detected by prenatal sonography. The higher contrast resolution allows better differentiation of normal from abnormal tissue.

An understanding of embryologic development and the correlation between US and MRI is critical in order to be able to diagnose structural brain defects prenatally.

### PRENATAL ASSESSMENT OF NORMAL BRAIN DEVELOPMENT IN THE FIRST TRIMESTER

Brain development in the embryonic phase is assessed only by US. Cortical development starts at about 7 weeks of gestation and other brain structures develop synchronously with the cortex, including the commissures and the cerebellum.

By the end of the first trimester (weeks 10 to 12), the cortex is about 1 to 2 mm thick and the crescent hemispheres fill the anterior part of the head. The insula appears as a slight depression on the lateral surface of the hemispheres. The corpus callosum is not yet visible. The cerebellar hemispheres seem to meet in the midline (Blaas and Eik-Nes, 2009).

Major structural defects, particularly malformations of dorsal induction and prosencephalic development, can be identified in first-trimester studies.

### PRENATAL ASSESSMENT OF NORMAL DEVELOPMENT OF THE CORTEX

Gyration can be observed by the second month of intrauterine life and continues to develop even after delivery. The primary sulci appear as shallow grooves on the surface of the brain that become progressively more deeply infolded and then develop side branches. The major fissures and sulci develop in predictable patterns, starting at about 16 weeks, and therefore the timing of their appearance is a reliable estimate of gestational age.

At 18 to 20 weeks, the brain surface is almost completely smooth, with only the major fissures present. The most active period of cortical development, as demonstrated by US, is between 27 and 30 weeks. During this time, most sulci

become detectable (Cohen-Sacher et al., 2006) (Table 33-1 and Figure 33-6).

MRI after about 20 weeks of gestation provides excellent information unimpeded by calvarial calcification. Brain MRI can depict the walls of the ventricles, which are lined by the ventricular zone (germinal matrix), which is very thick earlier in gestation, and appears as a smooth band of dark T2 signal and bright T1 signal lining the lateral ventricles. The cerebral mantle is seen on fetal MRI until about 28 weeks of gestation in a multilayered pattern (see Figure 33-6).

The development of the cortex can be visualized from mid-pregnancy. On MRI, gyration starts with the appearance of a shallow indentation of the fetal brain in the temporal regions at the 18th gestational week. The central sulcus begins to be visible at 24 weeks of gestation. Fissures then become deeper and tighter, and gyri bulge into the subarachnoid space. Until the 35th gestational week, all primary and most of the secondary sulci are present (Garel et al., 2001) (see Figure 33-6 and Table 33-1).

The development of the sylvian fissure is one of the major brain maturational processes occurring in fetal life, and abnormalities in this process are frequent in children with developmental delay. It is observed in all fetuses at 22 to 23 weeks of gestation as a shallow depression at the surface of the brain, and the insula is wide open at this time. There is progressive closure that begins posteriorly and extends anteriorly. By 33 weeks of gestation, insular sulci are recognizable and the surface of the sylvian fissure becomes more and more indented (Figures 33-1 and 33-2).

### PRENATAL ASSESSMENT OF NORMAL DEVELOPMENT OF THE CORPUS CALLOSUM

The corpus callosum develops between gestational weeks 8 and 20. A complete demonstration by US necessitates obtaining sagittal planes through the fontanelles with the transvaginal approach. Coronal planes are useful for studying the relationship between the corpus callosum and neighboring structures. The completely formed corpus callosum may be depicted using high-resolution transducers by 21 to 22 weeks of gestation, as an arched hypoechogenic structure delimited by the more echogenic callosal sulcus cranially and the anechogenic cavum septi pelucidi caudally. At this age, its shape is already very similar to that of the mature corpus callosum, and the genu, body, and splenium can be well demonstrated.

The corpus callosum can be depicted by MRI on midline sagittal T2 images by gestational week 20 as a band of low signal intensity superior to the fornix.

### PRENATAL ASSESSMENT OF NORMAL DEVELOPMENT OF THE POSTERIOR FOSSA

The ultrasonographic evaluation should include multiplanar images of the cerebellum. The cerebellar vermis can be detected by US in the midsagittal plane as early as 18 weeks of gestation. The midsagittal anterior-posterior diameters increase in a linear fashion.

**TABLE 33-1** Chronology of Sulcation According to Neuropathological, Sonographic, and Magnetic Resonance Imaging Studies

	Anatomic Appearance	Detectable in 25–75% of Brains by MRI	Detectable in 25–75% of Brains by Ultrasound	Present in > 75% of Brains by MRI	Present in > 75% of Brains by Ultrasound
Interhemispheric fissure	10			22–23	18
Sylvian fissure	14	24–25		29	18
Parieto-occipital fissure	16		18	22–23	20
Hippocampal fissure				22–23	18
Callosal sulcus	14			22–23	18
Calcarine fissure	16	22–23	20	24–25	22
Cingular sulcus	18	22–23	20	24–25	24
Central sulcus	20	24–25	26	27	28
Postcentral sulcus	25	27	28	28	30
Precentral sulcus	24	26	28	27	30
Superior temporal sulcus	23	26	28	27	30
Inferior temporal sulcus	30	30	28	33	30
Superior frontal sulcus	25	24–25	28	29	30
Inferior frontal sulcus	28	26	28	29	30
Secondary cingular sulcus	32	31	30	33	32
Insular sulcus	34–35	33	30	34	32
Secondary occipital sulcus	34	32	26	34	30
Olfactory sulcus	16		24		30
Marginal sulcus		22–23	26	27	30

The primary fissure is observed between 27 and 30 weeks of pregnancy. Some degree of differentiation between lobules is possible, starting from 30 to 32 weeks of gestation.

The fourth ventricle is uniformly observed as a triangular structure antero-caudal to the vermis. The cerebellar vermis is best assessed by MRI on direct midline sagittal images and on coronal images. The cerebellar hemispheres are best assessed on axial and coronal views.

Fetal MRI shows gestational age-specific changes in signal intensity in the normal development and maturation of the cerebellar hemispheres and brainstem. The cerebellar cortex, dentate nucleus, tectum, dorsal pons, and medulla are T1-hyperintense and T2-hypointense. By 26–27 weeks of gestation, a three-layered pattern is noted in the cerebellar hemispheres. Fetal brain MRI can show the fissures of the cerebellum, depending on the gestational age. The primary fissure is identified on sagittal images at 22 weeks but the cerebellar surface is smooth. From 24 to 29 weeks, foliation of the vermis and posterior lobes of the cerebellum is seen on sagittal images. The convoluted pattern of the cerebellum is well identified from 30 weeks on and is always seen beyond 33 weeks (Fogliarini et al., 2005a).

## PRENATAL DIAGNOSIS OF VENTRICULOMEGALY

Assessment of the width of the atria of the lateral cerebral ventricles is recommended as part of the routine anomaly scan.

The lateral ventricle should be measured by US in the axial plane, at the level of the frontal horns and cavum septi pellucidi, with the calipers positioned at the level of the internal margin of the medial and lateral wall of the atria.

Ventriculomegaly is defined as a lateral ventricular width  $\geq 10$  mm. Fetal ventriculomegaly may be classified as mild

when the lateral ventricular width is between 10 and 15 mm, and severe when larger than 15 mm; it may be unilateral or bilateral.

Ventriculomegaly is defined as isolated if there is no additional evidence of associated malformations or markers of aneuploidy. Mild ventriculomegaly represents a diagnostic and counseling difficulty, as it can be an apparently benign finding, but can also be associated with chromosomal abnormalities, congenital infection, cerebral vascular accidents, and other fetal cerebral and extracerebral abnormalities; it may also have implications regarding long-term neurodevelopmental outcome (Melchiorre et al., 2009). Therefore, upon confirmation of ventriculomegaly, a complete search for associated central nervous system (CNS) and non-CNS anomalies should be attempted, including a study of the brain in a multiplanar approach. The investigation should also include screening for in utero infection, amniocentesis, and fetal echocardiography. MRI can add important information to that obtained by US imaging. Information relevant enough to modify obstetric management can be obtained in 10% of cases.

Follow-up examinations at 3- to 4-week intervals are indicated to assess progressive enlargement of ventricles or to diagnose associated pathologies not previously detected.

When mild ventriculomegaly is isolated, the outcome is usually good. The risk for abnormal outcome increases when there are associated anomalies, the atrial width is greater than 12 mm, or there is a progressive increase of the lateral ventricular width.

The outcome of severe ventriculomegaly depends mainly on the presence of associated pathologies. When associated pathologies are diagnosed, the prognosis is usually poor unless the cause is intraventricular hemorrhage. Even when isolated, the risk of perinatal death or severe neurologic sequelae is in the range of 50% of survivors.

**Figure 33-6.** **A–D**, Maturation of the normal fetal cortex by ultrasound. Coronal slices at 23 (**A**), 27.5 (**B**), 31.5 (**C**), and 35 (**D**) weeks. **E–H**, Maturation of the normal fetal cortex by magnetic resonance imaging (MRI) (note opercularization). Coronal T2-weighted slices at 23 (**E**), 27 (**F**), 31 (**G**), and 35 (**H**) weeks. (*A–D*: Courtesy of Dr. Zvi Leibovitz.)

## PRENATAL DIAGNOSIS OF ABNORMALITIES OF THE CORPUS CALLOSUM

Developmental abnormalities of the corpus callosum include agenesis, hypogenesis (or partial agenesis), dysgenesis, hypoplasia, and secondary destruction. Agenesis of the corpus callosum (ACC) can be detected prenatally by routine sonography, for which the important signs include absence of the cavum septum pellucidum, colpocephaly, high-riding third ventricle, widening of the interhemispheric fissure, and radiating medial hemispheric sulci. US can also depict an abnormally thick corpus callosum, which may signify a poor prognosis.

Fetal MRI is clinically helpful in suspected cases of ACC because it can confirm the absence of the corpus callosum and diagnose associated anomalies. ACC is rarely isolated. Additional abnormalities occur frequently (46%). The most common findings are sulcation and posterior fossa abnormalities. Abnormal sulcal morphology can be detected as early as 19 gestational weeks. The gyral abnormalities include polymicrogyria, lissencephaly, pachygyria, and schizencephaly.

Interestingly, in 10% of fetuses with ACC, there may be evidence of destructive changes in the brain parenchyma, suggesting either an acquired etiology or a genetic/metabolic abnormality (Prasad et al., 2009).

## PRENATAL DIAGNOSIS OF MALFORMATIONS OF CORTICAL DEVELOPMENT

Although the migration process terminates around the end of the first half of pregnancy, malformations of cortical development are seldom diagnosed in utero, possibly because the time of appearance of significant morphologic changes is beyond the recommended time of the anatomic scan (19 to 23 weeks), and because US evaluation of the brain is often limited to visualization of the lateral ventricles and cerebellum.

Abnormal sulcation landmarks have been observed as early as the 22nd week of gestation in fetuses suffering from lissencephaly. In fetuses with migration disorders, US usually demonstrates one of the following patterns: delayed or premature appearance of sulcation, a thin and irregular cortical mantle, wide abnormal overdeveloped or underdeveloped gyri, wide opening of isolated sulci, nodular bulging into the lateral ventricles, cortical clefts, and intraparenchymal echogenic nodules (Malinger et al., 2007).

A definitive diagnosis is hard to reach prenatally; US can identify abnormal migration but cannot definitively differentiate between different pathologies.

MRI can identify cortical malformations more accurately, particularly late in pregnancy. The imaging signs suggestive of abnormal sulcation are: mild ventriculomegaly associated with delayed cortical development; dysgenesis of the sylvian fissure; delayed or abnormal sulcal appearance; callosal abnormality; cortical thickening; heterotopias; absence or abnormal appearance of fissures; irregular, abnormal, asymmetric gyri; and noncontinuous cortex in schizencephaly (Fogliarini et al., 2005b).

When the operculum is abnormally formed, the prognosis is usually poor and an underlying malformation of cortical development can be detected. An underdeveloped operculum for gestational age is usually associated with an abnormal head circumference or other brain anomalies. When it is an isolated finding, it may represent a metabolic disease, chromosomal anomaly, or benign delayed maturation of the operculum, usually associated with macrocephaly and enlargement of the subarachnoid spaces (Prasad et al., 2009).

## Prenatal Diagnosis of Lissencephaly Type I

Fetuses with lissencephaly type 1 can be diagnosed after 27 to 30 weeks of gestation when most of the primary sulci are already present, either by detailed neurosonography or by MRI, by demonstration of dysgenesis of the sylvian fissure, delayed sulcal appearance, callosal abnormality, and cortical thickening. Sometimes, zones of normal cortex and zones of pachygyric or agyric cortex alternate. The bilateral opercular dysplasia is responsible for a figure-eight-shaped brain.

Fetuses with Miller–Dieker syndrome have abnormal parieto-occipital and sylvian fissures by the time of the second-trimester US examination.

## Prenatal Diagnosis of Cobblestone Complex

Findings suggestive of cobblestone complex are early enlargement of the lateral ventricles, abnormal sulcation, abnormal vermis, a Z-shaped brainstem, retinal detachment, and cataract.

MRI can better visualize the posterior fossa, brainstem, and gyration pattern (Fogliarini et al., 2005b).

## Prenatal Diagnosis of Complex Cortical Malformations

Mutations in tubulin genes cause complex cortical malformations. Three subtypes of cortical malformations have been described in fetuses: microlissencephaly with corpus callosum agenesis, severely hypoplastic brainstem and cerebellum; lissencephaly, either classical or associated with cerebellar hypoplasia, with corpus callosum agenesis; and polymicrogyria-like cortical dysplasia with inconstant corpus callosum agenesis and hypoplastic brainstem and cerebellum.

## Prenatal Diagnosis of Periventricular Nodular Heterotopia

Periventricular nodular heterotopia should be considered when US depicts an irregular lateral ventricular wall with indentations of periventricular tissue and a signal similar to that of the cortex. The sonographic diagnosis is difficult, particularly when the lateral ventricle width is normal. MRI demonstrates multiple small nodular subependymal foci of low signal intensity, isointense to the germinal matrix, located in the margins of the lateral ventricles. They cannot be distinguished reliably from the subependymal nodules seen in tuberous sclerosis; therefore, it is important to search for other manifestations of tuberous sclerosis. A posterior fossa cyst, which can be seen in females with filamin A mutations, may be the initial abnormality and, in association with periventricular nodules, may suggest the prenatal diagnosis.

Heterotopia may go unrecognized when the nodules are small or subcortical.

## Prenatal Diagnosis of Polymicrogyria

The cortical changes of polymicrogyria take place late in pregnancy and appear as localized and/or generalized absence of normal sulcation with multiple abnormal infoldings of the affected cortex. It is more apparent on MRI than on US. In young fetuses (24 weeks), the identification of the cortical malformation is quite difficult, and the manifestations in both US and MRI are subtle (Adamsbaum et al., 2005). They include presence of sulci that are not as expected, according to the gestational age; an irregular surface of the brain; and absence of the normal signal of the cortical ribbon. Late in

pregnancy, the MRI features are similar to what is known in the postnatal period: packed and serrated microgyri, irregular cortex–white-matter junction, and an aberrant and asymmetric sulcal pattern (Fogliarini et al., 2005b). Because the MRI pattern of polymicrogyria changes with increasing gestational age, it is important to follow young fetuses and repeat the US and MRI examinations in order to confirm the diagnosis.

### Prenatal Diagnosis of Schizencephaly

Prenatal US enables diagnosis of schizencephaly, although prenatal MRI is more specific in detection of the gray matter lining the defect, communication with the ventricle, and other associated structural abnormalities. The prenatal diagnosis of schizencephaly depends on the extent of cleft separation; closed-lip and open-lip variants with a very small gap remain undiagnosed. The prenatal diagnosis of schizencephaly has been described as early as 21 weeks. Neurosonography demonstrates bilateral or unilateral open-lip wedge-shaped defects, usually in the parietotemporal regions, frequently accompanied by absence of the cavum septum pellucidum. Fetal MRI shows schizencephalic clefts extending from the pial surface to the ventricle lined with gray matter, which is seen as a low-signal-intensity line covering the edge of the remaining brain parenchyma. This finding allows differentiation of the defect from porencephaly (Fogliarini et al., 2005b).

### PRENATAL DIAGNOSIS OF POSTERIOR FOSSA ANOMALIES

Infratentorial anomalies are usually diagnosed in utero when associated with enlarged posterior fossa fluid spaces, with or without an abnormal fourth ventricle. The suspicion of abnormal cerebellar development is usually raised after the visualization of a small cerebellum or a large communication between the fourth ventricle and the cisterna magna, using the transcerebellar axial plane. Severe anomalies, such as Arnold–Chiari malformation type 2, Dandy–Walker malformation, and cerebellar hypoplasia, are usually detected during routine second-trimester US examinations.

Particular care should be taken in order to differentiate between the vermis and the cerebellar hemisphere in cases of suspected vermian agenesis or hypoplasia. Visualization of the normal triangular shape of the fourth ventricle, and of the primary vermian fissure, facilitates exclusion of vermian pathologies.

The in utero diagnosis of the pontocerebellar hypoplasias necessitates measurements of the pons diameter in addition to the cerebellar dimensions. It is important to note the relationship of the size of the midbrain to pons and medulla. In cases of diagnostic uncertainties, a follow-up examination is pertinent, because a false-positive diagnosis of partial vermian agenesis may be made before 24 weeks of pregnancy, because of delayed closure of the fourth ventricle owing to a persistent Blake pouch cyst, and cerebellar hypoplasia may be missed early in pregnancy because the arrest of growth occurs later.

A dysplastic cerebellum, which refers to disorganized development, such as an abnormal folial pattern or the presence of heterotopic nodules of gray matter, is rarely diagnosed in utero, even with MRI, because it does not produce signal abnormalities.

### Prenatal Diagnosis of Chiari Type II Malformation

The posterior fossa is relatively small in Chiari II malformation, and spinal neural tube defects are present with variable hindbrain herniation. The Chiari II malformation may be

associated with callosal anomalies, fenestration of the falx, and cortical malformations. The cisterna magna is obliterated by a low-lying torcula, vermian herniation through the foramen magnum, and a small slitlike fourth ventricle. The herniated cerebellum often degenerates. The cerebellum is banana shaped because of the herniation and small posterior fossa. The fetus may demonstrate a lemon-shaped skull.

### Prenatal Diagnosis of Dandy–Walker Malformation

Prenatal diagnosis of Dandy–Walker malformation is usually possible during the second trimester; midsagittal planes enable visualization of the abnormal vermis, the communication between the fourth ventricle and the enlarged cisterna magna, and the elevated torcula and tentorium. It should not be confused with partial vermian agenesis. Dandy–Walker malformation may be associated with other CNS anomalies, such as callosal dysgenesis, occipital encephalocele, polymicrogyria, or heterotopias. Hydrocephalus may develop only late in pregnancy or postnatally.

The prognosis after a prenatal diagnosis of Dandy–Walker malformation is variable; however, the prognosis is worse when there are associated brain anomalies (Bolduc and Limpopoulou, 2009).

### Prenatal Diagnosis of Mega Cisterna Magna, Posterior Fossa Arachnoid Cyst, and Blake’s Pouch Cyst

Isolated enlargement of the posterior fossa is frequently diagnosed by fetal US or MRI. It may be seen in three situations: mega cisterna magna, posterior fossa arachnoid cyst, and Blake’s pouch cyst. The prognosis in all three entities is usually good.

In mega cisterna magna, the posterior fossa depth is greater than 10 mm, but the vermis and torcula location are normal. The term has been loosely applied to a large-appearing retro-cerebellar cerebrospinal fluid space with a normal vermis and cerebellar hemispheres. It is usually an incidental finding, but it can be associated with other anomalies. Mega cisterna magna can be difficult to distinguish from an arachnoid cyst, as both are anechoic fluid spaces. Congenital arachnoid cysts are extraaxial, and 10% to 45% occur in the posterior fossa. They present on US as anechoic avascular cysts with mass effect on the cerebellum or internal table of the skull. Associated congenital anomalies are rare.

Blake’s pouches have the same radiographic appearance as do arachnoid cysts, with the exception that, in some cases, the choroid plexus can be identified, as it extends through the median aperture along the superior cyst wall, carrying the anterior lip of the median aperture far up the vallicula. Blake’s pouches communicate with the fourth ventricle and may or may not produce mass effect on the cerebellum. Occasionally, there is the appearance of compression or absence of the inferior vermis. It may be hard to differentiate between inferior vermian hypoplasia and a Blake’s pouch cyst.

### Prenatal Diagnosis of Vermis Hypoplasia/Agenesis

The term *Dandy–Walker variant* has been used to describe a heterogeneous group of disorders with different degrees of cerebellar vermian agenesis, slight or absent upward rotation of the vermis, and variably sized posterior fossa fluid collections,

but without enlargement of the posterior fossa. However, in recent years, it has been strongly advocated that the term be abandoned altogether, given its multiple and variable definitions. The terms *hypoplasia* and *agenesis* are used interchangeably in the literature on fetal vermian abnormalities, but the definitions of these entities are completely different. Vermian agenesis means either complete or partial absence of the vermis. In partial vermian agenesis, part of the vermis is absent and the remaining part is anatomically of normal volume. Because of the craniocaudal development of the vermis, partial agenesis involves its inferior part. Vermian hypoplasia means a small but complete vermis with congenital volume diminution.

Vermis agenesis is associated with CNS and non-CNS anomalies in up to 71% of children, with the most common being ventriculomegaly and agenesis of corpus callosum. Extra-CNS anomalies have also been reported in up to 65%, with cardiac, renal, extremity, and facial anomalies occurring most frequently (Bolduc and Limperopoulos, 2009).

Vermian development is assessed in the midline sagittal view from the caudal extent of the inferior vermis over the fourth ventricle. The diagnosis of inferior vermis agenesis is made when there is partial absence of the inferior portion of the cerebellar vermis with normal- or near-normal-shaped cerebellar hemispheres, a normal-sized posterior fossa without obvious cystic lesions, and normal supratentorial structures. The normal proportion of anterior vermis to posterior vermis (1:2) is lost. A correct diagnosis of inferior vermian agenesis is difficult and, even with MRI, there is a false-positive rate of 32%.

Inferior vermian agenesis should be differentiated from failure of "closure" of the vermis with normal morphology and biometry; this probably represents isolated elevation or rotation of the vermis because of a persistent Blake's pouch. Failure of "closure" seems to result from two potential processes: arrest of vermian development so that it does not cover the fourth ventricle at its inferior extent, or failure of adequate fenestration of the fourth ventricular outflow foramina, leading to a secondary elevation of an otherwise normal vermis. The prognosis in these situations is completely different.

### Prenatal Diagnosis of Cerebellar Hypoplasia

Cerebellar hypoplasia implies abnormal development rather than atrophy. Diagnosis is made by measurement of the transverse cerebellar diameter.

Severe cerebellar hypoplasia is easily identified in utero after 22 weeks as a very small cerebellum associated with a shallow brainstem and absence of the anterior bulging of the pons, resulting in pontocerebellar atrophy/hypoplasia of extremely poor prognosis. Isolated cerebellar hypoplasia is more challenging, and difficulty in distinguishing malformation from necrosis can occur, especially in unilateral hypoplasia. An intact cerebellar cortex is most likely seen in cerebellar hypoplasia, as opposed to cerebellar necrosis, in which the cortical ribbon is usually absent (Fogliarini et al., 2005b).

### Prenatal Diagnosis of Rhombencephalosynapsis

The diagnosis of rhombencephalosynapsis is raised, after demonstration of a small transcerebellar diameter. US and MRI both demonstrate a hypoplastic, single-lobed cerebellum

with fused cerebellar hemispheres, no vermis, and transverse folia. Associated cerebral abnormalities are usually found. Coronal and axial planes are superior for diagnosis of rhombencephalosynapsis, because a midline sagittal cut through the cerebellum can be mistaken for a vermis.

### Prenatal Diagnosis of Molar Tooth-Related Syndromes

The diagnosis of the molar tooth (deep interpeduncular fossa, thick and elongated superior cerebellar peduncles, vermian agenesis) is difficult to visualize in utero. However, the prenatal diagnosis of Joubert syndrome or related disorders usually follows a positive family history and the finding of abnormal posterior fossa anatomy on fetal ultrasonography or the presence of associated suggestive features, such as kidney anomalies, polydactyly. The molar tooth features can be visualized in the axial plane, including the interpeduncular fossa, cerebellar peduncles, and brainstem.

### Prenatal Diagnosis of Brainstem Anomalies

Brainstem malformations are usually described in utero when they are associated with cerebellar and cerebral anomalies. Fetuses with cobblestone malformations show a prominent elongation of the tectum, a thin pons, a small dysplastic vermis, and a kinked brainstem. Fetuses with pontocerebellar hypoplasia demonstrate a reduction of all midbrain and hindbrain measurements in addition to a short transcerebellar diameter.

### INTRODUCTION TO THE HUMAN GENOME

The human genome consists of approximately 3.08 billion base pairs of deoxyribonucleic acid (DNA) divided into 22 numbered chromosomes and two sex chromosomes (X, Y). Nearly 3% of the genome is protein coding, or exonic, and has come to be termed the exome. This coding region is responsible for some 20,000 genes, the primary units of heredity. The remainder of the genome (approximately 97%) is comprised of regions of repeats and segmental duplications (50%), and some highly conserved regulatory regions. Compared with many other organisms, the genome of *Homo sapiens* is modest in size, and the diversity of protein products in humans is greatly increased through the process of alternative splicing.

Chromosomes reside in the cell nucleus in a three-dimensional structure called a fractal globule with important consequences for short-range and long-range regulation of gene expression. The nucleotide sequence of the genome is the principle determinant of gene activity, but chromosomes are comprised of DNA upon a protein scaffold, the combination of which is termed chromatin. The proteins within chromatin include histones, which are strongly evolutionarily conserved DNA-associated proteins. Chromatin that is less condensed is termed euchromatin and contains coding DNA. The more condensed heterochromatin contains noncoding DNA. Epigenetic factors, defined as factors independent of the nucleotide sequence that affect gene expression, include methylation of DNA and histone acetylation. Taken together, the journey from primary DNA sequence to biological effect is a complex one with numerous opportunities for the introduction of pathology.

The numbered chromosomes are referred to as autosomes and exist in pairs in every cell, each member of the pair being derived from a parent. Chromosome X and Y have pseudoautosomal regions with distinct recombinatory properties. Through the process of X-inactivation, women selectively inactivate one X chromosome in every cell, leading to the observation that in this sense all females are mosaic.

In addition to the nuclear genome, cells have an additional mitochondrial genome that resides in those organelles and whose division and replication are regulated semiautonomously. The mitochondrial genome comprises 14 genes, and several well-characterized human disorders are associated with mutations in those genes. Many of the genes encoded in the mitochondrial genome produce proteins essential for function of the electron transport chain. Due to the lack of mitochondria in paternal sperm, an individual's mitochondrial genome is generally derived maternally. Mutations within the

mitochondrial genome can occur somatically with the result that any one cell may host several copies of that genome, some with mutations and some without, a phenomenon called heteroplasmy.

### Genomic Variation

The terminology used to describe genomic variation can be complex, and a glossary of terms is included in [Table 34-1](#).

### Chromosomal Structural Rearrangements

A variety of chromosomal structural rearrangements has been known to geneticists for many decades and includes translocations of part of one chromosomal arm onto another. Translocations are often visible on karyotype and are classified as balanced or unbalanced, depending on whether or not they result in net loss or gain of genomic material. On the whole balanced translocations are generally regarded as nonpathogenic, unless the translocation disrupts a critical locus. Balanced translocations can, however, result in chromosomal breakage and can mediate a chromosomal deletion or duplication in an offspring—for example Robertsonian translocations as a cause of Trisomy 21. These examples change recurrence risk inform the need to perform karyotypes in parents of children with chromosomal abnormalities.

### History of Cytogenetics

The origins of human cytogenetics can be attributed to Walther Flemming, who first described human chromosomes in the early 1880s. Improvements in technology in the early 20th century led to research into the number of human chromosomes and the configuration of sex chromosomes between males and females. However, it was not until the accidental “discovery” of hypotonic treatment in the early 1950s that the diploid complement of chromosomes was set at 46. This key step, which caused the cells to swell and allowed chromosomes to separate, was necessary to fully visualize each homolog pair. At the same time, the use of colchicine to destroy the mitotic spindle permitted scientists to view the chromosomes at the stage of maximal contraction. This combined hypotonic/colchicine technique led to the modern field of cytogenetic analysis that we know today ([Gerson and Keagle, 2013](#)).

With accurate visualization of chromosomes, various defects in chromosome number and structure were discovered. The first such discovery was made by Lejeune and colleagues in 1959 with the observation of an additional chromosome in the fibroblasts of patients with Down

**TABLE 34-1** Glossary of Terms Used to Describe Genomic Variation

Term	Definition
Aneuploidy	A chromosomal numerical abnormality, such as a trisomy or monosomy
Balanced translocation	A type of chromosomal structural rearrangement where there is no apparent loss or gain of genetic material
Heteroplasmy	Presence of more than one mitochondrial genome within a cell
Indel	An insertion or deletion of DNA.
Missense mutation	A coding single nucleotide variant that results in a change in amino acid sequence; a type of nonsynonymous variant
Mosaic	Presence of more than one populations of cells with different genotypes within an organism.
Mutation	A genetic variant that causes abnormal biologic function and is pathogenic, disease-causing; this can include any pathogenic genetic variant but is most commonly used to refer to pathogenic single nucleotide variants
Nonsense mutation	A coding variant that results in the premature introduction of a stop codon
Nonsynonymous variant	A coding variant that results in a change in amino acid sequenc.
Regions of homozygosity	Chromosomal regions where the pattern of DNA polymorphisms indicates decreased genetic diversity
Segmental duplication	Genomic sequences sharing >90% similarity over >1 kb with another genomic location
Short tandem repeats	Tracks of tandemly repeated short (1–6 bp) DNA sequence motifs; also called microsatellites
Single nucleotide polymorphism	Single nucleotide variant that is found in the general population and is considered benign; a type of single nucleotide variant
Single nucleotide variant	A single change in the nucleotide sequence that may be benign (polymorphism) or pathogenic (mutation)
Somatic mosaic	A form of mosaicism that occurs due to mitotic errors after fertilization
Structural rearrangements	Deletion, duplication, or translocation of chromosomal material
Synonymous variant	A coding variant that does not result in a change in amino acid sequence. Can affect exon splicing
Unbalanced translocation	A type of chromosomal structural rearrangement where there is loss or gain of genetic material
Uniparental disomy	The inheritance of both copies of a chromosome, or a chromosomal region, from one parent only
Variant of unknown significance	A variant whose pathogenicity is unknown

syndrome, later identified as chromosome 21. The sex chromosome abnormalities of Turner syndrome, Klinefelter syndrome, and Triple X syndrome were also defined in 1959, by Ford and colleagues, Jacobs and Strong, and Jacobs and associates, respectively. The next year brought the description of Patau syndrome and Edwards syndrome, later defined as trisomy 13 and trisomy 18, respectively. No additional advances in the field could be made until improvement in staining techniques.

When methods for examining chromosomes under the microscope were first developed, individual chromosomes could not be identified because of solid staining. Instead, they were separated into seven groups (A to G), based on their length and centromere position. Although not ideal, this was suitable for the analysis of simple monosomies and trisomies. However, the discovery of quinacrine mustard staining by Caspersson and colleagues in 1971 allowed the identification of individual chromosomes, the foundation of the numbering system in use today. The ability to positively identify a chromosome, along with the possibility of visualizing “bands” within each homolog, led to an explosion of defined chromosomal syndromes, including deletions, duplications, inversions, translocations, and other rearrangements.

The field has expanded, with development of new technologies that allow even finer resolution of the chromosomal complement. Several of these techniques use molecular genetics methodologies as discussed further in this chapter. Thus the distinction between cytogenetics and molecular genetics has become blurred. In general, traditional cytogenetic analyses examine large regions of the genome such as chromosomes or regions of chromosomes, whereas standard molecular genetics

methods focus on smaller regions of the genome, from single nucleotides to genes and gene regions. However, even in this era of nucleotide-level resolution, traditional cytogenetics remains critical for the study of rearrangements not routinely detected by new technologies, most importantly balanced rearrangements that disrupt crucial genes in development.

A uniform system of human chromosome classification and nomenclature is used to describe abnormalities. This system was developed at a series of international conferences and was most recently revised in 2013. In this system, the chromosomes are separated into bands, which are placed into regions defined by landmarks. As resolution increases, bands can be subdivided into subbands, which are designated with a decimal point. All bands are described in relation to the centromere, with higher region and subband numbers corresponding with more telomeric positions. The four required components of a band description are: (1) chromosome number; (2) arm symbol (p for short arm or q for long arm); (3) region number; and (4) band number within the region. Thus the designation 17p13.3 (read as “17-p-one-three-point-three”) corresponds to chromosome 17, short arm, region 1, band 3, subband 3. The use of this standardized system allows consistent description of chromosomal abnormalities regardless of the laboratory performing the analysis.

As with any technique, there are limitations to traditional cytogenetic analysis. Even with high-resolution banding techniques genomic imbalances smaller than three megabases cannot be visualized. In addition, cryptic rearrangements involving bands of similar size and staining density may not be recognized. On the other hand, polymorphic variations in banding, aside from common sites, can be confused for pathogenic changes if not further explored through family

studies. Mosaicism for multiple cell lines may not be recognized if the level of the secondary cell line is low (typically lower than 20%). Finally, the genetic composition of chromosomal material of unknown origin, either in the form of markers or material added on to existing chromosomes often cannot be confirmed through standard analysis. Additional techniques, such as fluorescent in situ hybridization (discussed later in this chapter) or microarray analysis, are often necessary to fully elucidate the genomic origin of such material (Haines et al., 2012).

## Fluorescence in Situ Hybridization

Fluorescence in situ hybridization (FISH) is a technique used to detect specific chromosomes or chromosomal regions through hybridization (attachment) of fluorescently labeled DNA probes to denatured chromosomal DNA. Examination under fluorescent lighting detects the presence or absence of the hybridized fluorescent signal (and hence presence or absence of the chromosome material). Described as a “molecular cytogenetic” technique, FISH has been accepted as the standard-of-care for a variety of chromosomal aberrations. These abnormalities are too small to be visualized using standard cytogenetic techniques and too large to be analyzed with standard DNA sequencing.

FISH studies can be performed on metaphase chromosomes or interphase cells, depending on the type of abnormality being considered and the probe type being used. Probes can be divided into three major categories: repetitive sequence, whole chromosome, or unique sequence. Repetitive sequence probes include those covering the alpha satellite regions at the centromeres of chromosomes. These probes can be used to detect aneuploidy in both metaphase and interphase cells. Whole chromosome probes, or chromosome painting probes, are comprised of both unique and mildly repetitive sequences covering the entire length of a particular chromosome. These are most often used in metaphase cells for the study of structural abnormalities.

The most widely used probe type, unique sequence, is used to study a particular genomic region, ranging in size from 1 kb to larger than 1 Mb. These probes can be used in interphase or metaphase cells to detect deletions, duplications, or other abnormalities. However, in contrast with metaphase FISH, interphase FISH does not permit visualization of the actual chromosomes; therefore most types of structural rearrangements cannot be reliably detected. An additional type of unique sequence probe that is commonly used is telomere-specific probes. These probes correspond to the telomeres of all of the chromosomes and are used to detect abnormalities at the ends of chromosomes that are not visible by routine chromosome analysis. The previous utility of these probes has now generally been replaced by microarray analysis or MPLA analysis (see later section). Most FISH analyses examine one to two chromosomal regions at once, although it is possible to multiplex probes with special fluorescent markers to increase the number of regions that can be assayed.

FISH analyses are also used in conjunction with microarray studies that have identified copy number variations. Although microarrays can provide the highest resolution of genomic gains and losses, FISH analysis is still necessary to identify the underlying mechanism of the genomic alteration. For example, FISH studies can discriminate between tandem duplication and duplication due to an unbalanced rearrangement. Even though the outcome of the two abnormalities is the same (gain of a particular region), the mechanism of the abnormality could have a substantial influence on family planning. In addition, FISH analysis is often less expensive and faster than additional microarray studies when determining the

inheritance pattern of a microarray abnormality. This can lead to a more rapid clinical assessment of the patient, given the possible pathogenicity of a de novo variant versus a likely benign familial copy number change.

## Copy Number Variations

The completion of the draft human genome sequence in 2000 inaugurated a new era of appreciation for the patterns of genomic variation. It was soon discovered that the human genome contains numerous areas of segmental duplication, which are nucleotide sequences sharing greater than 90% similarity over larger than 1 kb in size with another genomic location. There are over 1400 copy number variable regions in the human genome (about 12% of the entire genome), and 25% of these copy number variable regions are associated with segmental duplications. Segmental duplications are therefore an important mechanism mediating copy number variation. Copy number variants range in size from small insertions or deletions of single nucleotides, through duplication or deletion of chromosomal regions hundreds of kilobases (kb) in size or larger, all the way to include trisomies (duplications of entire chromosomes) or monosomies (loss of entire chromosomes). However, most copy number variants are benign and number in the hundreds of kb in size (Cooper et al., 2011; Kearney et al., 2011).

## Indels

Among genomic variants, insertions/deletions (indels) are the second most common type and the most common type of structural variant. Collectively, between 1.6 and 2.5 million indel polymorphisms are present in the human population, with approximately 0.4 million short indels (1 to 16 bp) present per individual. The presence of an indel may be associated with disease, particularly if the inserted or deleted nucleotides result in a frameshift in a coding region. In contrast, the biological function of indels located within noncoding regions, intragenic regions, introns, and untranslated regions are more likely to be benign variants.

## Short Tandem Repeats

Short tandem repeats (STRs), or “microsatellites,” are tracks of tandemly repeated short (1 to 6 bp) DNA sequence motifs. STRs may occur in both intergenic and intragenic regions, including within genes, and account for approximately 3% of the human genome. Some microsatellites are highly mutable and show both sequence and length polymorphism whereas others are more conserved and can be informative markers in population genetics, mapping, and linkage studies. A specific subclass of trinucleotide repeats are combinations of nucleotides arranged repetitively (i.e., CAG or CGG repeats).

## Mutations, Single Nucleotide Variants, and Single Nucleotide Polymorphisms

A word regarding nomenclature is important at the outset here. For geneticists, there are important distinctions between mutations, single nucleotide variants, and single nucleotide polymorphisms. All refer to alterations in a single nucleotide. The term mutation is best reserved for nucleotide changes that are clearly associated with a deleterious biological effect or a disease. Single nucleotide variants (or SNVs) are those nucleotide changes not clearly associated with abnormal biology or disease but not clearly benign population variants either. SNVs therefore may be understood to include variants of unknown significance. Finally, single nucleotide polymorphisms (or SNPs) are a special group of common nucleotide

variants present in a significant (generally greater than 0.05%) percentage of the human population and are widely understood not to be associated with abnormal biology or disease. SNPs that have been documented in the general population will have catalog numbers (beginning with “rs”) and will be present in the Database of Single Nucleotide Polymorphisms (dbSNP; <http://www.ncbi.nlm.nih.gov/SNP/>), often with an associated mean allele frequency.

Single nucleotide variants are the most common form of genomic variation, with 3 million SNVs typically present per individual. Of these, nearly 20,000 are located within coding regions. When SNVs located within coding regions do not result in a change in the amino acid sequence encoded, they are termed synonymous variants. There have usually no identifiable biological effects of synonymous SNVs except when they are located in splice regions at the exon-intron boundaries. When an SNV results in a change in the amino acid encoded, it is referred to as a nonsynonymous variant. These variants that alter the amino acid sequence may prove to be pathogenic if the change significantly affects the conformation or biological activity of the protein.

### Methods of General Mutation Detection

#### DNA Sequence Analysis

**Sanger Sequencing.** DNA sequence analysis is the most sensitive and direct method to detect mutations at the level of individual nucleotides. The most widely used method of DNA sequencing is the Sanger method, also known as dideoxy sequencing or chain termination. It is based on the use of synthetic nucleotide analogs—2, 3-dideoxynucleoside triphosphates (ddNTPs). Dideoxy NTPs differ from nucleotides found in natural DNA in that they lack the 3′-hydroxyl group. When integrated into a sequence, they prevent the addition of further nucleotides as phosphodiester bonds cannot form between a dideoxynucleotide and the next incoming nucleotide. Thus the DNA chain is terminated.

DNA sequencing most commonly is performed by the method of cycle sequencing, in which the DNA region to be sequenced (which is first generated by PCR) is denatured, and a short oligonucleotide is annealed to one of the template strands. DNA synthesis occurs in the presence of DNA polymerase, ddNTPs, and normal (deoxy) nucleotides and starts from the 3′ end of the annealed oligonucleotide. As the DNA is synthesized, nucleotides are added on to the growing chain by the DNA polymerase; however, on occasion, a ddNTP is incorporated into the chain in place of a normal nucleotide, resulting in a chain-terminating event. At the end of the sequencing reaction, multiple DNA molecules are present such that, at each nucleotide position, a proportion of molecules are terminated because of the incorporation of a ddNTP. These products are separated by size on capillary or polyacrylamide gel electrophoresis systems, and the fluorescently labeled ddNTPs are detected. Each ddNTP is labeled with a different fluorophore. Shorter DNA molecules migrate faster than longer molecules on electrophoresis, and by analyzing the different fluorescent signal of all of the different-sized molecules, the DNA sequence can be determined. For example, ddCTP is labeled with a blue fluorophore. Everywhere a G residue exists in the template DNA, either a dCTP or a ddCTP will be incorporated into the synthesized strand. For every G residue in the template DNA, a proportion of molecules with a ddCTP at that site will be present. Each of these molecules will be of a different size, depending on where a G residue resides in the sequence and will be distinguished by electrophoresis. The same applies for the other ddNTPs. Specialized DNA sequencing software exists that can convert the different fluorescent signals to different-color peaks that constitute a DNA sequence chromatogram.

After performing the necessary laboratory techniques, the sequence is analyzed by a trained molecular technician. Computer programs are used to facilitate the comparison of generated sequence with the reference sequence for the region of interest. If differences are discovered, they should ideally be confirmed. Such differences are then described using both nucleotide and amino acid designations in the standardized fashion. The nucleotide change is defined as the position in the coding sequence, with the adenine nucleotide of the initiator ATG designated as the first base, followed by the nucleotide change, all beginning with a “c” identifier. For example, a guanine to cytosine change at the fiftieth nucleotide in the coding sequence would be defined as “c.50G>C.” The amino acid change is then defined as the original amino acid (either three letter or single letter code), the numerical identifier of the amino acid in question, and the new amino acid, all beginning with a “p” identifier. For example, using the previous nucleotide change, the seventeenth codon changes from CCA to CGA, which results in a change from proline to arginine; this would be defined as “p.Pro17Arg” (alternatively “p.P17R”).

The next stage of analysis involves bioinformatics techniques. The variant identified through sequencing may be a known population polymorphism, a known pathogenic mutation, a completely novel variant, or a reported variant without clear phenotypic consequences. In order to determine which class contains the identified variant, a molecular geneticist queries public databases such as dbSNP, ClinVar, or HGMD. If the pathogenicity of the variant is unknown, this aspect can be explored using web-based prediction programs, such as PolyPhen, SIFT, MutPred, Condel, or FATHMM. However, it should be remembered that these are predictions only and are not definitive evidence of the functional effect of a given variant. A sequence variant is typically reported as pathogenic, of uncertain significance, or benign, and the final report should include all pertinent information regarding this designation.

The use of the Sanger technique to study the sequence of a genomic region of interest is limited only by the ability of the user to design appropriate oligonucleotides, or primers, to be used in PCR amplification and subsequent sequencing. However, several limitations exist for this technique and must be taken into account. First, as the Sanger technique relies on an initial PCR amplification, it is subject to PCR errors. These events are rare, but they can cause significant problems in final analysis if they occur early in the PCR cycling process. Second, Sanger sequencing is not well-adapted to analyzing mosaicism, again due to the initial PCR step. This is not a quantitative method, and a target sequence in a smaller proportion can be overwhelmed by another sequence present in the template. Third, care must be taken in the design of primers to ensure that the proper target is amplified, which is especially vital when considering genes with closely related pseudogenes. Finally, Sanger sequencing can only detect changes in sequence, not changes in copy number. If one allele carries a deletion or duplication, it will not be detected; the final chromatogram will be consistent with two homozygous alleles. These caveats must be considered when using Sanger sequencing.

**Deletion/Duplication Analysis.** The most common method of deletion/duplication analysis is Multiplex Ligation-dependent Probe Amplification, or MPLA. MLPA is used to detect copy number changes of small DNA fragments. This technique is most often used to assay individual exons of genes but can also be used to study the subtelomeric regions of chromosomes or multiple regions of specific chromosomes to detect aneuploidy. In this technique, special MLPA probes are hybridized to the ends of sequences under study; if both ends are present, the probes are ligated together. Only then can PCR be used to

amplify the complete sequences. The unique MLPA probes are comprised of a sequence compatible to the target sequence, a stuffer sequence for size variation, and a common PCR primer sequence. The combination of variable size products and a single set of PCR amplification primers allow this technique to assay up to fifty separate targets in a single reaction. MLPA utilizes the same laboratory equipment as PCR-based Sanger sequencing, specifically a thermocycler and a fluorescent capillary electrophoresis system.

MLPA is often the first-tier test in disorders primarily caused by exon or gene deletions/duplications, such as Duchenne muscular dystrophy (DMD), spinal muscular atrophy (SMN1), and Charcot-Marie-Tooth neuropathy (PMP22). In addition, the use of MLPA in conjunction with traditional gene sequencing can increase the rate of detection of pathogenic variants, typically up to an additional 10%.

MLPA is advantageous in that it can detect very small imbalances, to the level of 50 to 75 nucleotides, which is much smaller than the resolution of oligonucleotide microarrays or FISH analysis. In addition, the exact location of the imbalance does not need to be known a priori, as is required with standard PCR-based methods of deletion/duplication analysis. However, kits are only available commercially for defined genomic locations, without the ability to study less commonly affected regions. In addition, care must be taken when interpreting results that are indicative of deletions. Sequence variation within the probe target site can either abolish or reduce probe binding, which would generate an electrophoretic profile consistent with a deletion. As such, results must be considered in conjunction with clinical information, and ideally all results should be confirmed with a separate methodology.

**Methylation Studies.** Methylation of cytosine is a DNA modification associated with several biological processes, including imprinting, X chromosome inactivation, and silencing of repetitive DNA sequences. The most recent studies suggested approximately 151 genes in the mouse genome were subject to imprinting, and a similar number estimated for the human genome, despite some recent methodological controversy. Of these, the 15q11q13 region, associated with the Angelman, Prader-Willi, and Duplication of Maternal 15q11q13 syndromes is most notable. These are imprinting disorders, in which the phenotype is determined by the pattern of parental methylation of 15q11q13. Individuals with loss of the paternal methylation pattern present with Prader-Willi syndrome, whereas those with loss of the maternal methylation pattern present with Angelman syndrome.

This may occur through a number of molecular mechanisms, and for Angelman syndrome includes de novo deletion of 15q11q13 (70% to 75% of individuals) uniparental disomy for chromosome 15 (2% to 3% of individuals), imprinting center mutations (3–5% of individuals), or mutations in UBE3A (5% to 10% of individuals) a gene on 15q11q13 whose expression is directed by parent-of-origin allele-specific methylation. Therefore the best first test for diagnosis of Angelman syndrome is bisulfite methylation sensitive polymerase chain reaction (PCR), which will detect any of the methylation defects, whether caused by chromosomal deletion, uniparental disomy, or imprinting center mutation. Chromosomal microarray will only detect 15q11q13 deletions, will miss approximately 25% of Angelman patients and should not be used as the first diagnostic test. In individuals with normal 15q11q13 methylation studies, but who have a phenotype consistent with Angelman syndrome, UBE3A sequencing should be the second test sent.

**Chromosomal Microarray.** Copy number variants (CNVs) are identified by array-based methods that use comparative genome hybridization (CGH). CGH determines copy number of genomic DNA sequencing using varying intensity patterns

between hybridized patient and control DNA. Control DNA used in microarray either represents the whole genome or contains cloned fragments (targeted microarray) from the genome. Bacterial artificial chromosomes (BAC) probes are approximately 75,000 to 150,000 base pairs in length whereas oligonucleotide probes, used for oligonucleotide and single-nucleotide polymorphism (SNP) arrays, are approximately 50 to 60 base pairs in length, allowing for increased breakpoint specificity and improved accuracy of copy number variants. The resolution of the array depends on the number and types of probes used and whether the probes are targeted or cover the whole genome (Manning and Hudgins, 2010). SNP arrays can detect copy number neutral regions of homozygosity that can be associated with uniparental disomy or consanguinity by comparing reference DNA to hybridized patient DNA. Identifying a copy neutral region of homozygosity may suggest an autosomal recessive disease in the patient. Typically, clinical chromosomal microarrays can detect chromosomal imbalances of 20 to 50 kb in targeted regions.

Copy number variants (CNVs) are classified as either pathogenic/abnormal, variant of unknown significance (VUS), or likely benign. It should be kept in mind when interpreting results that the estimated mean number of benign CNVs per individual is 800 or more. When a copy number variant is identified by chromosomal microarray, fluorescence in-situ hybridization (FISH) studies to confirm the finding in the patient, parental FISH studies, clinical genetic evaluation, and genetic counseling are recommended. In general, when a CNV is found to be inherited from a healthy parent, is gene poor, or is a duplication with no known dosage-sensitive genes involved, this indicates that the variant is likely benign. Likely pathogenic CNVs include those which are inherited from an affected parent, are gene rich, or overlap a genomic coordinates for a known genomic-imbalance syndrome.

Several studies have validated chromosomal microarray as a first tier test, over G-banded karyotype, in the evaluation of developmental delay, intellectual disability, autism spectrum disorders, and multiple congenital abnormalities. In a study of 21,698 patients with developmental delay, intellectual disability, autism spectrum disorders, or multiple congenital abnormalities, chromosomal microarray was found to have a diagnostic yield of 12.2%.

Pathogenic CNVs have been shown to play a role in the etiology of epilepsy, providing evidence to support that chromosomal microarray be a part of the diagnostic evaluation for patients with unexplained epilepsy. It is estimated that up to 40% of epilepsies have a genetic component. Chromosomal microarray can identify recurrent CNVs for epilepsy “hotspots,” deletions, or duplications in known epilepsy genes, or nonrecurrent CNVs involving epilepsy genes. Chromosomal microarray has an even higher diagnostic yield in individuals with epilepsy and additional findings such as intellectual disabilities, dysmorphic features, malformations, developmental delay, and autism spectrum disorders. In a study of 102 patients with different types of epilepsy, either isolated or with intellectual disability/developmental delay, dysmorphic features, autism or other neurologic signs, 10 of 102 (9.8%) were found to have pathogenic CNVs associated with epilepsy. Limitations of chromosomal microarray include poor detection of low-level mosaicism, balanced rearrangement, and, in some arrays, polyploidy. Chromosomal microarray should not be used when a rapid turnaround time is needed, when a chromosomal trisomy such as Trisomy 21 is suspected, or when a well-described syndrome is suspected as a diagnosis.

**Southern Blot.** The Southern blot is a technique that uses gel electrophoresis combined with labeled probes for a DNA sequence of interest that allows for the detection of repeat expansions within specific genes. The technique is used to

detect the triplet repeat expansions seen in neurologic diseases such as myotonic dystrophy, fragile X syndrome, and many spinocerebellar ataxias. Despite advances in sequencing technologies, this technique remains the standard for direct molecular diagnosis of these disorders.

**Next-Generation Sequencing.** The term “next-generation sequencing,” or “high-throughput sequencing,” has become synonymous with the most recent appearance on the clinical and research scene of massively parallel sequencing of regions of interest. In 2009 the first use of next-generation sequencing, specifically whole-exome sequencing, as a proof-of-principle to confirm mutations in MYH3 as the causative gene for Freeman-Sheldon syndrome. Soon after, a similar technique was employed to identify DHODH as the causative gene for Miller syndrome, followed by the identification of MLL2 as the first causative gene for Kabuki syndrome. Of note, the identification of MLL2 highlighted the challenging bioinformatics aspects of next-generation sequencing analysis, as several iterations of analysis were required before mutations were found. In the years since those findings, an evolution of the technological platforms for next-generation sequencing has occurred, with the Illumina platform producing 100 bp paired-end reads, currently the most prevalent in research and clinical diagnostic settings, although alternatives exist.

Next-generation sequencing involves the targeted capture of defined genomic regions of interest. At the most narrow—for example, those available in disease gene panels such as epilepsy or intellectual disability panels—the region of interest may be the coding exons of several dozen genes. Larger regions of interest such as the exome include the coding regions of all genes. Variability in the percentage coverage of each gene is a factor in the capture of regions of interest and should be taken into account during the selection of a sequencing method. The bioinformatics analysis of next-generation sequencing data has emerged as a new field within genomics, and changes in best practices occur quickly.

## RESOURCES FOR INTERPRETING GENOMIC TESTING

A constant feature of current genomic testing is the rapid introduction of new technologies and, along with them, new methods to allow their interpretation. In an ideal setting, close collaboration exists with genetics colleagues who maintain currency with this evolving field. However, appropriate expertise may not be readily available in all of the settings where child neurologists evaluate individuals with neurodevelopmental disorders. A summary of the tools discussed here is found in [Table 34-2](#).

CNVs for which no literature exists to help interpretation can be evaluated using DECIPHER (<https://decipher.sanger.ac.uk/>), and the Database of Genomic Variants (<http://dgv.tcag.ca/dgv/app/home>).

Most genomic variants that are causative of neurodevelopmental diseases are rare, not present in the general population, and in the case of relatively common disorders such as autism and epilepsy (Epi4K Consortium), are often but not always due to de novo mutations that are not inherited from the parents. Other disorders are autosomal recessive or X-linked, in which case a disease causing variant may be present in one (usually the mother in the case of X-linked) or both parents (in the case of autosomal recessive). Several online resources provide expert-curated gene-phenotype associations relevant to child neurology ([Table 34-5](#)). Finally, the Developmental Brain Disorders Database (DBDB; <https://www.dbdb.urmc.rochester.edu/home>) provides a repository of genes, phenotypes, and syndromes specifically targeted at neurodevelopmental disorders.

**TABLE 34-2** Glossary of Terms Used for Genomic Diagnostic Technologies and the Genomic Variations They Detect

Diagnostic Technology	Genomic Variation Detected
Karyotype	Aneuploidy (trisomy, monosomy), structural rearrangements including balanced translocations, deletions and duplications >5 Mb.
Fluorescence in situ hybridization (FISH)	Specific deletions or duplications.
Methylation studies	Abnormal parental methylation patterns.
Chromosomal microarray (CMA)	Copy number variations (deletions, duplications) >50-100 kb. SNP arrays can detect loss of heterozygosity (regions of homozygosity), uniparental disomy.
Sanger sequencing	Single nucleotide variants, small frameshift indels
Multiplex ligation probe amplification	Exon-level deletions or duplications
Southern blot	Triplet repeat expansions
Next-generation sequencing	Massively parallel detection of single nucleotide variants, small indels in many genes simultaneously across targeted region of interest

Recently a statistical approach was proposed to determine whether or not variants in a given gene are likely to be disease causing based upon the prevalence overall of common variation in that gene, with the hypothesis that some genes are more tolerant of variation whereas others are not. The proposed residual variance intolerance score (RVIS) is derived from the regression of common coding variants in a gene upon all variants in that gene. A value lower than the 25th percentile is taken as a cutoff higher than which a gene is said to “tolerate” variation and therefore is unlikely to be a disease gene; indeed, many known neurodevelopmental disease genes fall lower than this percentile. A difficulty with this approach, however, is that it treats all variation as equal when clearly this is not the case. Null mutations anywhere in a gene may be deleterious, even in a gene with many common sequence variants. Likewise, specific amino acid substitutions at biologically critical loci within a gene (whether or not variations in the gene overall are frequent) can also cause disease.

Although the use of whole-exome sequencing for clinical diagnostics has resulted in the identification of causative mutations in many individuals, the overall diagnostic yield of 25% has not been as impressive as initially hoped. It is suggested that adoption of whole genome sequencing able to identify both CNVs and SNVs will increase the diagnostic yield of next-generation sequencing to over 40%.

## Somatic Mosaicism and Challenges of Tissue of Origin for DNA

DNA isolated from patient leukocytes has been the traditional source for diagnostic genetic testing, including in neurologic disorders. However, a spectrum of disorders has been identified in which the causative mutations are present in affected brain tissue in a somatic mosaic manner. This observation began with the identification of “second-hit” somatic mutations in TSC1/2, in neurons of individuals with tuberous sclerosis complex, and in germline mutations in the same gene. Then, mosaic mutations were identified in a spectrum

**TABLE 34-5** Summary of Online Tools Involved in Analysis of Genomic Diagnostic Testing

Tool and URL	Use Case
Database of Genomic Variants (DGV) <a href="http://dgv.tcag.ca/dgv/app/home">http://dgv.tcag.ca/dgv/app/home</a>	Evaluation of copy number variants
DECIPHER <a href="https://decipher.sanger.ac.uk/">https://decipher.sanger.ac.uk/</a>	Evaluation of copy number variants
Human Gene Mutation Database (HGMD) <a href="http://www.hgmd.cf.ac.uk/ac/index.php">http://www.hgmd.cf.ac.uk/ac/index.php</a>	Evaluation of known mutations in known disease genes
SIFT <a href="http://sift.jcvi.org/">http://sift.jcvi.org/</a>	Prediction of effect of amino acid substitution on protein function
PolyPhen <a href="http://genetics.bwh.harvard.edu/pph2/">http://genetics.bwh.harvard.edu/pph2/</a>	Prediction of effect of amino acid substitution on protein function
Ensembl's Variant Effect Predictor (VEP) <a href="http://grch37.ensembl.org/Homo_sapiens/Tools/VEP">http://grch37.ensembl.org/Homo_sapiens/Tools/VEP</a>	Allows batch annotation of genomic variants for SIFT, PolyPhen, dbSNP membership, and other annotations
dbSNP <a href="http://www.ncbi.nlm.nih.gov/SNP/">http://www.ncbi.nlm.nih.gov/SNP/</a>	Evaluation of single nucleotide polymorphisms for population frequency
UCSC Genome Browser <a href="http://www.genome.ucsc.edu/">http://www.genome.ucsc.edu/</a>	Allows visualization of a range of genomic regions of interest and multiple annotations
Eukaryotic Linear Motif server (ELM) <a href="http://elm.eu.org/">http://elm.eu.org/</a>	Evaluation of amino acids within functional protein domains
Exome Variant Server (EVS) <a href="http://evs.gs.washington.edu/EVS/">http://evs.gs.washington.edu/EVS/</a>	Allows search for variants in >6500 other whole exomes
Exome Aggregate Consortium browser (ExAC) <a href="http://exac.broadinstitute.org/">http://exac.broadinstitute.org/</a>	Allows search for variants in >63,000 whole exomes
GeneReviews <a href="http://www.ncbi.nlm.nih.gov/books/NBK11116/">http://www.ncbi.nlm.nih.gov/books/NBK11116/</a>	Expert curated chapters on well-described single gene syndromes
Online Mendelian Inheritance in Man (OMIM) <a href="http://www.ncbi.nlm.nih.gov/omim/">http://www.ncbi.nlm.nih.gov/omim/</a>	Expert curated information on a broad range of genetic syndromes
Developmental Brain Disorders Database (DBDB) <a href="https://www.dbdb.urmc.rochester.edu/home">https://www.dbdb.urmc.rochester.edu/home</a>	Expert curated gene-phenotype-syndrome associations specific to neurodevelopmental disorders

of megalencephaly polymicrogyria syndromes, hemimegalencephaly, and focal cortical dysplasia type II, with the mutations documented at varying levels in blood, skin, brain, and saliva-derived DNA. Clearly, blood-derived DNA may not be the most informative in these disorders, an issue now being addressed by diagnostic testing laboratories.

Determining an etiology for a child's developmental delays/intellectual disability or autism spectrum disorders may influence a child's treatment. In a survey of 48 patients with positive chromosomal microarray results, physicians noted a direct effect on the family in 70% of cases. The most beneficial effect to families was the ability to provide recurrence risks, providing access to educational and insurance services, avoiding other tests to determine a diagnosis, and helping target additional medical referrals such as to a cardiologist or ophthalmologist. Failure to diagnose a genetic disease can have negative effects for both the family, including lack of potential treatments, clinical trials, or recurrence risks, and for society as continued genetic testing or therapies increases medical expenditures.

A three-generation family pedigree should be recorded at the initial patient visit and should be periodically updated. There are several methods of gathering family history information, including physician-directed questions or a questionnaire given before the patient's visit. Factors to consider when assessing a family pedigree for patterns of inheritance include the possibilities of variable expressivity, age related penetrance, gonadal mosaicism, and incomplete penetrance.

Next generation sequencing panels and whole-exome sequencing are becoming more popular testing options and increase the complexity of the genetic counseling process.

Pretest counseling for whole-exome sequencing should include a formal consent process by a medical geneticist or genetic counselor and should include the expected outcomes of testing, likelihood and type of incidental findings, and what results will or will not be disclosed (ACMG Board of Directors). Patients should be informed of the possibility that incidental or secondary findings, as defined by the minimum list of incidental findings recommended by the American College of Medical Genetics, that are unrelated to the patient's symptoms, but may influence medical care may be detected on clinical whole-exome sequencing) and the patient should be given the option to opt-in or opt-out of this additional information (Allyse and Michie, 2013). Patients should be counseled regarding alternatives to testing and informed consent should be included with written documentation (ACMG Board of Directors, 2013). Pretest counseling should also include a description of the differences between research and clinical whole-exome sequencing.

It is important for healthcare providers to include the detailed family pedigree, information on physical examination, and previous laboratory tests with the patient's sample to assist with interpretation of results. Results of clinical whole-exome sequencing may include pathogenic variants known to be associated with the phenotype, variants of uncertain significance in genes possibly related to the patient's phenotype, and medically actionable pathogenic variants not related to the patient's phenotype (ACMG Board of Directors, 2013). Interpreting results of whole-exome sequencing should be done in the context of the patient and family history and requires an understanding of a range of inherited conditions. Candidate variants in genes suspected to be related to the

patient's phenotype are often identified and require further studies to determine its role in disease, but a variant of uncertain significance should not be used in the patient's medical decision making. It is strongly recommended to include parental sample with the proband to help in interpretation of variants. The majority of variants for autosomal dominant diseases can be ruled out with parental samples if either of the parents carry the same variant and are unaffected. In addition to information directly related to the patient's phenotype, additional information from whole-exome sequencing may include carrier status of a disease that may influence reproductive decisions and disease susceptibility or predisposition.

## Standards of Genomic Care

The recent advances in genomic medicine have brought new recommendations about best practices in the evaluation of individuals who may have genomic-mediated disorders. Arriving at a molecular genetic diagnosis may have care related consequences for affected individuals and may include recommendations for surveillance for known complications, in addition to affecting decisions about choice of medications. The difficulty is there are now so many characterized disorders and the spectrum of presenting symptoms can be so varied that any one practitioner is unlikely to be able to rule out a specific genetic syndrome solely on clinical grounds.

Identification of a genetic diagnosis also allows affected individuals to participate in clinical trials and/or natural history studies that may be available for that disorder. An accurate molecular diagnosis is usually an inclusion criterion for participation. Although it should be noted that insurance providers are not in the business of paying for diagnostic testing for the purpose of enabling participation in a clinical trial, it is still within the purview of the physician to provide optimal care to their patients, and this should include making families aware of the availability of clinical trials and/or natural history studies. Funding agencies are unlikely to provide resources to pay for genetic tests that are clinically available. This is one aspect of the current tension surrounding the best practices of care for children with developmental disorders. It should be noted that much of the medical surveillance recommendations for conditions such as MECP2-related disorder come in part from the results of natural history studies. The ability to identify individuals made possible the

recent treatment trials for fragile X syndrome and Duchenne muscular dystrophy.

## LOOKING TOWARD THE FUTURE

Genomic medicine as it applies to child neurology has undergone dramatic changes in the past decade. The advent of new molecular diagnostic technologies has meant that children once diagnosed with "developmental delay," "epilepsy," and "intellectual disability" now have access to much more specific molecular diagnoses. In many cases, more specific diagnoses now have specific health surveillance and treatment recommendations. Just one exciting example is the discovery of the molecular basis underlying focal cortical dysplasia and hemimegalencephaly and their associated intractable epilepsy, which means that new avenues of treatments that are based on biological pathways are now investigation.

The technology to assay the human genome will continue to mature, as will the computational algorithms to identify pathogenic variation. New methods are in development to address gaps in next-generation sequencing analysis, in particular structural rearrangements, copy number variants, repeat expansions, and large indels. Many of these mutational classes will be addressed through new targeting chemistries, longer read sequencing, and novel analysis techniques. Still, the current gaps mean that chromosomal microarray, Southern blot, MLPA, Sanger sequencing, as well as karyotype will continue to have their place in clinical diagnosis.

## EXAMPLE OF PRINCIPLES IN PRACTICE

Patient AB is a 3-year-old with a history of progressive complex partial seizures. Onset of seizures began approximately 5 weeks ago. Her mother describes AB as "blinking out and staring into space" during a seizure episode. Episodes usually last less than 2 minutes and are not followed by a prolonged postictal period. After diagnosis of her seizures, she was placed on Keppra; however, her seizures continued and changed in nature. Her seizures are now accompanied by lip smacking and stiffening, occurring up to 20 times a day. A brain MRI was normal. EEG activity appeared focal during seizures and best described as complex partial with a tonic component. A microarray was ordered (Fig. 34-9).

**Figure 34-9.** CMA result from the short arm of chromosome 20 in the case patient.

Clinical interpretation of CNVs requires knowledge of several factors including:

1. Performance characteristics of the chromosomal microarray being used for testing
2. Frequency of CNV in databases of both control individuals as well as individuals with disease
3. Gene content of the CNV
4. Deletion versus duplication status
5. Inheritance of the phenotype/disease under consideration and disease genes within the CNV
6. De novo or inherited status and cosegregation with disease phenotype in a family

The evaluation of a clinical CMA test begins with knowledge of the microarray platform being used. The ACMG recommends that CMA platforms should be able to detect genome-wide CNVs of at least 400Kb at 99% analytical sensitivity (with a lower limit at the 95% confidence interval greater than 98%) and a false-positive rate of less than 1% (Cooper et al., 2011). This is the minimum standard clinical CMA platforms must meet; however, most clinical laboratories offering CMA today use platforms that allow for the reliable detection of much smaller CNVs—typically on the order of 50 to 100kb. In the above referenced clinical case, the CMA platform used was able to detect CNVs as small as 50kb in size.

The first challenge in interpreting a clinical CMA test is determining which of the myriad of CNVs detected are benign and thus not needing of additional consideration as an underlying cause of disease. Several publically available databases exist to aid in this task, including the Database of Genomic Variants. The Database of Genomic Variants (DGV) is a comprehensive collection of curated structural variation found in the genomes of control individuals from numerous studies and multiple ethnicities. It is important to note that data from control individuals is not precisely the same as data from healthy, “unaffected” individuals. Many of the control individuals with data in DGV were not screened for the myriad of neurodevelopmental or psychiatric conditions that are often times a part of the clinical phenotypic spectrum of patients being evaluated by CMA testing. However, despite this limitation, the copy number variants deposited within DGV have other associated information that makes them suitable for the interpretation of potential pathogenicity. As with SNVs, one of the most consistently used pieces of data is the frequency at which a particular region of the genome is found to be copy number variable in control populations. Different clinical laboratories will often have different frequency thresholds but they are typically in the range of 1% to 5% variant frequency.

Furthermore, it is also recommended that, before a CNV be considered benign, it also be found at a relatively high frequency in more than one study deposited in DGV and in studies with a sufficient number of individuals. Lastly, given the rapidly evolving rate of both microarray and sequencing technologies, it is important to place higher confidence on those studies that used a CNV detection platform consistent with the one being used clinically. In addition to DGV, there are other clinical databases that can be used to help interpret the likely pathogenicity of CNVs, including the ClinGen Structural Variant database (formerly the International Standards for Cytogenetic Arrays Consortium, or ISCA) and Database of Chromosomal Imbalance and Phenotype in Humans (DECIPHER) (<http://clinicalgenome.org/> and (Zarrei et al., 2015). Lastly, each clinical laboratory should maintain a database of their own to identify both recurrent CNVs that may have disease significance but also those that are seen frequently enough to warrant exclusion as benign.

Once all likely benign CNVs have been removed, it is important to perform additional analysis to interpret those

remaining CNVs as either variants of unclear clinical significance or likely pathogenic. If a CNV is detected that is a well-established, disease-associated variant, such as a 22q11.2 deletion and DiGeorge syndrome or a 7q11.23 deletion and Williams syndrome, it can be interpreted fairly quickly and accurately. If, however, a CNV does not fall within one of these well-known disease loci, additional steps are necessary. First, does the CNV contain any genes? If no genes are located within the CNV, interpretation of its potential clinical significance is very difficult. Only 2% to 3% of the genome is known to code for protein and, as such, is the portion of the genome most easily interpreted in a clinical sense. If a CNV contains no genes there is very little confident information that can be conveyed about its potential effect on disease or human phenotypes. Such CNVs are typically not mentioned in clinical reports. Gene content of a CNV, as opposed to simply size, appears to be a larger determinant of phenotypic significance. Additionally, deletions tend to disrupt gene function more often than duplications that, when they do, exert a phenotypic effect can be via several different mechanisms. Deletions naturally cause haploinsufficiency of dosage sensitive genes.

Most importantly, interpretation of the clinical significance of a CNV requires knowledge of any disease-associated genes within the CNV as well as the inheritance pattern of the disease in the family under investigation. A thorough family history and creation of a pedigree is highly recommended before any type of genetic testing is ordered. If the condition being investigated has a clear inheritance pattern, interpretation of CMA results can be much more accurate. The majority of conditions diagnosable by CMA are autosomal dominant or X-linked recessive in nature as the vast majority of lesions identified by CMA are single allele deletions or duplications. Genes known to only cause disease in a recessive fashion are less likely to be of clinical significance in the interpretation of a CNV and typically require sequencing of the other allele to determine the status of the other gene copy. This is not the case, however, if a homozygous deletion is detected. Knowledge of other affected individuals within the family is very important as cosegregation of a CNV with disease can contribute to an interpretation of likely pathogenicity. If a potentially disease-associated CNV is found in a proband and is also found to be inherited from an unaffected parent, the likelihood of that CNV being the sole cause of the proband's condition is greatly reduced. In contrast, if such a CNV is found to be de novo in the proband and not found in either biological parent, then that increases the probability of pathogenicity. Parental testing should be considered to help refine the interpretation of CNVs of unclear clinical significance, however, it is likely to have a higher probability of being meaningful if other features of the CNV suggest pathogenicity (such as gene content, disease-associated genes of appropriate inheritance patterns, deletion status, and absence or rarity in control and/or clinical CNV databases).

In the present case, after benign CNVs have been excluded only two remained that were higher than the size threshold of 50kb. Microarray results showed a 540kb deletion at 20p13 followed by 216kb duplication immediately adjacent. There are no identical or very similar deletions or duplications within the DGV or other clinical databases; however, both ClinGen and DECIPHER do list patients with deletions and/or duplications that cover the region of the genome. The deletion contains 14 genes and the duplication contains four genes. Within the deletion interval there are two disease-associated genes: RBCK1 and TBC1D20. RBCK1 is implicated in polyglucosan body myopathy 1 with or without immunodeficiency, an autosomal recessive condition, and TBC1D20 is implicated

**Figure 34-10.** Karyotype result exhibiting a ring chromosome 20 in the case patient.

in Warburg micro syndrome 4, also an autosomal recessive syndrome. Neither of these conditions is a good phenotypic fit for the patient under consideration nor would a single copy loss be expected to result in an autosomal recessive phenotype. One gene within the duplication interval is listed as a disease-associated gene with the OMIM database: SLC52A3. This gene is implicated in the conditions Brown-Vialetto-Van Laere syndrome 1 and Fazio-Londe disease. Both of these conditions are autosomal recessive and unlikely to result from a duplication (gain of copy number) of the associated gene. Thus on the basis of the CMA data only, these CNVs would best be classified as variants of unclear clinical significance. However, in this case, convention chromosome analysis was also ordered and a ring chromosome 20 was discovered (Fig. 34-10).

This case illustrates one of the most important limitations of CMA: the inability to detect balanced structural rearrangements. Whereas in this case the formation of the ring chromosome 20 did involve the loss and gain of DNA sequence and was thus detectable by CMA, the true nature of this lesion was only elucidated by chromosome analysis. The ring chromosome 20 syndrome, also referred to as R(20) syndrome, is a rare chromosomal disorder associated with refractory epilepsy. The seizures in this condition are typically partial complex in nature and can be difficult to control. It is interesting and relevant to a discussion of CNVs that, whereas most patients with R(20) syndrome are mosaics with nearly completely balanced chromosomal rearrangements, those patients that are not mosaic, as was the case in Patient AB, typically do have small deletions or duplications identified that are associated with the ring. As is the case with Patient AB, the onset of seizures is typically in childhood and the seizures are typically partial complex in nature. Staring episodes along with automatism and focal motor symptoms are also common. Thus the phenotype described for R(20) syndrome very closely

matches that of Patient AB suggesting the etiology of her seizure conditions has been elucidated.

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

The development and maintenance of the human body is directed by an estimated 20,000 genes, consisting of some 3 billion base pairs (bp) of DNA. These genes encode the structure of proteins and noncoding RNAs, which together are responsible for the orderly unfolding of human development, beginning with the fertilized egg (zygote), and for the maintenance of body structure and function. The entire pool of genetic information must be replicated with each cell division and a complete set of information apportioned to the two daughter cells. In addition, the full complement of genes must be transmitted from generation to generation through the germ cells.

Genes do not exist as isolated entities within the cell nucleus but rather are arranged on structural units called chromosomes. Each chromosome contains hundreds or thousands of genes arranged in a linear order. This order is reproducible from cell to cell within an individual organism, and from individual to individual in the population. The normal human chromosome complement consists of 46 chromosomes, including 22 pairs of nonsex chromosomes (autosomes) and either two X chromosomes in females or an X and a Y in males. Each of these chromosomes has a characteristic structure and includes a specific set of genes arranged in a specific order. The chromosomes are units that ensure the orderly distribution of a complete set of genetic information during cell division.

Chromosome number and structure are tightly regulated, and deviations from the norm usually are associated with clinical problems. Multiple genes are simultaneously disrupted as a consequence of chromosomal abnormalities; accordingly, the phenotypic consequences usually are complex. Because of the complexity of the nervous system and its dependence on multiple genes, neurologic problems accompany most of the chromosomal disorders.

This chapter focuses on the approach to chromosomal disorders in pediatric neurology. The various methods of chromosomal analyses are considered first, followed by a description of the various types of chromosomal abnormalities. This discussion is followed by an overview of the clinical approach to chromosomal abnormalities and then a brief clinical description of chromosomal syndromes relevant to the practice of pediatric neurology. The chapter closes with a look at the future of cytogenetic analysis.

## METHODS OF CHROMOSOME ANALYSIS

### Chromosome Preparation

Chromosome structure is most easily appreciated during mitosis, when the chromatin fiber is condensed and coiled into a characteristic structure. Spontaneously dividing cells are rarely available, except in tumors or chorionic villus tissue used in prenatal diagnosis. Rather, cells are grown in short-term culture. For routine analysis, peripheral blood lymphocytes most commonly are used, although skin fibroblasts also may be cultured and analyzed. Phytohemagglutinin-stimulated peripheral blood usually is grown in culture for 3 days. Blocking the mitotic spindle with a drug such as colchicine leads to

accumulation of dividing cells, which then are induced to swell by treatment with hypotonic saline, fixed, and spread on to a microscope slide (Nussbaum, McInnes, and Willard, 2015a).

### Chromosome Banding

Until the 1970s chromosomes were identified on the basis of their size and the position of the centromeres. This allowed chromosomes to be classified into groups labeled A to G (A: chromosomes 1-3, B: chromosomes 4-5, C: chromosomes 6-12 and X, D: chromosomes 13-15, E: chromosomes 16-18, F: chromosomes 19-20, G: chromosomes 21-22 and Y), but not unambiguously identified. The introduction of banding techniques finally allowed each chromosome to be identified and permitted the identification of chromosome regions, bands, and subbands. Most laboratories use Giemsa stain banding (G-banding), which involves treatment of the metaphase chromosomes with a protease (i.e., trypsin), followed by Giemsa staining for routine analysis. The advent of chromosome banding stimulated a second wave of discovery of structural chromosomal abnormalities during the 1970s. Chromosomes are displayed as a karyotype, which is prepared by arranging homologous chromosomes in an orderly fashion, starting from chromosome 1 and ending with chromosome 22 and including the sex chromosomes. The resolution of this technique, however, is limited to 3 to 5 million bp (Mb) of DNA, which may include dozens of genes (Nussbaum et al., 2015a).

### Molecular Cytogenetics

The gap between light microscope resolution of chromosome structure and the gene was bridged by the introduction of several molecular cytogenetic techniques. Fluorescence in situ hybridization (FISH) involves hybridizing a fluorescently labeled single-stranded DNA probe to denatured chromosomal DNA on a microscope slide preparation of metaphase chromosomes and/or interphase nuclei prepared from the patient's sample. After overnight hybridization, the slide is washed and counterstained with a nucleic acid dye (e.g., DAPI, or 4',6-diamidino-2-phenylindole), allowing the region where hybridization has occurred to be visualized using a fluorescence microscope. FISH is now widely used for clinical diagnostic purposes. There are different types of FISH probes, including locus-specific probes, centromeric probes, and whole-chromosome paint probes (Nussbaum et al., 2015a).

FISH using locus-specific probes has been extremely useful in the detection of microdeletion syndromes resulting from deletions of multiple contiguous genes (Figure 35-2). These are subtle submicroscopic deletions that are below the resolution of the routine G-banded chromosome analysis. Use of FISH usually requires that the patient either exhibits features consistent with a well-defined syndrome with known chromosomal etiology or demonstrates an abnormal karyotype. This is because single FISH probes reveal rearrangements only of the segments being interrogated and do not provide

**Figure 35-2.** Fluorescence in situ hybridization (FISH) analysis using the DiGeorge/velocardiofacial syndrome probe. Note the deleted *TUPLE1* (22q11.2) red probe on one chromosome 22 (arrow). The *ARSA* (22q13.3) green probe is included as an internal control.

information about the rest of the genome. Another limitation of FISH is the number of probes that can be applied in a simultaneous assay.

The latest addition to molecular cytogenetic techniques is chromosomal microarray (CMA) technology, including array comparative genomic hybridization (array CGH) and single-nucleotide polymorphism (SNP) arrays (Nussbaum et al., 2015a). Array CGH involves hybridizing a test sample of interest and a control reference sample, each differentially labeled with different colored fluorescent dyes, to an array slide containing thousands of DNA probes. Following hybridization and washing to remove unbound DNA, the array is scanned and analyzed using computer software to measure the relative ratios of fluorescence of the two dyes and detect gains/losses of genomic regions represented on the array (Figure 35-3). High-density SNP arrays can also be used to detect genomic copy-number gains/losses. In these experiments, the patient's DNA is fluorescently labeled with a fluorescent dye and hybridized to a high-density SNP array. Following hybridization and washing, the array is scanned and analyzed using computer software. The deviation from the expected fluorescent intensities of the two alleles of an SNP are compared with previously analyzed control samples spanning several adjacent SNPs to detect genomic copy-number gains/losses. High-resolution CMAs can detect genomic copy-number gains/losses bigger than 50 kb across the euchromatic portion of human genome. In the past few years, high-resolution whole-genome-coverage CMA platforms have been increasingly used in clinical molecular cytogenetic labs (Miller et al., 2010). These provide a relatively quick method of scanning the entire genome for gains/losses with significantly higher resolution and greater clinical abnormality yield than was previously possible. This has led to the identification of novel genomic disorders in patients with autism spectrum disorders (ASDs), developmental delay (DD), intellectual disability (ID), and/or multiple congenital anomalies (MCAs).

## CHROMOSOMAL ABNORMALITIES

Most chromosomal abnormalities exert their phenotypic effects by increasing or decreasing the quantity of genetic

**Figure 35-3.** Array comparative genomic hybridization (array CGH) analysis using a whole-genome-coverage oligo-array. A chromosome 15 plot is shown with a one-copy loss (heterozygous deletion) in the Prader-Willi/Angelman region at 15q11.2q13.1.

material. Chromosomal abnormalities can be divided into numerical and structural abnormalities (Nussbaum et al., 2015a).

## Numerical Abnormalities

The most straightforward of chromosomal abnormalities are alterations of chromosome number. Deviation from the normal diploid complement of 46 chromosomes is referred to as *aneuploidy*; an extra chromosome results in *trisomy*, whereas a missing chromosome results in *monosomy*. Although all the possible chromosomal trisomies have been observed in spontaneous abortions, trisomies 13, 18, and 21 are the only autosomal trisomies to be observed in a nonmosaic state in liveborn infants. All autosomal monosomies are lethal. The only viable monosomy involves the X chromosome (45,X, resulting in Turner syndrome).

Aneuploidy results from an error in cell division referred to as *nondisjunction*, in which two copies of a chromosome go to the same daughter cell during meiosis or mitosis. Nondisjunction occurs most often in the first meiotic division in the maternal germline. Mitotic nondisjunction results in the presence of an aneuploid and a normal cell line, a condition referred to as *mosaicism*. The causes of nondisjunction are unknown. The only well-documented risk factor is advanced maternal age.

The term *polyploidy* refers to presence of a complete extra set of chromosomes; *triploidy* represents three sets with 69 chromosomes, whereas *tetraploidy* represents four sets with 92 chromosomes. Rarely, a triploid fetus will be liveborn, but in general polyploidy is lethal. In a few instances, however, mosaicism for a diploid and a triploid cell line producing congenital anomalies has been compatible with long-term survival.

## Structural Abnormalities

Structural chromosomal rearrangements result from chromosome breakage, with subsequent reunion in a different configuration. They can be balanced or unbalanced. In balanced rearrangements the chromosome complement is complete, with no loss or gain of genetic material. Consequently, balanced rearrangements are generally harmless, with the exception of rare cases in which one of the breakpoints disrupts an important functional gene. Carriers of balanced rearrangements are often at risk of having children with an unbalanced chromosome complement. When a chromosome rearrangement is unbalanced, the chromosome complement contains an incorrect amount of genetic material, usually with serious clinical effects.

### Deletions and Duplications

A deletion involves loss of part of a chromosome and results in monosomy for that segment of the chromosome, whereas duplication represents the doubling of part of a chromosome, resulting in trisomy for that segment. The result is either decrease (in a deletion) or increase (in a duplication) in gene dosage. In general, duplications appear to be less harmful than deletions. Very large deletions usually are incompatible with survival to term. Deletions or duplications larger than approximately 5 Mb in size can be visualized under the microscope using G-banded chromosome analysis. Clinical syndromes resulting from submicroscopic deletions or duplications (i.e., microdeletions/microduplications) with a size less than 5 Mb have been identified with the help of molecular cytogenetic techniques, including FISH and CMA (Stankiewicz and Lupski, 2010; Vissers and Stankiewicz, 2012).

## Translocations

Translocations involve the exchange of genetic material between chromosomes. In a balanced reciprocal translocation the exchange is equal, with no loss or gain of genetic material, although it is possible for a gene to be disrupted at one of the breakpoints. More often, the carrier of a balanced translocation is free of clinical signs or symptoms but is at risk for having offspring with unbalanced chromosomes. The risk for production of unbalanced gametes from a balanced translocation carrier depends on the chromosomes involved, the specific breakpoints of the translocation, and the sex of the carrier. Empirical data are available for some specific translocations. Risks include miscarriage and birth of a liveborn child with congenital anomalies, resulting from chromosome imbalance. The phenotype usually is a complex mixture of the results of loss or gain of at least two chromosome segments and therefore can be difficult to predict.

One specific type of translocation that is relatively common is Robertsonian translocation. This results from a fusion of two acrocentric chromosomes (chromosomes 13, 14, 15, 21, or 22) at the centromere. Carriers of a Robertsonian translocation have 45 chromosomes and are clinically unaffected. The most common clinically significant outcome is trisomy 21, in which a carrier for a Robertsonian translocation involving chromosome 21 produces a gamete with both the translocation chromosome and a normal 21, resulting in trisomy 21 after fertilization.

## Inversions

Inversions occur when there are two breaks in a chromosome and the intervening material flips 180 degrees. Inversions that span the centromere are referred to as *pericentric*, whereas those that do not are called *paracentric*. Inversions generally do not result in added or lost genetic material and therefore usually are viewed as neutral changes. Disruption of a gene at one of the breakpoints, however, could change the function of that gene. Also, alteration of gene order at the borders of the inversion could affect the function of blocks of genes that are coordinately regulated (*position effect*). If a crossover occurs in the inverted segment of a pericentric inversion during meiosis, two recombinant chromosomes result, one with duplication of one end and deletion of the other end, and the other having the opposite arrangement. Such a crossover event in a paracentric inversion results in dicentric or acentric chromosomes that tend to be unstable.

## Insertions

An insertion occurs when a segment of one chromosome becomes inserted into another chromosome. Because these changes require three chromosomal breakpoints, they are relatively rare. Abnormal segregation in a balanced insertion carrier can produce offspring with either duplication or deletion of the inserted segment, in addition to balanced carriers and normal offspring.

## Marker and Ring Chromosomes

A *marker chromosome* is a rearranged chromosome whose genetic origin is unknown based on its G-banded chromosome morphology. Usually, these chromosomes are present in addition to the normal chromosome complement and are thus called supernumerary marker chromosomes (SMCs). The birth prevalence of SMCs is in the range of 2 to 7 per 10,000, and 30% to 50% originate from chromosome 15.

*Ring chromosomes* are formed when a chromosome undergoes two breaks and the broken ends reunite in a ring

structure. Rings encounter difficulties in mitosis and are unstable, resulting in some cells that lose the ring and are therefore monosomic for the chromosome and others that have multiple copies of the ring.

### Isochromosomes

An *isochromosome* is a chromosome in which one arm is missing and the other duplicated in a mirror-image fashion. The most probable mechanism for the formation of an isochromosome is the misdivision through the centromere in meiosis II, wherein the centromere divides transversely rather than longitudinally. The most commonly encountered isochromosome is that which consists of two long arms of the X chromosome. This accounts for approximately 15% of all cases of Turner syndrome.

## Cytogenetic Nomenclature

By convention, each chromosome arm is divided into regions, and each region is subdivided into bands and subbands, numbered from the centromere outward. Cytogeneticists describe findings of chromosomal analysis using a standardized system of nomenclature (International System for Human Cytogenetic Nomenclature) (Nussbaum et al., 2015a). The normal male karyotype is designated 46,XY, and the normal female karyotype is 46,XX. Any chromosomal abnormality is described after the sex chromosome constitution.

## Incidence of Chromosomal Abnormalities

Estimates of the incidence of chromosomal abnormalities vary with the mode of ascertainment and the technology used for chromosome analysis. In general, the incidence falls rapidly from conception to birth. The highest rates have been observed among products of conception from first-trimester spontaneous abortions. Approximately 50% of these spontaneous miscarriages have a chromosomal abnormality. By birth, the rate of chromosomal abnormalities declines to approximately 0.5% to 1% in liveborn infants, although the rate is much higher (5%–10%) in stillborn infants.

## CLINICAL INDICATIONS FOR CYTOGENETIC ANALYSIS

Chromosome analysis has been incorporated in the routine battery of tests available to the clinician (Nussbaum et al., 2015a). Some of the more common clinical indications for chromosome analysis include:

1. Problems of early growth and development, including failure to thrive, DD, ID, dysmorphic facies, multiple congenital malformations, short stature, and ambiguous genitalia
2. Fertility problems
3. Family history of known or suspected chromosome abnormality
4. Unexplained stillbirth or neonatal death
5. Prenatal genetic diagnosis
6. Malignant tumor diagnosis and management

## SPECIFIC CYTOGENETIC SYNDROMES

### Polyploidy

Tetraploidy is an infrequent chromosomal abnormality, but triploidy occurs fairly often. Most triploid embryos miscarry in the first trimester. In approximately 20% of first-trimester spontaneous abortions, the conceptus is found to have a

triploid karyotype. Liveborn infants with triploidy exhibit multiple congenital anomalies and rarely survive the newborn period. Those that do usually are mosaics for a diploid and a triploid cell line.

The triploid phenotype is distinct and easily recognized. Polyhydramnios or preeclampsia may complicate the pregnancy. The placenta may be large, and hydatidiform changes may be seen. Birth weight usually is low. Syndactyly involving the third and fourth digits is characteristic. Craniofacial features include low-set and malformed ears, hypertelorism, and micrognathia. Cardiac, renal, and central nervous system malformations are common. Long-term survivors often are mosaics and may have less obvious phenotypic features. Body asymmetry and pigmentary dysplasia may be clues to chromosomal mosaicism in general, including, in some cases, triploidy.

### Aneuploidy

Only a minority of aneuploid embryos survive to term; the rest miscarry, usually in the first trimester. Only the most common trisomy and monosomy syndromes compatible with live birth are considered in the following discussion (Nussbaum et al., 2015b).

#### Trisomy 13 (Patau Syndrome)

Trisomy 13 occurs in approximately 1 in 7000 live births. A majority of affected persons have 47 chromosomes, with an extra copy of chromosome 13. Approximately 5% to 10% have trisomy because of translocation between 13 and another acrocentric chromosome, usually chromosome 14 (Robertsonian translocation). Mosaicism occurs in a small proportion of cases and may ameliorate the phenotype. Duplication of part of chromosome 13 resulting from unbalanced translocation can result in abnormal phenotypic features, although not necessarily similar to those seen in full trisomy 13. Advanced maternal age has been shown to be a factor in the occurrence of this aneuploidy syndrome.

Trisomy 13 is associated with congenital anomalies involving most major organ systems. Holoprosencephaly is the hallmark central nervous system anomaly, occurring in about 80% of cases. Other ocular anomalies include microphthalmia, iris colobomata, cataracts, and retinal dysplasia. Premaxillary agenesis and cleft lip or palate also may be present. Ulcer-like defects in scalp skin (cutis aplasia) occur commonly. Limb anomalies include postaxial polydactyly in two-thirds of patients and rocker-bottom foot. Congenital heart defects, especially ventricular septal defect (VSD), are common, as are renal anomalies, including cystic dysplasia.

#### Trisomy 18 (Edwards' Syndrome)

Trisomy 18 affects approximately 1 in 4000 live births. It is virtually always associated with a 47-chromosome karyotype, although a small proportion of affected newborns have a mosaic karyotype. Segregation of a parental balanced translocation may result in trisomy for part of the short or long arm of chromosome 18. Advanced maternal age has been shown to be a factor in the occurrence of this aneuploidy syndrome.

Infants with trisomy 18 have low birth weight and microcephaly. Other common features include a prominent occiput, low-set "simple" ears, and a small mouth. Hands usually are tightly clenched in a characteristic configuration, with the fourth and fifth fingers overlapping the first and second.

#### Trisomy 21 (Down Syndrome)

Trisomy 21 is the most common and widely recognized of the autosomal trisomy syndromes. It occurs in approximately 1 in

800 live births, with a striking increase in frequency with advanced maternal age. Full trisomy 21 occurs in about 95% of cases. Translocation, usually between chromosome 21 and another acrocentric chromosome, most often chromosome 14, is identified in approximately 4%. A parent who carries such a translocation may be at risk for recurrence of Down syndrome. The remaining 1% of affected persons have a mosaic karyotype.

Down syndrome consists of a set of characteristic physical features and developmental impairment. Craniofacial features include upslanted palpebral fissures, epicanthal folds, flat facial profile, and small, low-set ears with narrow ear canals. White speckles (Brushfield spots) may be seen on the iris. A common finding is redundant folds of nuchal skin, which is one of the markers used for prenatal diagnosis by ultrasound examination. Fingers are short, with incurving of the fifth finger (clinodactyly) and, often, a single transverse palmar crease. A wide space between the first and second toes is a frequent finding. The hallmark neurologic feature of Down syndrome is hypotonia. No gross central nervous system malformation is consistently seen, although lack of normal growth of the brain is typical. Impaired neurologic development is a universal feature, but the degree of impairment varies widely. Children with Down syndrome benefit from early intervention, physical therapy, and being reared in a family setting. Linguistic ability may be impaired out of proportion to cognitive impairment. Seizures, including infantile spasms, may be seen with increased frequency. An increased frequency of dementia, associated with pathologic changes of Alzheimer's disease, has been described in patients with Down syndrome. Congenital anomalies commonly associated with Down syndrome include heart and gastrointestinal defects.

### Turner Syndrome

Turner syndrome is associated with a 45,X karyotype, with a single X chromosome. Mosaicism is not uncommon, however, with a separate cell line containing either a normal 46,XX or XY karyotype, or 46 chromosomes including a structurally rearranged X or Y. Turner syndrome occurs in about 1 in 4000 female live births worldwide but it is much more common in stillbirths and miscarriages. Unlike other aneuploidy syndromes, the frequency of Turner syndrome does not increase with advancing maternal age.

Patients with Turner syndrome typically have a female phenotype, although those with a cell line including a Y chromosome may have some degree of virilization, often with ambiguous genitalia. At birth, infants may manifest pedal edema or diffuse edema. In older children and adults with Turner syndrome, short stature and webbing of the neck are commonly seen. The thorax is broad, with increased distance between the nipples. Congenital anomalies include abnormalities of the lymphatic system; cardiac defects, especially coarctation of the aorta and bicuspid aortic valve; and renal anomalies.

Although ID is rare, delays in both gross and fine motor development are common in females with Turner syndrome. Some patients display cognitive problems, but difficulties with visuospatial perception are most common. Hearing impairment occurs frequently, and children should be monitored for deficits or progression of impairment.

### Klinefelter Syndrome

Klinefelter syndrome occurs in about 1 in 1000 males and is associated with a 47,XXY karyotype. The incidence increases as a function of maternal age in half of the cases. Rare patients may have multiple X chromosomes (e.g., 48,XXXY or 49,XXXXY). Usually the presence of multiple X chromosomes

in such persons is associated with more severe cognitive impairment.

The diagnosis of Klinefelter syndrome usually is not suspected at birth. Affected males tend to be tall, with long limbs. They display hypogonadism, and virilization may be incomplete at puberty; gynecomastia develops in some patients. Azoospermia and infertility are characteristic. Breast cancer is 20 times more common in Klinefelter syndrome than in the normal male population. As in Turner syndrome, ID is not a typical feature of Klinefelter syndrome. Learning disabilities, language delay, and behavior problems are reported.

### Other Sex Chromosome Aneuploidies

Two other major sex chromosome aneuploidies are 47,XXX and 47,XYY. The XXX aneuploidy is associated with a female phenotype and tall stature; usually other major physical stigmata are absent. XYY is associated with a male phenotype and tall stature but no other physical features. Learning disabilities and neuromotor impairment occur commonly in 47,XXX females. The behavioral phenotype of XYY syndrome has been a source of some controversy because of reports associating the karyotype with criminal behavior. The frequency of learning disabilities and behavioral problems is increased among affected males, although widely ranging cognitive outcomes have been reported.

### Structural Abnormalities

Structural abnormalities of chromosomes cause phenotypic effects resulting from loss and/or gain of genetic material. In some cases, these occur sporadically as a result of de novo chromosome rearrangements, whereas in others, they may be inherited as a consequence of segregation of a familial balanced chromosomal rearrangement. Some deletion or duplication syndromes are fairly well characterized in terms of phenotypic effects and may be recognized clinically.

For many years, genomic disorders resulting from microdeletions and microduplications that are clinically recognizable by their typical constellation of clinical features were tested for by FISH using DNA probes specific to these genomic regions. The advances in CMA technologies over the past decade have allowed their widespread use not only in a research setting but also as a clinically diagnostic modality in a wide variety of human diseases. CMA analysis has been very useful in the study of copy-number variants (CNVs), which can be broadly classified as either benign polymorphic CNVs or pathogenic disease-causing CNVs. Between these two ends of the spectrum, many CNVs have uncertain clinical significance, and some of these could potentially be risk factors for human disease.

Clinically relevant CNVs can be either recurrent, with a common size and breakpoint clustering in the flanking segmental duplications, or nonrecurrent, with different sizes and variable breakpoints for each CNV (Stankiewicz and Lupski, 2010). These nonrecurrent CNVs typically share a common genomic region of overlap that encompasses the gene(s) associated with the observed phenotype. These nonrecurrent rearrangements occur at a relatively lower frequency at the individual locus level, but collectively they are as common as recurrent CNVs. Clinically relevant CNVs can encompass multiple contiguous genes, including dosage sensitive genes, with each contributing to the phenotype independently. Others encompass a single gene or just few genes.

Two types of microdeletions and microduplications have been distinguished: the syndromic forms in which the phenotypic features are relatively consistent, and those in which the same CNV can be associated with a diverse set of

diagnoses (Girirajan and Eichler, 2010; Cooper et al., 2011; Coe, Girirajan, and Eichler, 2012a, 2012b). The syndromic forms of CNVs were originally described as relatively large microdeletions or microduplications that are highly penetrant, almost always de novo in origin, and usually identified in individuals with ID or MCAs. These are clinically recognizable syndromes that were described well before their genetic causes were known. On the contrary, the more recently described nonsyndromic recurrent CNVs have been reported to have incomplete penetrance and variable expressivity. These have been associated with, but not limited to, DD, ID, autism, seizures, schizophrenia, cardiac and renal anomalies, and other congenital anomalies. Recently it was observed that more than one CNV (the “two-hit” model) can explain the phenotypic variability associated with the nonsyndromic recurrent CNVs (Girirajan and Eichler, 2010; Coe et al., 2012a). Therefore it was proposed that one hit (first CNV) is sufficient to reach a threshold just enough to cause some form of neuropsychiatric disease, whereas a second hit (e.g. second CNV) pushes that individual toward a more severe phenotype with DD and ID. It is worth mentioning that these two hits involve different regions/genes in the human genome as opposed to the two-hit model reported in cancer, which involves both alleles of a tumor-suppressor gene. Variable-expressivity CNVs are much more likely to be inherited from less severely affected parents, which suggests that they are by themselves insufficient to determine the disease outcome. Although the two-hit model was initially applied to large CNVs, it has been proposed that the second hit could also be a smaller CNV or a SNP involving a related gene or a risk allele inherited from a parent.

Approximately 70 microdeletion/microduplication syndromes have been reported to date, as shown in the DECIPHER database (<https://decipher.sanger.ac.uk/disorders/#syndromes/overview>). In the following section, some of the syndromic microdeletions and microduplications that are clinically relevant to the practice of pediatric neurology are discussed.

### 22q11.2 Deletion Syndrome

The 22q11.2 deletion syndrome includes the phenotypes previously called DiGeorge syndrome (DGS), velocardiofacial syndrome (VCFS, Shprintzen’s syndrome), conotruncal anomaly face syndrome, many cases of autosomal-dominant Opitz G/BBB syndrome, and Cayler’s cardiofacial syndrome (asymmetric crying facies) (Nussbaum et al., 2015b). The condition is clinically heterogeneous. Congenital heart defects are present in most affected individuals (74%), particularly conotruncal malformation. Additional findings include palatal abnormalities and velopharyngeal incompetence (VPI), learning disabilities, immune deficiencies, hypocalcemia, and characteristic facies. Also reported are hearing loss, seizures without hypocalcemia, speech delays, and behavioral difficulties. The 22q11.2 deletion affects an estimated 1:2000 to 1:4000 live births. Most cases are de novo, but inherited deletions have been reported in 6% to 28% of patients with the syndrome. The inheritance is autosomal dominant.

### Prader–Willi and Angelman Syndromes

The recognition of the phenomenon of genomic imprinting has led to the discovery of a new class of genetic disorders associated with aberrations of imprinted genes (Nussbaum et al., 2015b; Kalish, Jiang, and Bartolomei, 2014). The prototype disorders are Prader–Willi and Angelman’s syndromes (Nussbaum et al., 2015b). The features of these syndromes are described in Table 35-3. Prader–Willi syndrome (PWS) affects 1:5000 to 1:10,000 individuals. Approximately 70% to 75%

of the individuals with PWS have a deletion of the paternally contributed 15q11.2q13.1 region, whereas in Angelman’s syndrome (AS), 70% of affected individuals have a deletion of the maternally contributed 15q11.2q13.1 region. Approximately 1:40,000 children are affected with AS. Most patients with PWS who do not have the 15q11.2q13.1 deletions have uniparental disomy for chromosome 15, with two maternal copies and no paternal copies. Either mechanism—deletion or uniparental disomy—leads to deficiency of a gene or genes on chromosome 15 that are expressed in the paternal but not the maternal homolog. Deletion of a group of small nucleolar RNA (snoRNA) genes, known as the SNORD116 cluster, is thought to play a major role in causing the signs and symptoms of PWS. Paternal uniparental disomy accounts for a low percentage of cases of AS. Mutations in the *UBE3A* gene (a ubiquitin ligase gene involved in early brain development), located at 15q11.2, have been found in some patients with AS. This gene is imprinted in the brain and is the gene responsible for the AS phenotype. A small proportion of patients with PWS or AS may have a small deletion or other mutation that leads to aberrant imprinting of the region.

### William–Beuren Syndrome

William–Beuren syndrome (WBS) is a microdeletion syndrome of chromosome 7 at band q11.23 and occurs in 1:10,000 live births. Cardiovascular disease is present in 80% of affected individuals, mostly in the form of supravalvular aortic stenosis (SVAS), peripheral pulmonary stenosis, elastin arteriopathy, and hypertension. The 7q11.23 microdeletion encompasses the elastin gene (*ELN*). Characteristic facial features include periorbital fullness, long philtrum, wide mouth, full lips, full cheeks, and small, wide-spaced teeth. Affected individuals have mild to moderate ID, specific cognitive profile/learning disabilities, and unique or distinctive behavior/personality characteristics. Growth and endocrine abnormalities (hypercalcemia, hypothyroidism, hypercalciuria) and feeding difficulties in infancy are also common.

### 1p36 Deletion Syndrome

The 1p36 deletion syndrome results from a variable-sized deletion in the terminal end of the short arm of chromosome 1. It is considered to be the most common subtelomeric microdeletion syndrome, with an estimated incidence of 1 in 5000 to 1 in 10,000. It accounts for 0.5% to 1.2% of idiopathic ID. Clinical findings include a characteristic craniofacial appearance: microbrachycephaly, large and late-closing anterior fontanel, straight eyebrows, deep-set eyes, epicanthic folds, broad nasal bridge, midface hypoplasia, abnormally formed low-set ears, and limb and skeletal defects. DD and ID with absent/poor expressive language are constant features. Affected individuals often face serious physical disabilities that include congenital heart defects (70%), cardiomyopathy (25%), brain abnormalities (88%), seizures (44%), and electroencephalogram (EEG) abnormalities (100%). Ocular malformations or vision problems and hearing loss are observed in approximately 50% of affected individuals.

### Wolf–Hirschhorn Syndrome

Wolf–Hirschhorn syndrome (WHS) results from a variable-sized deletion in the terminal end of the short arm of chromosome 4. It is characterized by distinctive facial appearance, growth delay, psychomotor retardation, and seizures, and is confirmed by detection of a deletion of the Wolf–Hirschhorn critical region (WHCR) (chromosome 4p16.3). The syndrome has clinical and cytogenetic variability. Characteristic facial

(Mutation analysis data from Buiting K, Gross S, Lich C, et al. *Am J Hum Genet* 2003;72(12545427):571–7.; Jiang Y, Lev-Lehman E, Bressler J, et al. *Am J Hum Genet* 1999;65(10364509):1–6.)

features include the “Greek warrior helmet” appearance of the nose (the broad bridge of the nose continuing to the forehead), high forehead with prominent glabella, ocular hypertelorism, and microcephaly. ID ranges from mild to severe. Other birth defects have been reported in individuals with WHS. One-third of the patients have structural central nervous system defects, and seizures also can occur. In 75% of patients with WHS, the deletion is de novo; in about 13% of patients, the deletion results from the unbalanced segregation of a parental balanced translocation. It is now recognized that WHS and Pitt–Rogers–Danks syndrome (PRDS) represent the clinical spectrum associated with a single syndrome.

### Cri du Chat Syndrome

Cri du chat syndrome is a genetic syndrome resulting from a variable-sized deletion in the terminal end of the short arm of chromosome 5. The incidence ranges from 1:15,000 to 1:50,000. A high-pitched, cat-like cry is among the main clinical features in the newborn period; hence the name of the syndrome. Other frequently described features are microcephaly, broad nasal bridge, epicanthic folds, micrognathia, impaired growth, and severe psychomotor and ID. The syndrome has significant clinical and cytogenetic variability. Clinical analysis of affected individuals and detailed molecular cytogenetic analysis suggest the existence of two critical regions, one on 5p15.2 for facial dysmorphism, microcephaly, and ID, and another on 5p15.3 for the typical cry. In affected individuals, 80% of cases are the result of a de novo deletion, and 10% are the result of the unbalanced segregation of a parental balanced translocation.

### Chromosome 9q Subtelomeric Deletion

The chromosome 9q subtelomeric deletion represents one of the most common subtelomeric deletions (6%). The syndrome can be caused either by a 9q34.3 microdeletion or by mutations in the *EHMT1* gene, which is involved in histone methylation. Affected individuals invariably have severe hypotonia, with speech and gross motor delay. Facial features include micro-/brachycephaly, hypertelorism, synophrys, arched eyebrows, midface hypoplasia, short nose with upturned nares, protruding tongue, everted lower lip, and downturned corners of the mouth. Congenital heart defects have been reported in approximately 50% of affected individuals. Epilepsy and behavior and sleep disturbances have also been reported in some (10%–20%).

### Jacobsen Syndrome

Jacobsen syndrome is a contiguous-gene deletion syndrome caused by deletion of the distal portion of the long arm of chromosome 11 (11q23.3qter). Typical features include DD, ID, short stature, congenital heart defects, thrombocytopenia, and characteristic dysmorphic facial features. Some of the facial dysmorphism described includes skull deformities, hypertelorism, epicanthic folds, ptosis, broad nasal bridge, and small ears. Malformation of heart, kidney, gastrointestinal tract, central nervous system, and skeleton is common. The deletion is de novo in 85% of cases, and in the remaining patients it results from the unbalanced segregation of a parental balanced chromosome rearrangement.

## Charcot–Marie–Tooth Neuropathy Type 1A and Hereditary Neuropathy With Liability to Pressure Palsies

Charcot–Marie–Tooth neuropathy type 1A (CMT1A) represents 70% to 80% of all CMT1 and results from an approximately 1.5-Mb duplication at 17p12, which encompasses the *PMP22* gene (peripheral myelin protein 22). Reciprocal deletion of the same region results in the milder phenotype of hereditary neuropathy with liability to pressure palsies (HNPP). The duplication is inherited in around two-thirds of individuals and is de novo in the remaining third.

## Smith–Magenis Syndrome and Potocki–Lupski Syndrome

Approximately 90% of individuals with Smith–Magenis syndrome (SMS) have a deletion on chromosome 17 at band p11.2 that encompasses the *RAI1* gene. The remaining 5% to 10% of cases carry a mutation in the *RAI1* gene. Physical features include short stature, obesity, craniofacial dysmorphism, and small hands and feet. Behavior disturbances, especially sleep problems and self-injurious behavior, are frequently reported. All affected individuals have mild to severe learning disabilities. The phenotypic features may be subtle in infancy and early childhood.

The reciprocal duplication of this 17p11.2 region has been reported (Potocki–Lupski syndrome). The most frequent features of this syndrome are hypotonia in infancy, DD, language and cognitive impairment, autistic features, poor feeding and failure to thrive in infancy, oral-pharyngeal dysphagia, obstructive and central sleep apnea, structural cardiovascular abnormalities, EEG abnormalities, and hypermetropia. Most have short stature and mild to normal facies. Variability in the phenotype is observed. It is expected that persons with large duplications that encompass the more distal CMT1A region will have a more severe phenotype, including peripheral neuropathy.

## Miller–Dieker Syndrome

Miller–Dieker syndrome represents a microdeletion syndrome spanning the *PAFAH1B1* gene (also known as *LIS1*) at 17p13.3, which results in severe lissencephaly with characteristic facial changes, other more variable malformations, and severe neurologic and developmental abnormalities. The facial features consist of high and prominent forehead, bitemporal hollowing, short nose with upturned nares, protuberant upper lip with downturned vermillion border, and small jaw. The reciprocal duplication results in DD, hypotonia, and facial dysmorphism. In contrast to patients with the deletion, those with the duplication have neither gross brain malformations nor lissencephaly.

## Neurofibromatosis Type 1

Approximately 5% of patients with neurofibromatosis type 1 (NF1) have deletions of the entire *NF1* gene and contiguous genes at 17q11.2, resulting in the NF1 microdeletion syndrome. NF1 with large deletions is more likely to have dysmorphic features, cardiac anomalies, connective tissue dysplasia, and ID. Patients with reciprocal microduplications have been reported.

## X-Linked Ichthyosis Resulting From Steroid Sulphatase Enzyme Deficiency

Males with X-linked ichthyosis resulting from steroid sulphatase enzyme deficiency have generalized scaling that usually starts shortly after birth. In 90% of cases, it is caused by a

microdeletion encompassing the *STS* gene (Xp22.31). In 5% of cases, the deletion is extensive enough to involve adjacent genes, resulting in learning disabilities, autism, and epilepsy in some of the affected boys.

## Loss of Function of the *MECP2* Gene/Duplication of the *MECP2* Region (Xq28)

Loss-of-function mutations involving the *MECP2* gene at Xq28 result in Rett syndrome, a severe neurodevelopmental disorder that almost always occurs in females. Males with non-Rett mutations in *MECP2* demonstrate a wide variety of phenotypes, including X-linked ID with spasticity and other variable features. Males with Rett mutations in *MECP2* have neonatal severe encephalopathy that is usually lethal. Duplications at Xq28 that span the *MECP2* gene in males are associated with severe X-linked ID and progressive spasticity. These duplications usually also span the *LICAM* gene.

Finally, some of the nonsyndromic microdeletions and microduplications that present with neurodevelopmental problems are as follows:

Distal 1q21.1 microdeletion and microduplication  
2p15p16.1 microdeletion  
Terminal deletions of the long arm of chromosome 2 (2q37 microdeletion)  
3q29 microdeletion  
7q11.23 microduplication  
Maternal duplication of the 15q11.2q13.1 region  
15q13.3 microdeletion  
15q24 microdeletion  
16p11.2 microdeletion and microduplication  
16p11.2p12.2 microdeletion  
16p13.11 microdeletion and microduplication  
17q21.31 microdeletion  
Distal 22q11.2 microdeletions  
22q13 microdeletions (Phelan–McDermid syndrome)

## THE FUTURE OF CLINICAL CYTOGENETICS

Clinical cytogenetics began with the cytologic analysis of chromosomes in the 1950s but has steadily moved toward an increasingly molecular approach. This began with the advent of FISH and has accelerated since the introduction of CMA. CMA is moving us toward a whole-genome approach, with no need to know in advance where to look. This is raising questions about whether CMA should be used before a comprehensive dysmorphology evaluation because many of the deletions or duplications detected are not associated with well-delineated syndromes. A caution in use of this approach, however, is that some gene-dosage changes are not known to be associated with an abnormal phenotype and are likely to be benign variants of no clinical significance. Therefore correct interpretation of dosage changes still requires a high level of sophistication and care in counseling the patient/family. The resolution of genomic analysis will continue to increase. Clinical whole-exome or whole-genome DNA sequencing is currently being used to uncover clinically relevant gene mutations with a much higher power than previously possible. Both CMA and whole-exome or whole-genome sequencing will undoubtedly reveal an increasing number of genomic changes that underlie neurologic disorders, leading to an increase in the power and precision of genetic diagnosis.

## INTRODUCTION

Inborn errors of metabolism (IEMs) are genetic disorders that disrupt biochemical processes in the body by altering enzyme activity, cellular transport, or mitochondrial bioenergetics. Over 600 IEMs have been described to date, and this number is increasing with the more widespread use of whole exome sequencing. Although IEMs are individually rare, their collective incidence is approximately 1 in 1000. The clinical manifestations of IEMs are protean because almost every organ and tissue can be affected. The nervous system is often affected with selective vulnerability given its high bioenergetic demand and its reliance on a delicate balance of complex biochemical processes for normal functioning. It is particularly important for the pediatric neurologist to be familiar with the diagnosis of IEMs because most are associated with neurologic symptoms, and many have effective, disease-specific treatments.

## INHERITANCE

The inheritance pattern of most IEMs is autosomal recessive because residual enzyme activity is usually sufficient to preclude the development of disease; however, X-linked and autosomal dominant inheritance are possible (Table 36-1). X-linked recessive disorders can present variably in carrier females based on the pattern of X-inactivation. X-linked dominant disorders are often lethal in males. Disorders of mitochondrial DNA (mtDNA) are maternally inherited and show phenotypic variability based on the percentage and tissue distribution of mutant mtDNA (termed “heteroplasmy”). A detailed three-generation pedigree should be obtained in every patient presenting for evaluation for an IEM. Particular attention should be paid to any history of sudden infant death syndrome (SIDS), siblings with neurologic disorders, including epilepsy and “cerebral palsy,” and parental consanguinity.

## LABORATORY EVALUATION

Most inborn errors of metabolism can be diagnosed through specialized biochemical testing. This includes measurement of metabolites in body fluids and specific enzyme assays. Molecular testing is clinically available for most disorders, either as single gene tests or next generation targeted gene panels based on disease category. A molecular diagnosis may be useful for predicting prognosis and treatment response (e.g., cofactor responsiveness) and can be used for prenatal testing to reduce recurrence risk. Newborn screening protocols have been instituted in a number of countries that evaluate for some of the treatable IEMs, potentially including organic acidemias, fatty acid oxidation and carnitine disorders, some amino acidopathies, galactosemia, and biotinidase deficiency. The specific disorders included and methodologies vary considerably from country to country and even between states in the United States. Readers are encouraged to contact their local newborn screening laboratory to determine which disorders are included in their screening program. It should be emphasized that this testing represents screening and not diagnostic testing, and

both false positive and false negative results are possible. Normal newborn screening does not preclude the possibility of an inborn error of metabolism. Likewise, abnormal newborn screening must be followed by confirmatory diagnostic evaluation by a clinician with expertise in biochemical genetics.

## CLASSIFICATION

When evaluating a patient for an inborn error of metabolism, it is necessary to use a systematic and organized approach to maximize the potential for diagnosis. Different approaches to the diagnosis of IEMs have been described. One approach groups IEMs into categories based on the affected metabolic pathway (e.g., urea cycle) or organelle (e.g., lysosome) because most disorders in each grouping share some clinical and biochemical features (see Table 36-2). Another approach, particularly suited for the pediatric neurologist, is a symptoms-based approach focused on neurologic phenotype. This chapter provides a symptoms-based approach that incorporates age of onset and predominant neurologic signs.

Before approaching these aforementioned symptom categories, it is useful for the reader to adopt a broad framework for classifying IEMs based on pathophysiology and general symptomatology. This broad classification divides IEMs into *small molecule disorders*, *large molecule disorders*, *disorders of cerebral energy metabolism*, and *miscellaneous IEMs*. This is a modified version of the original classification proposed by Saudubray and associates that is adapted for the pediatric neurologist (Saudubray et al., 2012). This classification will be referred to throughout this chapter.

**Small molecule disorders** are IEMs affecting intermediary metabolism, including the metabolism of amino acids, organic acids, fatty acids, ketones, and ammonia. These disorders result in intoxication from accumulation of substrate and are often associated with basic and readily detectable biochemical abnormalities such as acidosis, hyperammonemia, or hypoglycemia. These disorders generally present acutely with encephalopathy and may also be accompanied by ataxia, headache, nausea, and respiratory abnormalities. The disease course of these IEMs is often episodic with periods of deterioration provoked by illness, fasting, or other bioenergetics stressors. Most of these disorders are amenable to specific treatments based on dietary modification and/or cofactor supplementation.

**Large molecule disorders** are IEMs that affect synthesis or catabolism of complex molecules and include disorders of the lysosome and peroxisome, disorders of glycosylation, and disorders of complex lipid metabolism. Large molecule disorders typically follow a chronic course that may be static or gradually progressive. Many of these disorders are associated with congenital malformations or dysmorphic physical features. A number of lysosomal disorders can be treated effectively with enzyme replacement therapy.

**Disorders of cerebral energy metabolism** include defects impairing mitochondrial bioenergetics, pyruvate metabolism, creatine metabolism, coenzyme Q10 biosynthesis, and the transport of glucose into the CNS. In general, disorders of

**TABLE 36-1** Iems With X-Linked and Autosomal Dominant Inheritance

Inheritance	Classification of IEM
<b>X-LINKED RECESSIVE DISORDERS</b>	
Ornithine transcarbamylase deficiency	Urea cycle disorder
Phosphoribosylphosphate synthetase deficiency	Disorder of purine disorder
Lesch Nyhan syndrome	Disorder of purine disorder
Lowe syndrome	Disorder of phospholipid metabolism
Fabry disease	Lysosomal disorder
Hunter syndrome	Lysosomal disorder
X-linked adrenoleukodystrophy	Peroxisomal disorder
Menkes syndrome	Disorder of copper transport
Monoamine oxidase A deficiency	Disorder of neurotransmitter metabolism
X-linked creatine transporter deficiency	Disorder of energy metabolism
<b>X-LINKED DOMINANT DISORDERS</b>	
X-linked chondrodysplasia punctata	Disorder of cholesterol biosynthesis
CHILD syndrome	Disorder of cholesterol biosynthesis
Beta propeller-associated neurodegeneration (X-linked dominant)	Neurodegeneration with brain iron accumulation
<b>AUTOSOMAL DOMINANT DISORDERS</b>	
Cystinuria	Disorder of amino acid metabolism
Glucose transporter 1 deficiency	Disorder of energy metabolism
SLC6A1-related myoclonic astatic epilepsy	Disorder of neurotransmitter metabolism
Autosomal dominant GTP cyclohydrolase deficiency	Disorder of neurotransmitter metabolism
POLG1-related progressive external ophthalmoplegia	Disorder of energy metabolism
HEM skeletal dysplasia	Disorder of cholesterol biosynthesis
Porphobilinogen deaminase deficiency	Disorder of heme biosynthesis

energy metabolism follow a chronically progressive course, often punctuated by episodic exacerbations. Developmental delay and seizures are a common manifestation, and many disorders in this group can also be associated with movement disorders. Several of these disorders have effective treatments: pyruvate dehydrogenase deficiency and glucose transporter 1 deficiency are treated with the ketogenic diet; creatine deficiency syndromes may respond to creatine supplementation; and disorders of coenzyme Q10 biosynthesis are treated with CoQ10 replacement.

Finally, there are a number of IEMs that are not easily classified into these categories, including disorders in the metabolism of *carbohydrates, purines and pyrimidines, vitamins, minerals/heavy metals, and biogenic amine neurotransmitters* (Table 36-3).

## PART 1: CLINICAL PRESENTATION OF IEMS IN THE NEONATE OR INFANT LESS THAN 2 YEARS OF AGE

As a general rule, the age of presentation and severity of an IEM is proportional to the degree of enzyme deficiency. Although this section describes IEMs that typically present in infancy, the reader should be cognizant that milder forms of many of these disorders may present for the first time in older children and adults.

## Acute Encephalopathy

Many inborn errors of metabolism present in early life with acute or subacute encephalopathy, particularly small molecule disorders and disorders of cerebral energy metabolism (Chapters 37 and 42). Many of these disorders present after a well period in the context of metabolic stressors such as prolonged fasting, illness, and some medications. Most small molecule disorders do not present in fetal life because the placenta is capable of removing many toxic metabolites.

IEMS presenting with acute encephalopathy may be accompanied by abnormalities in tone, seizures, ataxia, emesis, and respiratory abnormalities. Basic biochemical abnormalities are common and may suggest a specific disease category. Urine ketones are always abnormal in the neonate due to increased physiologic ketone utilization and suggest an IEM until proven otherwise. *Ketoacidosis with hyperammonemia* suggests an organic acidemia, of which propionic and methylmalonic acidemias are prototypical. Inappropriate ketosis is also a feature of maple syrup urine disease and disorders of ketone degradation (e.g., ketothiolase deficiency).

*Hyperammonemia without metabolic acidosis* suggests dysfunction of the urea cycle. There may be accompanying respiratory alkalosis (Chapter 38).

*Hypoglycemia with insufficient ketosis* is the hallmark of the fatty acid oxidation and carnitine disorders, disorders of ketone synthesis (e.g., HMG-CoA lyase deficiency), and hyperinsulinism. *Recurrent ketotic hypoglycemia accompanied by hepatomegaly* suggests a glycogen storage disorder or disorder of gluconeogenesis. Disorders of gluconeogenesis are also associated with fasting-induced blood lactate elevation (Chapter 39).

Persistent elevations of blood lactate in the neonate or infant that is not critically ill, septic, or hypoperfused should raise consideration for a mitochondrial disorder or disorder of pyruvate metabolism (Chapter 42). A normal blood lactate to pyruvate ratio (less than 20 to 25), a marker of cytoplasmic redox status, is seen in pyruvate dehydrogenase deficiency and some forms of pyruvate carboxylase deficiency. Pyruvate carboxylase deficiency may also be associated with hyperammonemia and hypoglycemia.

A number of IEMs can present with *acute liver failure in the neonate or infant* associated with hepatic encephalopathy, including galactosemia, tyrosinemia type 1, hereditary fructose intolerance, and mitochondrial disorders. Concurrent proximal renal tubulopathy may be present in any of these disorders and is a useful diagnostic clue. In addition, a *Rye-like syndrome*, including fulminant liver failure, metabolic acidosis, and cerebral edema, has been reported in fatty acid oxidation and carnitine disorders, organic acidemias, urea cycle disorders, ketogenesis disorders, gluconeogenesis defects, hereditary fructose intolerance, and mitochondrial disorders. This may be provoked by certain medications, including valproic acid and ASA.

In the absence of basic biochemical abnormalities, neuroimaging findings may suggest a specific IEM in the neonate or infant presenting with acute or subacute encephalopathy. *Symmetric signal change in the basal ganglia*, often associated with diffusion restriction, can be seen in organic acidemias, mitochondrial disorders, and biotin-thiamine responsive basal ganglia disease. These findings can mimic a hypoxic-ischemic injury. *Acute white matter injury* with diffusion restriction can be seen in maple syrup urine disease, glycine encephalopathy (nonketotic hyperglycinemia), and sulfite oxidase deficiency/molybdenum cofactor deficiency, although the specific patterns are different. *Stroke or stroke-like lesions* that cross classic vascular territories can be seen in mitochondrial disorders, congenital disorders of glycosylation, and Menkes syndrome (Van der Knaap and Valk, 2005).

**TABLE 36-2** Classification of IEMs by Pathway and Organelle

Category	Symptoms	Biochemical Investigations
Urea cycle disorders	Hyperammonemic encephalopathy	Ammonia, plasma amino acids, urine organic acids (orotic acid)
Fatty acid oxidation & carnitine disorders	Hypoketotic hypoglycemia, episodic rhabdomyolysis, cardiomyopathy, hepatopathy, Reye-like syndrome	Plasma acylcarnitines, free/total carnitine
Organic acidemias	Ketoacidosis, hyperammonemia, metabolic stroke, developmental delay	Urine organic acids, plasma acylcarnitines
Aminoacidopathies	Epilepsy, developmental delay, acute CNS events (toxic, ischemic)	Plasma amino acids, additional metabolic studies based on suspected diagnosis
Peroxisomal disorders	Retinopathy, sensorineural hearing loss, brain malformation, dysmorphism, leukoencephalopathy	Plasma VLCFAs, phytanic acid, pristanic acid, pipercolic acid, RBC plasmalogens, bile acid intermediates in blood and urine
Lysosomal disorders	Hurler phenotype (coarse facial features, dysostosis multiplex, hepatosplenomegaly, corneal opacity), leukoencephalopathy, progressive myoclonus epilepsy, cherry red spot, organomegaly, gaze palsy	Enzymology, urine MPS screen, urine oligosaccharides
Disorders of cholesterol biosynthesis	Multiple congenital anomalies, static developmental delay	Measurement of plasma cholesterol precursors
Congenital disorders of glycosylation	Congenital anomalies, hypotonia, abnormal fat pads, abnormal coagulation profile	Plasma transferrin analysis, urine oligosaccharides and free glycans
Biogenic amine disorders	Movement disorder, diurnal fluctuation, dysautonomia, oculogyric crisis	CSF neurotransmitters, CSF/urine pterins, plasma phenylalanine
Mitochondrial disorders	Highly pleiotropic presentations, including CNS, PNS, multiple organs, failure to thrive, retinopathy, hearing loss, ophthalmoparesis, stroke-like events, epilepsy	Elevated lactate in blood or CSF, elevated plasma alanine

MR spectroscopy can occasionally provide additional information beyond structural imaging. Maple syrup urine disease may be associated with a branch-chain ketoacid peak at 0.9 ppm. Mitochondrial disorders, disorders of pyruvate metabolism, and organic acidemias may be associated with lactate elevations in regions of structurally normal brain. The clinician must keep in mind that if regions of brain affected by stroke, infection, or injury are sampled, lactate may be secondarily elevated. Hyperammonemia may be associated with an elevated glutamine peak.

A few small molecule disorders are associated with abnormal urine odor, including the maple syrup odor of urine and ear wax in maple syrup urine disease, the musty odor of urine and sweat in phenylketonuria, and the sweaty feet odor of urine in isovaleric acidemia and glutaric acidemia type 2.

Specific diagnosis requires evaluation of: urine organic acids and plasma acylcarnitines for organic acid disorders; plasma acylcarnitine profile and free/total carnitine for fatty acid oxidation and carnitine disorders; and plasma amino acids for amino acidopathies and urea cycle disorders. A number of urea cycle disorders are also associated with elevations of urine orotic acid. Homocysteinurias require the measurement of total serum homocysteine for biochemical diagnosis, which is not included in standard plasma amino acid analyses. Biochemical abnormalities in some of these disorders may be normal when the child is well, warranting reevaluation at times of illness.

## Epilepsy

Epilepsy in the neonate or infant should raise suspicion for an inborn error of metabolism in a number of circumstances, including medically refractory epilepsy, myo-

clonic seizures/myoclonus, concurrent nonneurologic manifestations (see Table 36-4), microcephaly, and epileptic encephalopathies, including early myoclonic encephalopathy (Chapter 76).

Seizures beginning in the first weeks of life that do not respond to standard anticonvulsant treatment should always prompt early evaluation for treatable metabolic epilepsies, including vitamin and cofactor responsive epilepsies and small molecule disorders (see Table 36-5). Pyridoxine and pyridoxal-5-phosphate responsive epilepsies may be associated with irritability, grimacing, and abnormal eye movements, a useful clinical clue at the bedside. The neonate with medically refractory epilepsy should be trialed on pyridoxine, pyridoxal-5-phosphate, folinic acid, and biotin pending metabolic test results.

Myoclonus with profound hypotonia, respiratory failure, and persistent hiccups beginning hours to days after birth suggests glycine encephalopathy. This diagnosis is further supported by burst suppression on EEG, and neuroimaging demonstrating agenesis of corpus callosum and diffusion restriction of the actively myelinating structures. MR spectroscopy may demonstrate a glycine peak at 3.55 ppm. CSF and often plasma glycine are elevated with a CSF to plasma ratio greater than 0.08 in the classic form.

Microcephaly is a useful clinical clue when evaluating the neonate or infant with severe epilepsy for an IEM. Congenital microcephaly is a feature of amino acid synthesis disorders, including serine, asparagine, and glutamine synthetase deficiencies. Postnatal microcephaly is common in severe methylene-tetrahydrofolate reductase (MTHFR) deficiency, glucose transporter 1 deficiency, sulfite oxidase deficiency, molybdenum cofactor deficiency, and Menkes syndrome.

In some circumstances, the electroclinical epilepsy syndrome can suggest specific inborn errors of metabolism.

As previously mentioned, early myoclonic encephalopathy should prompt evaluation for glycine encephalopathy but has also been described in sulfite oxidase deficiency/molybdenum cofactor deficiency, organic acidemias, pyridoxine/pyridoxal-5-phosphate dependent epilepsies, Zellweger syndrome, and adenylosuccinate lyase deficiency. Atypical absence epilepsy has been described in glucose transporter 1 deficiency and serine synthesis disorders. Myoclonic-astatic epilepsy has been reported with glucose transporter 1 deficiency and defects in the presynaptic GABA transporter SLC6A1. Malignant migratory focal epilepsy of infancy has been reported in association with defects in the phospholipase C-beta 1 enzyme.

Specific EEG patterns have been described in some IEMs, including a theta frequency waveform resembling mu waves in the central head regions termed “comb waves” in the neonate with maple syrup urine disease and rhythmic high amplitude delta waves with superimposed spikes and poly-spikes (RHADS) in the posterior head region in the mitochondrial disorder Alpers syndrome. Progressive attenuation of the EEG has been reported in the infantile form of neuronal ceroid lipofuscinosis, and a photoparoxysmal response at slow flash frequencies is characteristic of the late infantile form.

Any relation of seizures to meals should be determined; fasting induced (normoglycemic) seizures can be seen in glucose transporter 1 deficiency. Postprandial exacerbation of seizures can be seen in disorders of pyruvate metabolism and hyperammonemic disorders.

An atypical response to specific anticonvulsants should also be noted. Phenobarbital may exacerbate seizures in glucose transporter 1 deficiency, and valproic acid can worsen seizures in glycine encephalopathy and urea cycle disorders. Valproic acid can also induce liver failure in POLG1 associated mitochondrial disorders.

### Abnormal Development Associated With Congenital Anomalies and/or Dysmorphic Physical Features

The presence of congenital anomalies or dysmorphic physical features in the neonate or infant with abnormal development should alert the clinician to a possible underlying genetic disorder. In addition to chromosomal disorders and monogenic nonmetabolic genetic syndromes, the pediatric neurologist should maintain a high index of suspicion for inborn errors of metabolism—particularly large molecule disorders—because a number of these disorders have specific treatments (Chapter 41).

Static developmental delay associated with congenital microcephaly, craniofacial dysmorphism (ptosis, short and upturned nose, cleft palate), 2 to 3 toe syndactyly, genitourinary and cardiac malformations, and midline brain anomalies, including dysgenesis of corpus callosum and holoprosencephaly are features of Smith-Lemli-Opitz Syndrome (SLOS), a disorder of cholesterol biogenesis. Serum cholesterol levels are often low, but specific measurement of the cholesterol precursor 7-dehydrocholesterol is necessary for biochemical diagnosis. Additional disorders of cholesterol biosynthesis are also associated with developmental delay and may have associated ichthyosis and skeletal abnormalities (Jira, 2013).

Developmental delay and regression associated with craniofacial dysmorphism (high forehead, epicanthal folds, hypoplastic supraorbital ridges), large anterior fontanelle, redundant neck skin, cystic kidneys and liver, proximal limb shortening, and brain malformations, including polymicrogyria, are features of the peroxisomal biogenesis disorders, of which Zellweger syndrome is prototypical. Affected children

typically have significant central hypotonia that can mimic a neuromuscular disorder. Epilepsy is also common. There may be accompanying retinopathy and sensorineural hearing loss. In addition to structural brain anomalies, there is progressive white matter injury in the CNS. The biochemical evaluation for a peroxisomal biogenesis disorder includes measurement of plasma very long chain fatty acids for elevated fractions of C26:C22 and C24:C22 fatty acids. In addition, there may be decreased levels of RBC plasmalogens, elevated plasma pipercolic acid, abnormal bile acid intermediates in urine and blood, and elevated plasma phytanic and pristanic acid (NB: phytanic acid is derived entirely from the diet and is not a reliable marker in the neonate) (Chapter 43) (Klouwer et al., 2015).

Moderate to severe developmental delay associated with nonspecific facial dysmorphism, abnormal fat pads, and cerebellar hypoplasia is characteristic of the congenital disorders of glycosylation, particularly the most common type 1a. Affected children are hypotonic, which is typically central in etiology although there may be superimposed neuropathy. There are often associated clotting abnormalities. This group of disorders can be screened for by evaluating the pattern of glycosylated transferrin and measuring urinary oligosaccharides and free glycans (Chapter 40) (Freeze et al., 2012).

Multiple congenital anomalies, including anorectal malformations and shortening of distal phalanges, can be seen in disorders of glycosylphosphatidylinositol (GPI) anchor biosynthesis, often in association with abnormal alkaline phosphatase levels (high or low) and epilepsy. Seizures may be responsive to supplementation with pyridoxine. This group of disorders can be screened for by evaluating GPI-linked epitopes on granulocytes using flow cytometry.

Progressive developmental regression associated with coarsening of the facial features, skeletal anomalies, corneal opacity or cataracts, hernias, and hepatosplenomegaly are features of many lysosomal storage disorders, including the mucopolysaccharidoses, oligosaccharidoses, and mucopolipidoses (Chapter 41). Neuroimaging may demonstrate prominent perivascular spaces with surrounding white matter gliosis; over time, this pattern may become more confluent resembling a leukodystrophy. A skeletal survey may show characteristic features of dysostosis multiplex, including j-shaped sella turcica, beaking of vertebral bodies, and abnormally shaped acetabulum and phalanges. Screening for a lysosomal storage disorder begins with measurement of urine mucopolysaccharides to evaluate for mucopolysaccharidoses and urine oligosaccharides to evaluate for oligosaccharidoses. Salla disease/infantile sialic acid storage disease is evaluated by measuring urinary free sialic acid. If a specific disorder is suspected, enzyme activity can be measured blood or fibroblasts (Pastores and Maegawa, 2013).

Developmental regression beginning at several months of age associated with lax-appearing skin, fair complexion, sparse and wiry hair, and progressive microcephaly should suggest Menkes syndrome. There may be associated vascular tortuosity and bladder diverticulae. Epilepsy and autonomic dysfunction are common. There may be subdural collections mimicking nonaccidental injury. Serum copper and ceruloplasmin are low, as is urinary excretion of copper (NB: serum copper and ceruloplasmin are often low in the first month of life in healthy children). There is an elevated HVA to VMA ratio in urine due to secondary dysfunction of the copper dependent enzyme dopamine beta hydroxylase (Chapter 46) (Bandmann et al., 2015).

Less often, small molecule disorders and disorders of energy metabolism are associated with malformations and dysmorphic features. Untreated maternal phenylketonuria is associated with congenital microcephaly and heart defects in

the neonate. The congenital form of glutaric acidemia type II is associated with polymicrogyria, renal cysts, anterior abdominal wall defects, and rocker bottom feet. Multicystic dysplastic kidney and neuronal migration abnormalities can also be seen in the congenital form of carnitine palmitoyltransferase 2 (CPT2) deficiency, a disorder of carnitine metabolism. As previously mentioned, glycine encephalopathy is associated with dysgenesis of the corpus callosum. Glutamine synthetase deficiency is associated with complex brain malformations, enteropathy, and necrolytic skin lesions. The most severe presentation of serine synthesis disorders, termed "Neu Laxova syndrome," is associated with multiple congenital anomalies and early lethality. Pyruvate dehydrogenase deficiency is associated with dysgenesis of corpus callosum and large periventricular cysts; individuals may also have facial features reminiscent of fetal alcohol syndrome. Finally, mitochondrial disorders may be associated with brain malformations.

### Abnormal Development in the Absence of Congenital Anomalies or Dysmorphic Physical Features

IEMs account for up to 1% to 5% of children with static developmental delay, making IEMs an uncommon cause relative to chromosome disorders and fragile X syndrome. It is even more uncommon for IEMs to cause static developmental delay without additional neurologic or extraneurologic signs or symptoms. Untreated phenylketonuria is an example of an IEM that can rarely present with essentially isolated developmental delay.

In contrast, IEMs are a relatively common cause of developmental regression in childhood and must always be evaluated for in these circumstances. IEMs presenting with progressive developmental regression include disorders of energy metabolism, the chronic presentation of small molecule disorders, some large molecule disorders in the lysosomal and peroxisomal categories, and additional disorders in the miscellaneous category.

### Associated Neurologic Symptoms

Epilepsy is a common accompanying feature in IEMs and was covered in the previous section (Chapter 76).

The motor pathways are also frequently affected in IEMs and manifest with abnormalities of tone, ataxia, and/or extrapyramidal symptoms. Spasticity is a relatively nonspecific sign but can be prominent in metabolic leukodystrophies such as Krabbe disease, Canavan disease, and metachromatic leukodystrophy. Spastic diplegia mimicking cerebral palsy is also a notable feature of arginase deficiency and hyperammonemia, hyperornithemia, and homocitrulluria (HHH) syndrome.

Prominent extrapyramidal symptoms, including dystonia, chorea, and parkinsonism, may be seen in the primary disorders of biogenic amine (neurotransmitter) metabolism and transport. Additional useful clinical clues include diurnal fluctuation, oculogyric crises, and dysautonomia. Extrapyramidal symptoms may also be seen in the purine and pyrimidine disorders, mitochondrial disorders, disorders of creatine metabolism, cerebral folate deficiency, glucose transporter 1 deficiency, and in organic acidemias after metabolic basal ganglia injury (Chapter 93).

An exaggerated startle may be seen in GM2 gangliosidosis, hyperekplexia disorders, sulfite oxidase deficiency, and asparagine synthetase deficiency.

The motor findings in IEMs are almost always bilaterally symmetric because metabolic CNS insults affect specific tracts and pathways symmetrically. An exception to this rule is

mitochondrial disorders, which may present with asymmetric stroke-like involvement (e.g., MELAS syndrome). In addition, disorders of neurotransmitter metabolism may present with focal dystonia.

Specific behavioral abnormalities may provide a useful clue to the underlying diagnosis. Autistic behavior can be seen in disorders of creatine metabolism, untreated PKU, cerebral folate deficiency, succinic semialdehyde dehydrogenase deficiency, and purine/pyrimidine disorders, including adenylosuccinate lyase deficiency. Autistic features associated with aggressive and hyperactive behavior are seen in Sanfilippo syndrome (MPSIII), a mucopolysaccharidosis that is associated with more subtle extraneurologic features. Children with Sanfilippo syndrome may also demonstrate a lack of fear (Kluver-Bucy syndrome). Prominent self-mutilation is a feature of Lesch-Nyhan syndrome, a disorder of purine metabolism.

### Associated Nonneurologic Symptoms (Table 36-4)

Nonspecific failure to thrive is a feature of many small molecule disorders and disorders of energy metabolism.

A formal ophthalmology evaluation is an important component in the diagnostic evaluation of the infant with neuroregression. Many of the neuronopathic lysosomal disorders have telltale ophthalmologic stigmata including cherry red macular spot, corneal opacities, and supranuclear gaze palsy. Mitochondrial disorders may be associated with retinopathy, ptosis, ophthalmoparesis, and, rarely, cataracts. Peroxisomal disorders may also be associated with retinopathy and cataracts.

The skin and hair may be affected in IEMs presenting with developmental regression. Menkes disease was mentioned in the previous section. Sparse and fragile hair, the result of trichorrhexis nodosa, is seen in the urea cycle disorder arginosuccinate synthetase deficiency. Skin rash and alopecia are features of biotinidase deficiency and holocarboxylase synthetase deficiency. Eczema is a feature of untreated phenylketonuria.

Developmental regression with hepatosplenomegaly in a nondysmorphic infant should raise the possibility of a neuronopathic lysosomal storage disorder, particularly Niemann-Pick and Gaucher disease.

### Neuroimaging

When evaluating an infant for a neurodegenerative metabolic disorder, neuroimaging is often useful to narrow the differential diagnosis. If possible, the clinician should attempt to distinguish between primary white matter disorders (leukodystrophies) and gray matter disorders.

Progressive demyelination is seen in Krabbe leukodystrophy, metachromatic leukodystrophy, multiple sulfatase deficiency, peroxisomal disorders, cerebral organic acidurias (Canavan disease, L2 hydroxyglutaric aciduria), and mitochondrial disorders, particularly involving complex 1 of the respiratory chain. Hypomyelination, or permanently deficient myelination, is a feature of Salla disease/infantile sialic acid storage disease, fucosidosis, and cerebral folate deficiency (Chapter 99) (Schiffmann and van der Knaap, 2009).

Early cerebral cortical atrophy may be seen in GM1 and GM2 gangliosidosis, neuronal ceroid lipofuscinoses, mitochondrial disorders, and disorders of amino acid biosynthesis, including serine and asparagine synthetase deficiencies. The clinician should be aware that early cerebral atrophy may be associated with *secondary dysmyelination*. Significant cerebellar atrophy in an infant can be seen in mitochondrial disorders, disorders of coenzyme Q10 biosynthesis, neuronal ceroid lipofuscinoses, congenital disorders of glycosylation,

adenylosuccinate lyase deficiency, and infantile neuroaxonal dystrophy; associated T2 hyperintensity of the cerebellar cortex consistent with gliosis is a feature of infantile neuroaxonal dystrophy, congenital disorders of glycosylation, and mitochondrial disorders.

Abnormalities of the deep gray nuclei may be a useful clue to the underlying diagnosis. Many lysosomal disorders are associated with T2 hypointensity of the thalamus (dark thalamus sign). Symmetric basal ganglia T2 hyperintensity may suggest a mitochondrial disorder, disorder of pyruvate metabolism, biotin-thiamine responsive basal ganglia disease, or an organic acidemia.

MR spectroscopy demonstrates an increased NAA peak in Canavan disease. A decreased or absent creatine peak suggests one of the creatine deficiency syndromes, including X-linked creatine transporter deficiency, guanidinoacetate methyltransferase deficiency, and arginine-glycine amidinotransferase deficiency.

## Neuromuscular Weakness

In the course of evaluating the neonate or infant with peripheral hypotonia and weakness, a number of inborn errors of metabolism should be considered (Chapter 150). As always, appropriate localization within the neuraxis is a prerequisite step.

The infantile form of Pompe disease presents in the first months of life with progressive skeletal myopathy with hyperCKemia, hypertrophic cardiomyopathy, and feeding and respiratory difficulties. Macroglossia is a useful clinical clue. ECG demonstrates very short PR intervals with giant QRS complexes. Biochemical diagnosis is made through enzyme assay of alpha glucosidase. Treatment is available with enzyme replacement therapy.

Barth syndrome, an X-linked recessive disorder of phospholipid metabolism, is associated with infantile-onset skeletal myopathy, dilated cardiomyopathy that may be associated with endocardial fibroelastosis or left ventricular noncompaction, failure to thrive, and neutropenia. Urine levels of 3-methylglutaconic acid are elevated.

Skeletal myopathy is a common presentation of mitochondrial disorders. Involvement of the CNS, cardiomyopathy, hepatic or renal dysfunction, retinopathy, or sensorineural hearing loss are common accompanying features. Laboratory studies may demonstrate elevations of serum lactate and alanine. Muscle biopsy rarely shows ragged red fibers in infants. Electron microscopy may demonstrate dysmorphic mitochondria. Studies of mitochondrial complex enzyme activity, typically normalized to levels of citrate synthase activity, may be decreased. These abnormalities are not specific, and it is important for the clinician to be cognizant of the possibility that these abnormalities represent secondary mitochondrial dysfunction due to a different underlying disease process.

Skeletal myopathy with elevated CPK may be seen in disorders of long chain fatty acid oxidation and carnitine metabolism; however, these abnormalities are often intermittent and provoked by fasting or intercurrent illness. In the neonate or infant, skeletal muscle involvement is often overshadowed by recurrent hypoglycemia, cardiomyopathy, and hepatopathy. Fatty acid oxidation and carnitine disorders causing rhabdomyolysis will be further described in a subsequent section.

Neuropathy developing in the first 2 years of life has been described in mitochondrial disorders, congenital disorders of glycosylation, neonatal adrenoleukodystrophy, disorders of cobalamin metabolism, infantile neuroaxonal dystrophy, Arts syndrome, serine deficiency syndromes, and riboflavin

transporter disorders. A demyelinating neuropathy often accompanies Krabbe and metachromatic leukodystrophies. Lysosomal storage disorders may present with compressive mononeuropathies. Abnormal neuromuscular transmission has been described in DPAGT1 (dolichyl-phosphate N-acetylglucosamine phosphotransferase) deficiency, a congenital disorder of glycosylation.

## CLINICAL PRESENTATION OF IEMS IN CHILDHOOD (GREATER THAN 2 YEARS OF AGE) AND ADOLESCENCE

### Ataxia

Whereas cerebellar pathway dysfunction can occur in infancy, frank ataxia is more noticeable in the older child who is ambulatory and relies on a high degree of dexterity for activities of daily living. IEMs presenting with ataxia as a predominant feature can be divided into three groups: disorders associated with insidiously progressive ataxia; disorders associated with episodic ataxia; and ataxic disorders associated with myoclonus and epilepsy (progressive myoclonus epilepsies).

IEMs manifesting in childhood or adolescence with chronically progressive ataxia as the presenting feature include ataxia with vitamin E deficiency, abetalipoproteinemia, Refsum disease, cerebrotendinous xanthomatosis, the subacute and chronic forms of GM2 gangliosidosis, Niemann-Pick disease type C, mitochondrial disorders, PHARC (polyneuropathy, hearing loss, ataxia, retinitis pigmentosa, and cataract) syndrome, and disorders of coenzyme Q10 biosynthesis (Lyon et al., 2006). Many of these disorders are also associated with peripheral neuropathy and ophthalmologic signs.

Episodic ataxia has been reported in a number of small molecule disorders and disorders of energy metabolism, including maple syrup urine disease (intermittent form), urea cycle disorders, Hartnup disease, pyruvate dehydrogenase deficiency, pyruvate carboxylase deficiency, biotinidase deficiency, and mitochondrial disorders. Episodes are often provoked by bioenergetic stressors such as infectious illness or by increased protein intake in MSUD and urea cycle disorders. These disorders must be distinguished from episodic ataxia resulting from genetic channelopathies.

The combination of progressive ataxia, myoclonus, epilepsy, and cognitive regression are features of the progressive myoclonus epilepsies. This category includes a number of lysosomal disorders such as the neuronal ceroid lipofuscinoses (NCLs), sialidosis, and a subtype of Gaucher disease type 3; mitochondrial disorders, including myoclonic epilepsy with ragged red fibers (MERRF) syndrome; and Lafora disease. Many of these disorders are associated with vision disturbance, either from retinal disease (NCLs, sialidosis, mitochondrial disease) or occipital seizures in Lafora disease. Progressive myoclonus epilepsy can also be caused by a number of non-metabolic genetic defects.

### Dystonia

Dystonia beginning in childhood or adolescence as a presenting symptom is a feature of a number of IEMs (Chapter 93). Glutaric acidemia type 1 can present with acute metabolic striatal stroke in the first 5 years of life in a previously developmentally normal child, resulting in severe generalized dystonia. Acute basal ganglia injury associated with extrapyramidal signs can also be seen in mitochondrial Leigh syndrome and biotin-thiamine responsive basal ganglia disease. The latter

disorder has an excellent response to the combination of thiamine and high dose biotin.

Exercise-induced paroxysmal dystonia is a feature of glucose transporter 1 deficiency. Intermittent dystonia can also be seen in pyruvate dehydrogenase deficiency. Focal dystonia with diurnal variation is a feature of Segawa disease due to dysfunction in one of two enzymes involved in dopamine biosynthesis, GTP cyclohydrolase, or tyrosine hydroxylase. This dystonia has an excellent and sustained response to low dose L-dopa.

Gradually progressive generalized dystonia is a prominent feature of late onset GM1 gangliosidosis. MR brain imaging in this disorder may demonstrate T2 hypointensity of globi pallidi. There may be subtle extraneurologic features, including skeletal anomalies and short stature.

There are a growing number of IEMs associated with progressive brain mineralization and extrapyramidal signs. The classic brain mineralizing disorder is Wilson disease, in which copper accumulates in the liver and brain. Pediatric Wilson disease is usually associated with hepatic disease, but pure neurologic presentations are possible. Dystonia may be accompanied by prominent bulbar dysfunction, parkinsonism, ataxia, psychiatric symptoms, and cognitive regression. Ophthalmologic evaluation demonstrates pathognomonic Kayser-Fleischer rings, copper deposits in Descemet's membrane of the cornea, in 90% of patients with CNS disease. Neuroimaging is characteristic and demonstrates T1 hyperintensity of globus pallidus, T2 hyperintensity thalami and striatum, white matter hyperintensities, and a characteristic pattern of involvement in the midbrain and pons. Serum ceruloplasmin and total copper are decreased, and 24-hour urine copper is increased.

Another category of neurodegenerative disorders with brain mineralization is the disorders of brain iron accumulation (NBIA). The prototypical disorder in this category is pantothenate kinase associated neurodegeneration that in its classic form presents in the first decade with chronically progressive generalized dystonia, pyramidal signs, and retinal degeneration. Neuroimaging demonstrates mineralization of globus pallidus, most evident on susceptibility weighted sequences, with a central region of T2 hyperintensity creating the appearance of an "eye of the tiger." Additional disorders in this category presenting in childhood include: mitochondrial membrane protein-associated neurodegeneration (MPAN); PLAG2-related neurodegeneration (PLAN); Beta-propeller protein-associated neurodegeneration (BPAN); fatty acid hydroxylase-associated neurodegeneration; Kufor-Rakeb syndrome; Woodhouse-Sakati syndrome; and COASY protein-associated neurodegeneration. Each of these disorders is clinically distinct and has a specific neuroimaging pattern. Diagnosis is made through molecular studies; multigene panels are available.

In recent years, the first genetic disorder of brain manganese deposition was described due to mutations in the SLC30A10 gene. This disorder presents in childhood with progressive dystonia associated with polycythemia and liver disease. Neuroimaging demonstrates T1 hyperintensity of the globus pallidus. Blood manganese is markedly elevated. This disorder may be amenable to treatment with chelation therapy and iron supplementation.

## Recurrent Rhabdomyolysis

Recurrent rhabdomyolysis should prompt evaluation for a metabolic myopathy or channelopathy (Chapters 49 and 150). IEMs associated with rhabdomyolysis include disorders of long chain fatty acid oxidation and carnitine metabolism

(e.g., CPT2 deficiency), muscle glycogenoses, lipin-1 deficiency, mitochondrial disorders, and myoadenylate deaminase deficiency. Some of these disorders can be associated with a progressive chronic myopathy between episodes of rhabdomyolysis.

The precipitants for rhabdomyolysis are important in establishing the differential diagnosis. Muscle breakdown in the long chain fatty acid oxidation and carnitine disorders may be precipitated by prolonged moderate intensity exercise, illness, or prolonged fasting (typically longer than 12 hours). Symptoms provoked by exercise typically begin *hours after the exercise*. Associated symptoms include liver dysfunction, cardiomyopathy, cardiac arrhythmia, and hypoketotic hypoglycemia. Carnitine palmitoyltransferase 2 deficiency is the most common of these lipid disorders to present in childhood or adolescence with isolated exercise-induced rhabdomyolysis (Berardo et al., 2010).

Muscle glycogenoses presenting with recurrent rhabdomyolysis include myophosphorylase deficiency (McArdle disease), phosphofructokinase deficiency, adolase A deficiency, lactate dehydrogenase deficiency, phosphoglycerate kinase deficiency, and phosphoglycerate mutase deficiency. Muscle fatigue, weakness, and rhabdomyolysis in these disorders are typically provoked by anaerobic activity, in particular isometric muscle contraction. Symptoms often begin *during* exercise with muscle stiffness and painful cramps. In myophosphorylase deficiency, muscle symptoms may improve after 10 minutes of aerobic activity ("second wind" phenomenon) due to increased utilization of blood-borne glucose and free fatty acids. Phosphofructokinase deficiency, phosphoglycerate kinase deficiency, and aldolase A deficiency are associated with hemolytic anemia, which may be well compensated. Myophosphorylase deficiency is the most common of the muscle glycogenoses and typically presents in the first decade of life.

Lipin-1 deficiency, a disorder of phospholipid metabolism, presents in childhood with severe episodes of rhabdomyolysis provoked by febrile infectious illness.

Myoadenylate deaminase deficiency is a disorder of the purine-nucleotide cycle, an important pathway in muscle for replenishing the citric acid cycle during exercise. Some individuals present with recurrent exercise induced rhabdomyolysis, whereas others remain asymptomatic, which has raised the question of whether this enzyme deficiency alone is sufficient to cause disease.

## Vascular Stroke

Classic homocystinuria due to cystathionine beta-synthase deficiency can present in childhood or adolescence with arterial ischemic or venous infarction. Associated features include developmental delay, marfanoid habitus, high myopia, lens dislocation, and osteopenia. Complexion is often pale, and there may be malar flushing or livedo reticularis. Diagnosis is confirmed by the finding of elevated serum total homocysteine.

Fabry disease is an X-linked, semidominant lysosomal disorder with multisystem involvement. Males may present with arterial ischemic stroke in adolescence or early adulthood from large vessel vasculopathy; the posterior circulation is preferentially affected. Over time, affected individuals develop progressive white matter disease from small vessel angiopathy. A classic neuroimaging finding is a T1-weighted bright pulvinar of the thalamus. Associated features in childhood include gastrointestinal symptoms, painful acroparasthesia, hypohidrosis, and skin lesions termed "angiokeratomas." Cardiomyopathy and renal disease may develop in adulthood. Diagnosis

in males is accomplished by measuring alpha-galactosidase enzyme activity in nucleated cells; females require molecular testing because enzyme results overlap with the normal range.

### Cognitive and Motor Regression

Gradually progressive loss of cognitive faculties as the predominant symptom in the older child or adolescent can be seen in a number of IEMs, including X-linked adrenoleukodystrophy, neuronopathic lysosomal disorders, mitochondrial disorders, and disorders of brain mineralization. All of these disorders are ultimately associated with additional neurologic findings, potentially including ataxia, spasticity, dystonia, and epilepsy with disease progression (Chapter 52).

The childhood cerebral form of X-linked adrenoleukodystrophy typically presents between 4 to 8 years of age with cognitive decline, behavior change, and auditory verbal agnosia. With disease progression, children develop vision loss, spasticity, ataxia and occasionally epilepsy. MR imaging typically demonstrates characteristic white matter abnormalities of periventricular white matter with a posterior predominance associated with a rim of contrast enhancement. Imaging abnormalities typically precede the onset of symptoms. Most boys have associated adrenal insufficiency at the onset of neuroregression. The diagnosis is established by demonstrating elevated levels of plasma very long chain fatty acids (Chapter 99).

The subacute form of GM2 gangliosidosis classically presents between 2 to 10 years with progressive cognitive impairment, spasticity, ataxia, seizures, retinopathy and optic atrophy. A cherry red macular spot is usually absent. The chronic form of GM2 gangliosidosis presents in the first decade with cognitive and motor regression, psychosis, motor neuron disease, and cerebellar atrophy. The diagnosis is made by finding reduced enzyme activity of hexosaminidase A in nucleated cells.

Niemann-Pick Type C classically presents in middle to late childhood with cognitive regression, ataxia, and vertical supranuclear gaze palsy. Children may also develop dystonia and epilepsy. There may be hepatosplenomegaly. A history of gelastic cataplexy is another useful diagnostic clue. Biochemical diagnosis can be made with filipin staining and cholesterol esterification studies of cultured skin fibroblasts. Plasma oxysterols can be used as a screening test.

### Psychiatric Symptoms

A number of IEMs can present in childhood or adolescence with psychiatric symptoms as the predominant manifestation. In these circumstances, more common etiologies should first be considered, including drug ingestion, primary psychiatric disease, and inflammatory brain disorders.

Cobalamin C deficiency, a disorder in the metabolism of vitamin B12, can rarely present after a normal early childhood with subacute psychiatric symptoms, often associated with signs of subacute combined degeneration of the spinal cord. Decompensation can be provoked by exposure to nitrous oxide, an inhibitor of the enzyme methionine synthase. The diagnosis is confirmed by elevated serum total homocysteine and plasma or urine methylmalonic acid in the presence of normal plasma vitamin B12 levels.

Milder forms of the urea cycle disorders often associated with some residual enzyme activity can present with episodic psychiatric symptoms. These episodes may be variably associated with alteration of consciousness, headache, emesis, and ataxia. Episodes may be provoked by illness, high protein intake, and some medications such as valproic acid.

Acute intermittent porphyria, a disorder of heme biosynthesis, rarely presents in the pediatric age group with the exception of the very rare, autosomal recessive 5-aminolevulinic acid (ALA) dehydratase deficiency. The classic presentation of acute intermittent porphyria includes acute episodes of psychosis, peripheral neuropathy, autonomic dysfunction, abdominal pain, and hyponatremia from SIADH. Episodes may be provoked by medications and hormonal factors, including menses. Diagnosis is confirmed by elevated levels of urine ALA, coproporphyrin, and RBC zinc protoporphyrin. Secondary inhibition of ALA dehydratase can also be seen in tyrosinemia type 1 due to accumulating succinylacetone.

As mentioned in the previous sections, Niemann-Pick Type C, the chronic form of GM2 gangliosidosis, and Wilson disease can occasionally present initially with isolated psychiatric symptoms. With progression of disease, cognitive regression and additional focal neurologic signs become apparent.

### CONCLUSIONS

Although individually rare, inborn errors of metabolism collectively are not uncommon in the practice of child neurology. Given its high energetic demand, the nervous system is especially vulnerable and is often the sole presenting system of these disorders that may have protean manifestations. Laboratory diagnosis can be made by testing of metabolites, enzymatic function, or single gene or next generation gene sequencing panels. The IEMs can be conceptualized as disorders of small molecules, large molecules, and bioenergetics. Age of onset and severity tend to be related to degree of enzyme insufficiency. Many of the disorders, especially of small molecule and cerebral energy metabolism, present in early life with acute or subacute encephalopathy. Seizures in the first weeks of life that do not respond to standard anticonvulsant treatment should prompt early evaluation for treatable metabolic epilepsies including vitamin and cofactor responsive epilepsies and small molecule disorders. The presence of dysmorphism may suggest a metabolic disorder, especially large molecule disorder, which may have a specific treatment as well. IEMs are an uncommon cause of static developmental delay, compared with chromosome disorders and Fragile X, but a relatively common cause of developmental regression. IEMs in the older child and adolescent may present with ataxia, dystonia, rhabdomyolysis, stroke, cognitive or motor regression, or psychiatric symptoms.

## Aminoacidemias and Organic Acidemias

Renata C. Gallagher, Gregory M. Enns, Tina M. Cowan, Bryce Mendelsohn, and Seymour Packman

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Approximately 4% of individuals born in the United States have a genetic or partly genetic disorder. Inborn errors of metabolism contribute significantly to this total. Although each disease is individually rare, the aggregate incidence of metabolic disease is relatively high and may be greater than 1 in 1000 newborns. Newborn screening programs using tandem mass spectrometry, which can detect approximately 20 inborn errors of metabolism, typically have reported an incidence of 1 in 2000 to 1 in 4000. Because there are hundreds of known metabolic conditions, the aggregate estimate seems reasonable.

Metabolic diseases infrequently produce symptoms immediately at birth, and they can manifest with slowly progressive encephalopathies. In this setting, histologic or biochemical abnormalities may be present in the fetal central nervous system (CNS) by 4 to 5 months' gestation. Inborn errors of metabolism also can manifest with rapid clinical deterioration in the newborn period or after an interval period of good health. Presenting clinical features are often nonspecific, and they may be misdiagnosed as infection, cardiovascular compromise or other causes of hypoxemia, trauma, primary brain anomalies, or the effects of a toxin. Recognition of patterns of clinical presentation and rapid implementation of laboratory investigations are essential for the initiation of appropriate therapy without delay. If appropriate therapy is not initiated in a timely manner, there is a high risk of morbidity or mortality, regardless of the cause of the acute illness.

This chapter provides an overview of the diagnosis and treatment of two categories of inborn errors: aminoacidopathies and organic acidemias. The general approaches described are broadly applicable to other heritable metabolic disorders, such as disorders of fatty acid oxidation, urea cycle disorders, and lactic acidosis syndromes. Descriptions of selected disorders of amino acid and organic acid metabolism are provided to illustrate and emphasize the approaches to diagnosis, treatment, and genetic counseling in this area of genetic medicine. In this print version of the chapter, we discuss phenylketonuria, followed by representative aminoacidopathies and organic acidemias likely to be encountered by the pediatric neurologist in an acute or critical clinical setting. For a comprehensive and detailed discussion of additional organic acidemias and aminoacidopathies and important general concepts in the diagnosis, treatment, and genetic counseling involved in heritable metabolic disorders, readers are referred

## AMINOACIDEMIAS

### Phenylketonuria

Phenylketonuria (PKU) is an autosomal-recessive disorder caused by deficient activity of phenylalanine hydroxylase (PAH), a hepatic enzyme that converts phenylalanine to tyrosine (Figure 37-1). The biochemical block results in the accumulation of phenylalanine, which is then converted to phenylpyruvic acid and phenyllactic acid, phenylketones that are excreted in the urine. A range of reduced PAH-specific activity correlates broadly with the severity of the phenotype. Tetrahydrobiopterin is a necessary cofactor in the PAH reaction, and elevated phenylalanine levels rarely may be caused by inherited disorders of tetrahydrobiopterin synthesis (see Figure 37-1). Mandatory population newborn screening for PKU, in combination with postnatal presymptomatic therapy, was begun in the 1960s.

Phenylalanine is neurotoxic, and untreated or poorly treated patients with classic phenylketonuria typically have profound intellectual disability. Patients exposed to chronically elevated phenylalanine levels ultimately develop microcephaly, seizures (e.g., tonic-clonic, myoclonic, infantile spasms), tremors, athetosis, and spasticity, and they may be misdiagnosed as having cerebral palsy. Psychiatric and behavior problems, including autistic behavior and attention-deficit hyperactivity disorder, are common. Brain magnetic resonance imaging (MRI) may detect dysmyelination, especially T2 enhancement in the periventricular white matter, a finding that is potentially reversible with the initiation of dietary therapy.

Elevated maternal blood phenylalanine levels can cross the placenta and cause fetal birth defects, including microcephaly, dysmorphic features, and congenital heart defects. Dietary control (phenylalanine levels < 360  $\mu$ M) should ideally be achieved before 3 months before conception, and mothers with PKU should be monitored carefully by an experienced center throughout pregnancy.

The presymptomatic institution of and continued adherence to specific dietary therapy prevents intellectual disability. However, children and adults with PKU may experience

**Figure 37-1. Regulation of phenylalanine hydroxylase activity.** Phenylalanine is converted to tyrosine (1) by the holoenzyme phenylalanine hydroxylase (PAH). PAH requires tetrahydrobiopterin (BH<sub>4</sub>) as an active cofactor and is recycled by the sequential actions of carbinolamine dehydratase (2) and dihydropteridine reductase (3). BH<sub>4</sub> is synthesized *in vivo* through a complex series of steps that involve guanosine triphosphate (GTP) cyclohydrolase (4), 6-pyruvoyltetrahydropterin synthase (5), and sepiapterin reductase (6). Genetic defects at any of these steps may be associated with hyperphenylalaninemia. (From Wilcox WR, Cederbaum SD. *Amino acid metabolism*. In: Rimoin D, Connor J, Pyeritz R, Korf B, eds. *Principles and practice of medical genetics*, 4th ed. Philadelphia: Churchill Livingstone, 2002:2406.)

cognitive symptoms, such as problems in executive functioning, and disturbance in emotional (e.g., depression, anxiety, phobias) and behavioral (e.g., hyperactivity) functioning despite early and continuous treatment. Selective restriction of phenylalanine intake by using phenylalanine-free medical formulas and foods (and tyrosine supplementation), which provides enough additional protein and nutrients to support normal growth, remains the mainstay of PKU therapy. Most clinics in the United States strive to maintain plasma phenylalanine levels between 120 and 360  $\mu\text{M}$  in children younger than 12 years and between 120 and 600  $\mu\text{M}$  in individuals older than 12 years, although there is some evidence to suggest that lowering upper phenylalanine targets even further improves neurocognitive function. An expert, coordinated team approach is clearly the most effective way of managing phenylketonuria; stricter management improves developmental outcome.

In conjunction with dietary therapy, oral administration of tetrahydrobiopterin, the naturally occurring cofactor for the PAH reaction, may be used to control plasma phenylalanine levels. Response to tetrahydrobiopterin is especially robust in mild hyperphenylalaninemia but has also been documented in patients with classic or variant PKU. A trial of tetrahydrobiopterin may be offered to PKU patients of any severity to determine clinical response. Administration of dietary supplementation of large neutral amino acids (LNAA) is a complementary approach to therapy. LNAA compete with phenylalanine for transport across the blood-brain barrier by the L-type amino acid carrier and consequently decrease the level of phenylalanine in the central nervous system (CNS) and may increase brain neurotransmitter and essential amino acid concentrations. A novel therapeutic approach currently in clinical trials uses the nonmammalian enzyme phenylalanine ammonia lyase (PAL). This enzyme converts phenylalanine to

transcinnamic acid, a harmless compound, and it has been found to reduce hyperphenylalaninemia in PKU animal models and patients in clinical trials. Other novel therapies are under close investigation, especially given the findings of suboptimal outcomes in phenylketonuria patients who have been continuously treated from the neonatal period. ## Maple Syrup Urine Disease

In 1954, John Menkes and colleagues described four siblings who died in early infancy from a cerebral degenerative disease, with onset occurring when they were 3 to 5 days old. Symptoms included feeding difficulty, irregular respiratory pattern, hypertonia, opisthotonus, and failure to thrive. All had urine with the smell of maple syrup. Soon thereafter, another patient with a similar history was found to have elevated levels of branched-chain amino acids in urine and blood, and the syndrome was initially referred to as maple sugar urine disease. Maple syrup urine disease is caused by mitochondrial branched-chain  $\alpha$ -ketoacid dehydrogenase complex deficiency. The enzymatic defect leads to accumulation of branched-chain amino acids and branched-chain  $\alpha$ -ketoacids. Five forms of

maple syrup urine disease (i.e., classic, intermediate, intermittent, thiamine-responsive, and dihydrolipoyl dehydrogenase [E3] deficiency) have been delineated based on clinical presentation, level of enzyme activity, and response to thiamine administration.

## Clinical Manifestations

**Classic Maple Syrup Urine Disease.** In the classic form, the clinical phenotype is one of severe neonatal encephalopathy, unless presymptomatic therapy is initiated because of abnormal newborn screening, prenatal diagnosis, or positive family history. Untreated neonates typically develop symptoms by the end of the first week of life. Feeding difficulties, alternating hypertonia and hypotonia, opisthotonic posturing, abnormal movements (“fencing” or “bicycling”), and seizures commonly occur. The characteristic urine smell develops on day 5 to 7 of life. Unless an underlying inborn error of metabolism is suspected, affected children may be misdiagnosed as having sepsis and progress to coma and death. Ketosis is often found, and hypoglycemia may occur, but severe metabolic acidosis tends not to occur. Plasma amino acid analysis reveals elevated levels of branched-chain amino acids and the diagnostic presence of alloisoleucine in plasma. Urine organic acid analysis demonstrates excretion of branched-chain  $\alpha$ -ketoacids. Hyponatremia and cerebral edema are frequent sequelae during acute metabolic decompensation. Other complications include pseudotumor cerebri, pancreatitis, and eye abnormalities. Ocular findings in untreated or late-diagnosed patients include optic atrophy, gray optic papilla, nystagmus, ophthalmoplegia, strabismus, and cortical blindness. Children who survive the initial metabolic crisis typically have significant neurodevelopmental delays and spasticity. Although motor, visual, and learning deficits may occur, rapid identification of affected infants and careful institution of appropriate therapy can result in normal development.

Neuroimaging studies (Figure 37-3) are typically abnormal in patients with untreated classic maple syrup urine disease (MSUD) who are in crisis. Computed tomographic (CT) scans appear normal in the first few days of life, but they reveal progression to marked generalized cerebral edema if the patient remains untreated. An unusual pattern of edema may occur, characterized by involvement of the cerebellar deep white matter, posterior brainstem, cerebral peduncles, posterior limb of the internal capsule, and posterior aspect of the centrum semiovale. Edema tends to subside in the second month of life. Patients with classic maple syrup urine disease in metabolic crisis with associated hyponatremia demonstrate a prominently increased T2 signal on brain MRI in the brainstem reticular formation, dentate nucleus, red nucleus, globus pallidus, hypothalamus, septal nuclei, and amygdala. One report observed that brain MRI abnormalities were absent or only slight in sick patients with maple syrup urine disease in the absence of hyponatremia. Cranial ultrasonography of neonates in acute metabolic crisis reveals symmetrically increased echogenicity of the periventricular white matter, basal ganglia, and thalami. Chronic changes, including hypomyelination of the cerebral hemispheres, cerebellum, and basal ganglia and cerebral atrophy, may supervene in poorly controlled patients. CT- and MRI-defined abnormalities and the clinical phenotype may improve after implementation of appropriate dietary therapy. Diffusion-weighted imaging and spectroscopy have also documented abnormalities during the acute phase of disease. Markedly restricted proton diffusion, suggestive of cytotoxic or intramyelinic sheath edema, was demonstrated in the brainstem, basal ganglia, thalami, cerebellar and periventricular white matter, and cerebral cortex in six patients with maple syrup urine disease.

MR spectroscopy demonstrated abnormal elevations of branched-chain amino acids, branched-chain  $\alpha$ -ketoacids, and lactate in the four patients. All of these changes were reversed after the institution of appropriate nutritional and antibiotic therapy to treat intercurrent illness. However, in a recent study of a cohort of classic MSUD adolescents and adults under dietary control, persistent signal changes were noted in the cerebral hemispheres, internal capsule, brainstem, and central cerebellum (Klee et al., 2013). The authors ascribed the signal alterations to dysmyelination and considered them consonant with clinical studies showing that learning disabilities and variable social, educational, and professional outcomes are present in teenagers and adults with MSUD.

A characteristic comblike electroencephalogram (EEG) pattern may be demonstrated for some patients with classic MSUD between the second and third weeks of life. This unusual rhythm pattern resolves with the institution of dietary therapy.

**Intermediate Maple Syrup Urine Disease.** Children who have the intermediate form of MSUD do not present in the neonatal period, despite having persistently elevated plasma levels of branched-chain amino acids. Developmental delay and failure to thrive are common. Severe neurologic impairment is absent; episodes of metabolic decompensation may occur, although severe ketoacidosis episodes are variable. These children have a higher tolerance for dietary protein than those who have the classic form. Rarely, patients with intermediate-type MSUD respond to thiamine administration.

**Intermittent Maple Syrup Urine Disease.** Patients with intermittent MSUD typically come to medical attention when they are 5 months to 2 years old and after stress induced by infection or high protein intake; some have been detected as late as the fifth decade of life. The intermittent form of MSUD can be particularly difficult to diagnose because affected individuals have normal levels of branched-chain amino acids and no odor between episodes of metabolic decompensation. Episodic decompensation is characterized by ataxia, disorientation, and altered behavior, which may progress to seizures, coma, and even death unless therapy is instituted. Early development and intellect are usually normal.

**Thiamine-Responsive Maple Syrup Urine Disease.** The clinical course of patients with the thiamine-responsive variant of MSUD is similar to that of the intermediate form of the disease. Plasma levels of branched-chain amino acid and urine excretion of branched-chain  $\alpha$ -ketoacids decline days to weeks after thiamine administration (10-1000 mg/day) is started. Patients are also treated with nutritional regimens similar to those used in other forms of MSUD. Developmental delay may be present, but normal intelligence has also been documented.

**Dihydrolipoyl Dehydrogenase-Deficient Maple Syrup Urine Disease.** The dihydrolipoyl dehydrogenase (E3)-deficient form of MSUD is characterized by ketoacidosis crises in infancy. There is also lactic acidemia because the E3 subunit of the branched-chain  $\alpha$ -ketoacid dehydrogenase complex is also required for catalytic function of pyruvate dehydrogenase and  $\alpha$ -ketoglutarate dehydrogenase. In addition to the typical MSUD metabolites, urine organic acid analysis reveals the presence of lactate, pyruvate, and  $\alpha$ -ketoglutarate. The neonatal period is usually uneventful, but progressive neurologic deterioration, characterized by developmental delay, hypotonia or hypertonia, and dystonia, supervenes. Death in early childhood is common. Attempts at therapy had limited success in early reports. However, more recent case reports and studies have identified patients with a wide clinical spectrum, with survival to at least the third decade. In some such patients, and

**Figure 37-3. Maple syrup urine disease.** **A**, Axial view, T2-weighted image shows edema in the internal capsules, lateral thalami, and globus pallidi. **B**, Axial view, calculated apparent diffusion coefficient image at the same level shows hypointensity, indicated by reduced water diffusion, in the affected areas. **C**, Proton MR spectroscopy (echo time of 26 msec) shows a large peak at 0.9 ppm, believed to represent resonances of methyl protons from branched-chain amino acids and branched-chain  $\alpha$ -ketoacids that accumulate as a result of defective oxidative decarboxylation of leucine, isoleucine, and valine. (Courtesy of Dr. A James Barkovich, University of California, San Francisco, CA.)

depending on the mutations, there is a positive clinical response to riboflavin, perhaps based on a chaperone-like effect of enzyme stabilization.

### Laboratory Tests

MSUD can be detected easily and accurately by tandem mass spectrometry analysis of the newborn blood spot. Plasma amino acid analysis demonstrates elevations of leucine, isoleucine, and valine (5- to 10-fold greater than normal) and the pathognomonic finding of elevated alloisoleucine. Levels of branched-chain amino acids are greatly elevated in urine and cerebrospinal fluid (CSF). The branched-chain  $\alpha$ -ketoacids 2-oxoisocaproic acid, 2-oxo-3-methylvaleric acid, and 2-oxoisovaleric acid, derived from the branched-chain amino acids leucine, isoleucine, and valine, respectively, are found to be elevated on urine organic acid analysis during metabolic crises. Branched-chain amino acids levels and excretion of branched-chain  $\alpha$ -ketoacids may be normal between episodes of decompensation in the intermittent form of disease.

The branched-chain  $\alpha$ -ketoacid dehydrogenase complex consists of three catalytic components—a thiamine pyrophosphate-dependent carboxylase (E1) with an  $\alpha_2\beta_2$  structure, a transacylase (E2), and a dehydrogenase (E3)—and two regulatory enzymes (a kinase and a phosphatase). Deficient activity of this complex leads to the accumulation of leucine, isoleucine, and valine and their corresponding  $\alpha$ -ketoacids. The decarboxylation activity can be measured in leukocytes, lymphoblasts, or fibroblasts, and it is loosely related to the clinical phenotype: 0% to 2% of normal activity in classic MSUD, 3% to 30% activity in intermediate, 5% to 20% in intermittent, 2% to 40% in thiamine-responsive, and 0% to 25% in E3 deficiency. Because significant overlap exists between measured enzyme activity and clinical phenotype, enzymatic activity cannot be used to predict the clinical course with certainty. In parallel findings on molecular analyses, identified mutations also cannot be correlated with phenotype.

### Genetics

MSUD is a pan-ethnic, autosomal-recessive condition that can be caused by mutations in any of the components of the mitochondrial branched-chain  $\alpha$ -ketoacid dehydrogenase complex. In a study of 63 individuals, E1 $\beta$  subunit mutations were most common (38%), followed by E1 $\alpha$  (33%), and E2 (19%) mutations. Branched-chain  $\alpha$ -ketoacid dehydrogenase phosphatase or kinase mutations are also thought to cause MSUD. The overall incidence is approximately 1 case per 150,000 people in the general population, but MSUD is more common in Old Order Mennonites in southeastern Pennsylvania (1 in 176 births). A novel founder mutation in the E1 $\beta$  subunit has been reported in the Ashkenazi Jewish population.

### Treatment

Chronic care of the child with MSUD includes regular visits to an integrated metabolic clinic for medical and nutritional assessment. Adequate calories (100-120 kcal/kg per day) and protein (2-3 g/kg per day) are needed for growth. Chronic valine or isoleucine deficiency may cause an exfoliative dermatitis, and supplementation of these amino acids is often needed. Thiamine supplementation is administered to patients with thiamine-responsive forms of MSUD. Because patients on restricted diets are at risk for micronutrient and essential fatty acid deficiencies, patients should be periodically monitored for such deficits and supplementation given as needed.

Acute metabolic decompensation (e.g., fasting or illness severe enough to cause catabolism) is a medical emergency

that requires prompt intervention. Initial intervention is aimed at correcting dehydration, starting high-dose intravenous thiamine, and providing adequate calories (approximately 120-140 kcal/kg per day) to prevent further protein catabolism and higher rise in plasma leucine levels. To this end, high-dextrose intravenous fluids (to provide approximately 10 mg/kg per minute) and intralipid are often administered. Branched-chain amino acid-free parenteral nutrition or enteral formula, delivered by continuous nasogastric drip, can also be used. The rate of decrease of leucine is slowed in the face of valine and isoleucine levels inadequate to stimulate protein synthesis. Acute valine and isoleucine deficiency can be avoided by careful supplementation of these amino acids. Leucine is reintroduced to the diet after therapeutic levels are achieved. Hemodialysis and continuous venovenous extracorporeal removal therapies result in more rapid fall in plasma levels of branched-chain amino acids, and this modality is now established as an effective standard-of-care therapy for acute metabolic decompensation.

Liver transplantation has been increasingly performed on large numbers of patients as an essential component of long-term therapy in classic MSUD, even in nonexigent (i.e., elective) clinical circumstances (Strauss et al., 2006). It has become apparent that as patients reach adolescence and adulthood, they show variable intellectual deficits, attention deficits, deficits in executive function, psychological symptoms (e.g., anxiety, depression), and poor social adjustment, even with a history of apparently excellent dietary control and an absence of a history of acute metabolic crises (Strauss et al., 2006). Following transplant, leucine levels either remaining normal or are in a treatment range on an unrestricted protein diet. Long-term clinical evaluations are proceeding, but neuropsychological and patient and family reporting appear to support improvement or stabilization of neurologic status. Three patients who underwent successful transplantation were able to resume normal diets and were no longer at risk for metabolic decompensation. In an important variation of the transplant protocol, domino hepatic transplantation for MSUD has been successfully performed.

A novel treatment approach under investigation takes advantage of the observation that when used in the treatment of urea cycle disorders, Na phenylbutyrate causes a lowering of branched-chain amino acid levels (Burrage, Nagamani, Campeau, and Lee, 2014). Na phenylbutyrate was found to increase the activity of the branched-chain ketoacid dehydrogenase by preventing phosphorylation—and, thereby, inactivation—of the E1 $\alpha$  subunit. The increased residual enzyme activity of the branched-chain ketoacid dehydrogenase would be expected to lower branched-chain amino acid levels. Studies are under way using Na phenylbutyrate in cohorts of MSUD patients (Burrage et al., 2014).

### Glycine Encephalopathy

Glycine encephalopathy is an autosomal-recessive disorder caused by defective function of the glycine cleavage enzyme system, leading to accumulation of glycine in all body tissues, including the CNS (Figure 37-4). The glycine cleavage enzyme system has four components: glycine decarboxylase, also known as the P protein (it uses pyridoxal-phosphate as a cofactor); aminomethyltransferase, also known as T protein (it is a tetrahydrofolate dependent protein); the glycine cleavage system H protein (a hydrogen carrier protein); and the L protein or lipoamide dehydrogenase (the cofactor is lipoate). Infants with classic disease present in the first week of life with apnea, lethargy, severe hypotonia, and feeding difficulties. Respiratory failure, hiccups, and intractable seizures develop, and many infants die unless assisted ventilatory support is

**Figure 37-4. The glycine cleavage system.** Circles designate proteins with the active group shown. In the presence of P and H proteins, glycine is decarboxylated, and the remaining aminoethyl group binds to the reduced lipoic acid on the H protein. T protein is required to release ammonia and transfer the x carbon of glycine to tetrahydrofolate (THF), forming 5,10-CH<sub>2</sub>-THF. The L protein is necessary to regenerate the correct form of the H protein. (From Scriver C, Beudet A, Sly W, Valle D, eds. *The metabolic and molecular basis of inherited disease*, 8th ed. New York: McGraw-Hill, 2001:2066, Fig, 90-2. Reprinted with permission from The McGraw-Hill Companies.)

provided. The EEG commonly has a burst suppression pattern, but hypsarrhythmia has rarely been reported. There are also later-onset forms, including presentation at greater than 4 months of age. A review of 124 patients stratified affected individuals into four categories. Those who could only smile were termed severe. Those who had achieved additional developmental milestones were termed attenuated. Three attenuated forms were delineated, poor, intermediate, and mild; these were defined as a developmental quotient (ratio of developmental age to chronologic age) of less than 20, between 20 and 50, and greater than 50, respectively. Predictors of outcome included age at seizure onset, CSF glycine value, ratio of CSF to plasma glycine, and the presence of severe brain malformations (Swanson et al., 2015). Of presenting neonates, 85% have the severe form of the disease and 15% the attenuated; the proportion for infantile onset is 50% severe and 50% attenuated. In the previously described series of 124 affected individuals, 21% died in the neonatal period, 45% had the severe form, and 34% had an attenuated form (Swanson et al., 2015).

Brain imaging results are normal for about one-half of the neonatal-onset cases. Relatively common brain abnormalities include agenesis of the corpus callosum, progressive atrophy, and delayed myelination.

Mild and transient forms of glycine encephalopathy have been reported. Mild forms manifest in infancy or early childhood after an uneventful pregnancy and neonatal period. Clinical features include seizures (in most cases) and relatively mild developmental delay. Transient glycine encephalopathy is characterized by the same initial clinical and biochemical findings as the classic form, but it has only rarely been reported. In the transient form, elevated CSF and plasma glycine levels partially or completely normalize, and most patients have normal development.

The diagnosis of glycine encephalopathy is established by detecting an elevated CSF glycine concentration, typically 15 to 30 times normal, in association with an increased ratio of CSF to plasma glycine (normal < 0.02). Classic neonatal-onset patients often have ratios higher than 0.2, whereas atypical patients have ratios of approximately 0.09. A ratio higher than

0.08 is usually considered diagnostic of glycine encephalopathy. The plasma and CSF samples should be obtained as closely as possible to one another, and the presence of blood in the CSF invalidates the amino acid results. Other causes of increased CSF glycine levels include valproate therapy, brain trauma, and hypoxic-ischemic encephalopathy. Secondary elevations of plasma glycine, associated with ketosis, are often encountered in organic acidemias (e.g., methylmalonic, propionic, and isovaleric acidemias and  $\beta$ -ketothiolase deficiency; these are the ketotic hyperglycinemias). Because pyridoxine-dependent epilepsy, pyridoxamine 5'-phosphate oxidase deficiency, and cerebral folate deficiency may have presentations similar to that of glycine encephalopathy, concentrations of alpha-amino adipic semialdehyde, pyridoxal 5'-phosphate, and 5-methyltetrahydrofolate should also be assessed in the CSF. Urine S-sulfocysteine should be sent to test for isolated sulfite oxidase deficiency and molybdenum cofactor deficiency, which may also present with intractable seizures in the newborn period.

Confirmation of the diagnosis may be accomplished by assaying the glycine cleavage system in liver tissue, although, in practice, molecular testing of the genes encoding glycine cleavage system subunits is less invasive and more widely available, and the enzyme defect may be secondary, as described in the following discussion.

Comprehensive mutation analysis in 68 families with glycine encephalopathy detected *GLDC* (P protein gene) or *AMT* (T protein gene) mutations in 68% of neonatal and 60% of infantile types, respectively. No *GCSH* (H protein gene) mutations were identified.

Strikingly, evaluation of patients with abnormal glycine cleavage activity in liver, but without mutations in genes encoding the enzymes of the glycine cleavage system, were identified to have defects in mitochondrial lipoate synthesis. These defects include those in enzymes involved in lipoate synthesis and transfer and those in iron-sulfur cluster biogenesis because lipoate synthase is a protein that contains iron-sulfur clusters. Importantly, individuals with lipoate synthase defects, sometimes also referred to as variant or atypical glycine encephalopathy, have varied biochemical and clinical

presentations. It is important to be aware of these classes of defects and the biochemical and phenotypic overlap of lipoate synthesis defects, which include iron-sulfur cluster biogenesis defects, with glycine encephalopathy.

Treatment of glycine encephalopathy has not improved the overall dismal prognosis in the classic form of disease. Therapy is focused on controlling seizures with antiepileptic drugs, decreasing tissue glycine levels, and administering *N*-methyl-D-aspartate (NMDA) receptor antagonists to diminish glycine-induced neuronal excitotoxicity. Valproate is contraindicated because it can inhibit the glycine cleavage enzyme system and can cause hyperglycinemia in patients without glycine encephalopathy. Sodium benzoate is given because of its ability to conjugate to glycine to form hippurate, which can then be excreted in the urine. A glycine-specific mitochondrial enzyme, benzoyl-coenzyme A (CoA):glycine acyltransferase, catalyzes the condensation of benzoate and glycine to form hippurate. Sodium benzoate therapy can reduce plasma levels of glycine to the normal range and may have a mild effect on CSF glycine levels, but it does not affect the very poor prognosis. Because high-dose sodium benzoate therapy can result in carnitine deficiency, plasma carnitine levels should be monitored closely and appropriate supplementation provided. Dextromethorphan, an antagonist of the NMDA receptor, is also commonly used in therapy. Treatment with dextromethorphan may lead to improved seizure control and level of interaction in some patients. Rarely, ketamine has been used, but it may provide benefit in controlling seizures and improving overall level of interaction. A low-protein diet has no proven efficacy and may result in severe protein malnutrition, micronutrient deficiency, and exfoliative dermatitis if not monitored carefully.

### Methylmalonic Acidemias

Multiple genetic defects can lead to methylmalonic acidemia, alone or in combination with elevated homocysteine because both compounds are processed by enzymes that require  $B_{12}$ .  $B_{12}$  is acquired through dietary sources and must be appropriately transported and modified to participate in methylmalonic acid and homocysteine metabolism. The isolated methylmalonic acidemias and those in combination with elevated homocysteine are caused by deficiencies in the transport or modification of vitamin  $B_{12}$  (cobalamin) or by mutations in enzymes requiring a  $B_{12}$  cofactor, in addition to several other mechanisms, such as a transcription factor defect that causes combined methylmalonic acidemia and homocystinuria (see [Figure 37-6A and B](#)). Because there are a variety of causative defects, this group of conditions has significant

clinical heterogeneity and differences in response to therapy. Incidence is estimated at 1 case per 50,000 persons, or greater.

### Pathophysiology

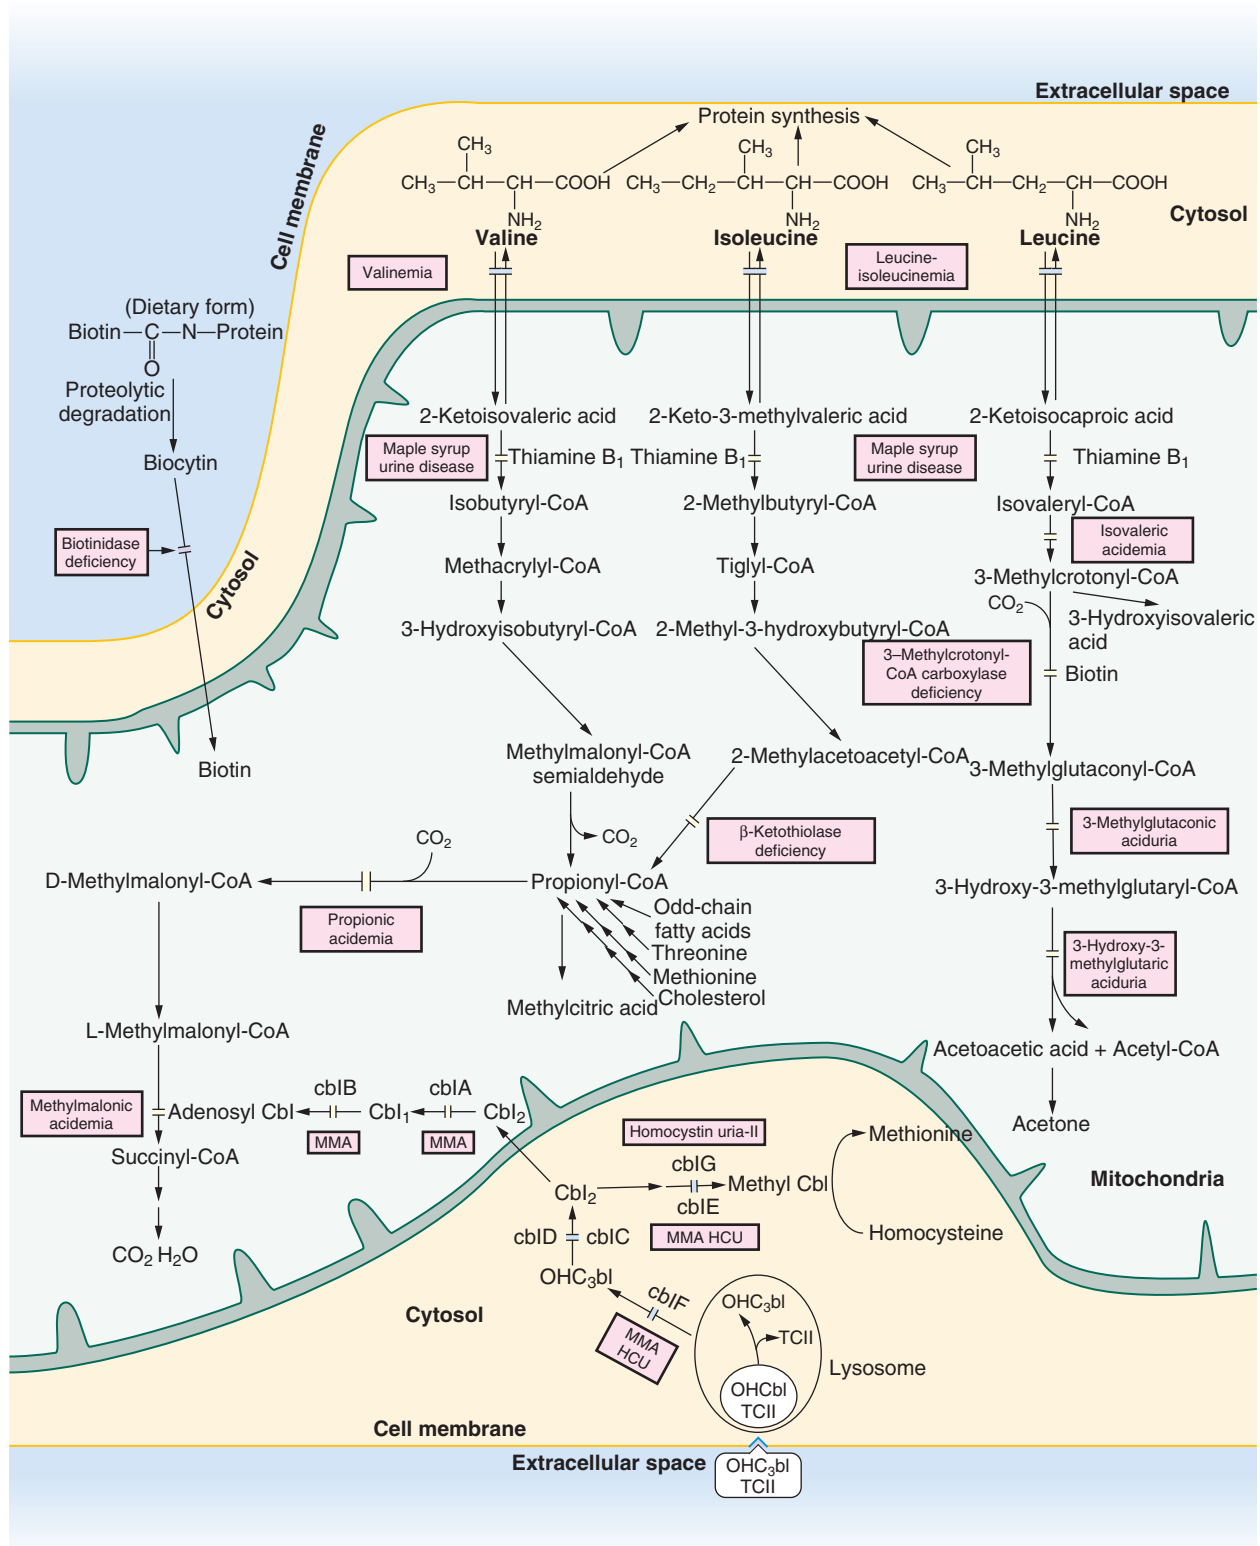

The canonical inherited isolated methylmalonic acidemias are caused by defects in the enzyme methylmalonyl-CoA mutase, which requires an adenosylcobalamin cofactor, or in the enzymes that modify  $B_{12}$  to adenosylcobalamin. The latter cases are sometimes denoted by the genetic complementation group because the causative genes were identified over time; these are *cblA*, *cblB*, and *cblD-MMA*. Isolated methylmalonic acidemia can also be caused by a defect in methylmalonyl-CoA epimerase (encoded by the *MCEE* gene), which converts D-methylmalonyl-CoA to L-methylmalonyl-CoA; in methylmalonate semialdehyde dehydrogenase (*ALDH6A1*); in a disorder of mitochondrial energy metabolism, succinyl-CoA synthase deficiency (*SUCLA2*, *SUCLG1*); and in association with mutations in *ACSF3*, in which malonic acid may also be elevated ([Pupavac et al., 2016](#)). Elevations of both methylmalonic acid and homocysteine are caused by defects in other genes encoding enzymes, transport proteins, and receptors that affect cobalamin trafficking and modification and can also be caused by dietary deficiency of  $B_{12}$  ([Pupavac et al., 2016](#)). Methylmalonyl-CoA is derived from propionyl-CoA; both are intermediates in the catabolism of isoleucine, valine, threonine, methionine, thymine, uracil, cholesterol, and odd-chain fatty acids. Methylmalonyl-CoA mutase converts L-methylmalonyl-CoA to succinyl-CoA, which then enters the tricarboxylic acid cycle.

The major causes of isolated methylmalonic acidemia are mutase deficiency ( $mut^0$ ,  $mut^-$ ), *cblA*, and *cblB*. *CblD-MMA* (formerly described as *cblH*) is also a cause of isolated methylmalonic acidemia but is more rare. Mutase activity is completely and partially abolished in the  $mut^0$  and  $mut^-$  groups, respectively. *CblC*, *cblD-combined*, *cblF* (*LMBRD1*), and *cblJ* (*ABCD4*) are associated with elevations of both methylmalonic acid and homocysteine, as is *cblX*, an X-linked defect in *HCFC1*, a transcription factor that affects expression of the gene defective in *cblC* disease, *MMACHC*. Defective adenosylcobalamin synthesis is responsible for *cblA*, *cblB*, and *cblD-MMA*. *CblC* and *cblD-combined*, *cblF*, and *cblJ* cause methylmalonic acidemia and homocystinuria because of their effects on both adenosylcobalamin and methylcobalamin biosynthesis ([Figure 37-6A and B](#)). *CblE* (*MTRR*), *cblG* (*MTR*), and *cblD-HC* affect methylcobalamin synthesis and therefore homocysteine metabolism alone.

### Clinical Manifestations

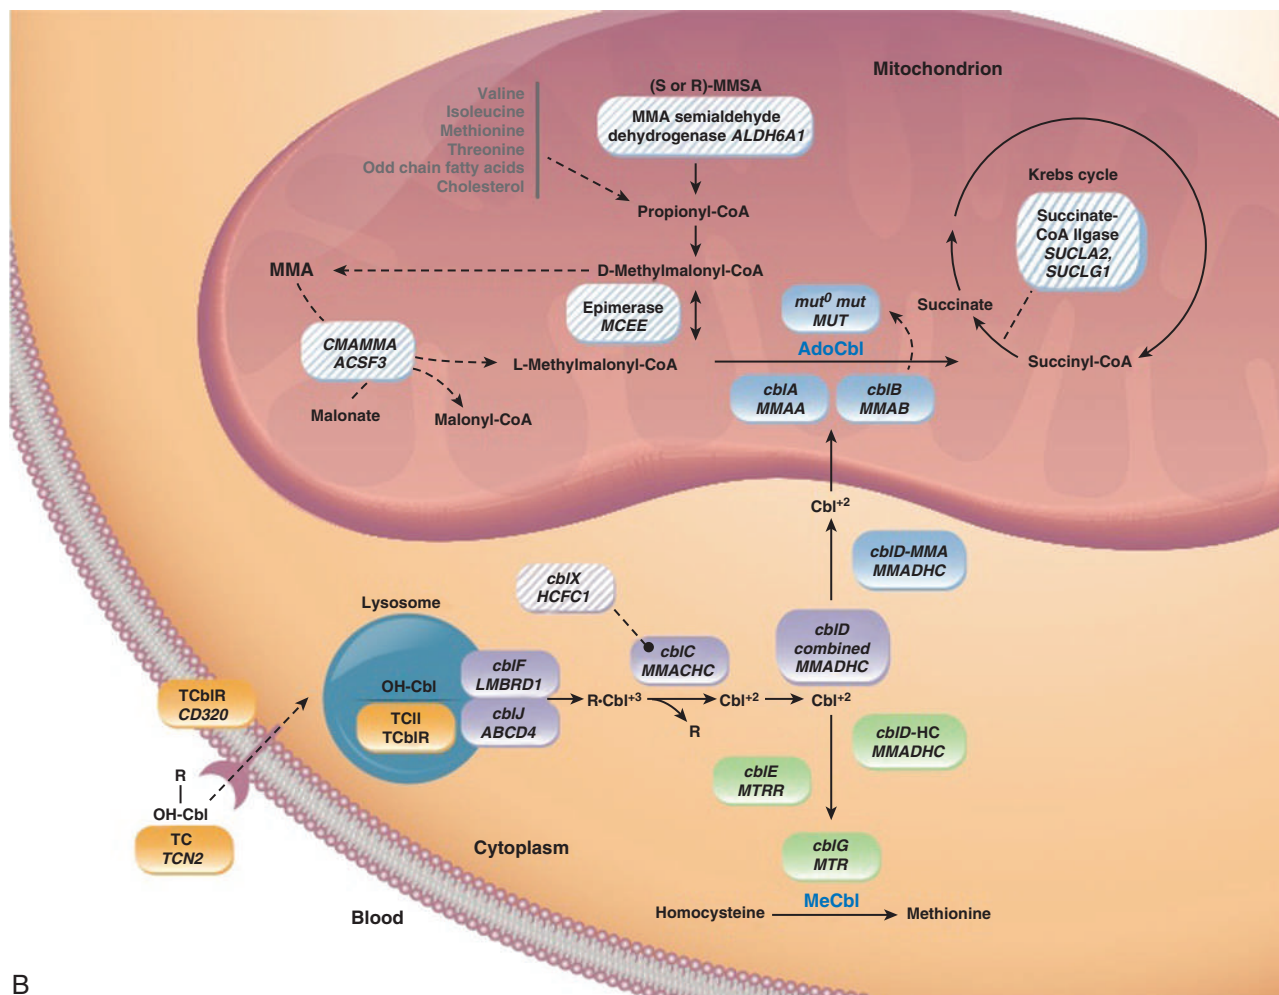

As with propionic acidemia and other disorders, there are early- and late-onset forms, which likely result, in part, from residual protein function. There is significant variability in presentation of the methylmalonic acidemias, depending on the particular underlying defect. Common features of the canonical isolated methylmalonic acidemias are failure to thrive, developmental delay, megaloblastic anemia, and neurologic dysfunction.  $mut^0$ , *cblA*, and *cblB* patients often present in the first days to weeks of life with poor feeding, dehydration, increasing lethargy, emesis, and hypotonia. Metabolic acidosis and secondary hyperammonemia, as with propionic acidemia, may be catastrophic. Mild  $mut^-$  or other forms of methylmalonic acidemia may present later in infancy or in childhood with hypoglycemia, acidosis, seizures, and lethargy. A patient with *cblC* disease can present early in infancy with signs and symptoms of metabolic decompensation, in later childhood, or in adulthood with myopathy, lower-extremity paresthesias, and thrombosis as a result of elevated plasma homocysteine. Other features of *cblC*

disease include hemolytic-uremic syndrome, cardiomyopathy, subacute combined degeneration of the cord, and psychiatric manifestations such as psychosis. Children with *cbiC* disease can have ocular abnormalities, including optic atrophy, and progressive pigmentary retinopathy with resultant nystagmus, strabismus, and worsening vision (Fischer et al., 2014). They may also exhibit hydrocephalus and microcephaly. Cranial imaging may reveal pathology of the basal ganglia and white matter. The two initial cases reported with *cbiD* presented in later childhood with mental retardation and behavioral problems, although subsequent reports have documented infantile onset with hypotonia and seizures and early childhood presentations with ataxia and gait abnormalities. *CblF* patients have been reported to have minor facial anomalies and hematologic defects. Transcobalamin II deficiency, a  $B_{12}$  transport deficiency, can manifest as failure to thrive in the first months of life, with neurologic disease, hematologic disease, and mental retardation. A benign form of methylmalonic acidemia has been reported in otherwise healthy children; some of these may be caused by mutations in the genes encoding mutase, those encoding epimerase, or in *ACSF3*. There are also reports of individuals with mutations in the receptor for

transcobalamin bound to cobalamin (TCbIR); this may be a benign condition.

### Laboratory Tests

Methylmalonic acidemia can clinically resemble other organic acidemias, necessitating analysis of urine organic acids for diagnosis. Elevated C3 (propionyl) acylcarnitine identifies methylmalonic acidemia, propionic acidemia, and  $B_{12}$  deficiency; therefore, urine organic acid analysis is required after an abnormal newborn screen with elevated C3 acylcarnitine. As with propionic acidemia, some cases are not identified through newborn screening, and some infants will develop clinical symptoms before the newborn screen results are available. Therefore if there is a clinical concern, testing for an organic aciduria should be performed. Ketosis and hyperammonemia are common in the acute neonatal presentation of these conditions, and if these are present, urine organic acids and other biochemical tests should be performed. Urine organic acid analysis reveals large amounts of methylmalonic acid, methylcitrate, propionic acid, and 3-hydroxypropionic acid in mutase deficiency and *cbiA* and *cbiB* disease. Serum

amino acids sometimes demonstrate elevation of glycine. When elevated serum or urine methylmalonic acid is identified, it is critical to obtain a total plasma homocysteine as a specific test to assess for defects that cause elevations of both compounds because elevated homocysteine may not be detected through plasma amino acid analysis. Serum B<sub>12</sub> levels must be assessed to ensure that elevated methylmalonic acid and homocysteine levels, if present, are not the result of a nutritional deficiency of cobalamin. Total plasma homocysteine levels are elevated in cblC, cblD-combined, cblE, cblJ, and CblX diseases. Total and free carnitine levels tend to be low. The cobalamin transport deficiencies are assessed by measuring serum cobalamin levels and absorption by the Schilling test, in addition to DNA testing (Pupavac et al., 2016). Determination of the form of methylmalonic acidemia was often performed through complementation studies in fibroblasts, but this does not identify all causes (Pupavac et al., 2016). DNA mutation analysis is now the appropriate first test. One next-generation sequencing panel includes 24 genes associated with elevated methylmalonic acid (Pupavac et al., 2016).

### Treatment

Guidelines for acute and chronic management of methylmalonic acidemia have been developed (Baumgartner et al., 2014). The principles of management are similar to those for propionic acidemia. One critical difference is that some forms of methylmalonic acidemia are responsive to vitamin B<sub>12</sub>, and hydroxocobalamin (preferred) or cyanocobalamin should be given empirically to a child presenting with hyperammonemia and ketosis. If methylmalonic acidemia is identified, intramuscular or subcutaneous hydroxocobalamin should be continued if the child appears to have a form that is responsive to B<sub>12</sub> (cblA, mut<sup>-</sup>), which can be difficult to assess. During acute metabolic crises, treatment of known methylmalonic acidemia is directed toward stopping catabolism and restricting protein intake. The usual protein intake is stopped for 12 to 24 hours from last intake, and fat and glucose are given orally or intravenously. Chronic and acute therapy include carnitine; intramuscular, subcutaneous, or intravenous hydroxocobalamin; and metronidazole or neomycin to decrease intestinal propionate production in some cases. Betaine and folate are used if homocysteine is elevated. Treatment of hyperammonemia, which can be marked in the initial presentation, is similar to that for propionic acidemia (Baumgartner et al., 2014). Improved growth and enhanced nutritional status are seen in patients with methylmalonic acidemia fed an elemental medical food. Patients should consume a diet low in the macronutrient precursors proximal to the metabolic block and receive adequate calories and total protein to enable growth. Plasma methylmalonic acid levels are followed for metabolic control. Frequent complications in methylmalonic acidemia include tubulointerstitial nephritis, leading to end-stage renal disease, and basal ganglia stroke, often affecting the globus pallidus. Cardiomyopathy is reported but is less common than in propionic acidemia (Baumgartner et al., 2014). Liver transplantation has been performed but is not curative of the disease. It protects against recurrent metabolic crises but not against metabolic stroke, and it does not lead to a complete clinical or biochemical correction because the pathway is active in other tissues. Kidney transplant, often performed for renal failure, may also protect against metabolic decompensation (Baumgartner et al., 2014), although this is still unclear.

### Glutaric Aciduria Type I

In 1975, glutaric acidemia and aciduria were described in siblings with a neurodegenerative disorder beginning in infancy and characterized by opisthotonus, dystonia, and athetosis. Glutaric acidemia type I, also known as glutaryl-CoA dehydrogenase deficiency, is an autosomal-recessive condition caused by deficiency of glutaryl-CoA dehydrogenase and has an estimated prevalence of approximately 1 case per 100,000 persons. In the United States glutaric acidemia type I is relatively common in the Old Order Amish. Glutaric acidemia type II is also known as multiple acyl-CoA dehydrogenase deficiency (MADD) and is associated with defects in mitochondrial electron transfer flavoprotein or electron transfer flavoprotein dehydrogenase; it is discussed further in Chapter 37. Glutaric aciduria type III is not associated with clinical symptoms and is the result of a deficiency of the enzyme that converts glutarate to glutaryl-CoA. Glutaryl-CoA dehydrogenase is a key enzyme in the degradation pathway of lysine, hydroxylysine, and tryptophan. Deficiency results in accumulation of glutarate and, to a lesser extent, of 3-hydroxyglutarate and glutaconate in body tissues, blood, CSF, and urine (Hedlund, Longo, and Pasquali, 2006).

The classic symptom of glutaric acidemia type I (GAI) is irreversible focal striatal necrosis during an acute illness, most often between the ages of 3 and 18 months. Such an event is termed an encephalopathic crisis. Sequelae of the acute injury to the basal ganglia include irreversible disabling dystonia and, in some cases, dyskinesia, in addition to shortened life expectancy (Kolker et al., 2006). Crucially, newborn screening has changed the natural history of this condition. The combined use of chronic management and emergency management in the treatment of individuals identified presymptomatically greatly reduces neurologic injury (Hedlund et al., 2006; Kolker et al., 2006). Macrocephaly is a feature of GAI and may not be present at birth, but head growth velocity is increased; in some cases progressive macrocephaly has led to the identification of GAI before striatal injury (Kolker et al., 2006). Intraretinal hemorrhages and subdural hematoma caused by the rupture of bridging veins associated with macrocephaly may be present and may be mistaken for nonaccidental injury; this can also lead to the identification of affected individuals before striatal injury. In some cases, striatal injury is not associated with an identified encephalopathic crisis but is insidious, with gradual appearance of symptoms. Systemic manifestations typical of

many other organic acidemias, such as pronounced metabolic ketoacidosis, hypoglycemia, and hyperammonemia, generally do not occur (Hedlund et al., 2006). There is a window of neurologic susceptibility to striatal damage during the first years of life. A seminal natural history study of 279 individuals in 37 countries demonstrated that 95% of encephalopathic crises occurred before 2 years of age and that additional basal ganglia injury occurred up to roughly 6 years of age but not beyond (Kolker et al., 2006). Crucially, individuals who are identified presymptomatically and treated according to established guidelines may avoid the devastating neurologic injury in the vulnerable period (Kolker et al., 2006). A late-onset leukodystrophy has been described, and the natural history of this manifestation is unknown.

A characteristic early brain MRI finding is symmetric widening of the sylvian fissure with poor operculization (“bat wing” appearance) caused by frontotemporal atrophy or hypoplasia (Figure 37-8). Other features include basal ganglia injury, subdural hematoma, ventriculomegaly, and delayed myelination (Hedlund et al., 2006). Diffusion-weighted imaging may be more sensitive in demonstrating brain lesions than CT or MRI.

Urine organic acid analysis often documents highly elevated glutaric acid and lesser elevations of 3-hydroxyglutarate and glutaconate, but some children with a classic neurologic phenotype have low or undetectable levels of these metabolites (so-called low excretors). Newborn screening using tandem mass spectrometry has the potential for presymptomatic detection of GAI, although the existence of a low-excretor phenotype can result in missed cases. Roughly one-third of affected individuals have a low excretor phenotype, which is associated with residual enzyme activity of up to 30%. Crucially, these individuals are at no less risk of severe neurologic injury (Kolker et al., 2006).

Increased glutarate and 3-hydroxyglutarate levels in the CNS may induce an imbalance in glutamatergic and GABAergic neurotransmission by inhibiting glutamate decarboxylase, the key enzyme in gamma-aminobutyric acid (GABA) synthesis,

or through direct damage to striatal GABAergic neurons. 3-Hydroxyglutarate may mimic the excitatory neurotransmitter glutamate and thereby cause excitotoxic cell damage mediated through activation of NMDA receptors. Glutarate was shown to inhibit synaptosomal uptake of glutamic acid and produce striatal lesions when injected directly into the brain of a rat. Other potential contributors to neurotoxicity include cytokine-induced cell damage, mitochondrial dysfunction, increased production of reactive oxygen species, and production of toxic quinolinic acid, an intermediate in tryptophan metabolism in the brain. Other reports have emphasized the relatively weak neurotoxicity of glutarate and 3-hydroxyglutarate in animal models and primary neuronal cell cultures. The pathogenesis of striatal necrosis and brain lesions in GAI remains the subject of intensive investigation. Animal models may help resolve these conflicting results.

Presymptomatic treatment of GAI includes restriction of dietary lysine intake, carnitine, and sometimes riboflavin; supplementation; and rapid intervention in times of intercurrent illness (Kolker et al., 2006). This therapy is continued in symptomatic patients, who also require symptom management, which includes anticholinergic drugs such as trihexyphenidyl and botulinum toxin to treat generalized or focal dystonia resulting from striatal injury. Stereotactic pallidotomy has been performed, as has deep brain stimulation.

Inherited disorders of the urea cycle represent a group of inborn errors of metabolism that are associated with hyperammonemic encephalopathy and high mortality and morbidity. They comprise deficiencies of a cofactor-synthesizing enzyme, five catalytic enzymes, and amino acid transporters involved in urea synthesis (Fig. 38-1). These disorders are classified as follows (estimated prevalence rates are given in parentheses) (Brusilow and Horwich, 2001; Tuchman et al., 2008; Ah Mew et al., 2003):

- Deficiency of cofactor synthesis
  - *N*-acetylglutamate synthase (NAGS) deficiency (prevalence unknown)
- Deficiency of catalytic enzymes
  - carbamoyl-phosphate synthase 1 (CPS1) deficiency (1 per 62,000)
  - ornithine transcarbamylase (OTC) deficiency (1 per 14,000)
  - argininosuccinate synthase 1 (ASS1) deficiency (citrullinemia) (1 per 57,000)
  - argininosuccinate lyase (ASL) deficiency (argininosuccinic aciduria) (1 per 70,000)
  - arginase 1 (ARG1) deficiency (hyperargininemia) (1 per 353,000)
- Deficiency of transporters
  - citrullinemia type II (mitochondrial aspartate/glutamate carrier [citrin] SLC25A13 deficiency) (1 per 21,000 in Japan; possibly more common in China)
  - hyperornithinemia-hyperammonemia-homocitrullinuria (HHH) syndrome (mitochondrial ornithine transporter, ORNT1 or SLC25A15 deficiency) (prevalence unknown)

All of the urea cycle disorders (UCDs) are inherited as autosomal-recessive traits, except for OTC deficiency, which is X-linked. Other than in ARG1 deficiency, infants with a complete deficiency of any other urea cycle enzyme commonly present in the newborn period with hyperammonemic coma. Universal newborn screening and the availability of drugs and hemodialysis for treatment of hyperammonemia have resulted in improved survival; mortality, however, still remains high, and the majority of survivors have intellectual disability. Patients with late-onset disease may present at any age with hyperammonemic crises that carry a risk of mortality (10%) and intellectual disability.

## THE UREA CYCLE

Dietary protein, on average, contains approximately 16% nitrogen. More than 90% of the nitrogen that is not used for anabolic processes is typically metabolized and excreted as urea. Deficiency of one of the enzymes or transporters required for urea synthesis results in accumulation of nitrogen in the form of ammonia, leading to encephalopathy.

One cofactor and its synthesizing enzyme, five catalytic enzymes, and two transporters are necessary for optimal urea cycle activity (see Fig. 38-1). The cofactor *N*-acetylglutamate, which is synthesized by NAGS, activates CPS1, the first enzyme

catalyzing the rate-limiting step of the urea cycle. CPS1 uses ATP, bicarbonate, and glutamine or ammonia to synthesize carbamoyl-phosphate. This reaction is where the first atom of waste nitrogen enters the cycle. OTC, a mitochondrial enzyme, synthesizes citrulline from carbamoyl-phosphate and ornithine. Citrulline is actively transported by the ornithine transporter (ORNT1/SLC25A15) from the mitochondrion to the cytosol, where it is conjugated with aspartate to form argininosuccinic acid by ASS1. Here, the second atom of waste nitrogen is contributed to the cycle by aspartate. ASL cleaves argininosuccinic acid to yield fumarate and arginine. The final step in the urea cycle involves cleavage of arginine by ARG1 to form urea and ornithine. The ornithine is transported back into the mitochondrion by ORNT1/SLC25A15.

Although the complete urea cycle is only present in hepatocytes, other tissues also express some urea cycle enzymes. The intermediates of the urea cycle are linked to the citric acid cycle, the nitric oxide cycle, and possibly other pathways. The enzymes ASS1 and ASL are also required for synthesis of arginine, which is important for generation of nitric oxide (NO), creatine, polyamines, and agmatine. Thus deficiency of urea cycle enzymes may also affect nonureagenic functions, which may contribute to some of the distinct features observed in urea cycle disorders.

## CLINICAL DESCRIPTION OF UREA CYCLE DISORDERS

### *N*-Acetylglutamate Synthase Deficiency

Inherited NAGS deficiency leads to hyperammonemia by causing a secondary deficiency of CPS1 activity. NAGS deficiency is characterized by hyperammonemia in the newborn period or later in life that can be fatal or lead to intellectual and developmental disabilities. Plasma amino acid analysis usually demonstrates an increased level of glutamine and reduced or absent levels of citrulline. Urinary orotic acid levels are normal or low. Because enzyme analysis requires large amounts of liver tissue and may not be entirely reliable, analysis of genomic DNA for mutations in the NAGS gene is the preferred diagnostic method. Previously, treatment for NAGS deficiency was limited to low-protein diet and use of ammonia scavengers (Table 38-1); however, synthetic cofactor therapy with *N*-carbamyl-L-glutamate is now approved.

### Carbamoyl-Phosphate Synthase 1 Deficiency

CPS1 deficiency can manifest with hyperammonemic crises in the newborn period or later in childhood. Biochemically, the principal findings are hyperammonemia, increased glutamine, and reduced or absent citrulline in plasma. Urinary orotic acid levels are normal or low. Patients with neonatal-onset disease generally demonstrate less than 5% of the normal CPS1 activity in liver, whereas those with late-onset disease have higher residual activity. Therapy consists of dialysis and/or intravenous ammonia scavengers during severe hyperammonemic episodes and low-protein diet and oral ammonia scavengers

**TABLE 38-1** Long-Term Alternative-Pathway Treatment of Urea Cycle Disorders (UCDs)\*

Disorder	L-Citrulline	L-Arginine Free Base	Sodium Phenylbutyrate	N-Carbamylglutamate
NAGS deficiency	—	—	—	~0.10 g/kg/d
CPS1 or OTC deficiency	0.15–0.20 g/kg/d or 3.8 g/m <sup>2</sup> /d	—	0.45–0.60 g/kg if < 20 kg 9.9–13.0 g/m <sup>2</sup> /d in larger patients	—
Citrullinemia	—	0.40–0.50 g/kg/d or 8.8–15.4 g/m <sup>2</sup> /d	0.45–0.60 g/kg if < 20 kg 9.9–13.0 g/m <sup>2</sup> /d in larger patients	—
Argininosuccinic acidemia	—	0.40–0.50 g/kg/d or 8.8–15.4 g/m <sup>2</sup> /d	0.45–0.60 g/kg if < 20 kg 9.9–13.0 g/m <sup>2</sup> /d in larger patients	—
Argininemia	—	—	0.45–0.60 g/kg/d if < 20 kg 9.9–13.0 g/m <sup>2</sup> /d in larger patients	—

\*Drugs and dose ranges are those commonly used in patients with UCDs; however, doses can vary and need to be adjusted based on the severity of the disorder and patient response. When using doses at the upper recommended range or above, consideration should be given to increased risk of drug toxicity.

CPS1, carbamoyl-phosphate synthase 1; NAGS, *N*-acetylglutamate synthase; OTC, ornithine transcarbamylase.

**Figure 38-1. The urea cycle.** AcCoA, acetyl coenzyme A; ASL, argininosuccinate lyase; ARG1, arginase 1; ASS1, argininosuccinate synthase; CTR, citrin; CoASH, coenzyme A; CPS1, carbamoyl-phosphate synthase 1; NAGS, *N*-acetylglutamate synthase; ORNT1, ornithine transporter 1; OTC, ornithine transcarbamylase.

for chronic treatment (see [Table 38-1](#)). Patients with the neonatal-onset form who survive the initial crisis generally require liver transplantation to have any quality of life.

### Ornithine Transcarbamylase Deficiency

OTC deficiency is transmitted as an X-linked recessive disorder and thus is much more severe in males ([Lichter-Konecki et al., 2013](#)). The classic presentation of OTC deficiency in hemizygous males is that of a catastrophic illness in the first week of life. In symptomatic female heterozygotes and in males with partial OTC deficiency, symptoms may occur at any time from infancy to adulthood. These patients generally have 5% to 30% of normal OTC activity in the liver. Biochemically, the findings are hyperammonemia, hyperglutaminemia, reduced or absent citrulline in plasma, and increased urinary orotic acid.

More than 340 different point mutations and polymorphisms have been found in the *OTC* gene. Although most families have point mutations, small and large deletions have been identified. When the mutation has been identified, carrier testing and prenatal diagnosis can be offered to the family.

Detection of heterozygous females with OTC deficiency is important for both identifying at-risk family members and prenatal diagnosis. Such detection can be accomplished by either molecular studies or, in cases where no mutation is found, by an allopurinol load. When administered allopurinol (300 mg given orally to adults), in 90% of heterozygotes with OTC deficiency, there is increased excretion of orotic acid. Approximately 15% of OTC-deficient heterozygous females will become symptomatic during their lifetime. Therapy for neonatal-onset OTC deficiency consists of dialysis and intravenous ammonia scavengers, followed by maintenance on a low-protein diet and long-term ammonia scavengers (see [Table 38-1](#)). Patients with the neonatal-onset form who survive the initial crisis generally require liver transplantation for prevention of recurrent metabolic crises.

### Citrullinemia

Citrullinemia is characterized by marked elevation of citrulline in the blood ([Quinonez and Thoene, 2004](#)). Two distinct forms have been reported: neonatal- or childhood-onset citrullinemia (type I; with diminished levels of ASS1 in all organs) and citrullinemia type II or citrin deficiency, an adult-onset citrullinemia that in some but not all cases is preceded by neonatal cholestasis and liver dysfunction.

Biochemically, the principal findings in type I are hyperammonemia, citrullinemia, and citrullinuria. Citrulline levels are elevated 50-fold to 100-fold above normal. Urinary orotic acid levels are also increased. Therapy consists of dialysis during severe hyperammonemic crises, followed by low-protein diet and long-term ammonia-scavenger therapy (see [Table 38-1](#)). After the initial crisis, patients are, in general, more stable and easier to manage than patients with more proximal urea cycle defects.

### Citrullinemia Type II or Citrin Deficiency

Citrin deficiency is caused by mutations in *SLC25A13*, a gene that encodes citrin, a mitochondrial membrane protein. This carrier enables the exchange of mitochondrial aspartate for cytosolic glutamate across the inner mitochondrial membrane. The lack of aspartate to conjugate with citrulline in this condition leads to a block in urea synthesis. Citrulline levels can be elevated up to 400  $\mu\text{mol/L}$ ; plasma ammonia levels are less severely elevated compared with other UCDs.

Citrin deficiency can manifest in adulthood with cyclical bizarre behavior (aggression, irritability, and hyperactivity), dysarthria, seizures, motor weakness, and coma. Treatment

generally relies on ammonia scavengers (arginine and phenylbutyrate); however, liver transplantation is becoming a more common therapy because of the possible liver complications. More recently, a neonatal-onset form of citrin deficiency has been identified; it is associated with intrahepatic cholestasis. Affected infants have multiple metabolic abnormalities, including aminoacidemia, galactosemia, hypoproteinemia, hypoglycemia, and cholestasis. Treatment usually consists of high-protein/low-carbohydrate diet, and the symptoms often disappear within a year. A few children, however, have a severe form of the disorder with liver damage and tyrosinemia that necessitates liver transplantation. Hyperammonemia is not a major component of this disorder.

### Argininosuccinic Aciduria

Argininosuccinic aciduria derives its name from the marked elevation of argininosuccinic acid in the blood and urine of affected persons. In the severe forms, this disorder can present with hyperammonemic coma in the newborn period, whereas those with mild forms have fewer, if any, episodes of symptomatic hyperammonemia (Nagamani, Erez, and Lee, 2011). A specific abnormality of the hair termed *trichorrhexis nodosa* develops in affected children. Some patients develop chronic hepatomegaly. Liver function tests can be abnormal and patients may develop cirrhosis. The reasons as to why some patients with this condition develop cirrhosis, and others do not, are not yet understood. Even individuals with no history of hyperammonemia can have intellectual and learning disabilities, and some develop hypertension that is difficult to control. Biochemically, the principal findings are elevated citrulline level, hyperammonemia, argininosuccinic acidemia, and argininosuccinic aciduria. After the initial hyperammonemic crisis and establishment of the diagnosis, treatment consists of a low-protein diet and L-arginine supplementation (see Table 38-1). Ammonia scavengers may be required in those who have metabolic decompensations. Recent evidence also suggests that ASL is required for synthesis of nitric oxide (NO) and that NO deficiency in this disorder may lead to hypertension.

### Argininemia

Argininemia characterized by significant elevations of arginine is caused by a deficiency of ARG1. Argininemia presents differently from all of the other UCDs (Wong, Cederbaum, and Crombez, 2004). Although rarely hyperammonemia can be observed, this condition usually manifests as a progressive neurologic disorder rather than as an acute encephalopathy. The disease runs a chronic course with development of progressive spasticity (diplegia or quadriplegia). Affected children generally do not succumb to hyperammonemic coma and therefore have a longer life span than those affected by proximal UCDs. Patients may also have acute episodes of ataxia, behavioral disturbances, vomiting, lethargy, and seizures precipitated by intercurrent illnesses. The principal biochemical finding is markedly elevated plasma arginine. Urinary excretion of orotic acid and guanidine compounds also is markedly increased. The diagnosis can be confirmed by measuring ARG1 activity in erythrocytes.

The mechanism responsible for the spasticity and cognitive deficits in argininemia is unknown but is unlikely to be the result of the generally moderate hyperammonemia. Arginine, its guanidine metabolites, and altered biogenic amines are candidate neurotoxins. Arginine is the substrate for nitric oxide synthase, so overproduction of NO may play a role in neuropathology. Treatment with ammonia-scavenger therapy and lowering of the arginine level appears to halt the progres-

sion of the spasticity, and botulinum toxin (Botox) and surgical tendon release may improve function.

### Hyperornithinemia-Hyperammonemia-Homocitrullinuria Syndrome

HHH syndrome is rare, and only about 50 individuals have been reported in the literature. Clinical symptoms are similar to those in other UCDs but rarely develop in infancy. Plasma ornithine concentrations are elevated, ranging from 400 to 600  $\mu\text{mol/L}$ . Plasma lysine level typically is low, and urinary excretion of homocitrulline is increased. HHH syndrome is caused by mutations in the ornithine transporter gene, *ORNT1*, also called *SLC25A15*. The decreased activity of the transporter leads to decreased ornithine levels in mitochondria and secondary impairment of urea synthesis. The expression of *ORNT2*, an intronless gene, encoding a protein about 90% identical to ORNT 1, may explain the milder clinical signs and symptoms compared with those in CPS1 and OTC deficiencies. Treatment of HHH syndrome involves protein restriction, ammonia scavengers, and citrulline supplementation.

### COMMON CLINICAL PRESENTATIONS OF UREA CYCLE DISORDERS

The classic presentation of a complete defect in the urea cycle (other than ARG1 deficiency) is that of a catastrophic illness in the first week of life. Clinical manifestations typically appear between 24 and 72 hours of age, starting as a poor suck, hypotonia, vomiting, lethargy, and hyperventilation, with rapid progression to seizures and coma (Ah Mew et al., 2003). The electroencephalogram (EEG) pattern during hyperammonemic coma is one of low voltage with slow waves and asymmetric  $\delta$  and  $\theta$  waves. The tracing may demonstrate a burst-suppression pattern, and the duration of the interburst interval may correlate with the peak of ammonia levels. Neuroimaging studies reveal cerebral edema with small ventricles, flattening of cerebral gyri, and diffuse low density of white matter; evidence of intracranial hemorrhage also may be seen.

Partial deficiencies of a urea cycle enzyme have a spectrum of presentations, with hyperammonemic episodes developing in infancy in some, childhood in others, and not until adulthood in still others. Symptoms may be delayed in onset by dietary self-restriction and avoidance of high-protein foods. Signs and symptoms in childhood include anorexia and behavioral abnormalities such as episodes of erratic behavior, acting out of character, irritability, cloudiness to frank changes in mental status and ataxia, nocturnal restlessness, and attention deficit and hyperactivity. In adults, signs and symptoms may mimic those of psychiatric or neurologic disorders and include migraine-like headaches, nausea, dysarthria, ataxia, confusion, hallucinations, and visual impairment (blurred vision, scotomas, vision loss).

Neurologic findings in those with severe manifestations may include increased deep tendon reflexes, papilledema, and decorticate/decerebrate posturing. In metabolic decompensation, seizures generally are a late complication; the seizure episode typically is preceded by alteration in consciousness. There are indications that patients with UCDs may also be prone to seizures outside of hyperammonemic episodes; seizures were observed more often in patients with UCDs than in the general population in one clinic. Analysis of data collected longitudinally from patients with UCDs will allow further investigation of this impression.

In affected individuals, hyperammonemic episodes can be precipitated by any event that induces catabolism, including

infections, high-protein meals, medication, trauma, surgery, and childbirth. It is not uncommon for the initial hyperammonemic episode in a child with a partial deficiency to occur after weaning, when low-protein breast milk is replaced by formula or cow's milk. The puerperium in OTC-deficient heterozygotes and valproate therapy in partial CPS1 and ASL deficiencies also have been associated with hyperammonemic crises.

## HISTOPATHOLOGIC FEATURES OF UREA CYCLE DISORDERS

Histopathologic examination of the liver in UCDs may be normal but often demonstrates diffuse microvesicular steatosis, marked increased glycogen in periportal cells, and variable portal fibrosis. Cirrhosis has been identified in some patients with argininosuccinic aciduria (ASA), citrullinemia type II, and ARG1 deficiency.

Neuropathologic findings in UCDs are similar to those following the hepatic encephalopathy of acute liver failure. They depend on both the duration of hyperammonemic coma and the interval between coma and death. Neonates who die as a result of hyperammonemic coma have prominent cerebral edema and generalized neuronal cell loss on postmortem examination. Histologically, astrocyte swelling was one of the first observations made in an animal model for hepatic encephalopathy, leading to the hypothesis that swollen astrocytes may be the cellular correlate of the brain edema in acute hyperammonemia. In survivors of prolonged coma, changes observed on neuroimaging studies obtained months after the insult include ventriculomegaly with increased sulcal markings, bilateral symmetric low-density white-matter defects, cystic degeneration, injury to the bilateral lentiform nuclei, and diffuse atrophy with sparing of the cerebellum. Neuropathologic findings in those children who subsequently died were consistent with the neuroimaging findings and included ulegria, cortical atrophy with ventriculomegaly, prominent cortical neuronal loss, gliosis (often with Alzheimer type II astrocytes), and spongiform changes at the gray–white matter interface and in the basal ganglia and thalamus.

## MECHANISM OF NEUROPATHOLOGY

The mechanism of ammonia-induced neuropathology remains unclear. Ammonia normally is detoxified in astrocytes by glutamate dehydrogenase and glutamine synthase. Accumulation of ammonia and glutamine in the brain has a number of potentially toxic effects.

### Downregulation of Astrocytic Glutamate Transporters

The downregulation of astrocytic glutamate transporters and elevations of extracellular glutamate observed in hyperammonemia have led to the hypothesis that the brain damage is caused by overstimulation of neurons by elevated extracellular glutamate levels, a mechanism of brain damage called excitotoxicity.

### Elevated Glutamine Levels

A negative correlation between the height of brain glutamine levels and brain myoinositol levels has been observed, suggesting depletion of the osmolyte myoinositol by high glutamine levels. High brain glutamine levels may have an osmotic effect and cause brain swelling.

## Altered Water Transport

Water transport at blood–brain and brain–cerebrospinal fluid interfaces is facilitated by channel proteins called aquaporins. Aquaporin 4 (AQP4) is the main astrocytic water channel, and altered expression of *Aqp4* has been reported in hyperammonemia.

## Altered Glucose Metabolism/Disturbed Energy Metabolism

Ammonia stimulates phosphofructokinase, the key enzyme of glycolysis. The ammonium ion ( $\text{NH}_4^+$ ), under physiologic conditions *in vivo*, may play a significant role in the regulation of glycolysis in astrocytes. Increased ammonia levels, conversely, inhibit  $\alpha$ -ketoglutarate dehydrogenase in the brain. Stimulation of phosphofructokinase and inhibition of  $\alpha$ -ketoglutarate dehydrogenase, the key enzyme of the citric acid cycle, cause increased formation of lactate and compromised brain energy metabolism.

## Interference With the Normal Flux of Potassium Ions

$\text{NH}_4^+$  can cross cell membranes through ion channels or membrane transporters, and it can replace  $\text{K}^+$  on different transporters. Downregulation of the major astrocytic water, gap-junction, and potassium channels during hyperammonemia was described in an animal model for UCDs and led to the conclusion that hyperammonemia may disturb potassium and water homeostasis in the brain.

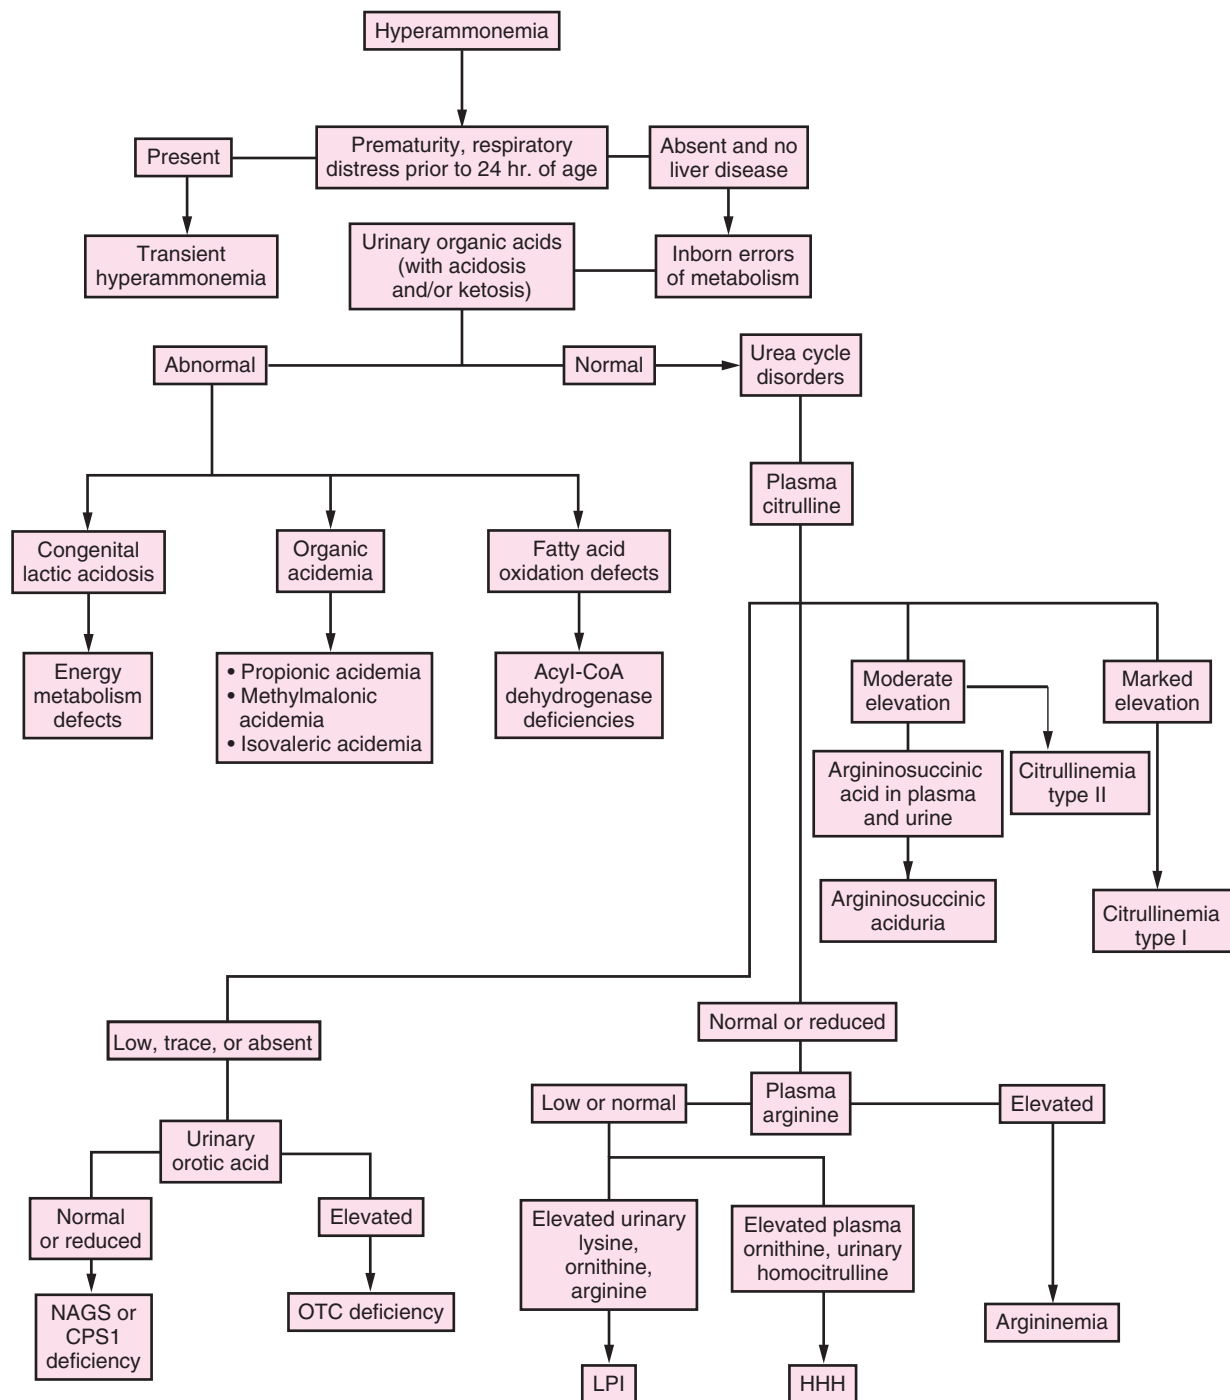

## Oxidative and Nitrosative Stress

An increase in free radical production and nitric oxide synthesis causes oxidative/nitrosative (O/N) stress. Ammonia causes free radical production and a decrease in antioxidant enzyme activity. In addition to oxidative stress, there is also nitrosative stress in hyperammonemic encephalopathy, and increased amounts of NO have been found in animal models of hyperammonemia.

## DIFFERENTIAL DIAGNOSIS

In the newborn period, hyperammonemia is similar in presentation to a number of acquired conditions, including sepsis, intracranial hemorrhage, and cardiorespiratory disorders. The measurement of plasma ammonia levels is critical to distinguish between these conditions and hence should be a part of the routine evaluation for serious illnesses in the newborn period. Apart from UCDs, a number of other inborn errors of metabolism can cause hyperammonemia. These include organic acidemias, nonketotic hyperglycinemia, congenital lactic acidoses, lysinuric protein intolerance, and defects in fatty acid oxidation. An algorithm for distinguishing between these disorders is presented in Fig. 38-2. Plasma amino acid patterns also are often distinct in the specific types of UCDs and help narrow the diagnosis (Fig. 38-2). Specific enzymatic or DNA analyses may be required in some instances for diagnosis; however, such testing should not delay the initiation of treatment.

In older children and adults, identification of UCDs resulting from partial deficiencies of enzymes has often been delayed through their misdiagnosis as migraine, cyclical vomiting, viral encephalitis, stroke, Reye's syndrome, drug toxicity, child abuse, psychosis, postpartum depression, seizure disorder, and cerebral palsy. Studies have found a mean delay of 8

**Figure 38-2. Algorithm for differential diagnosis of hyperammonemia.** Plasma amino acids, serum lactate, and urinary excretion of orotic acid and organic acids are measured. Acyl-CoA, acyl coenzyme A; CPS1, carbamoyl-phosphate synthase 1; HHH, hyperornithinemia-hyperammonemia-homocitrullinuria syndrome; LPI, lysinuric protein intolerance; NAGS, *N*-acetylglutamate synthase; OTC, ornithine transcarbamylase.

to 16 months between the onset of symptoms and diagnosis of late-onset UCDs. Plasma ammonia levels may be elevated during symptomatic episodes and normal when the patient is clinically stable.

## TREATMENT

Long-term therapy for UCDs consists of dietary modifications, supplementation with urea cycle intermediates (e.g., arginine and citrulline), and use of oral nitrogen-scavenging agents.

Treatment during hyperammonemic crises involves intravenous nitrogen scavengers and hemodialysis. Liver transplantation may be required in individuals who have recurrent metabolic decompensation.

## Dietary Therapy

In all UCDs other than citrullinemia type II, a protein-restricted diet should be combined with alternate-pathway therapy unless liver transplantation has been performed. In general,

using the minimum daily protein requirement for age is recommended. For neonatal-onset disease, half of the protein is given as an essential amino acid supplement (e.g., Cyclinex, Ross Pharmaceuticals), and the remaining half is provided as natural protein. In children receiving sodium phenylbutyrate, monitoring of branched-chain amino acid levels and supplementation of these as needed has been suggested. Additional calories can be provided via nonprotein formulas, such as Prophree or MJ80056. The diet should be supplemented with vitamins, minerals, and trace elements. Routine monitoring of weight, height, hair, skin, nails, and biochemical indices of nutritional status is recommended.

### Alternative-Pathway Therapy

Long-term therapy generally involves protein restriction combined with alternative-pathway therapy (see Table 38-1). Approaches to stimulating alternative pathways of waste nitrogen excretion vary with the site of the enzymatic block. In the case of ASS1 and citrullinemia type II or ASL deficiencies, arginine can stimulate waste nitrogen excretion through enhanced production and excretion of citrulline and argininosuccinic acid, respectively (Batshaw, MacArthur, and Tuchman, 2001). In CPS1 and OTC deficiencies, and in severe deficiencies of ASS1 and ASL, sodium phenylbutyrate has been used to provide an alternative pathway. It initially is converted to sodium phenylacetate, which is then conjugated with glutamine to form phenylacetylglutamine and excreted by the kidney. Sodium phenylbutyrate, although effective, has an unpalatable taste, is a gastric irritant, and has a high sodium load. To circumvent these shortcomings, glycerol phenylbutyrate, a compound that has three molecules of phenylbutyrate attached to a glycerol backbone, was developed. This medication, which is a colorless and odorless oil, was shown to be as efficacious as sodium phenylbutyrate in prevention of hyperammonemia and was recently approved for use in children greater than 2 years of age. ARG1 deficiency typically has been managed with an arginine-restricted diet supplemented with sodium phenylbutyrate when required. Sodium benzoate, a medication that combines with glycine to form hippuric acid, is also used as an alternate-pathway therapy.

### N-Carbamyl-L-Glutamate

In NAGS deficiency, administration of *N*-carbamyl-L-glutamate may be an effective therapy because this structural analog of *N*-acetylglutamate crosses the mitochondrial membrane and activates CPS1. Several patients with NAGS deficiency have been reported to respond clinically to treatment with *N*-carbamyl-L-glutamate.

### Liver Transplantation

Long-term treatment of UCDS depends on the severity of the disease. For neonatal-onset severe CPS1 and OTC deficiencies, current clinical guidelines recommend that liver transplantation be considered as a form of enzyme replacement therapy. This procedure usually is performed at 6 to 12 months of age, with use of alternate-pathway therapy before surgery. More recently, and as a result of favorable outcome with liver transplantation, other neonatal-onset and poorly controlled late-onset UCDS also have been considered for this treatment.

The Studies in Pediatric Liver Transplantation (SPLIT) reported on 114 children with UCDS who received a liver transplant between December 1995 and June 2008 (Arnon et al., 2010). The 5-year patient survival rate was 88.7%, and the 5-year graft survival rate was 83.7%. Transplantation corrects most of the metabolic abnormalities in OTC and

CPS1 deficiencies (although citrulline levels remain low) and prevents future hyperammonemic episodes. In terms of morbidity, concerns have included neurodevelopmental delay, and frequent and prolonged hospitalizations for treatment of infections and regulation of immunosuppressive drugs. Overall, however, the reported quality of life has been much improved, with normalization of diet and a decreased frequency of hospital admissions.

### Management of Hyperammonemic Crises

In infants with hyperammonemic coma, hemodialysis should be started immediately. In addition, L-arginine HCl (except in hyperargininemia), sodium benzoate, and sodium phenylacetate should be given intravenously.

In children with intercurrent hyperammonemia, treatment involves temporary complete elimination of protein and institution of intravenous administration of sodium benzoate, sodium phenylacetate, and potentially L-arginine. (Caution: Arginine HCl may cause metabolic acidosis, and extravasation may lead to tissue necrosis.) Although these medications are not associated with severe adverse events when they are given at therapeutic doses, severe toxicity and death have resulted from dosing errors. Therefore double-checking of drug administration orders and use of dosing per m<sup>2</sup> of body surface area in older children and adults are essential. Monitoring of plasma levels of the drug or its metabolites is recommended.

In the event that ammonia levels do not respond to conservative management and biochemical abnormalities or clinical signs and symptoms worsen, hemodialysis or high-flow continuous veno-venous hemofiltration should be initiated. The relative effectiveness of peritoneal dialysis, exchange transfusion, hemodialysis, and continuous arteriovenous hemofiltration has been the subject of some controversy. Yet nitrogen balance studies clearly demonstrate the advantage of hemodialysis, with continuous arterio-venous hemodiafiltration being second best if hemodialysis is unavailable. Hemodialysis or high-flow continuous veno-venous hemofiltration should be continued until ammonia levels fall to 200 μmol/L; continuous hemofiltration should then be used to stabilize the ammonia level and prevent a rebound.

## THERAPIES UNDER INVESTIGATION

### Hepatocyte Transfer

Infusion of donor hepatocytes into a patient's liver through the portal vein or one of its branches is under investigation as a bridge to liver transplantation in children with severe forms of the disease. This application relies on a proportion of the infused cells to cross the vessel endothelium and to adhere and survive in the liver parenchyma. More studies are required to evaluate the efficacy of this approach. Current research is also exploring biomaterials and induction of liver tissue regeneration as ways to improve engraftment and expansion of the transfused cells. Resection, irradiation, and drug toxicity are being explored as means to induce regeneration.

### Gene Therapy

An adeno-associated virus (AAV) vector with the OTC cDNA has been created and has been successfully and efficiently delivered to the livers of animal models.

### Neuroprotection

A pilot study has assessed the feasibility and safety of whole-body therapeutic hypothermia during rescue treatment for

neonatal hyperammonemic coma resulting from metabolic diseases. Further studies are required to assess the efficacy of this procedure in UCDs.

## Nitric Oxide Supplementation Therapy

Although there are animal and human data suggesting that NO supplements may be of benefit in ASL deficiency, this has not been evaluated systematically in humans. An ongoing trial is evaluating the effects of short- and long-term NO supplementation on vascular and cognitive features in this disease. (Clinical trials involving UCDs can be found at [www.clinicaltrials.gov](http://www.clinicaltrials.gov).)

## OUTCOME

Before the development of alternative-pathway therapy, few children with a severe UCD survived infancy. Most died in the newborn period, and the remainder succumbed to intercurrent hyperammonemic episodes or protein malnutrition later in childhood. The mortality and morbidity rates obtained in the 1980s, when the index of suspicion for these disorders was low and a standardized treatment regimen was unavailable, demonstrated 5-year survival rates of approximately 25%; the rate of morbidity (e.g., intellectual disability, seizure disorders) was near universal for infants rescued from hyperammonemic coma. A correlation between intellectual function and duration of hyperammonemic coma rather than the height of the ammonia level was shown. Children in a coma for less than 3 days had a far better outcome than those in a coma for longer periods.

With the general availability of plasma ammonia assays at most hospitals, newborn screening, increased index of suspicion for metabolic disorders, standardized alternative-pathway therapy, and prompt institution of dialysis for neonates at tertiary care centers, the outcome has improved, and it is estimated that 70% of those with neonatal-onset disease and 90% of those with later-onset disease survive their initial crisis. With regard to outcome, the Longitudinal Study of the UCD Consortium recently reported that 66% of children with neonatal-onset UCDs ages 4 years and older and 25% of children with late-onset UCDs have intellectual disability and problems with emotional/behavioral regulation, attention, and executive function (Krivitzky et al., 2009).

## SUMMARY

UCDs are inborn errors of hepatic metabolism that can have significant neurologic consequences. Newborn screening programs, a high-degree of suspicion, and a proactive evaluation strategy that routinely incorporates metabolic tests in evaluation of neonates and young children with encephalopathy are critical for appropriate diagnosis. The availability of special diets, medications, dialysis, and hepatic transplantation has improved survival, but long-term intellectual outcomes are far from optimal.

## INTRODUCTION

Carbohydrates are essential elements in the cellular energy economy, and the inability to activate sugars ingested in the diet for use as metabolic fuels (as in the galactosemias), to mobilize glucose from glycogen (as occurs in the glycogen storage diseases), or to oxidize glucose in the glycolytic pathway leads to a variety of phenotypes. The more frequent include symptoms and signs referable to the liver and musculature predominantly and include hepatomegaly, altered volume of skeletal muscle (both increases and decreases), decompensation in the face of stress (manifest as weakness, cramping, and myoglobinuria), and nonspecific manifestations of hypoglycemia. This chapter surveys the primary diseases of carbohydrate metabolism, particularly as they affect the developing nervous system.

## ABNORMALITIES OF GALACTOSE METABOLISM

### Galactosemia

Galactosemia describes a family of autosomal-recessive disorders characterized by increased blood levels of galactose. Galactose cannot be used directly for glycolysis, and must be converted to glucose-1-phosphate. Five enzymes are involved in this interconversion in most species: galactose mutarotase, galactokinase, galactose-1-phosphate uridylyltransferase, uridine diphosphogalactose-4-epimerase, and phosphoglucomutase (Coelho et al., 2015).

Mutations in the *GALK*, *GALT*, and *GALE* genes that encode the second, third, and fourth enzymes, respectively, cause deficiency or absence of these enzymes, with consequent galactosemia (Timson, 2015). These enzymes comprise the Leloir pathway.

### Galactose-1-Phosphate Uridyltransferase Deficiency

Galactose-1-phosphate uridylyltransferase (*GALT*) deficiency is by far the most common cause of galactosemia. The incidence of galactosemia in Western Europe varies between 1 in 23,000 and 1 in 44,000. Neonatal screening programs have found population incidence rates as high as 1 in 19,700 in Estonia.

**Pathology.** The precise link between the metabolic abnormality and the neuropathologic condition remains unknown. Galactose-1-phosphate uridylyltransferase is present in the brain in low concentrations. Hypoglycemia may contribute significantly to the pathologic findings in many cases. The toxic effect of galactitol accumulation is not fully understood but is clearly relevant to adverse outcomes in the brain and lens.

**Biochemistry.** The primary abnormality in galactosemia is the deficiency of activity of galactose-1-phosphate uridylyltransferase (Fig. 39-1) that leads to accumulation of

galactose-1-phosphate in red blood cells, liver, and brain (Coelho et al., 2015).

Galactose is metabolized through the following four possible pathways:

1. The reduction of galactose to galactitol
2. Oxidation of galactose to galactono- $\gamma$ -lactone
3. The reaction of galactose-1-phosphate with uridine triphosphate to form uridine diphosphate galactose and eventually glucose-1-phosphate
4. The reaction of galactose-1-phosphate with uridine diphosphate-glucose to form uridine diphosphate-galactose and glucose-1-phosphate

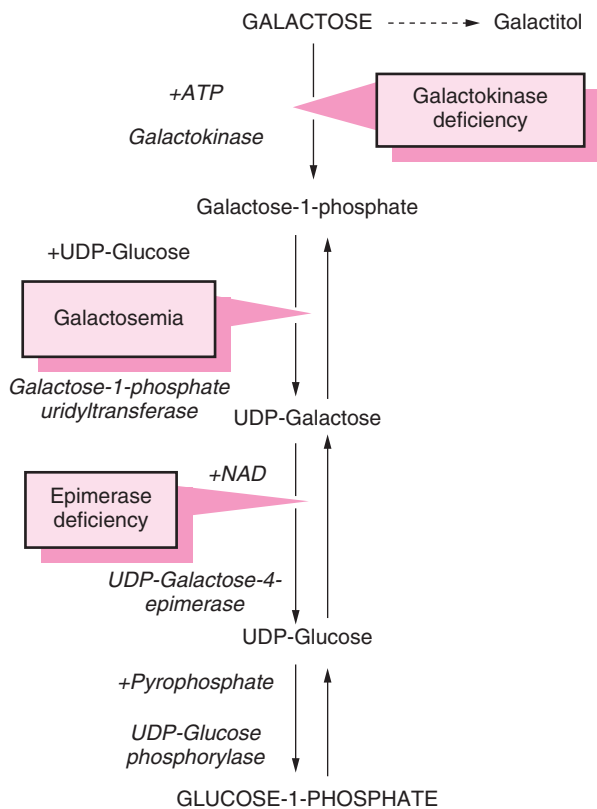

In classic galactosemia, the fourth pathway is obstructed; the other pathways function normally.

The *GALT* locus is at 9p13; various genetic forms of galactosemia result from the presence of inefficient isoenzymes of galactose-1-phosphate uridylyltransferase (Table 39-1). Most patients are compound heterozygotes, not true molecular homozygotes.

The isoenzymes are separated and identified by electrophoresis. Transferase activity is absent in homozygous classic galactosemia (Q188R is the most common mutation in the United States). Activity is normal in the Los Angeles variant (L218L). Newborn screening for galactosemia is now performed in every state in the United States, but the detection rate for Duarte galactosemia varies with methodology. The *GALT* mutation database ([http://www.arup.utah.edu/database/galt/GALT\\_display.php](http://www.arup.utah.edu/database/galt/GALT_display.php)) contained 336 variants when accessed in 2015, most of which were missense mutations.

**Clinical Characteristics.** Infants usually are normal at birth, except for a slight decrease in birth weight. Symptoms become apparent when milk feedings begin. Jaundice usually develops between 4 and 10 days of age and persists for a longer period than does physiologic jaundice; it may be severe and the hyperbilirubinemia may be indirect, requiring exchange transfusion. Progressive hepatic involvement in the first several weeks causes edema, hepatomegaly, and hypoprothrombinemia. Renal dysfunction is accompanied by generalized aminoaciduria, proteinuria, and acidosis. *Escherichia coli* sepsis is common, and may be the only (and recurrent) feature. Mild hypoglycemia also is common. Cataracts appear between 4 and 8 weeks, reflecting the accumulation of galactose-1-phosphate or galactitol.

Central nervous system impairment is manifested by lethargy and hypotonia, often associated with cerebral edema, which has been correlated with increased brain galactitol on magnetic resonance (MR) spectroscopy. A subgroup of patients may develop marked ataxia and tremor, which does not correlate with cognitive abilities or dietary restriction.

**Figure 39-1.** Pathway of galactose metabolism depicting sites of metabolic block that lead to galactosemia. ATP, adenosine triphosphate; NAD, nicotinamide adenine dinucleotide; UDP, uridine diphosphate.

**TABLE 39-1** Biochemical Criteria for Assigning Phenotypes of Galactosemia\*

Galactose-1-Phosphate Uridyltransferase			
Activity†	Mobility†	Phenotype	Zyosity
Normal	Normal	Normal	–
Absent	None	Galactosemia (classic form)	Homozygous
Decreased	Duarte (fast)	Duarte variant	Homozygous
Absent	None	African American variant	Homozygous
Decreased	Normal	Galactosemia (classic form)	Heterozygous
Decreased	Slower	Indiana variant	Heterozygous
Much less	Slower	Rennes variant	Heterozygous
Increased	Faster	Los Angeles variant	Heterozygous
Decreased	Fast	Chicago variant	Heterozygous
Decreased	Normal	Munster variant	Heterozygous

\*Characteristics of galactose-1-phosphate uridylyltransferase.  
†Compared with normal.

Galactosemia may prove fatal at any time. Cirrhosis progresses inexorably in patients who do not receive treatment. Gonadal function in women with galactosemia is abnormal and usually manifests as primary ovarian failure.

If treatment is not instituted, moderate to severe intellectual and motor retardation ensue in a majority of cases. Even

in patients who are treated adequately, cognitive disability is common.

**Clinical Laboratory Tests.** Biochemical tests for galactosemia screen for elevated levels of small molecules and directly assay the enzymes in the Leloir pathway.

Beside urine testing is positive for reducing substances but negative for glucose by the glucose oxidase method. Generalized aminoaciduria, proteinuria, and abnormalities on liver function tests are common.

Magnetic resonance imaging (MRI) shows a variety of findings, including mild cerebral atrophy, cerebellar atrophy, ventriculomegaly, delayed maturation of white matter, and multiple small hyperintense lesions in the cerebral white matter on T2-weighted images.

**Management.** Because galactose is nonessential, exclusion from the diet is relatively easy. Milk and certain fruits and vegetables contain relatively high concentrations of galactose. Studies of the long-term outcome of therapy have been relatively disappointing, particularly in regard to preservation of central nervous system and ovarian function.

### Uridine Diphosphogalactose Epimerase Deficiency

Uridine diphosphogalactose epimerase (GALE) deficiency has conventionally been separated into peripheral and generalized forms. Children previously recognized with generalized (severe) deficiency of GALE (see Fig. 39-1) had manifestations resembling those in classic galactosemia. Most survivors were dysmorphic and deaf. The GALE locus is at 1p36–p35. The patients are either homozygotes or compound heterozygotes for mutations. Three mutations (S81R, T150M, and P293L) have been reported in children with this intermediate form of GALE deficiency. Patients with GALE deficiency require exogenous galactose for the synthesis of glycolipids and glycoproteins.

### Galactokinase Deficiency

The birth incidence of galactokinase deficiency varies, ranging from a high of 1 in 52,000 in Bulgaria to 1 in 2200,000 in Switzerland. Deficiency of galactokinase activity causes a clinical condition similar to that in classic galactosemia. Patients have cataracts and accumulation of galactose. The *GALK1* gene is located at 17q24.

**Biochemistry.** Galactokinase deficiency causes the accumulation of galactose, which eventually is metabolized to galactitol (see Fig. 39-1). Enzyme activity is reduced rather than absent in erythrocytes. Galactose-1-phosphate does not accumulate.

**Clinical Characteristics.** In a review of 55 patients, cataract was present in all cases, except for those detected by newborn screening. Thirty-five percent of the patients had other manifestations; only mental retardation and pseudotumor occurred in more than one patient in this series. The mental retardation was thought to be unrelated to the *GALK* deficiency.

Cataracts, the only consistent manifestation of galactokinase deficiency, form in the first months of life.

**Management.** Treatment consists of elimination of galactose from the diet, as is the case for classic galactosemia.

## ABNORMALITIES OF FRUCTOSE METABOLISM

### Hereditary Fructose Intolerance

#### Biochemistry

Fructose is rapidly absorbed from the gut, facilitated by the glucose transporters GLUT 2 and GLUT5, and is metabolized

in the liver by the fructokinase pathway, through which it is linked to glycolysis, gluconeogenesis, glycogenolysis, and lipid metabolism. Fructose can also be synthesized endogenously from sorbitol, an important point in management. This condition results from a deficiency of hepatic fructose-1-phosphate aldolase B. The enzyme deficiency is inherited as an autosomal-recessive trait and has an estimated prevalence in central Europe of 1 in 26,100.

Urinary fructose excretion also is present in a harmless metabolic variant resulting from fructokinase deficiency that should not be confused with hereditary fructose intolerance.

### Clinical Characteristics and Differential Diagnosis

Patients with hereditary fructose intolerance who ingest fructose experience nausea and vomiting; with continued exposure, weight gain is poor. Hypoglycemia begins immediately and reaches its low point 30 to 90 minutes after ingestion. Subsequent clinical and neuropathologic alterations result primarily from the hypoglycemia.

Neurologic impairment is relatively uncommon but may result from hypoglycemia, cardiovascular collapse, or liver failure. Central nervous system complications include seizures with subsequent epilepsy, increased intracranial pressure, mental retardation, quadriplegia, and deafness.

### Clinical Laboratory Tests and Diagnosis

A hydrogen breath test is often employed to screen for HFI but may produce serious adverse effects. Assay of fructose-1-phosphate aldolase B in liver tissue permits definitive diagnosis, but liver biopsy may be avoided by direct genotyping in most patients. Fructosemia causes abnormal glycosylation of transferrin, leading to misdiagnosis of CDG1x on occasion.

### Management

Fructose elimination from the diet is accomplished by limited selection of vegetables and cereal products. Sorbitol should also be avoided, as it is an endogenous source of fructose. Dietary counseling is essential for successful therapy.

## Fructose-1,6-Diphosphatase Deficiency

 Details are available online.

## GLYCOGEN STORAGE DISEASES

The biochemistry of the glycogen storage diseases (GSDs) illustrates the diverse effects of genetically determined enzymatic deficiencies along a single metabolic pathway. In spite of a few inconsistencies and a number of unexplained conditions, a logical approach to these diseases is practical. The GSDs are a family of diseases *sui generis*, with the exception of at least two disorders that can be included under the rubric of lysosomal diseases—Pompe disease and Danon disease. Indeed, the first lysosomal disease defined as such was Pompe disease. General characteristics of this disease family are discussed in Chapter 41. Patients have also been described who accumulate glycogen in autophagic vacuoles but who do not appear to have an enzymatic deficiency. This phenotype, named Danon disease, is known to result from deficiency of lysosomal-associated membrane protein 2. This X-linked dominant disorder has multisystem effects, most consistently involving the heart and skeletal muscle (Endo et al., 2015).

There is general agreement on the numeric designations of GSDs I to VI, but the nomenclature beyond that is confusing.

For example, GSD types VIII and X were originally considered distinct conditions but are now classified with GSD VI by many authors.

Clinical manifestations of GSD often result from glucose deficiency, with ensuing hypoglycemia occurring separately or in association with increased glycogen storage. The location of the enzymatic block in the pathway determines whether the configuration of the glycogen is normal or abnormal.

GSDs result in the accumulation in various tissues of increased concentrations of glycogen of normal or abnormal configuration (Table 39-2). These diseases result from a deficiency or absence of specific enzyme activity in the metabolic pathway of glycogen.

The glucose molecule is the prime building block in the multistep synthesis of glycogen (Fig. 39-2; see also Table 39-2). Glycogen synthesis occurs in many tissues, predominantly in liver, kidney, and muscle. The details of the metabolic pathway are described online.

## Glucose-6-Phosphatase Deficiency (Von Gierke Disease, Glycogen Storage Disease Type I, Hepatorenal Glycogenosis)

### Pathology

Patients with von Gierke disease, now known as glycogen storage disease type I, have hepatomegaly and renomegaly. Light microscopy reveals enormous amounts of glycogen in liver cells and in the cells of the renal convoluted tubules. No increase in the concentration of glycogen is found in skeletal muscle, tongue, or heart.

### Biochemistry

Two distinct subgroups of glycogen storage disease type I have been identified: those with primary glucose-6-phosphatase deficiency (type Ia) and those phenocopies with additional features of immune impairment (neutropenia and neutrophil adherence defects), now designated as glycogen storage disease type I non-a. Glycogen storage disease type I non-a disorder originally was thought to result from defects in a multicomponent translocase system responsible for transporting glucose-6-phosphatase into microsomes. Cloning of the glucose-6-phosphatase translocase gene (*G6PT*) demonstrated that the previously proposed subtypes b, c, and d all were associated with mutations in *G6PT*, producing different kinetic variants. The *G6PC* gene that codes for glucose-6-phosphatase is located at 17q21.

All forms share common clinical manifestations that are attributable to abnormal metabolism of glucose-6-phosphate. In type Ia, glucose-6-phosphatase deficiency results in storage of glycogen of normal configuration in the liver and kidneys. The enzyme activity is absent or extremely low.

### Clinical Characteristics

Hypoglycemia causes much of the morbidity during the first year of life. Seizures are frequent and almost invariably are the presenting complaint of affected children. Hypoglycemia may result in severe, chronic neurologic impairment, including hemiplegia. Hepatomegaly and the failure to thrive syndrome are commonly present. Epilepsy, deafness, and neuroradiologic abnormalities occur far in excess of the rates in the general population or in children with other causes of neonatal hypoglycemia. MRI abnormalities include dilatation of occipital horns and/or hyperintensity of subcortical white matter in the occipital. Subcutaneous fat often is increased, and xanthomas occur over the extensor

**TABLE 39-2** Glycogen Storage Diseases (GSDs)

Name*	Clinical Manifestations	Glycogen Structure	Enzyme Defect
1. Glucose-6-phosphatase deficiency (von Gierke disease, Type I GSD)	Enlarged liver and kidneys; hyperlipidemia; hypoglycemia; ketoacidosis; seizures	Normal	Glucose-6-phosphatase
2. Infantile acid $\alpha$ -glucosidase deficiency (Pompe disease, Type II GSD)	Cardiomegaly; death in infancy; progressive hypotonia and weakness; swallowing and respiratory difficulty	Normal	Acid $\alpha$ -Glucosidase
3. Late infantile acid $\alpha$ -glucosidase deficiency, adult acid $\alpha$ -glucosidase deficiency	Atonic anal sphincter; calf muscle hypertrophy; hip weakness (Gowers' sign); slow or regressing motor development, contractures of Achilles tendons	(?)Abnormal—short outer chains	Acid $\alpha$ -Glucosidase
4. Debrancher deficiency (Cori disease; Forbes limit dextrinosis, Type III GSD)	Hepatomegaly; hypoglycemia; late-onset weakness; mild growth failure; early, severe weakness with myopathy rare	Abnormal—short outer chains, increased branch points	Amylo-1,6-glucosidase
5. Brancher deficiency (Andersen's disease, Type IV GSD)	Cirrhosis; growth failure; hepatosplenomegaly; hypotonia; muscle wasting in lower extremities; slow motor development; weakness	Abnormal	Amylo-1,4 $\rightarrow$ 1,6-transglucosidase
6. Myophosphorylase deficiency (McArdle disease, Type V GSD)	Atrophy in older patients; myoglobinuria; poor stamina; severe muscle cramps with exercise	Normal	Muscle phosphorylase
7. Hepatophosphorylase deficiency (Hers disease, type VI GSD)	Growth retardation; hepatomegaly; hypoglycemia; mild ketosis	Normal	Liver phosphorylase
8. Phosphorylase kinase deficiency; Type IX GSD (also deficiency of activation sequence including loss of activity of 3',5'-AMP-dependent kinase in muscle and probably liver); Type IX GSD	Marked hepatomegaly, with glycogen storage; no hypoglycemia; no skeletal muscle disease; normal mental development	Normal	Phosphorylase kinase or 3',5'-AMP-dependent kinase
9. Phosphoglucomutase deficiency (PGM1-CDG; CDG 1t)	Calf hypertrophy; mild generalized weakness; regression in motor development; toe-walking	Normal	Phosphoglucomutase
10. Phosphohexose isomerase deficiency	Late-onset myopathy; muscle cramps; poor stamina	Normal	Phosphohexose isomerase
11. Phosphofructokinase deficiency (Tarui disease; Type VII GSD) Other defects of terminal glycolysis, including deficiency of phosphoglycerate kinase and lactate dehydrogenase	Similar to those in myophosphorylase deficiency	Normal	Muscle Phosphofructokinase Phosphoglycerate kinase; lactate dehydrogenase
12. Glycogen synthetase deficiency; Type 0 GSD	Hypoglycemia; mental retardation; seizures	Normal	Glycogen synthetase

\*The accompanying numerals identify these abnormalities in the pathway of glycogen metabolism shown in [Figures 39-2 and 39-3](#).

surfaces of the limbs and buttocks. Affected children frequently have massive enlargement of the liver. Hepatic adenomas develop in between one-half and three-quarters of adults with glycogen storage disease I; about 10% undergo malignant transformation.

Type I non-a patients typically have recurrent stomatitis, frequent infections, and chronic inflammatory bowel disease secondary to neutropenia and neutrophil dysfunction.

### Clinical Laboratory Tests

The diagnosis can be made by assaying the enzyme activity in liver and peripheral white blood cells. Direct assay of hepatic glucose-6-phosphatase activity in liver has been replaced by mutational analysis in most patients.

Severe hypoglycemia frequently occurs because of the failure of glucose formation from glucose-6-phosphate. Severe acidosis is usually associated with lactic acidemia and pyruvic acidemia; hyperuricemia is frequent.

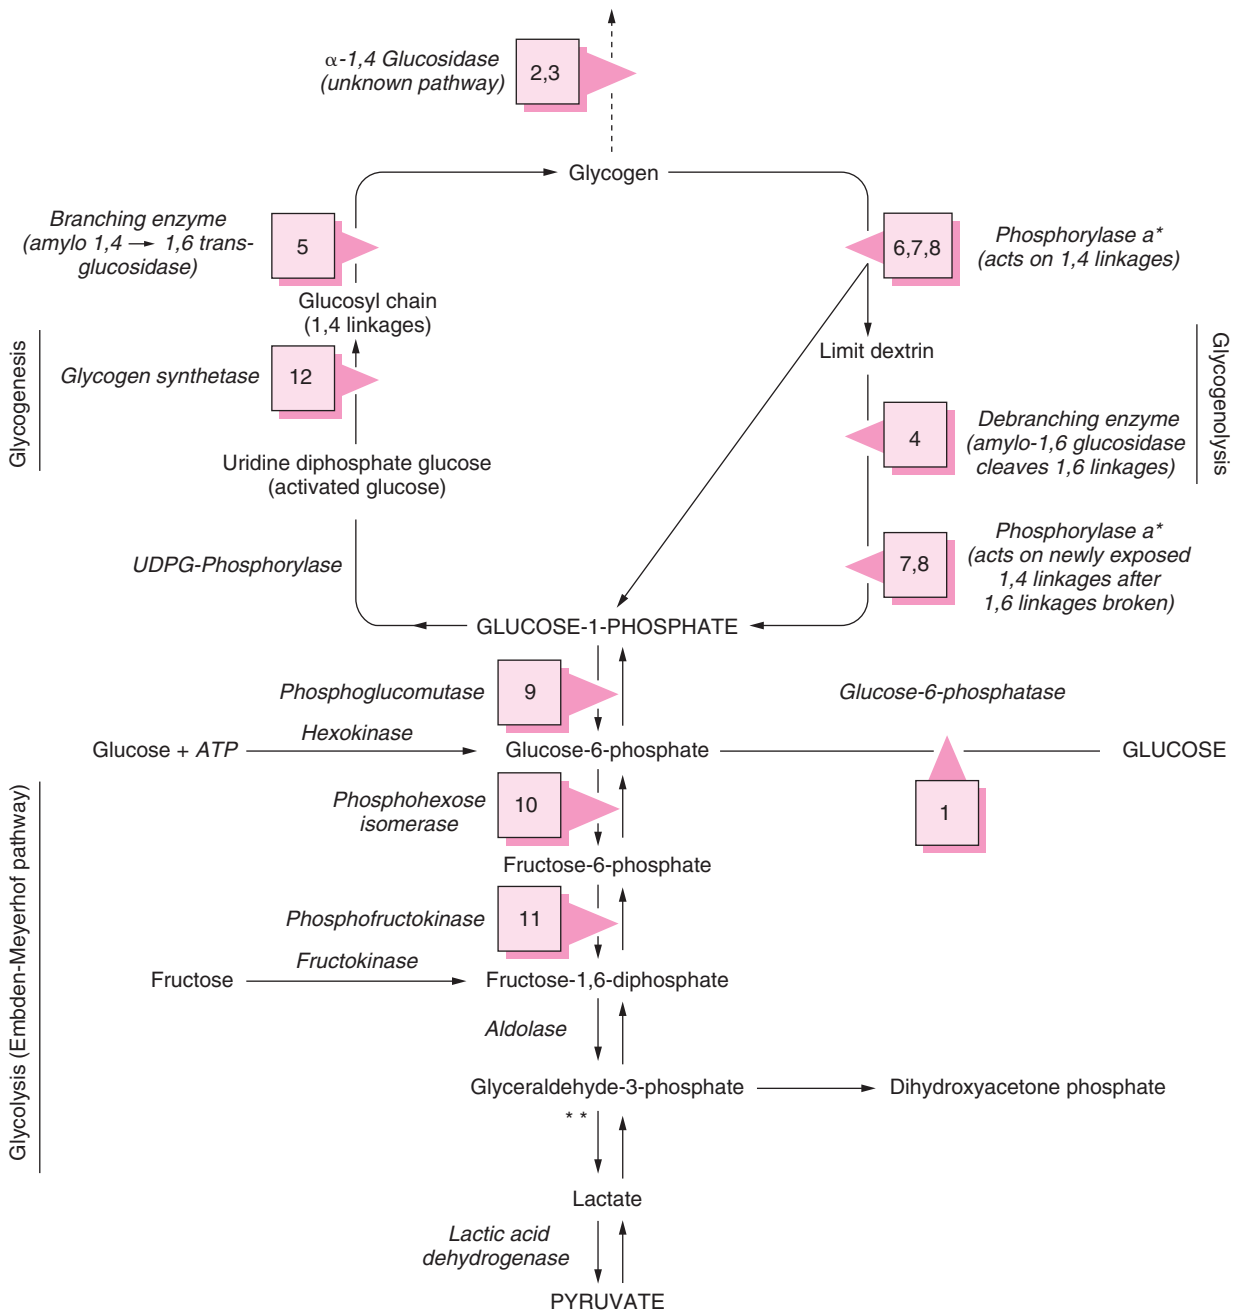

### Management

The goal of therapy is to provide sufficient free glucose to maintain a normal blood glucose concentration. Continuous nocturnal intragastric infusion of glucose has been relatively successful, but is challenging for many children. Subsequently, the use of cornstarch suspensions given during the day obviated the need for nocturnal infusion in some children.

Substitution of medium-chain triglycerides for long-chain triglycerides in the diet, along with normal carbohydrate consumption, leads to significant decrease in serum lipid levels, disappearance of eruptive xanthomas, and decrease in liver mass.

Surgical treatment for glucose-6-phosphatase deficiency involves creation of a portacaval shunt, which increases the peripheral blood glucose by allowing portal blood to bypass the liver after absorption of glucose from the gut; excellent metabolic control can be achieved over the long term, and the operation does not preclude subsequent liver transplantation.

**Figure 39-2.** Pathways of glycogen metabolism depicting sites of metabolic block that lead to glycogen storage disease. See Table 39-2 for description of abnormalities denoted by Arabic numerals enclosed in boxes. \*See Figure 39-3 for phosphorylase activation sequence. \*\*Other defects of terminal glycolysis.

Liver transplantation has been reported to produce beneficial results.

### Acid $\alpha$ -Glucosidase (GAA, Acid maltase) Deficiency, Infantile Type (Pompe Disease, Idiopathic Generalized Glycogenosis, Glycogen Storage Disease Type II)

#### Pathology

Infants with GSD type II have a severe vacuolar myopathy, with accumulation of large amounts of periodic acid–Schiff-positive material within cardiac, skeletal, and smooth muscle

fibers and in liver, renal tubules, lymphocytes, glial cells, anterior horn cells, and brainstem nuclei in infantile cases. Storage in later-onset cases is largely restricted to skeletal muscle.

#### Biochemistry

GSD II is associated with deficient activity of the lysosomal enzyme acid  $\alpha$ -glucosidase ( $\alpha$ -1,4-glucosidase), located at 17q25.2–q25.3; this is the only enzyme capable of hydrolyzing glycogen to glucose in the acidic environment of the lysosome. Glycogen structure has consistently been normal, and its accumulation is restricted primarily to lysosomes, although lysosomal breakdown and cytoplasmic accumulation with disruption of muscle fibers occur in severe cases. The

accumulation of autophagosomes impairs the effectiveness of enzyme replacement therapy by acting as a sink for infused enzyme.

A number of allelic variations have been described and may explain the differences in age at onset. In general, the location and nature of mutations predict the phenotype, but exceptional cases are described in which relatively mild phenotypes occur despite low levels of  $\alpha$ -glucosidase expression in cultured fibroblasts.

### Clinical Characteristics

Development is usually normal for several weeks to several months; then the affected infant presents with feeding difficulties, weakness, or respiratory impairment (Fig. 39-4). Little spontaneous movement occurs, and the cry is short-lived and weak. Swallowing is grossly limited, and the accessory muscles of respiration are weak. Massive cardiomegaly develops, and a serial echocardiography reveals progressive left ventricular posterior wall diastolic thickening. Hepatomegaly is almost universally present. Subcutaneous fat is sparse, and the muscles are small and firm. The tongue often is enlarged. Deep tendon reflexes are lost by the age of 6 months. Affected infants undergo progressive debilitation, and almost all die by 2 years.

### Clinical Laboratory Tests

Acid  $\alpha$ -glucosidase ( $\alpha$ -1,4-glucosidase) activity can be measured in blood samples or dried blood spots; mutational analysis is increasingly used as a first line diagnostic approach. A urinary glucose tetrasaccharide, Glc- $\alpha$ -1,6-Glc- $\alpha$ -1,4-Glc- $\alpha$ -1,4-Glc (Glc4) has proven to be a sensitive biomarker for Pompe disease.

Electromyography (EMG) shows myopathic changes; polyphasic potentials and a reduced interference pattern with low voltage. Unusual high-frequency discharges, best described as myotonic, are very common.

### Genetics

GAA deficiency is inherited as an autosomal-recessive trait. The gene for human acid  $\alpha$ -glucosidase maps to chromosome 17q25.3; it is approximately 20 kb in length and contains 20 exons. More than 300 mutations have been reported in 2015 and are cataloged online at <http://cluster15.erasmusmc.nl/kgm/pompe/mutations.html?lang=en>.

### Management

Dietary supplementation with L-alanine, designed to reduce the elevated protein turnover characteristic of acid  $\alpha$ -glucosidase deficiency, has apparently slowed progression of weakness and even reversed cardiomyopathy in some patients with late infantile and juvenile forms.

In 2006, ERT received Food and Drug Administration (FDA) approval for treatment of acid  $\alpha$ -glucosidase deficiency. Infants who received treatment early in the course of their illness demonstrated improved strength and cardiac function, with survival now extending over several years. It has become apparent that ERT is most effective at reversing cardiomyopathy and extending the life span of infants, but that skeletal muscle disease is relatively resistant to this modality (Hahn et al., 2015).

### Late Infantile GAA Deficiency

A number of children have been reported who are deficient in acid  $\alpha$ -glucosidase activity without the phenotype of Pompe disease. These children are asymptomatic during the first

year of life and live beyond the age of 2 years. Most have slowly progressive weakness but no gross signs of overt deposits of glycogen in skeletal or heart muscle or in visceral organs.

Symptoms and signs may mimic those of Duchenne muscular dystrophy (Fig. 39-5). Achilles tendon contractures result in equinus gait. Cardiomegaly is absent, and an intermittent soft, systolic murmur may be heard.

### Clinical Laboratory Tests

Light and electron microscopy of muscle biopsy material displays moderate glycogen storage; the glycogen-containing areas appear vacuolated (Fig. 39-6).

EMG documents polyphasic potentials and a reduced, low-voltage interference pattern. The bizarre, myotonic potentials described in early infantile acid  $\alpha$ -glucosidase deficiency also occur in the late infantile form.

### Biochemistry

Aside from the accumulation of glycogen and its possible abnormal architecture, the most prominent abnormality described is a deficiency of acid  $\alpha$ -glucosidase activity.

### Management

Attempts to manage patients by dietary means enjoyed modest success after initially disappointing results (see previous mention).

At present, ERT appears to offer the best hope for definitive treatment in this group of patients.

### Juvenile and Adult GAA Deficiency

A slowly progressive myopathy characterizes juvenile and adult GAA deficiency. Limb girdle weakness is the most common presentation, but muscle pain is relatively common. Most patients complain of fatigue. Ventilatory failure may be the presenting complaint in as many as one-third of adults, sometimes with predominantly nocturnal symptoms.

Laboratory abnormalities include increased serum enzyme activity of creatine, aspartate aminotransferase, and lactate dehydrogenase. Adult cases cannot be delineated from infantile and late infantile cases on the basis of muscle GAA activity.

Adult patients do not have enlargement of the liver, heart, or tongue.

EMG changes and histologic and electron microscopic findings in muscle biopsy specimens in adult cases are similar to changes in infantile and late infantile cases.

Enzyme replacement therapy tends to slow rather than reverse weakness in late onset cases based on a recent open-label study (Park et al., 2015).

### Amylo-1,6-Glucosidase Deficiency (Debrancher Deficiency, Cori Disease, Forbes Disease, Limit Dextrinosis, Glycogen Storage Disease Type III)

#### Pathology

Electron microscopy of skeletal muscle has demonstrated glycogen deposits just inside the sarcolemmal membrane and between the filaments of the I and A bands, as well as between the myofibrils. These abnormalities are not pathognomonic for this glycogenosis, now classified as glycogen storage disease type III. Glycogen storage in liver is indistinguishable from glycogen storage in other hepatic glycogenoses.

## Biochemistry

The human muscle glycogen debranching enzyme (*AGL*) is localized to 1p21. It encodes six isoforms that manifest two distinct functions, both as a debranching enzyme and as a transferase. GSD type III has marked genetic heterogeneity. GSD type IIIa is associated with mutations downstream to exon 3, whereas GSD type IIIb is associated with mutations in exon 3.

Several designated biochemical categories of type III glycogenesis have been identified. In type IIIa deficiency (both transferase and glucosidase deficiency), debranching enzyme activity is either absent or greatly reduced in liver and muscle. When the enzyme activity is deficient in liver alone, the condition is designated type IIIb. Type IIIc patients have deficient glucosidase but not transferase activity.

Myogenic hyperuricemia is common in this condition but is not unique; hyperuricemia also accompanies glycogenesis type V and type VII.

## Clinical Characteristics

**Infantile Type.** Patients with debrancher enzyme deficiency may have muscle or liver involvement, or both. The infantile type usually manifests in the first few months of life and is associated with hypoglycemia, failure to thrive, and hepatomegaly. Affected infants are hypotonic and weak and have poor head control. Glycogen deposition in cardiac muscle is rarely sufficient to create clinical disturbances.

Association of debranching disease with profound cardiac muscle and skeletal muscle involvement accompanied by thyroid insufficiency also has been reported.

**Childhood Type.** GSD type III presents with exercise intolerance and heart failure. Cardiac and skeletal muscle contains increased stores of glycogen. Branching enzyme deficiency was confirmed with further studies. Hyperlipidemia, hypertriglyceridemia, and reduced bone density may all occur.

**Adult Type.** Debrancher enzyme deficiency also occurs in older children and adults. Adult patients with GSD type III manifesting as chronic progressive myopathy in middle age have been described; they account for a minority of this population. Progression of muscle disease can be monitored with serial ultrasound examinations. Patients with debrancher deficiency should be monitored for cardiac involvement, although this is usually asymptomatic. Progressive cirrhosis may be more common in adult GSD type III than was previously recognized and, occasionally, is complicated by hepatocellular carcinoma.

Debrancher deficiency is often associated with hypotonia and hepatomegaly. Later in childhood, patients complain of muscle fatigue without tenderness, cramping, or associated hematuria. Persistent diffuse weakness is present, and wasting of the hand and forearm muscles with loss of body weight ensues. Patients may experience recurrent seizures.

## Clinical Laboratory Tests

Electromyography and nerve conduction studies show no evidence of peripheral neuropathy, but myopathic discharges are common. Serum creatine kinase activity may increase before and after exercise. Fasting ketotic hypoglycemia is characteristic of GSD, type III; hypertriglyceridemia, hyperlactic acidemia, and hyperuricemia may be observed. Blood lactic acid does not increase on ischemic exercise.

## Genetics

GSD type III is inherited as an autosomal-recessive trait. The diagnosis is generally confirmed by gene sequencing.

## Management

Patients with growth failure and hepatic dysfunction, including hypoglycemia, appear to benefit from the administration of oral cornstarch, but overtreatment with carbohydrates may be harmful. Cardiomyopathy has been shown to improve with either a high protein or ketogenic/high protein diet.

## Amylo-1, 4 →1,6 Transglucosidase Deficiency (Brancher Enzyme Deficiency, Glycogen Storage Disease Type IV)

GSD type IV (Andersen disease) results from a deficiency of glycogen branching enzyme (GBE), leading to the accumulation of abnormal glycogen resembling amylopectin in affected tissues. The reported phenotypes are marked primarily by liver involvement. GSD type IV has been characterized as the most heterogeneous of the glycogen storage diseases ([Magoulas and El-Hattab, 1993](#)).

## Pathology

Glycogen may accumulate disproportionately in the tongue and diaphragm in comparison with other striated muscles. The characteristic lesion is the polyglucosan body, a periodic acid–Schiff-positive inclusion that also is seen in phosphofructokinase deficiency, Lafora body disease, double athetosis (Bielschowsky bodies), and aging (corpora amyloacea).

## Biochemistry

The first patient described with deficiency of brancher enzyme activity manifested cirrhosis of the liver and glycogen accumulation, but patients with normal and decreased muscle glycogen concentrations also have been described. These biochemical phenotypes correspond to clinical forms with rapidly progressive cirrhosis through nonprogressive liver disease. Brancher enzyme deficiency results in the synthesis of unbranched glycogen composed of elongated chains of glucose molecules joined together in 1,4 linkages. As a result, the glycogen is composed of long outer chains, has few branch points, and resembles the pattern of starch also known as amylopectin.

## Clinical Characteristics

Manifestations of the disease—failure to thrive, hepatosplenomegaly, and liver failure with cirrhosis—usually appear in the first 6 months of life. Affected infants exhibit delayed motor and social development, hypotonia, weakness, and muscle atrophy, accompanied by absent or decreased deep tendon reflexes. Fetal onset with cervical cystic hygroma, akinesia, polyhydramnios and multiple pterygia is the most severe manifestation of GSD IV. A mild, predominantly myopathic variant has been reported in older children and has a highly variable course. Adults with polyglucosan body disease who manifest late-onset pyramidal quadriplegia, micturition difficulties, peripheral neuropathy, and mild cognitive impairment have been described. Jewish families with adults with polyglucosan body disease were homozygous for a Tyr329Ser mutation in *GBE1*. Not all such patients have recognized *GBE* mutations or impaired GBE activity, suggesting both phenotypic and genotypic heterogeneity.

## Clinical Laboratory Tests

Diagnosis of brancher deficiency by assay of peripheral white blood cells, skin fibroblasts, and amniotic cell activity is feasible, but diagnosis by mutational analysis is usually preferable.

## Genetics

Inheritance is autosomal-recessive. Prenatal testing using cultured amniocytes and chorionic villi is feasible, but has been superseded by molecular analysis when available. The gene encoding brancher enzyme, *GBE1*, may contain missense, nonsense, intronic donor and acceptor splice-site mutations, small deletion frame shift mutations, small insertion frame shift mutations, or large deletions. Missense mutations are more likely to be associated with milder phenotypes, and truncating mutations or large deletions with severe forms of the disease.

## Management

Attempts at enzyme replacement were unsuccessful. Liver transplantation has been successful in a number of patients, but mortality in GSD IV patients may be high.

## McArdle Disease (Myophosphorylase Deficiency, Glycogen Storage Disease Type V)

In 1951, McArdle reported a condition characterized by weakness, fatigue, and severe muscle cramping with pain after exercise. He subsequently noted the lack of normal lactate production in the affected muscles after ischemic work. McArdle disease is classified as glycogen storage disease type V (GSD V).

## Pathology

Light microscopic studies of muscle reveal moderately increased stores of glycogen beneath the sarcolemmal membrane. Electron microscopy demonstrates disorganization of the I band region and distortion of the myofibrils secondary to glycogen deposition. Quantitative biochemical studies show reduced or absent myophosphorylase activity.

## Biochemistry

Glycogen breakdown to lactate begins with the initial disruption of the 1,4 linkage between glucosyl units. The enzyme myophosphorylase facilitates this reaction in skeletal muscle. After this linkage is cleaved, glucose-1-phosphate is freed and metabolized to lactate through the Embden-Meyerhof pathway. The myophosphorylase enzyme is regenerated in a complex reaction involving a number of other enzymes, including phosphorylase kinase (see Fig. 39-3).

Absence of myophosphorylase activity results in decreased glucose-1-phosphate production; as a result, lactic acid is not formed in exercised muscle, and serum lactic acid concentration is not appropriately elevated (Fig. 39-7).

## Clinical Characteristics

Affected children have decreased stamina and tire easily. Severe cramping pain after minimal exercise is noted in the involved skeletal muscles. Cardiac symptoms are not usually reported, but cardiac muscle is involved. Myoglobinuria occurs with moderate or strenuous exercise. In adolescence and adulthood, persistent weakness may develop, with moderate loss of muscle bulk. A "second wind" phenomenon has been described. This phenomenon has been attributed to improved energy production when metabolic dependence switches from glycogen stores to blood-borne fuels, including glucose and fatty acids, and is consistently seen in GSD type V but not in GSD type VII, whose phenotype is otherwise indistinguishable. Prolonged or frequent repetitive episodes of myoglobinuria may result in both acute and chronic renal failure.

Onset usually is in childhood; neonatal and adult onset has been reported. A very severe phenotype, lethal in infancy, was reported in a child born to consanguineous parents with mutations in both *PYGM* and *dGK*, the gene encoding deoxyguanosine kinase, whose deficiency causes the hepatic form of mitochondrial depletion syndrome.

## Clinical Laboratory Tests

Exercise results in elevated serum creatine kinase activity and increase in activity of other serum enzymes released from muscle, ostensibly a result of loss of sarcolemmal membrane integrity. The ECG may demonstrate an increased QRS amplitude, a prolonged R-S interval, T wave inversion, and bradycardia.

Electromyographic study of contracted muscles after exercise reveals a decreased interference pattern; after ischemic exercise, the contracted muscles may demonstrate no electrical activity.

Ischemic exercise testing is described online.

## Genetics

The gene encoding synthesizing myophosphorylase, *PYGM*, is located at 11q13. A number of mutations have been described but do not appear to explain the clinical heterogeneity of GSD type V. A initial study of potential genetic modifiers found a strong association between angiotensin-converting enzyme genotype and clinical phenotype, suggesting that angiotensin-converting enzyme is a modifier of *PYGM*; a further study also found that female gender conferred a more severe phenotype. GSD V is transmitted as an autosomal-recessive trait and may manifest in a heterozygote.

## Management

A controlled trial of oral sucrose loading showed improved exercise tolerance and stable glucose levels in 12 adults with GSD type V. Although not suitable for continuous use owing to its tendency to induce weight gain, this regimen, combined with aerobic conditioning, appears likely to be useful in improving performance under stressful conditions and may protect against acute rhabdomyolysis. A review of published trials found that there was low-quality evidence of improvement in some disease measures with creatine, sucrose, ramipril, and a carbohydrate rich diet but no unequivocal evidence of clinical benefit (Quinlivan et al., 2014).

## Hepatophosphorylase Deficiency (Hers Disease, Glycogen Storage Disease Type VI)

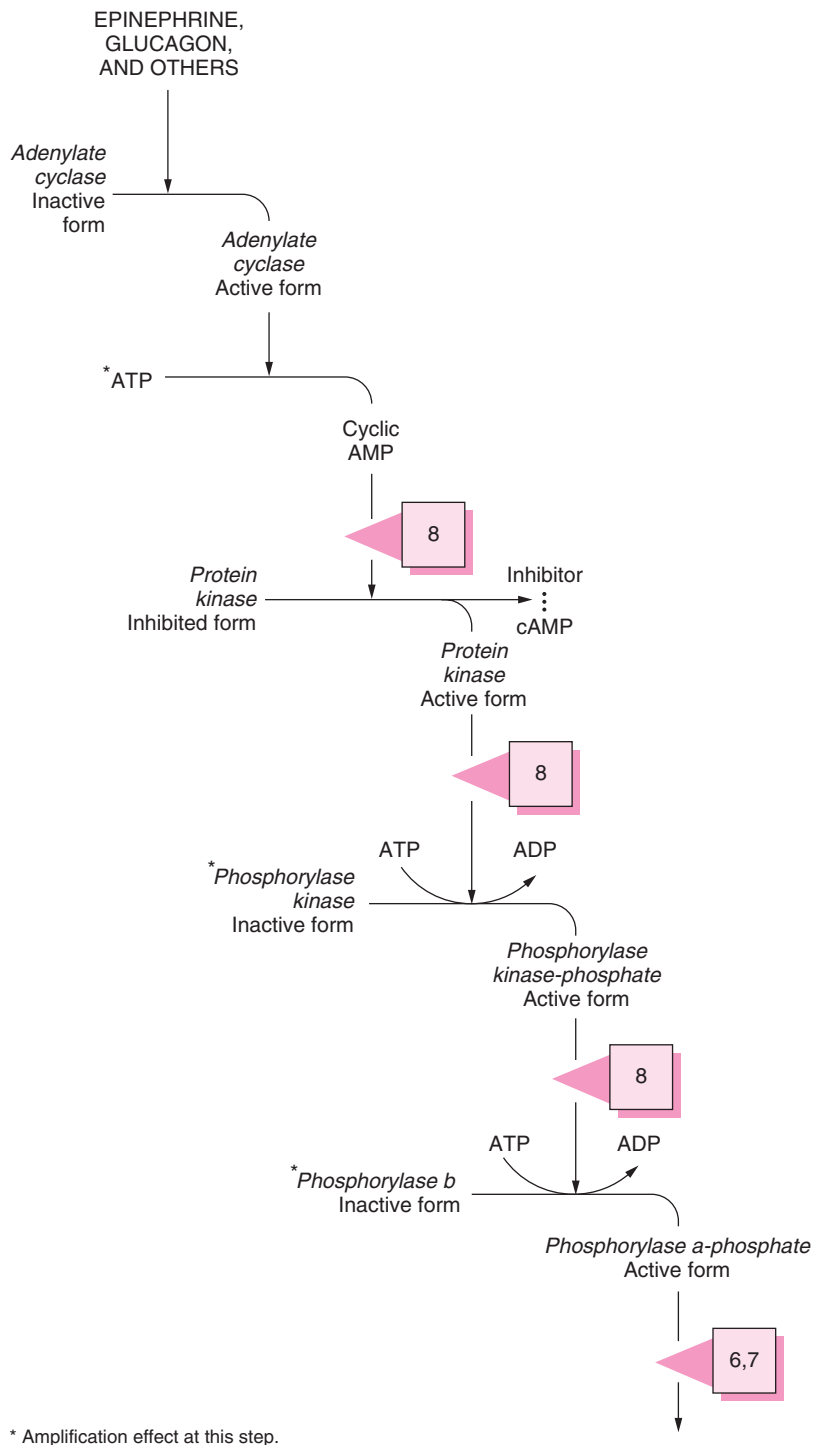

### Biochemistry

GSD type VI was described by Hers in 1959 and is characterized by increased glycogen stores of normal configuration in the liver. Hepatic phosphorylase (hepatophosphorylase) activity is diminished or absent.

Because of the possibility of abnormalities in the complex activating mechanism of hepatophosphorylase, systematic study of enzyme activity in suspected hepatophosphorylase deficiency is necessary to exclude phosphorylase kinase deficiency and other metabolic errors in the activating sequence.

GSD VI could only be diagnosed by enzymology of liver tissue until the *PYGL* gene was identified. A series of eight patients with GSD VI from seven families were studied and found to harbor 11 novel mutations, most of which were missense. The patients' symptoms ranged from hepatomegaly and subclinical hypoglycemia, to severe hepatomegaly with recurrent severe hypoglycemia and postprandial lactic acidosis.

**Figure 39-3. Activation sequence of phosphorylase.** See Table 39-2 for description of abnormalities denoted by the Arabic numerals enclosed in boxes. ADP, adenosine diphosphate; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate. (Modified from Goldberg, N.B., 1974. *Vigilance against pathogens. Hosp Pract* 9, 127.)

### Clinical Characteristics

The patients display various degrees of growth retardation, hypoglycemia, ketosis, and hepatomegaly. Specific neurologic findings are absent. Muscle and cardiovascular tissues are not primarily involved.

### Genetics

The gene coding for the enzyme liver glycogen phosphorylase is located on chromosome 14 at 14q21–22. The condition is transmitted as an autosomal-recessive trait. Most mutations are missense; there are no common mutations.

## Management

Symptoms can be controlled with frequent small carbohydrate meals. No other forms of therapy have been necessary or recommended.

### Muscle Phosphofructokinase Deficiency (Tarui Disease, Glycogen Storage Disease Type VII)

#### Biochemistry

The enzyme phosphofructokinase transforms fructose-6-phosphate to fructose-1,6-diphosphate. Decreased activity of this enzyme results in increased muscle glycogen stores of normal structure and increased concentration of glucose-6-phosphate and fructose-6-phosphate (Musumeci et al., 2012). Phosphofructokinase exists in five different isoforms with tissue-specific distribution.

#### Clinical Characteristics

Motor development is normal during the first decade, but patients experience decreased exercise tolerance and easy fatigability during childhood. They complain of muscle stiffness and weakness and, occasionally, muscle cramps. Myoglobinuria may follow moderate to strenuous exercise and has precipitated acute renal failure. The clinical pattern is reminiscent of McArdle disease, except for the absence of a "second wind" phenomenon in GSD type VII.

Physical examination in patients with GSD type VII is unremarkable, except for variable weakness and loss of skeletal muscle bulk.

#### Clinical Laboratory Tests

After exercise, serum creatine kinase and other serum enzymes released from muscle may be elevated. EMG findings may be normal. Ischemic exercise testing, as described earlier for McArdle disease, results in muscle contracture and decreased lactic acid production. The definitive diagnosis is made by enzymatic assay of muscle tissue.

#### Genetics

The phosphofructokinase gene (*PFKM*) is encoded at 12q13.3. GSD type VII is prevalent in Ashkenazim; 95% of mutant alleles in this population are accounted for by a splicing mutation in exon 5 (IVS5 + 1 G>A) or a single nucleotide deletion (del C2003).

### Hepatic Phosphorylase Kinase Deficiency (Glycogen Storage Disease, type IX) and Activation Abnormalities

Some patients with glycogen storage disease have defects in control of the phosphorylase system at the phosphorylase kinase level, rather than a deficiency of the phosphorylase enzyme (see Fig. 39-3). Although they appear to have hepatic phosphorylase deficiency disease, further studies identify the presence of the enzyme when activation cycle materials are added in vitro.

Phosphorylase kinase has a hexadecameric structure: ( $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ )<sub>4</sub>. The  $\delta$  subunit is calmodulin, which interacts with calcium. The  $\alpha$  subunit is encoded by *PHKA2* (at Xp22), the  $\beta$  subunit by *PHKB*, and the  $\gamma$  subunit by *PHKG2*. Mutations in these three genes have been associated with phosphorylase kinase deficiency and a GSD phenotype. Current nomenclature subdivides phosphorylase kinase deficiency into four types, GSD IX a through d.

Most cases are grouped together as GSD IXa, X-linked liver glycogenosis, or *PHKA2*-related phosphorylase kinase deficiency. This relatively mild phenotype most often presents with hepatomegaly in childhood, associated with fasting hypoglycemia, growth and motor delays. Hyperketotic hypoglycemia may be associated with nausea and vomiting; transaminases are often elevated. Some patients experience liver fibrosis or cirrhosis.

GSD IXb affects liver and muscle and is associated with mutations in *PHKB*. Liver manifestations usually predominate, and weakness is not apparent in some patients. Hypoglycemia and short stature are also encountered.

Phosphorylase kinase deficiency type c (GSD IXc) has a phenotype very similar to types a and b, but generally more severe. The *PHKG2* gene is mutated; inheritance is autosomal recessive. Splenomegaly may occur, and the risk of cirrhosis may be greater than in the preceding types.

The least common form of phosphorylase kinase deficiency (GSD IXd) is a pure muscle form, associated with mutations in *PHKA1* in which the liver is unaffected. The phenotype is characterized by progressive weakness, cramps, and pain after exercise. Most cases present in adults, although earlier onset has been reported. Some patients with the genetic and biochemical defect may be asymptomatic.

There are no systematic studies of therapy in type IX glycogen storage disease.

### Phosphohexose Isomerase Deficiency (Satoyoshi Disease)

Phosphohexose isomerase is also known as glucose phosphate isomerase and phosphoglucose isomerase. This enzyme catalyzes the interconversion of glucose-6-phosphate and fructose-6-phosphate in the Embden-Meyerhof pathway. Most reported cases of deficiency of this enzyme have been manifested as hemolytic anemia, but a few kindreds have been reported with skeletal muscle dysfunction.

Satoyoshi and associates described a family whose members experienced muscle pain and stiffness with exercise beginning in childhood. The symptoms become more prominent in later life. Muscle contractures do not occur after ischemic exercise. Routine examination is normal. Heavy exercise leads to stiffness and tenderness of the muscles without apparent weakness. Lactic acid does not increase during ischemic exercise and serum creatine kinase is increased, but findings on EMG remain normal.

*GPI* has been assigned to 19cen-q12. It consists of 18 exons and is 40 kb in length. The gene codes for two proteins in addition to hexose phosphate isomerase: neuroleukin, a chemokine, and autocrine motility factor. Antibodies to glucose phosphate isomerase have been shown to sustain a rheumatoid arthritis-like condition in experimental animals and humans. A Japanese report summarized the expanded phenotype of Satoyoshi disease, which includes painful muscle cramps, alopecia, intractable diarrhea, bone and joint deformity, and endocrine disturbances.

### Phosphoglucomutase Deficiency (Thomson Disease)

The phosphoglucomutases are a family of enzymes catalyzing the interconversion of glucose-1-phosphate and fructose-1-phosphate. The first recognized case presented in early infancy. This was a boy who experienced numerous episodes of supraventricular tachycardia, requiring digitoxin treatment; development then proceeded normally until the age of 2 years, when he began to walk on his toes. Examination revealed mild weakness and poor muscle development. His calf muscles

were bulky and firm, and shortening of the Achilles tendons was noted. No clinical history of exercise intolerance, muscle pain, or myoglobinuria was elicited. Serum enzyme activities, including creatine kinase, aldolase, glutamic-oxaloacetic transaminase, and glutamic-pyruvic transaminase, were elevated. Examination by EMG showed myopathic changes.

In vitro study of biopsy tissue indicated a number of relative enzymatic deficiencies, but phosphoglucomutase deficiency was most pronounced. Glycogen structure appeared normal. Also evident was extensive replacement of muscle tissue by glycogen.

A 35-year-old man with exercise-induced cramps, mild limb girdle weakness, episodes of rhabdomyolysis, normal elevation of lactate, and hyperammonemia on a forearm-exercise test has also been reported. The investigators suggested that this disorder should be designated glycogenosis type XIV, a suggestion which has not been widely accepted, given the already confusing state of glycogenosis nomenclature. A follow up study of this patient, two others identified by an independent group and sixteen new patients, described the findings in a total of 19 patients (Tegtmeyer et al., 2014). Although the phenotypes were highly variable, all had evidence of liver disease, with elevated transaminases, and, in some cases, steatosis or fibrosis. Most had clinical muscle disease, with weakness and exercise intolerance. Five subjects had experienced rhabdomyolysis. Dismorphic features included cleft palate and bifid uvula. Cardiomyopathy, short stature, and delayed puberty occurred in fewer than half of the subjects. Laboratory abnormalities included elevated creatine kinase and hypoglycemia. This spectrum of findings is highly suggestive of a congenital disorder of glycosylation (see Chapter 40), and these patients were found to have mixed type I and type II patterns of transferrin glycoforms. Oral galactose treatment improved these laboratory abnormalities in some patients, with resolution of hypogonadotropic hypogonadism in two girls. This disorder is now designated PGM1-CDG (CDG 1t using the older nomenclature).

### Other Defects of Glycolysis Causing Glycogen Storage

Three enzyme defects affecting the terminal glycolysis pathway have been reported, involving phosphoglycerate kinase, phosphoglycerate mutase, and lactate dehydrogenase. Phosphoglycerate kinase deficiency is an X-linked disorder manifesting with varying combinations of hemolytic anemia, seizures, mental retardation, and exercise intolerance with myoglobinuria. Up to 2007, 26 families had been reported.

Phosphoglycerate mutase deficiency (PGAMD—glycogen storage disease, type X) has been associated in adults with myalgia, cramps, and myoglobinuria after exercise. Twelve well-verified patients had been described by 2009, nine of whom were African American. A patient with PGAMD who experienced muscle cramps on forearm ischemic exercise testing was protected from cramps by dantrolene, suggesting that cramps in this disease reflect excessive calcium release from the sarcoplasmic reticulum relative to calcium reuptake capacity.

Lactate dehydrogenase M subunit deficiency has been reported in three families with exertional myoglobinuria. Additional cases have been identified, and a number of mutations identified in the responsible.

### Defects Impairing Glycogen Formation

Muscle glycogen storage disease (glycogen storage disease, type 0) results from deficiency of glycogen synthase 1, encoded by the GYS 1 gene. Glycogen synthase 1 catalyzes the addition

of glucose monomers to the glycogen molecule through alpha-1,4-glycoside linkages. Three families have been reported. Clinical manifestations include exercise intolerance and cardiac disease (leading to seizures and sudden death associated with long QT syndrome in the index case), recurrent syncope, weakness, and muscle pain.

Mutations in GYG1, which encodes glycogenin, may also cause muscle glycogen depletion. Glycogenin is required to activate glycogen synthesis; glucose molecules attach to glycogenin to form oligosaccharide chains. The index case was a 27-year-old man who experienced palpitations and dizziness after exercise. He had mild proximal arm, shoulder, and trunk weakness, and an abnormal ECG; an echocardiogram was normal. Skeletal muscle biopsy showed profound depletion of glycogen; endomyocardial biopsy demonstrated hypertrophic cardiomyocytes with enlarged nuclei and central vacuoles. The term glycogen storage disease, type XV was suggested for this entity. Seven adult patients have since been described with a slowly progressive myopathy; in these cases, muscle biopsy demonstrated polyglucosan bodies.

### CONCLUSIONS

The disorders of carbohydrate metabolism are a large, heterogeneous group, which are most likely to present to the child neurologist with manifestations of a metabolic myopathy. The presence of cardiac, hepatic, or hematologic abnormalities is often helpful in guiding the practitioner to the correct diagnosis. Although molecular testing is increasingly available to accurately diagnose these disorders (Wang et al., 2013), many still require sophisticated biochemical investigation, electrodiagnostic testing and tissue biopsy—guided, as always, by a complete and accurate history and careful physical examination.

## Disorders of Glycosylation

Hudson H. Freeze, Bobby G. Ng, and Marc C. Patterson

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Eukaryotic cells synthesize hundreds of types of sugar chains called glycans, which function within the cell, at the cell surface, and beyond. Within the cell, glycans influence protein folding, stability, turnover, and intracellular trafficking (Varki and Lowe, 2009). At the cell surface, they influence or determine cell-cell binding, receptor-ligand interactions, assembly of signaling complexes, binding to the extracellular matrix, tissue pattern formation, trafficking of lymphocytes, and much more (Varki and Lowe, 2009). The same glycan can function differently on different proteins or in different settings. This three-dimensional complexity makes understanding the roles of glycans challenging, but provides the body with an extraordinarily sensitive fine-tuning mechanism for many physiologic functions. It is not surprising that disrupting normal glycosylation causes moderate to severe pathology in multiple human organ systems.

Well over 100 rare inherited disorders of glycan biosynthesis have been identified. Most of these are called congenital disorders of glycosylation (CDG) (previously called carbohydrate-deficient glycoprotein syndrome). Others such as muscle-eye-brain disease and Walker-Warburg syndrome were well known, but elucidation of their relation to glycosylation has provided new insights into their pathophysiology and opens new therapeutic possibilities.

### DEFINING TYPES OF GLYCOSYLATION

Glycan linkage to proteins or lipids defines the biosynthetic pathway. Most CDG defects occur in the N-linked pathway that couples asparagine (Asn) to N-acetylglucosamine (GlcNAc). O-linked glycans occur in many linkages, but mannose (Man) O-Man glycans bound to threonine/serine (Thr/Ser) cause muscle-eye-brain disease and some cases of Walker-Warburg syndrome. A few disorders result from mutations that impair the synthesis of glycosphingolipids, and those deficient in glycosphosphatidylinositol (GPI) anchors comprise a rapidly expanding group. Defects in Golgi homeostasis and intracellular trafficking also cause CDG. We focus on glycosylation abnormalities that cause neurologic disorders. Defects in dystroglycan O-Man glycosylation (dystroglycanopathies) are described in Chapter (49).

### N-LINKED GLYCOSYLATION

#### Overview

Sugar chains are added to newly synthesized proteins in the lumen of the endoplasmic reticulum; most are quickly and extensively remodeled there and, later on, in the Golgi apparatus. All eukaryotic cells make a 14-sugar, lipid-linked oligosaccharide in the endoplasmic reticulum membrane that is composed of Man, GlcNAc, and glucose (Glc). This entire chain is transferred to Asn within an Asn-X-Thr/Ser/Cys consensus sequence (X is any amino acid except proline) concurrently or shortly after newly made proteins emerge from the ribosome into the endoplasmic reticulum lumen. Over 50

genes are required to synthesize and transfer this glycan to proteins.

Remodeling begins soon after sugar chain transfer. Up to two-thirds of the original lipid-linked oligosaccharide glycan is discarded, and 6 to 15 other sugar units are then added to create a dazzling array of sugar chains. Why generate this complex process? The initial glycan helps proteins fold and also provides important checkpoints for monitoring proper protein folding in the endoplasmic reticulum. The addition of more sugars in the Golgi usually imparts greater specificity to the sugar chain function.

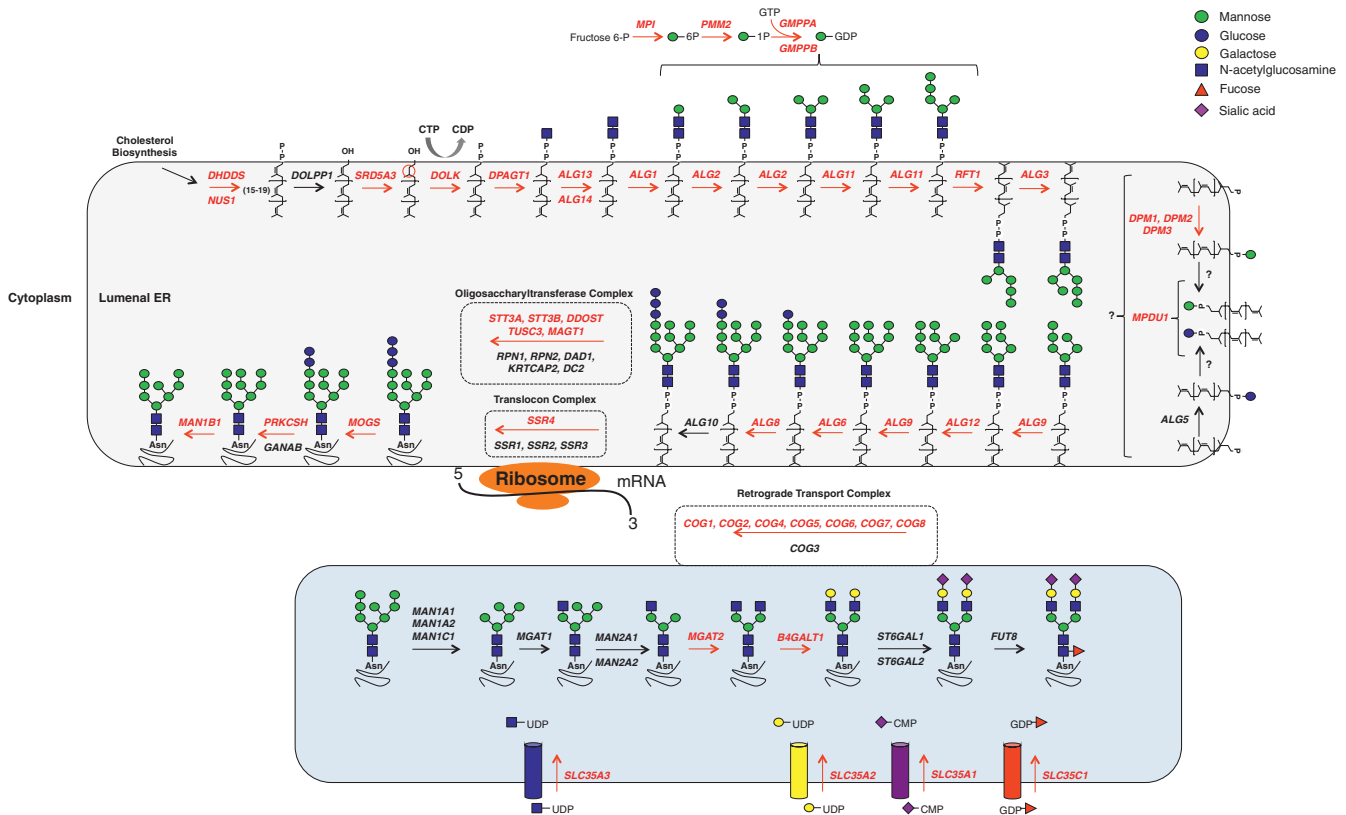

### Biosynthesis

Individual monosaccharides can be synthesized from glucose, derived from the diet, or salvaged from degraded glycans. They must be activated to their nucleotide sugar derivatives to construct glycans. The top of Figure 40-1 depicts the pathway for mannose using standard symbols for the sugar (Varki, et al., 2009). Monosaccharide phosphorylation is the first step, and some pathways interconvert phosphorylated forms such as Man-6-P→Man-1-P. Other routes generate uridine diphosphate (UDP)-GlcNAc, UDP-galactose (Gal), and guanosine diphosphate (GDP)-fucose (Fuc) for adding these sugars. For some types of glycosylation, the nucleotide sugar donates the sugar to a lipid carrier dolichol phosphate (P-Dol). These products include Man-P-Dol and Glc-P-Dol. Dolichol itself is made from polyprenols using a specific reductase.

### N-Linked Glycan Biosynthesis

The lipid precursor is built stepwise, adding sugars in specific linkages and in a specific order (Freeze and Elbein, 2009) as shown in Figure 40-1. It begins with P-Dol + UDP-GlcNAc forming GlcNAc-P-P-Dol on the cytosolic face of the endoplasmic reticulum. Another UDP-GlcNAc donates a second GlcNAc using a different GlcNAc transferase, and this is followed by the addition of five Man units derived from GDP-Man. A “flippase” reorients the entire molecule from the cytosolic face into the endoplasmic reticulum lumen in which a series of Man transferases use Man-P-Dol to add four more Man units, to make a three-branched structure. Three glucosyltransferases sequentially add Glc from Glc-P-Dol to one branch to complete the sugar chain. This 14-sugar unit molecule is the optimal substrate for the 8-subunit oligosaccharyl transferase (OST) complex that recognizes the Asn-X-Thr/Ser/Cys consensus sequence on the protein and adds the sugar chain to Asn. Post transfer, the P-P-Dol is converted back to P-Dol and then to Dol for recycling.

Within a few minutes of transfer to protein, the sugar chain is processed (Fig. 40-1) using a set of two glucosidases that remove the Glc units. For some proteins, processing stops here; however, for the majority, a series of  $\alpha$ -mannosidases in the endoplasmic and Golgi remove up to six Man units, and UDP-GlcNAc, UDP-Gal and CMP-Sialic acid (Sia) and GDP-Fuc donate their respective sugars to multiple branches

**Figure 40-1. N-linked glycan synthesis.** The biosynthesis and assembly of the lipid-linked oligosaccharide precursor (LLO), its transfer to protein, and subsequent processing are presented here. The first steps involve the activation and interconversion of monosaccharides such as mannose to form sugar donors, the nucleotide sugars or phosphoryldolichols. Dolichol phosphate serves as the lipid carrier for the sugar chain, which is synthesized in a series of precisely ordered steps that involve addition of N-acetylglucosamine, mannose, and glucose. The completed glycan is transferred to proteins. After transfer to proteins, oligosaccharide processing begins by removing all three glucose units and a mannose unit. Mannose trimming of the protein-bound sugar chains may stop or continue. Addition of a single N-acetylglucosamine or continued mannose trimming next leads to the build-up of sugar chains with two to five branches containing N-acetylglucosamine, galactose, and sialic acid. Fucose may be added to some chains using specific transferases. All of these reactions require delivery of the nucleotide sugar into the Golgi by specific transporters. A series of mutations in seven of the eight COG subunits and a vacuolar H<sup>+</sup>/ATPase disturb N-glycan processing and other biosynthetic pathways by disrupting Golgi homeostasis. Congenital disorders of glycosylation (CDGs) result from defects in some of these steps, indicated by the gene name in red. ER, endoplasmic reticulum; CMP, cytidine monophosphate; GDP, guanosine diphosphate; UDP, uridine diphosphate.

of the chains. Each nucleotide sugar donor must be translocated from its origin in the cytoplasm or nucleus to the Golgi by a substrate-selective transporter. The transferases and transporters recycle through the dynamic Golgi to maintain their correct relationship to the maturing glycoproteins as they pass through the Golgi. Therefore correct trafficking of the biosynthetic machinery is essential for optimal function.

## CONGENITAL DISORDERS OF GLYCOSYLATION

Glycosylation is complex, and its disorders defy symptomatic pigeonholing. Congenital disorders of glycosylation (CDG) nomenclature transitioned from a biochemical pathway designation to one based on the mutated gene name. Previously, defects in lipid-linked glycan biosynthesis and transfer to protein defined “group I,” and those affecting biosynthesis and processing of the protein-bound sugar chains constituted “group II.” Each unique gene disorder carried a lower-case letter (e.g., CDG-Ia, CDG-Ib, CDG-IIa). This nomenclature became too complex, and now the mutated gene name adds a “-CDG” suffix. Both monikers will coexist for some time, but the gene designation is preferred (Jaeken, et al., 2008).

## Diagnosis

Most CDG patients were first recognized by abnormal glycoforms of serum transferrin. Commercially available tests include isoelectric focusing, mass spectrometry, zone electrophoresis, and high performance liquid chromatography; however, electrospray ionization-mass spectrometry (ESI-MS) (Babovic-Vuksanovic and O’Brien, 2007) is the most informative because it differentiates absence of entire sugar chains from one or more monosaccharide units. Normal transferrin has two sugar chains, each containing two negatively charged Sia molecules, designated tetraasialotransferrin. Loss of one or two entire chains produces disialotransferrin or asialotransferrin respectively, but this is a misnomer because it is the loss of more than sialic acid. ESI-MS shows losses of 2200 or 4400 mass units, respectively. ESI-MS can also detect loss of single or multiple individual sugars. This distinction helps narrow gene candidates from whole exome or genome sequencing results. ESI-MS is the preferred method (Babovic-Vuksanovic and O’Brien, 2007) and is suitable for routine diagnostics.

Transferrin isoform analysis produces few false-positive results. Uncontrolled fructosemia, galactosemia, and recent

heavy alcohol consumption produce a pattern typical of group I disorders. Sometimes, patients with genetically confirmed CDGs develop normal transferrin, and in some patients, previously abnormal patterns normalized in preadolescence. Thus a normal transferrin pattern should not exclude follow-up testing. Healthy neonates sometimes have a slightly abnormal transferrin pattern, which normalizes within a few weeks. Suspicious results in neonates should be repeated.

Some genetic centers and commercial laboratories now offer various CDG gene diagnostic panels (Greenwood Genetic Center, Baylor Medical Genetics, Emory Genetic Laboratory), but falling costs and improved bioinformatics make whole exome sequencing the first choice. However, the proven power of transferrin analysis should always accompany a putative genetic result. Prenatal testing is available for confirmed at-risk families.

## General Clinical Features

Over 1000 CDG patients have been identified, most presenting with multiple organ dysfunctions (Hauptle and Hennet, 2009). Patients with CDGs have protean presentations that, in some cases, may mimic mitochondrial (oxidative phosphorylation) disorders. An informal survey of CDG-affected families indicated that earlier nonspecific diagnoses frequently included a metabolic defect or cerebral palsy. Most patients first present to pediatric neurology or metabolic clinics. They frequently have combinations of liver, gastrointestinal, and coagulation disturbances. The possibility of a CDG should be investigated in any child presenting with developmental delay, seizures, hearing loss or strabismus, particularly if any of these manifestations is accompanied by abnormal coagulation, liver dysfunction, or a gastrointestinal disorder. Most affected children are hypotonic and demonstrate failure to thrive.

## SPECIFIC DISORDERS

Table 40-1 summarizes the known glycosylation defects, utilizing the classification scheme published in 2009. This includes the mutated genes and major signs and symptoms. The known defects cover every aspect of the N-linked biosynthetic pathway. Activation or presentation of precursors (PMM2, PMI, DPM1, DPM3, MPDU1 [CDG-Ia, Ib, Ie, If]), glycosyltransferases for lipid-linked oligosaccharide biosynthesis (ALG6, ALG3, ALG12, ALG8, ALG2, DPAGT1, ALG1, ALG9, ALG11, ALG13 [CDG-Ic, Id, Ig, Ih, Ii, Ij, Ik, Il, Ip, Is]), glycosidases that trim the protein-bound sugar chain (MOGS [CDG-IIb], MAN1B1 [MRT15]), Golgi-localized nucleotide sugar transporters (SLC35C1, SLC35A1, SLC35A2 [CDG-IIc, IIf, IIm]), and glycosyltransferases that extend the trimmed chain (MGAT2, B4GALT1 [CDG-IIa and IIId]). DOLK (CDG-Im) impair dolichol kinase function and impair the final step of the *de novo* synthesis of dolichol phosphate. SRD5A3 (CDG-Iq) encodes the  $\alpha$ -reductase that converts various polyprenols to dolichols. The conserved, eight-subunit, oligomeric Golgi (COG) complex that binds to the cytoplasmic face of the Golgi is needed for intra-Golgi or Golgi to endoplasmic reticulum retrotrafficking of multiple resident glycosyltransferases and nucleotide sugar transporters. Disorganized trafficking impairs multiple glycosylation pathways. Defects have now been identified in COG7, COG1, COG4, COG8, COG5, COG6, and COG2 [CDG-IIe, IIg, IIj, IIh, Ili, III, IIn). Appreciation of the importance of Golgi homeostasis in glycosylation led to the discovery of another disorder caused by mutations in a subunit of a vacuolar H<sup>+</sup>/ATPase that maintains appropriate pH of various organelles within the endocytic and exocytic pathways. The intravesicular pH progressively decreases from

the endoplasmic reticulum to Golgi, endosomes, and, finally, lysosomes.

The remainder of this chapter will focus on prominent CDGs with significant neurologic manifestations. Table 40-1 lists those disorders and their common clinical features.

## Defects in Protein N-Glycosylation

### PMM2-CDG (Ia)

PMM2-CDG (CDG-Ia) is the best-known and most frequently recognized form of CDG, first reported by Jaeken and colleagues in 1980 (Jaeken et al., 1980). The defective gene was identified in 1995 as PMM2, which encodes the phosphomannomutase (PMM) that converts Man-6-P→Man-1-P. This defect results in insufficient production of lipid-linked oligosaccharide, leading to empty glycosylation sites. More than 800 patients are known worldwide, and more than 100 mutations have been cataloged (Hauptle and Hennet, 2009).

Hagberg and associates described four stages of the typical (severe) phenotype. The first is the infantile phase, marked by various combinations of dysmorphism, abnormal fat distribution (supragluteal and vulval fat pads, focal lipoatrophy), inverted nipples, cryptorchidism, esotropia, recurrent infections, cardiomyopathy or pericardial effusions, coagulopathies, nephrotic syndrome, hypothyroidism, life-threatening episodes of hepatic failure, and unexplained coma. Up to 20% of infants with PMM2-CDG succumb in this phase. In the second phase (comprising the remainder of the first decade), children experience seizures and strokelike episodes, often precipitated by intercurrent infections. The third phase (in the second decade of life) is marked by slowly progressive cerebellar ataxia and limb wasting and by progressive visual loss secondary to pigmentary retinopathy. Adult survivors have moderate intellectual disability with severe ataxia and hypogonadism, with or without skeletal deformities. Presentations are highly variable. In one girl with PMM2-CDG, findings on computed tomography (CT) of the head were normal at 9 months of age, but subsequent imaging studies demonstrated progressive atrophy. The investigators concluded that the cerebellar hypoplasia reported in infancy in most children with CDG-Ia likely reflects atrophy of antenatal onset rather than hypoplasia.

More extensive testing for CDGs has led to the identification of milder PMM2-CDG phenotypes. The patients often have high residual levels of PMM2 activity. Some patients have only borderline cognitive impairment, but strabismus persists in these very mild cases. Few adult CDG-Ia patients are employed. A longitudinal study of eight Spanish patients confirmed the wide range of clinical manifestations, ranging from neonatal hemorrhage, nonimmune hydrops, and death through intellectual disability and motor impairment without acute decompensation in patients in their 20s to one individual with normal development and only gastrointestinal dysfunction in childhood.

The carrier frequency of the most common mutant allele (c.422G>A, p.R141H) is about 1 in 70 in the northern European population. The public Exome Aggregation Consortium (ExAC) database, composed of 60,000 exomes, finds a carrier frequency of 1 in 76. It is lethal in the homozygous state. No effective specific therapy for PMM2-CDG exists. Experiments using patient cells suggested that increasing dietary mannose might improve glycosylation in patients, but clinical trials demonstrated no benefit. Subsequent trials on a few patients did not show any clinical improvement.

Population studies find the risk of having a second child with PMM2-CDG to be close to 1 in 3 rather than the expected Mendelian ratio of 1 in 4, suggesting that reduced glycosylation

may have some selective advantage. At-risk couples should be counseled appropriately.

### MPI-CDG (Ib)

MPI-CDG (Ib) is caused by mutations in MPI, the gene encoding phosphomannose isomerase, which interconverts Man-6-P and Fructose (Frc)-6-P. This reaction produces most of the mannose for glycoprotein synthesis. About 25 patients have been identified since its discovery in 1998 (de Lonlay and Seta, 2009). This phenotype is not associated with any primary neurologic symptoms. Gastrointestinal and hepatic pathology, with hypoglycemia, coagulopathy, and protein-losing enteropathy, is characteristic. MPI-CDG is unique in that simple dietary mannose therapy corrects the abnormalities, except for liver fibrosis. Liver transplantation proved effective in one patient with severe hepatic fibrosis.

### ALG6-CDG (Ic)

Initial cases of ALG6-CDG (Ic) resembled a less severe version of PMM2-CDG, but more severe cases have appeared. It is characterized by moderate psychomotor retardation, hypotonia, esotropia, seizures, and ataxia. Nevertheless, at least five children have died of CDG-related complications. The defect is in a glycosyltransferase hALG6, which results in production of a truncated lipid-linked oligosaccharide sugar chain that is inefficiently transferred to proteins. Patients sometimes experience life-threatening protein-losing enteropathy during bouts of gastroenteritis. Skeletal dysplasia, including a unique form associated with brachytelephalangy, has been described in a compound heterozygote for ALG6. An adult woman has been identified in whom ALG6 deficiency was associated with intellectual disability, skeletal anomalies, virilization, and deep vein thrombosis. ALG6 deficiency was first identified in 1998 and subsequently in over 90 patients, making it one of the most common forms of CDG.

### DPAGT1-CDG (Ij)

DPAGT1-CDG (Ij) is caused by a deficiency in UDP-GlcNAc:dolichol phosphate *N*-acetylglucosamine-1 phosphate transferase (GPT) activity encoded by DPAGT1. Two patients had severe hypotonia, intractable seizures, intellectual disability, microcephaly, and exotropia. Using exome sequencing, Ng and associates have identified an additional seven previously unreported cases of DPAGT1-CDG. In four of the seven cases, the patients were characterized by an extremely severe, multicongenital anomaly phenotype that resulted in death for all four. The remaining individuals have severe hypotonia, intractable seizures, intellectual disability, and microcephaly. Subsequent reports have focused on DPAGT1-CDG as a cause of a myasthenic syndrome characterized by fatigable limb girdle weakness with bulbar sparing, response to cholinesterase inhibitors, and the presence of tubular aggregates on muscle biopsy; there is evidence of both presynaptic and postsynaptic neuromuscular transmission defects.

### ALG1-CDG (Ik)

Eighteen patients with ALG1-CDG (Ik) had been described by 2014. Fifty percent had complications during pregnancy, and several had postnatal complications. Eighty percent were hypotonic, and all had at least one seizure, most being intractable; 8 of the 10 were dysmorphic; 7 of the 10 had visual impairment; and 5 of the 10 were microcephalic. Fifty percent had a fatal outcome. Patients with ALG1-CDG are deficient in GDP-Man:GlcNAc<sub>2</sub>-P-P-dolichol mannosyltransferase, encoded by the *hALG1* gene, which adds the first Man to the lipid-linked oligosaccharide chain.

More recently, Ng and associates identified 39 additional ALG1-CDG cases by various methods, including exome sequencing, targeted gene panels, and traditional Sanger sequencing. It is the largest report of ALG1-CDG cases and triples the number of known cases, making it the third most common CDG in the N-linked pathway. Nearly all the affected had a pronounced neurologic presentation that included developmental delay, hypotonia, seizures/epilepsy, microcephaly, and, for those who could be tested, varying degrees of intellectual disabilities. Other clinical manifestations included facial dysmorphism, coagulopathy, gastrointestinal and skeletal abnormalities. Lethality in the first 5 years occurred in about 45% of the cases.

### TUSC3-CDG

Twenty-one patients in six kindreds have been described with TUSC3-CDG. Seven of the original cohort all had nonsyndromic, moderate to severe intellectual disability. Two were siblings from a small French family. TUSC3 encodes a subunit of the oligosaccharyltransferase complex (OST). It is not clear why these patients have no other systemic manifestations of hypoglycosylation, but it is theorized that differential tissue expression of another subunit associated with the OST (IAP) might compensate for TUSC3 deficiency in nonneurologic tissues. About one-third of patients have microcephaly and short stature.

### SRD5A3-CDG (Iq)

Nearly twenty cases of SRD5A3-CDG have been described with virtually all being either homozygous or compound heterozygous for complete loss of function mutations (INDEL, premature stop codons, complete gene deletions). No missense mutations have been identified to date. SRD5A3 encodes for a polyprenol reductase that converts polyprenol to dolichol, and unlike SRD5A1 and SRD5A2, does not appear to play a physiologic role in testosterone production. Affected individuals manifest with neurologic deficiencies and nearly always with some form of ocular problems including nystagmus, cataracts, glaucoma and optic nerve atrophy.

### NGLY1-CDG

Recently discovered mutations in NGLY1 cause global developmental delay, a movement disorder, hypotonia microcephaly and diminished reflexes, and alacrima by unknown mechanisms (Enns et al., 2014). It shares many symptoms with other typical CDGs. NGLY1 cleaves intact N-glycans from misfolded N-glycosylated proteins that retrotranslocate into the cytoplasm as part of the ERAD pathway, often linked to ER-stress response. It could be considered a highly specific "disorder of de-glycosylation." The liberated N-glycan chains are further degraded by the proteasome in the cytoplasm and lysosomes, and the proteins are degraded in the proteasome. Over 40 patients have been identified in less than 3 years since its discovery, mostly due to the outreach efforts of parents of the index patient.

## Defects in Protein O-Glycosylation

The most important defects in O-glycosylation are those based in O-mannose pathway, which is covered in Chapter 39. These disorders are listed in Table 40-1.

## Defects in Glycosphingolipids (GSL)

The GSL biosynthetic pathway is shown in Figure 40-2. Developmental delay, seizures, and blindness are found in

autosomal-recessive Amish infantile epilepsy. A large Amish family was identified with a nonsense mutation in *SIAT9* that truncated protein. The presence of abnormal pigmentation that becomes more prominent over time may be a useful diagnostic clue to the presence of this otherwise clinically nonspecific disorder; 20 of 38 affected children were found to have freckled hyperpigmentation on the limbs, with variable hypopigmentation on the limbs and face. *SIAT9* is a sialyltransferase needed for synthesis of gangliosides GM3 (Sia $\alpha$ 2-3Gal $\beta$ 1-4Glc-ceramide) from lactosylceramide (Gal $\beta$ 1-4Glc-ceramide). Patients accumulate nonsialylated plasma glycosphingolipids such as GM3 and also lack downstream GM3-dependent molecules. Two children with homozygous nonsense mutations in *SIAT9* were found to have evidence of secondary respiratory chain dysfunction and apoptosis in their cultured fibroblasts, attributed to accumulation of globosides Gb3 and Gb4.

GalNAc is transferred onto GM3 and GD3 precursors by B4GALNT1 in the biosynthesis of GM2 and GD2 glycosphingolipids and is mutated in hereditary spastic paraplegia subtype 26. Individuals showed developmental delay with varying cognitive impairment and an early onset progressive spasticity due to axonal degeneration.

In twelve affected individuals who had IQ<40, ST3GAL3, mutations were identified that resulted in loss of enzyme activity or mislocalization of ST3GAL3 protein. Furthermore mutations in ST3GAL3 were also identified as an underlying cause of West syndrome with developmental delay. Loss of ST3GAL3 function may result in varying clinical presentation because this enzyme has multiple substrates that include both gangliosides as well as N- and O-glycans.

### Glycosylphosphatidylinositol Glycosylation

In mammals, hundreds of proteins require a GPI-anchor for proper function. To carry out this essential pathway, at least 27 proteins are required to synthesize and transfer a functional GPI anchor to its target protein (see Fig. 40-3). Several disorders of GPI-anchor synthesis with neurologic features have been described. Mabry syndrome, comprising intellectual disability, hyperphosphatasia, unusual facial features, hypotonia, and seizures, has been associated with mutations in several glycosylphosphatidylinositol synthase genes, including *PIGV*, *PIGO*, *PIGL*, *PIGW*, *PGAP2*, and *PGAP3*; *PIGV* mutations are found in most cases. The *PIGV* gene encodes the second mannosyltransferase used for GPI-anchor synthesis. Total surface anchors are reduced, including GPI-anchored alkaline phosphatase, which is instead found at very high levels in the plasma. *PIGT* mutations have been described in children with encephalopathy, dysmorphism, and hypophosphatasia. *PIGL* is mutated in the CHIME syndrome (ocular coloboma, heart defects, ichthyosis, mental retardation, and ear anomalies). More recently, a single patient with the hallmarks of Mabry syndrome was also found to have mutations in *PIGL*. Mutations in *PIGA*, which have long been known as a cause of paroxysmal nocturnal hemoglobinuria (PNH), can also cause distinct neurologic disorders, including: (1) severe syndromic form of X-linked intellectual disability; (2) early onset epileptic encephalopathies (EOEEs); (3) X-linked syndrome associated with neurodegeneration, cutaneous abnormalities associated with systemic iron overload; and (4) multiple congenital anomalies-hypotonia-seizures syndrome-2. Mutations also occur in *PIGN* causing multiple congenital anomalies-hypotonia-seizures syndrome-1. Mutations in *PIGQ* can result in Ohtahara syndrome, whereas defects in *PGAP1* cause intellectual disability with encephalopathy (Murakami et al., 2014). The one GPI anchor protein deficiency that has a targeted treatment is

due to mutations in *PIGM*. In this deficiency, patients carry a promoter mutation resulting in loss of *PIGM* protein, but treatment with butyrate resulted in increased *PIGM* expression and correction of both the biochemical defect as well as complete cessation of the child's intractable seizures.

### Defects in Multiple Glycosylation and Other Pathways

Several rare disorders are included in this group; they include DPM1-CDG (Ie), DPM2-CDG, DPM3-CDG (Io), MPDU1-CDG (If), B4GALT1-CDG (IId), SLC35A1-CDG (IIf), SLC35A2-CDG, all of which feature varying degrees of intellectual disability, epilepsy (often intractable), dysmorphism, and dystroglycanopathy. Systemic involvement in the form of skeletal, hepatic, and coagulation anomalies is also variable; carbohydrate-deficient transferrin cannot be relied on to make a diagnosis in these forms. A more detailed discussion is available online.

#### SLC35C1-CDG (IIc)

SLC35C1-CDG (IIc) is one of the few CDG for which disease-modifying therapy is available. It was originally described as leukocyte adhesion deficiency II and is characterized by moderate to severe intellectual disability, rhizomelic short stature, a broad flat nasal bridge, microcephaly, elevated leukocytes, frequent infections, persistent marked neutrophilia, and periodontitis. The disorder is caused by mutations in the GDP-fucose transporter, which limits the synthesis of fucosylated glycans. One of these is sialyl Lewis-X (sLeX), a glycan essential for leukocyte rolling before extravasation. Oral fucose supplements effectively reduced leukocytosis in two patients by allowing synthesis of sufficient sLeX. These patients also lack fucosylated H-antigen, the precursor for the ABO blood group. Fucose supplements have not provoked antigen synthesis or immunologic reactions. Transferrin glycosylation is normal in this type. Patients may present with short stature and developmental delay, without clinical evidence of increased susceptibility to infection.

#### COG Complex

The COG complex consists of eight (COG1-8) subunits encoded by different genes. Glycosylation disorders have been identified in all except COG3. A wide range of phenotypes has been described; most have an early, severe onset, with intractable epilepsy, profound developmental delay, and early death from infection or multiorgan failure. A detailed discussion of several subtypes is available online.

### WHEN TO SUSPECT AND TEST FOR CONGENITAL DISORDERS OF GLYCOSYLATION

CDG should be suspected and tested for in any child presenting with an unexplained syndrome, particularly those characterized by developmental delay, hearing loss, hypotonia, and seizures, especially in combination with lipodystrophy, skeletal dysplasia, or gastrointestinal, hepatic, or coagulation abnormalities. However, nonsyndromic intellectual disability or "pure" neurologic syndromes do occur, including dramatic episodes of regression, apparently provoked by intercurrent illness or immunization. Although transferrin should be done, not all types will show an abnormality; a few confirmed patients even normalized over time. Therefore it is best to test patients early (1 to 18 months of age). Patients with CDGs may have phenotypes resembling mitochondrial disorders, Joubert syndrome, or Dandy-Walker malformation. Abnormal

transferrin results still require genetic analysis to identify the defect. Some commercial laboratories now offer various CDG gene panel analyses. Improved technology and decreasing costs of genome or exome sequencing will continue to identify specific defects. However, in many cases the variants may be predicted to be damaging, but additional biochemical and physiologic analysis is required needed to provide certainty as well as hopes for therapeutics.

## SUMMARY

Glycosylated molecules are present on the surface and in the interior of all cells. The biosynthesis of glycans is complex, with the potential to produce thousands of different structures at different times and in response to endogenous and exogenous signals. At least 2% of the known genes encode proteins that either synthesize or bind to glycans, often with exquisite specificity. Disrupting glycan biosynthesis leads to a multitude of downstream effects that may involve every aspect of central nervous system's development and function. The analysis of transferrin glycosylation status can point to glycosylation abnormalities in many, but not all, patients. A few patients respond to simple dietary supplements of sugars. Although glycosylation disorders appear to be rare, their recent discovery makes it likely that the true frequency is unknown. As for all inborn errors of metabolism, many patients with mild or atypical manifestations will be found, and new disorders will be recognized as diagnostic testing—particularly whole exome and genome sequencing—becomes more widely available and applied (Freeze et al., 2015).

## Lysosomal Storage Diseases

Gregory M. Pastores and Raymond Y. Wang

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

### OVERVIEW AND GENERAL CONCEPTS

The lysosomal storage diseases (LSDs) encompass a heterogeneous group of approximately 50 disorders caused by genetic defects in a lysosomal acid hydrolase, receptor, activator protein, membrane protein, or transporter, causing progressive lysosomal accumulation of undegradable substrates specific to each disorder (Valle et al., 2014). As storage of substrate progresses, derangements of lysosomal function and transport result in deterioration of affected tissues and organs. Many LSDs have central nervous system (CNS) manifestations and other multisystemic pathologies resulting in decreased life span and significant morbidity.

LSDs are often categorized according to the type of substrate stored (i.e., mucopolysaccharidoses, oligosaccharidoses, sphingolipidoses, gangliosidoses, etc.). Although lysosomes and their constituent proteins are usually expressed in cells throughout the body, storage occurs only in those deficient tissues in which relevant substrates are normally turned-over (e.g.,  $G_{M1}$  ganglioside is present predominantly in the myelin of the CNS; deficiency of  $\beta$ -D-galactosidase, which acts on the  $G_{M1}$  ganglioside and can be measured in the blood, causes  $G_{M1}$  gangliosidosis, a condition that manifests with neurodegeneration and other systemic signs). In all cases, the diagnosis can be established with biochemical enzymatic assays and/or confirmed by mutational analysis of the gene in question (Wang 2011).

Although each disorder is individually rare, LSDs as a group have an estimated frequency of one in 7000 to 8000 live births. As more countries adopt presymptomatic newborn screening for LSDs, the actual frequency appears to be more common as increasing numbers of infants with attenuated or adult-onset forms of the diseases are being identified. All LSDs are inherited in an autosomal-recessive fashion, except for the X-linked disorders Fabry, Hunter (mucopolysaccharidosis type II [MPS II]), and Danon diseases. Some population groups have higher prevalence rates for certain LSDs (e.g., Gaucher, Tay-Sachs, Niemann-Pick type A, and mucopolipidosis IV are more common in Ashkenazi Jews) as a result of ancestral founder mutations. For other LSDs, such as Fabry disease, most kindreds have private mutations.

LSDs can demonstrate locus heterogeneity, where a clinical entity such as Sanfilippo disease (MPS III) is caused by recessive mutations encoding one of four enzymes involved in heparan sulfate catabolism. Conversely, LSDs frequently demonstrate phenotypic heterogeneity, where different mutations in one lysosomal gene result in a spectrum of manifestations depending on the amount of residual enzyme activity and other modifiers. As a general rule, mutations that result in negligible lysosomal enzymatic activity tend to result in more severe, earlier-onset disease with more rapid velocity of disease progression, whereas the mutations that confer residual enzymatic activity tend to manifest with later-onset, more attenuated disease manifestations. However, the age of onset, severity of symptoms, organ systems affected, and CNS manifestations can vary in patients with identical mutations, even those from the same families. Although certain mutations in LSD genes are fairly reliable in predicting clinical outcomes,

for many disorders genotype-phenotype correlations are not completely reliable. For example, patients with Gaucher disease who have the common p.N370S mutation may present in childhood or even be asymptomatic throughout adult life. It is likely there are modifying factors that influence disease expression, but these have not been fully elucidated. For a tabular summary of the LSDs discussed in this chapter, please refer to Table 41-1; for a general algorithm for the diagnosis of LSDs, please refer to Figure 41-1.

### Sphingolipidoses

Glycolipids are amphiphilic compounds especially found in CNS cell membranes and are composed of a hydrophobic ceramide attached to polar components, such as saccharide oligomers, phosphocholine, or phosphoethanolamine. The exact nomenclature of a glycolipid depends on its polar moiety: gangliosides contain at least one sialic acid residue; globosides and cerebrosides contain multiple and single hexoses, respectively; and sphingomyelins have either phosphocholine or phosphoethanolamine. Deficiencies of specific degradative enzymes result in lysosomal accumulation of the cognate substrate (Sandhoff, 2013).

### $G_{M1}$ Gangliosidosis

$G_{M1}$  gangliosidosis is allelic to mucopolysaccharidosis IVb and arises from complete deficiency of the  $\beta$ -D-galactosidase enzyme.  $G_{M1}$  gangliosidosis often can be recognized in the neonatal period with macrocephaly, frontal bossing, gingival hypertrophy, macroglossia, and edema. The placenta may have a tougher consistency, and pathologic examination often reveals vacuolization of syncytiotrophoblasts. Infants display hypotonia and exaggerated startle to sounds. Development stagnates, and they become deaf, blind, and minimally interactive within the first year of life. Also within the first year, MPS-like symptoms of facial coarsening, hepatosplenomegaly, joint contractures, and vertebral dysplasia arise from accumulation of the keratan sulfate glycosaminoglycan, a polymer of galactose and *N*-acetyl 6-sulfogalactosamine. As the disease progresses, seizures and macular "cherry-red spots" develop as  $G_{M1}$  ganglioside accumulates in the CNS and retina, respectively. Most severely affected children die before their third birthday from aspiration pneumonia. Attenuated cases of  $G_{M1}$  gangliosidosis manifest in childhood or adolescence with dystonia, dysarthria, stuttering, and hip dysplasia. There are no currently effective treatments for this disorder, although intracerebroventricular gene therapy is currently being investigated.

### $G_{M2}$ Gangliosidoses

Once galactose is cleaved off the  $G_{M1}$  molecule, the distal sugar residue on the ganglioside becomes an *N*-acetyl-D-hexosamine. This sugar is removed by the heterodimeric enzyme hexosaminidase, composed of an A and B subunit encoded by the

\*Three types imply infantile, childhood, and adulthood presentations.

**Figure 41-1.** General algorithm for the diagnosis of lysosomal storage disorders.

*HEXA* and *HEXB* genes, respectively. Recessive deficiency in hexosaminidase A results in Tay–Sachs disease, whereas hexosaminidase B deficiency results in Sandhoff disease. Collectively, the two disorders are known as the G<sub>M2</sub> gangliosidoses because their symptoms are fairly similar and are caused by accumulation of G<sub>M2</sub> ganglioside. Initial growth and development are normal until 3 to 6 months of age, when hypotonia and exaggerated startle reflex are the usual initial symptoms. As in G<sub>M1</sub> gangliosidosis, a period of developmental regression ensues in which the child loses all acquired milestones and is minimally interactive, with blindness, deafness, and dysphagia. Seizures develop as gray-matter loss progresses. Cherry-red spot maculae are often visualized, but, importantly, absence of this finding does not rule out the disorder. In

affected children, aspiration pneumonia is the usual reason for death, typically before age 3 years. Intermediate and attenuated forms of these diseases also exist, with disease onset in adolescence or adulthood and manifesting with ataxia, dysarthria, movement disorder, and even isolated psychiatric symptoms such as psychosis or bipolar disease. Although Tay–Sachs disease is well known as a disorder that affects people of European Jewish descent, premarital testing has considerably reduced the prevalence of the disorder in this population; it also occurs with higher frequency in French Canadians of Quebec, Old Order Amish of Pennsylvania, and Cajuns of southern Louisiana. Like G<sub>M1</sub> gangliosidosis, intracerebroventricular gene therapies are currently being investigated.

### $\alpha$ -Galactosidase a deficiency (Fabry Disease)

$\alpha$ -Galactosidase A deficiency (Fabry disease) is an X-linked LSD caused by deficiency in  $\alpha$ -galactosidase A, which removes terminal galactose from various galacto-glycolipids, such as globotriaosylceramide (Gal-Gal-Glu-Cer) and blood group B antigen. Typical presenting symptoms are burning pain in the hands and feet, called acroparesthesia, which is often exacerbated by temperature; reduced sweating; gastrointestinal pain; and diarrhea (Rombach et al., 2014). Although hemizygous males tend to have more severe symptoms with onset between the ages of 5 and 10 years, heterozygous females are often equally symptomatic even with random X-inactivation. Progression of systemic glycolipid storage leads to worsening hypertrophic cardiomyopathy, myocardial microvascular ischemia and scarring, increased risk of cerebrovascular ischemia, proteinuria, and loss of renal filtration. Strokes in Fabry disease can be either ischemic or hemorrhagic, involve either the carotid or vertebrobasilar vasculature, and typically affect small vessels. Enzyme replacement therapy with recombinant  $\alpha$ -galactosidase (Agalsidase alfa, Shire; Agalsidase beta, Genzyme-Sanofi) can halt or slow loss of creatinine clearance if initiated before onset of significant renal disease; the enzyme can also reduce cardiomyopathy provided it is started before development of cardiac fibrosis. Small molecule therapy to increase endogenous enzymatic activity in patients with specific missense *GLA* mutations is being investigated. Adjunctive therapy for treatment of neuropathic pain, proteinuria, and cardiomyopathy is often required.

### $\beta$ -D-Glucosidase Deficiency (Gaucher Disease)

Gaucher disease, caused by a deficiency in  $\beta$ -D-glucosidase or glucocerebrosidase, was one of the first lysosomal storage conditions to have its enzymatic deficiency elucidated. The enzyme removes glucose from glucosylceramide, the final glycolipid in ganglioside catabolism. Like most lysosomal storage disorders, Gaucher disease manifestations range in severity from an acute "type II" infantile-onset form, to an intermediate "type III" form, to the most common "type I" or "nonneuronopathic" form. Patients with type I disease can present at almost any age, typically with hepatosplenomegaly and thrombocytopenia. Other presentations include osteonecrosis of the femoral head and painful lytic bone lesions. In addition to typical type I symptoms, infants with type II Gaucher disease demonstrate ophthalmoplegia, dysphagia, and other bulbar palsies, whereas type III patients typically have some degree of static cognitive impairment. Type I patients have a higher relative risk of multiple myeloma (5.9 $\times$ ) and hematologic (1.23 $\times$ ) malignancies, although the overall absolute risk of malignancy still remains low. In addition, type I patients and carriers have a higher risk of developing Parkinson's disease (4.7% risk to develop Parkinson's by age 60 for patients, 1.5% for carriers, and 0.7% for noncarriers). Three forms of enzyme replacement therapy (Imiglucerase, Genzyme-Sanofi; Velaglucerase alfa, Shire; and Taliglucerase alfa, Protalix BioTherapeutics) and two forms of substrate reduction therapy (Miglustat, Actelion Pharmaceuticals; Eliglustat, Genzyme-Sanofi) exist for the treatment of nonneurologic manifestations of Gaucher disease.

### Sphingomyelinase Deficiency (Niemann–Pick Disease Types a and B)

Lysosomal acid sphingomyelinase deficiency results in types A and B Niemann–Pick disease (NPA and NPB, respectively). Undegraded sphingomyelin accumulates primarily in CNS neurons and reticuloendothelial cells. Collectively, the prevalence of the disorders is 1 in 250,000 live births; NPA is seen

more frequently in the Ashkenazi Jewish population, with an incidence of 1:40,000 live births, whereas NPB is more common in individuals of Northern African descent. NPA is characterized by neonatal onset hepatosplenomegaly, thrombocytopenia, neurodegeneration beginning in the first year of life, pulmonary infiltrative disease, and early death before age 3 years. NPB has a more variable presentation, but age of onset is typically in later childhood or adulthood. Primary symptoms are related to hepatosplenomegaly and impaired pulmonary function as a result of accumulation of sphingomyelin in reticuloendothelial and pulmonary tissues. Both disorders may have macular cherry-red spots. Intravenous recombinant human acid sphingomyelinase has been investigated for treatment primarily for NPB, but administration of the enzyme must be closely monitored because ceramide, a degradation product of sphingomyelin, has potent proinflammatory properties.

### Niemann–Pick Disease Types C and D

Originally named because affected patients demonstrated hepatosplenomegaly and sphingomyelin accumulation, but were ultimately not linked to the acid sphingomyelinase gene, these two disorders are now known to be caused by deficient lysosomal transport of unesterified cholesterol. Free cholesterol accumulation in lysosomes and cell membranes results in secondary impairment of other lysosomal functions, such as sphingomyelin catabolism. Mutations in the *NPC1* gene are responsible for about 95% of cases, and the remainder result from recessive *NPC2* mutations. Affected individuals of French-Canadian descent from Nova Scotia were termed to have Niemann Pick D (NPD) disease, but eventually found to have *NPC1* mutations. NPC/D clinical manifestations are extremely broad and can present as early as the neonatal period with hepatosplenomegaly and cholestatic jaundice or anytime afterward with a combination of vertical supranuclear gaze palsy, dysarthria, dysphagia, ataxia, dystonia, seizure disorder, or developmental delay. Pulmonary parenchymal disease leading to childhood-onset respiratory failure and death typically affects patients with *NPC2* mutations. The neurologic disease is progressive, and in later stages it is often accompanied by dementia. Miglustat (Actelion Pharmaceuticals), an inhibitor of glycosphingolipid synthesis, may stabilize or slow disease progression, but it is not approved for use in NPC patients in the United States. Therapy with cyclodextrins, circular glucose oligomers that remove cholesterol from cell membranes, is being investigated for NPC disease, as are carbamazepine and histone deacetylase inhibitors.

### Acid Ceramidase Deficiency (Farber Disease)

Acid ceramidase deficiency (Farber disease), a lysosomal storage disorder caused by deficiency of acid ceramidase, is classically known for a triad of characteristic subcutaneous lipogranulomas, hoarseness, and swollen, painful arthropathy. Patients with this canonical form also demonstrate hepatosplenomegaly, developmental delay, and pulmonary infiltration. There are also a number of other described "subtypes" of Farber disease, but the very small number of cases in each makes generalizations difficult. However, recessive mutations in the acid ceramidase gene were recently linked to a rare disorder with childhood-onset combined spinal muscular atrophy and progressive myoclonus epilepsy. Affected patients also developed cognitive regression, dysphagia, and difficulty managing airway secretions. Hematopoietic stem cell transplant (HSCT) has been reported as a possible therapy for affected patients without neurologic involvement, and recombinant enzyme replacement therapy is also being developed.

## Galactosylceramidase Deficiency (Krabbe Disease)

The galactosylceramidase enzyme functions to remove galactose from galactosylceramide, galactosylsphingosine, and other galactolipids. Both galactosylceramide and galactosylsphingosine have potent proinflammatory effects, and the latter molecule causes oligodendrocyte and Schwann cell death. The symptoms of Krabbe disease correspond to the toxic effects of these lipids. Brain magnetic resonance imaging (MRI) of affected infants demonstrates contrast-enhancing inflammatory demyelination. Peripheral demyelination, delayed conduction velocities, and combined motor and sensory neuropathy are evident on nerve conduction studies even at 1 day of age. Infants with early-onset, severe Krabbe disease are irritable, arching, and even opisthotonic, and they are sometimes misdiagnosed with severe gastroesophageal reflux. Progression of demyelination results in developmental regression. Eventually dysphagia and poor airway clearance lead to aspiration pneumonia. Data regarding treatment are sparse but indicate that HSCT must be performed before 1 month of age to prolong life span, although peripheral neuropathy and posttransplantation gross motor outcomes may continue to worsen in survivors. Transplantation performed following onset of clinically evident symptoms is not effective at preventing central demyelination and regression. Atypical, later-onset variants of Krabbe disease also exist and may be more amenable to treatment with HSCT.

## Arylsulfatase a Deficiency (Metachromatic Leukodystrophy)

Metachromatic leukodystrophy (MLD) is an autosomal-recessive disorder caused by insufficient enzymatic activity of arylsulfatase A. This enzymatic defect results in moderate to massive accumulation of sulfated glycolipids, in particular, galactosylceramide-3-O-sulfate (sulfatide), in the brain, peripheral nervous system, and kidneys. Although the age of onset and dynamics of disease progression vary, MLD is primarily characterized by progressive neurodegeneration of the central and peripheral nervous systems. The severe form of the disease presents before the fourth birthday with hypotonia, muscle weakness, areflexia, and peripheral neuropathy. Psychomotor regression is rapid, leading to loss of ambulation, vision, hearing, and swallow ability. Death from aspiration pneumonia typically takes place about 5 years from symptom onset. Symptoms of attenuated, later-onset forms of MLD are characterized by ataxia, gait disturbance, and deterioration of fine motor function. There are also psychiatric presentations of MLD manifesting as personality changes, onset of bizarre behaviors, or frank psychosis. The attenuated forms of MLD also progress toward loss of cognition and function. Early HSCT at a presymptomatic stage for infantile-onset MLD is completely ineffective and is not recommended. When performed for attenuated disease, HSCT before onset of clinical symptoms is able to stabilize cerebral demyelination and arrests or slows disease progression. Peripheral demyelination, however, is not addressed by HSCT, and survivors develop neuropathic motor deficits later on. Intrathecal administration of recombinant human arylsulfatase A enzyme is being investigated as a therapeutic option for MLD.

## Mucopolysaccharidoses

The mucopolysaccharidoses (MPSs) are a family of inborn errors of metabolism characterized by deficiencies in enzymes that catabolize glycosaminoglycans (GAGs), highly polar polymers of uronic acid-substituted acetylhexosamine disaccharides (Wraith, 2013). Although symptoms of each individual MPS type vary according to the type of GAG accumulated,

in general MPS disease manifestations are multisystemic in nature because of the near-ubiquity of GAGs throughout the body. Severe and attenuated forms exist, both of which are associated with similar but varying degrees of somatic involvement, whereas primary neurodegeneration is encountered mainly in severely affected patients. The following discussion summarizes the potential disease symptoms.

## Neurologic Manifestations

Patients with certain MPS types have progressive neurocognitive deterioration. Early neurologic signs of disease, manifest as gross motor or speech delay, may be evident in late infancy or later. Patients may initially be suspected to have an autism spectrum disorder. Those with MPS III (Sanfilippo syndrome) and severe forms of MPS I, II, and VII typically develop neurodegeneration. This may be partly attributable to the buildup of heparan sulfate, a GAG localized mostly within the CNS and linked possibly to neuroinflammation. Although the onset and rate of disease progression vary, patients with severe MPS I (Hurler syndrome), who have near complete deficiency of  $\alpha$ -L-iduronidase enzyme, and MPS IIIA, who lack sulfoglucosamine sulfohydrolase, have earlier childhood onset and more rapid deterioration. Patients with more attenuated versions of MPS I, II, and VII may have varying degrees of cognitive impairment, which is nonprogressive; this is true as well for some patients with MPS IV and VI.

Secondary neurologic problems may also develop as a consequence of "communicating" hydrocephalus, caused by GAG accumulation in the arachnoid granulations impairing the normal reuptake of cerebrospinal fluid. Additionally, GAG storage in the meninges ("pachymeningitis") and soft tissues surrounding the upper cervical vertebrae can lead to spinal cord compression, typically at the craniocervical junction. Myelopathy may also develop in patients with odontoid hypoplasia at risk for cervical subluxation, and carpal tunnel syndrome is also often encountered.

## Ophthalmologic Manifestations

MPS types I, IVA, VI, and VII may develop progressive clouding of the corneas. Early in the disease, this is subtle and appears as a haze that is evident only upon examination with a direct light source. Advanced corneal clouding will disrupt visual acuity and may require corneal transplantation. Glaucoma, as a result of GAG storage in the canals of Schlemm and impaired anterior chamber fluid drainage, develops in older MPS patients.

## Otolaryngologic Manifestations

Many affected patients experience recurrent otitis media requiring placement of middle ear drainage tubes. Caregivers often report chronic rhinorrhea and nasal congestion, often predating the diagnosis of MPS. Airway GAG storage, together with macroglossia and abnormal craniocervical bone structure, contribute to the high frequency of obstructive sleep apnea in these patients. Progression of airway compromise, airway floppiness, risk of cervical spinal cord compression with neck hyperextension, and reduced mandibular opening result in very challenging anesthesiologic issues for MPS patients. Intubations are often performed videoscopically and/or nasotracheally by otolaryngologists or anesthesiologists in operating rooms, and patients with severe airway compromise often require tracheostomies.

## Cardiovascular Manifestations

Cardiac hypertrophy and progressive valve thickening and dysfunction (typically involving the mitral and aortic valves)

are common manifestations of all MPSs. Before treatment, myocardial infarction from coronary artery GAG accumulation and stenosis was a common cause of death for patients with MPS I. Long-term follow-up in the posttreatment era indicates that cardiovascular MPS manifestations continue to progress despite “successful” treatment with either stem cell transplantation or enzyme replacement therapy. MPS patients continue to have arterial storage, as evidenced by increased intimal-medial thickness and severely reduced arterial compliance.

### Gastroenterologic Manifestations

GAG storage in the liver and spleen resulting in hepatosplenomegaly is a cardinal sign of nearly all MPS types. Inguinal, umbilical, and hiatal hernias (with resultant gastroesophageal reflux) are extremely common, possibly as a result of increased intraabdominal pressure from enlarged viscera.

### Orthopedic Manifestations

Most bones develop from endochondral ossification of growth plate cartilage. Because GAGs are a primary component of cartilage, nearly all patients with MPS develop bony dysplasia (“dysostosis multiplex”) of varying severity, as cartilaginous GAG storage impairs chondrocytic proliferation and promotes articular inflammation. The skeletal dysplasia typically is worse in MPS IVA and VI and severe forms of MPS I, II, and VII, and it is most attenuated in MPS III. Indeed, subtle somatic involvement in those with MPS III (Sanfilippo syndrome) may lead to delayed diagnosis. Patients usually have disproportionately short stature, and those with MPS IVA have a short trunk and prominent pectus deformity. Craniofacial structure is altered, resulting in nasal bridge depression and nasopharyngeal airway problems. Vertebral body dysplasia, resulting in platyspondyly (flattened, wafer-like vertebrae) or hook/wedge-shaped vertebrae, often manifests early in infancy or childhood as kyphosis (“gibbus” deformity). Polyarticular joint contractures are extremely common and significantly impair activities of daily living. GAG-induced joint inflammation results in adolescent-onset degenerative joint disease, which is most prominent in the hip and spinal facet joints.

### Treatment

Regulatory-approved enzyme replacement therapies currently exist for MPS types I, II, IVA, and VI. As with enzyme-replacement therapy (ERT) for other LSDs, intravenous administration of the cognate exogenous recombinant enzyme relies on cellular uptake via cellular mannose-6-phosphate receptors. HSCT can also be performed for the same MPS types, but it is typically undertaken only for severe MPS I because of the CNS impermeability of intravenous ERT. HSCT has not been shown to alter ultimate neurologic prognosis in patients with MPS II and III, although it continues to be performed primarily in Japan for severe MPS II patients.

Although these treatments usually normalize hepatosplenomegaly and increase patient endurance, each share significant limitations as a result of insufficient access of circulating enzyme to refractory tissues such as bone. Orthopedic disease continues to be extremely common in ERT- and HSCT-treated MPS I patients. Surgeries are often required in treated MPS patients to address carpal tunnel syndrome, degenerative joint disease, and spinal cord compression. It is likely that the avascularity of growth plate and articular cartilage limits enzyme delivery to these tissues. Corneal clouding continues to progress, leading to eventual need for corneal transplant surgery in some patients. Cardiovascular disease also progresses despite treatment, likely because the dense network

of connective tissue in the endocardium, heart valves, and vascular intima prevents enzyme access to cardiovascular parenchyma.

Multiple clinical trials for neurologic MPS disease are currently under way to bypass the blood–brain barrier (BBB) completely, through intrathecal ERT in MPS I, II, IIIA, and IIIB, and through protein-tagged enzymes that may allow for intravenous delivery of the enzyme and its subsequent BBB transcytosis and delivery to the CNS in MPS I and II. Clinical trials are also in progress to assess the efficacy of intravenous ERT for MPS VII, and gene therapy is under consideration.

### Oligosaccharidoses and Mucopolidoses

Oligosaccharides are short glycan chains released from hydrolysis of glycosylated proteins. Conceptually, oligosaccharidoses are lysosomal storage disorders involving oligosaccharide degradation following detachment from proteins (Figure 41-2), whereas congenital disorders of glycosylation can be thought of as inborn errors of oligosaccharide synthesis, modification, and attachment to proteins.

### Mannosidoses

Within the oligosaccharide glycan, there are at least two mannose  $\alpha$ -linkages and one  $\beta$ -linkage. Distinct lysosomal enzymes,  $\alpha$ -mannosidase and  $\beta$ -mannosidase, are required to hydrolyze the corresponding linkages. Deficiencies of each enzyme result in unique symptoms, despite their closely related functions and substrates.

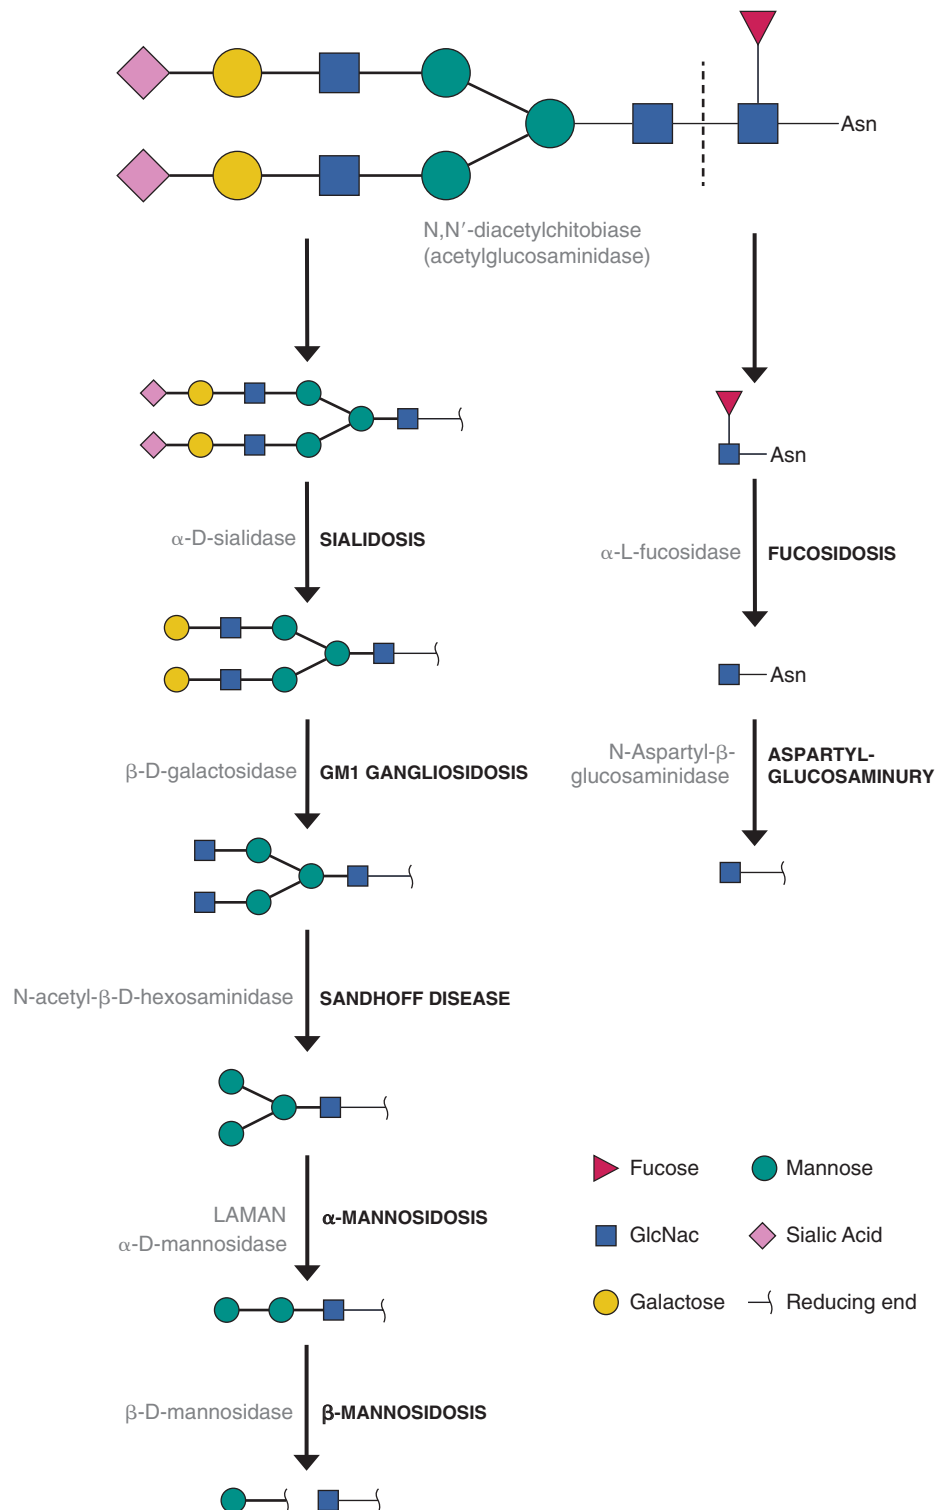

Individuals with  $\alpha$ -mannosidosis have distinct facies notable for macrocephaly, broad prominent forehead, depressed nasal bridge, prognathism, and macroglossia (Govender and Mubaiwa, 2014). Orthopedic manifestations include osteopenia, genu valgum, joint contractures, scoliosis, and hip dysplasia. Neurologic involvement is common because nearly all patients have some degree of moderate to severe intellectual disability and hearing loss, with varying degrees of ataxia, dysarthria, and dysmetria. Depression, anxiety, or hallucinations may occur in response to emotional or physical stressors. In contrast to other LSDs, the natural history of neurologic disease appears to be nonprogressive, although the duration of follow-up is up to 2 years in most reports, and severely affected patients have early childhood mortality. An intravenous ERT is being developed for  $\alpha$ -mannosidosis.

There is significant clinical heterogeneity in the clinical manifestations of patients with  $\beta$ -mannosidosis, but most affected patients have intellectual disability and behavioral manifestations such as hyperactivity, aggression, or social withdrawal. They have a higher risk of developing seizures, and many have recurrent respiratory infections. Cutaneous angiokeratomas resembling those of Fabry disease are often seen. Recent exome-based studies have identified  $\beta$ -mannosidase deficiency in patients with “nonclassical” symptoms such as spinocerebellar ataxia and neonatal-onset refractory seizure disorder.

### Fucosidosis

Deficiencies of  $\alpha$ -L-fucosidase manifest with a broad range of severity. The early-childhood-onset form features neurodegeneration, seizures, extrapyramidal symptoms, hepatosplenomegaly, and bony dysplasia resembling the MPS diseases. Attenuated forms of disease demonstrate mild to moderate developmental delay and coarse facial features. Genotype-phenotype correlations are poor; severe and attenuated siblings have been reported in multiple kindred. Many patients have cutaneous angiokeratomas reminiscent of those seen in Fabry

**Figure 41-2.** Pathway for the catabolism of the N-linked glycan oligosaccharide, enzymes involved, and disorders corresponding with each enzyme deficiency. (With permission from Bonesso L, Piraud M, Caruba C, et al, *Fast urinary screening of oligosaccharidoses by MALDI-TOF/TOF mass spectrometry*. *Orphanet J Rare Dis*. 2014 Feb 6;9:19.)

disease patients. Brain MRIs of affected patients reveal a very characteristic pattern of T1-weighted hyperintensity and pronounced T2-weighted hypointensity in the globus pallidus, accompanied by generalized subcortical and deep white-matter hypomyelination (Figure 41-3). Presymptomatic HSCT

has been performed in a handful of cases. Although cognitive status stabilized posttransplant, it is unclear if this took place as a result of the intervention or, given the intrafamilial variability of the condition, included patients with attenuated disease and a slower disease progression.

**Figure 41-3.** Classic MRI findings in fucosidosis. T1-weighted axial (A), T2-weighted axial (B), and coronal (C) MRI of the brain. Bilateral globi pallidi (arrows) show hyperintensity on T1-weighted images and marked hypointensity on T2-weighted images. In addition, there is diffuse symmetric hyperintensity of bilateral subcortical and deep white matter on T2-weighted images with normal appearance on T1-weighted images consistent with hypomyelination. (With permission from Jain P, Ramesh K, Mohamed A, et al, *Neurology*. 2012 Jan 31;78[5]:e33.)

### Aspartylglycosaminuria

Deficiency of aspartylglycosaminidase, whose function is to detach the oligosaccharide from the asparagine residue of the glycoprotein, is a disorder more prevalent in Finns that results in slowly progressive intellectual degeneration that begins in childhood and continues throughout adolescence and adulthood. Early symptoms are hypotonia and increased propensity for recurrent acute otitis media and upper and lower respiratory tract infections. Facial features coarsen with time. Adults with this condition are invariably nonverbal and suffer early mortality in their fourth to fifth decade. Brain MRI displays reduced T2 signal intensity in the thalamus, especially the pulvinar region, with poor gray-/white-matter differentiation and atrophy of the cerebrum, cerebellum, and corpus callosum.

### Sialidosis (Mucopolipidosis I)

Numerous different presentations can be seen in sialidosis, which is also known as neuraminidase deficiency and cherry-red spot myoclonus syndrome. The latter presentation is an attenuated form of the disease that does not significantly affect intelligence or result in early mortality; it presents in adolescence or early adulthood with myoclonus and reduced visual acuity. Affected patients with cherry-red spot myoclonus syndrome eventually lose the ability to ambulate independently because the myoclonus increasingly impairs walking. Sialidosis is also one of the lysosomal storage disorders that causes non-immune hydrops fetalis. This can be severe enough to cause intrauterine death, but even the neonates who survive to be born have severe respiratory distress and hepatosplenomegaly and do not live long. There are also “intermediate” forms of the disease without hydrops, which present in infancy or early childhood with developmental delay, coarse facial features, organomegaly, and skeletal dysplasia. These patients usually develop macular cherry-red spots and myoclonus. Some have developed gram-quantity proteinuria and hypoalbuminemia, with subsequent ascites and peripheral edema. Life expectancy with intermediate sialidoses is also reduced. Currently, there are no treatments available or in preclinical development.

### Galactosialidosis

One of the few LSDs whose symptoms reflect a simultaneous dysfunction of two enzymes, galactosialidosis is caused by deficiency of cathepsin A, also known as lysosomal protective protein. Although cathepsin A has lysosomal protease

domains, it also forms a complex with neuraminidase and  $\beta$ -D-galactosidase. Without cathepsin A, the latter two enzymes are rapidly degraded, resulting in a disorder that combines features of both sialidosis and  $G_{M1}$  gangliosidosis (Caciotti et al., 2013). A neonatal lethal form resembles the severe form of sialidosis, with the development of fetal hydrops, ascites, macular cherry-red spots, and hepatosplenomegaly. A later infantile form develops cherry-red spots, organomegaly, coarse features, sensorineural hearing loss, skeletal dysplasia, and cardiac valvular thickening in the first year of life. Most of the reported patients with the juvenile/adult form are Japanese, and presentation includes intellectual disability, ataxia, myoclonus, very slow neurocognitive decline, and angiokeratomas.

### Schindler–Kanzaki Disease

Schindler–Kanzaki disease is a very rare condition, with less than 15 patients identified, and is characterized by oligosaccharidosis, attributed to  $\alpha$ -N-acetylgalactosaminidase deficiency. The clinical phenotype is somewhat unclear. The original siblings described with Schindler disease had early onset neurodegeneration, seizure disorder, and hypotonia leading to spastic quadriplegia, cortical blindness, and loss of interaction. Elevated N-acetylgalactosaminyl oligosaccharide excretion and neuroaxonal spheroids were noted. Similar clinicopathologic findings were reported in a second kindred; however, subsequent patients have been identified with neither neurodegeneration nor neuroaxonal dystrophy. Affected patients have a variety of symptoms, including “autism” without facial dysmorphism, neurologic findings, or organomegaly; hepatosplenomegaly; cardiac valvular disease; and infantile death. Some patients have mild psychomotor retardation associated seizures. Because the three original Schindler patients with the infantile neuroaxonal dystrophy form were from two distantly related, consanguineous German kindred, and the gene associated with infantile neuroaxonal dystrophy is immediately proximal to the Schindler–Kanzaki gene, it is possible that the severe expression is a result of the families having two monogenic recessive conditions.

### Other Lysosomal Storage Disorders

#### Mucopolipidosis II/III

Two genes, *GNPTAB* and *GNPTG*, encode subunits of the N-acetylglucosamine-1-phosphotransferase enzyme complex,

which participates in the formation of the crucial mannose-6-phosphate sugar residue on the glycan complexes of proteins destined for transport to lysosomes. Deficiencies of any subunit result in absent or reduced mannose-6-phosphate, causing lysosomal enzymes to be mistargeted for secretion into plasma. Various substrates accumulate because cells lack the proper intralysosomal hydrolases. Molecular sequencing establishes the diagnosis, but, biochemically, patients have markedly increased plasma levels of lysosomal enzymes (normally measured in leukocytes) and have elevated urinary oligosaccharide excretion.

Mucopolipidosis II, historically known as I-cell disease, is the severe form of the disease that resembles rapidly progressive MPS type I. Affected neonates are noticeably coarse with gingival hypertrophy. Spinal kyphosis and other features of dysostosis multiplex are already evident at birth. Growth typically stops by the second birthday. Gross motor development is impaired. Cognitive development, although blighted, allows for the children to interact and have limited communication. Cardiorespiratory failure is the usual cause of death.

Mucopolipidosis III, historically known as pseudo-Hurler dystrophy, is an attenuated form of the disease. Age of onset is typically before 3 years, when slowing of growth, joint stiffness, bone pain, and coarsening of facial features becomes evident. Short stature, dysostosis multiplex, bilateral hip dysplasia, and painful ambulation become prominent in the first decade of life. Intelligence ranges from mild impairment to normal. Progressive restrictive lung disease, mitral insufficiency, and aortic regurgitation cause left ventricular enlargement and heart failure, the usual causes of death in early to middle adulthood.

#### Mucopolipidosis IV (ML IV)

Unlike most of the other LSDs, ML IV is not a deficiency of a lysosomal hydrolase. The missing protein, mucopolipin-1, is involved in lysosomal substrate transport and exocytosis. Storage granules are evident in skin or conjunctival biopsies. Severe psychomotor delay develops in the first year of life; patients are rarely able to speak or ambulate, and dysphagia is common. Initial neonatal hypotonia eventually evolves into a static, spastic quadriplegia (Wakabayashi et al., 2011). In fact, this condition should be suspected in any child with a cerebral palsy diagnosis, especially if there is concomitant corneal clouding or retinal dystrophy. Ophthalmologic disease is progressive, and by adolescence patients with classical ML IV, most of whom are of Ashkenazi Jewish descent, have severe visual impairment. Achlorhydria, hypergastrinemia, and iron deficiency are common chemical markers of ML IV. No specific treatment exists for this condition.

#### Cystinosis

Cystinosis is a lysosomal storage disorder like ML IV, but the deficient protein is a transporter rather than a hydrolase. The cystinosis protein transports cystine (the dibasic dimer of the amino acid cysteine) into the cytosol from the lysosome. Intralysosomal cystine crystal storage, caused by cystinosis deficiency, results in a disorder with a range of severity. The classical nephropathic form causes neonatal-onset renal Fanconi syndrome, with resultant hyponatremic, hypokalemic metabolic acidosis, glycosuria, and hypophosphatemic rickets (Ivanova et al., 2014). Consequently, infants have polydipsia, polyuria, and very short stature. Intelligence is not affected. Deposition of cystine crystals in the cornea may result in photophobia and, ultimately, blindness. Untreated, affected children die before the second decade of life because of progressive renal failure. Cystinosis is currently treated with enteral and ophthalmic instillation of cysteamine, which

enables cysteine to exit the lysosome using a different transporter. However, cysteamine is not well tolerated because of its foul odor and side effect of gastrointestinal irritation. Although an enteric-release form has been developed, investigations are under way to determine whether autologous gene-transfer HSCT can effectively treat the condition.

### Neuronal Ceroid Lipofuscinoses

The neuronal ceroid lipofuscinoses (NCLs) are a group of lysosomal storage disorders united by their progressive, neurodegenerative course, characterized by visual loss, seizures, and cognitive dysfunction. Despite the overlap in clinical manifestations, there is broad genetic heterogeneity, and the cellular roles of the cognate proteins remain incompletely defined. Interestingly, subcellular localization for the NCL-associated proteins have also been diverse, localized mostly in lysosomes (CLN1, CLN2, CLN3, CLN5, CLN7, CLN10, CLN12, and CLN13) but also in the endoplasmic reticulum (CLN6 and CLN8) or in the cytosol associated with vesicular membranes (CLN4 and CLN14) (Cárcel-Trullols et al., 2015).

Although individual NCL subtypes vary according to age of onset and initial symptoms, the ultimate prognosis for all clinical variants has not changed significantly, and development of treatment and characterization of disease pathogenesis severely lags behind the identification of new gene loci.

Identification of underlying gene defects has not been concordant with prior nomenclature for NCLs, which classified the various subtypes according to age of onset (e.g., infantile-onset NCL [INCL], late-infantile-onset NCL [LINCL], juvenile-onset NCL [JNCL], adult-onset NCL [ANCL]). Currently, there are 14 distinct NCL gene loci, with up to 7 shown to cause LINCL phenotypes. Moreover, four of these seven LINCL loci have also been identified among ANCL cases, whereas three distinct loci have been associated with ANCL phenotypes. This review focuses primarily on the classical NCL gene loci and phenotypes. For information about the more recently described variant loci, please consult the online chapter version.

#### Ophthalmologic Manifestations

Many of the NCLs demonstrate a characteristic progressive decline in visual acuity. Changes are detected by electroretinography (ERG) before noticeable decline in vision. Depending on the subtype, the first initial observation on ERG may be an abnormal cone/rod downstream signaling in the case of CLN1 (caused by protein palmitoyl thioesterase deficiency [PPT1], previously known as INCL); delayed and reduced cone amplitudes for CLN2 (caused by tripeptidyl peptidase deficiency [TPP], previously known as classical LINCL); or absent rod and reduced cone amplitude responses for CLN3 (caused by Battenin deficiency [CLN3], previously known as classical JNCL).

CLN1 and CLN2 patients typically develop reduced visual attention after onset of neurologic symptoms, whereas CLN3 patients typically manifest first with reduced nighttime visual acuity that then progresses to daytime peripheral vision loss. Eventually, patients with CLN types 1 through 3 become completely blind, with nonresponsive ERGs. Optic nerve pallor, attenuation of retinal vasculature, or pigmentary retinopathy may be visualized on dilated ophthalmologic examination.

Before the availability of genetic testing for NCL, examination of conjunctival biopsies for presence and morphology of cellular inclusion bodies was utilized to identify NCL subtype. With the identification of underlying gene defects, the same

morphology of inclusion body was often found in different subtypes. Furthermore, multiple inclusion body types could be found within a single CLN genotype. A summary of these ultrastructural abnormalities, together with causative CLN genes, is presented in Table 41-2.

### Neurologic Manifestations

Seizures and neurodegeneration are clinical features shared by nearly all of the NCLs. Affected patients develop mixed generalized tonic-clonic, partial, and absence seizures, with subsequent development of myoclonus. Age of seizure onset overlaps somewhat, but generally follows NCL subtype, with seizures typically beginning in the first 2 years of life for CLN1, 2 to 4 years of life for CLN2, and in the second decade of life for CLN3. Seizures in cathepsin D-deficient NCL have been observed in two neonates, leading to its designation as “neonatal NCL.” However, cathepsin D mutations have also been described in two families presenting during school age (8–15 years) with ataxia, cerebellar atrophy, pigmentary retinopathy, and neurodegeneration, highlighting the phenotypic heterogeneity of these disorders.

Most classic patients with the “ANCL” phenotype, manifesting with ataxia, progressive dementia, seizures, and myoclonus after age 30 years (previously referred to as Kufs syndrome), have been shown to have recessive *CLN6* mutations. Recessive mutations in cathepsin F (*CTSF*) have been found in some variant ANCL patients without seizures, but with more prominent behavior abnormalities, movement disorders, and dementia. Mutations that confer residual protein function account for survival past childhood.

Neurodegenerative disease in CLN types 1 through 3 is often preceded by a period of developmental delay or

cognitive stagnation. Any cognitive and verbal abilities are pruned and eventually lost, as are ambulation and other motor skills. Dysphagia and difficulty with management of oral secretions leads to cachexia and recurrent aspiration pneumonia. Behavioral abnormalities may be present in CLN3 disease, and they may be more prominent in the *CTSF*-ANCL phenotype.

Brain MRIs demonstrate progressive loss of cerebral and cerebellar gray and white matter that roughly correlates with progression of seizure severity, neurodegeneration, and ataxia. Pneumonia, sepsis, and seizure-related complications are the usual causes of death for CLN patients.

### Diagnostic Testing

Quantitative enzymatic testing can be performed to assay for deficiencies of PPT1 (CLN1), TPP (CLN2), CTSD (CLN10), and *CTSF* (CLN13). If these enzymatic activities are normal, then targeted or next-generation sequencing of the remaining CLN loci can be performed, depending on the ethnicity of the patient. Neutrophil inclusion bodies can be seen in, but are not specific for, CLN3 disease. Recessive mutations in *CLN5* are responsible for most of the “INCL” presentations in patients of Finnish descent. Another NCL that occurs more frequently in those of Finnish descent is “Northern epilepsy,” caused by *CLN8* mutations and characterized by onset of seizures between ages 5 and 10 and followed by intellectual decline, ataxia, and adult-onset vision loss.

### Treatment

Currently, there are no effective therapeutic options for any of the NCLs. Supportive care is recommended to reduce the

**TABLE 41-2** Neuronal Ceroid Lipofuscinosis

*Listing of Neuronal Ceroid Lipofuscinosis Forms, Including Gene Locus, Type of Protein Product, and Morphology of Storage Material Visualized on Electron Microscopy*

Clinical Form	Gene	Locus	Gene Product and Localization	Electron Microscopy of Storage Material
Congenital	<i>CLN10</i> ( <i>CTSD</i> )	11p15.5	Cathepsin D	Lysosome
Infantile and juvenile variant	<i>CLN1</i> ( <i>PPT1</i> )	1p34.2	Lysosomal palmitoyl-protein thioesterase	Granular osmiophilic deposits
Classic, late infantile, and juvenile variant	<i>CLN2</i> ( <i>TPP1</i> )	11p15.4	Lysosomal tripeptidyl peptidase	Curvilinear/mixed
Infantile, Finnish variant	<i>CLN5</i>	13q22.3	Novel 407 AA lysosomal membrane protein	Fingerprint, curvilinear, rectilinear complex
Late infantile, Costa Rican variant	<i>CLN6</i>	15q23	Novel 311 AA endoplasmic reticulum membrane protein	Curvilinear, fingerprint, rectilinear
Late infantile, Turkish variant	<i>CLN7</i> ( <i>MFSD8</i> )	4q28.2	Membrane protein	Fingerprint/mixed
Late infantile, rare variant	<i>KCTD7</i>	7q11.21	289 amino acid cytosolic protein connected with ubiquitin ligase complex	Fingerprint, granular osmiophilic deposits, none
Classic, juvenile	<i>CLN3</i>	16p11.2	Lysosomal membrane protein (438 AA)	Fingerprint/mixed
Epilepsy with intellectual disability, Northern epilepsy	<i>CLN8</i>	8p23.3	286 AA endoplasmic reticulum membrane protein	Curvilinear or osmiophilic granular-like
Juvenile variant	<i>CLN1</i>	1p34.2	—	—
Juvenile variant	<i>CLN2</i>	11p15.4	—	—
Juvenile variant	<i>CLN9</i>	?	—	—
Kufs disease (adult variant)	<i>CTSD</i> , <i>PPT1</i> , <i>CLN3</i> , <i>CLN5</i> , <i>CLN6</i> , <i>CTSF</i> , <i>GRN</i>	Multiple	Multiple	Varies

impact of seizures, dysphagia, and aspiration pneumonia. Lamotrigine may be more efficacious with CLN3-associated seizures, but it may worsen CLN2-related seizures and myoclonus. Valproic acid (which can lead to sedation), clonazepam (sialorrhea), and carbamazepine and phenytoin (both associated with seizure exacerbation) are typically not well tolerated by patients with an NCL. HSCT has not been effective, nor was a trial of intracerebroventricular human embryonic stem cell injection. Enteral *N*-acetylcysteine and cysteamine administration to CLN1 patients prolonged the mean time to isoelectric electroencephalograms and reduced microscopic evidence of storage deposits, but patients continued to demonstrate progressive loss of cognitive and retinal function and failed to acquire developmental milestones. Currently active clinical trials for NCLs include intraventricular delivery of recombinant human TPP enzyme or intracerebral adeno-associated viral gene therapy for CLN2 and immunosuppressive mycophenolate mofetil treatment for CLN3 disease.

## HISTORY AND MITOCHONDRIAL GENETICS

Mitochondrial diseases represent one of the most exciting chapters of modern medicine. During the last half of the 19th century, scientists gradually recognized the presence of subcellular organelles that were termed *mitochondria* in 1898. The metabolic role of mitochondria in cellular function was defined by a series of observations during the early part of the 20th century: the cytochrome system and oxidation-reduction processes were described, the Krebs cycle was conceptualized, and later the phosphorylation of adenosine diphosphate to adenosine triphosphate was documented, together with the dependence of phosphorylation on oxygen consumption. By the middle of the 20th century, it was clear that the mitochondrion represented the intracellular domain for intermediary metabolism. In 1961 the chemiosmotic theory was proposed to explain the proton-motive force that facilitated the synthesis of adenosine triphosphate. In parallel with these biochemical observations, a series of ultrastructural studies characterized the four components of the organelle, including the outer mitochondrial membrane (OMM), the inner mitochondrial membrane (IMM), the intermembranous space (IMS), and the inner matrix compartment. Subsequent studies have demonstrated that the IMM is largely impermeable to molecules of all sizes, and special adaptive mechanisms are necessary for the translocation of metabolites from the IMS to the matrix. The protein importation process is energy-dependent and requires the macromolecules to be unfolded before traversing the mitochondrial membranes and refolded after entering the mitochondrial matrix.

Two important observations were made in 1963 that were central to the understanding of mitochondrial diseases. The first observation recognized the presence of intramitochondrial fibers with DNA characteristics, documenting DNA in mitochondria (mtDNA). The second observation described ragged-red fibers with abundant mitochondria in biopsied skeletal muscle.

Twenty-five years later, the era of “mitochondrial genetics” opened up with two seminal papers that introduced human diseases due to mutations in mtDNA. As all mtDNA is derived from the ovum, it is inherited exclusively from the mother—hence the terms *mitochondrial inheritance*, *maternal inheritance*, and *cytoplasmic inheritance*. These interchangeable terms describe a non-Mendelian pattern of inheritance that characterizes human diseases resulting from mtDNA mutations (Schon et al., 2012).

Each mitochondrion contains 2 to 10 copies of the mtDNA genome. Because cells have hundreds or thousands of mitochondria, more than 10,000 copies of mtDNA may exist in each cell. This genome is a small, double-stranded, circular molecule containing 16,569 base pairs; each molecule contains a light strand and a heavy strand, and each strand contains its own origin of replication (Fig. 42-1). Clear differences exist between the mitochondrial genome and the nuclear genome (Table 27-1). The mitochondrial genome contains no introns. The only noncoding region in mtDNA is the displacement loop (D-loop). The D-loop region contains 1000 base

pairs and is the site of origin for replication of the heavy strand and the promoter regions for both light and heavy strand transcription. Because the universal genetic code does not apply to mtDNA, the mitochondrial genome requires its own transcriptional and translational factors for synthesis of mitochondrial proteins. The mitochondrial genome contains 37 genes. Thirteen genes encode structural proteins in the respiratory chain. The mitochondrial genome also contains 24 genes for protein synthesis. These genes include two ribosomal RNAs (rRNAs) and 22 transfer RNAs (tRNAs). The mtDNA genes code for 13 messenger RNAs, and all 13 gene products are located in the respiratory chain (Fig. 42-1).

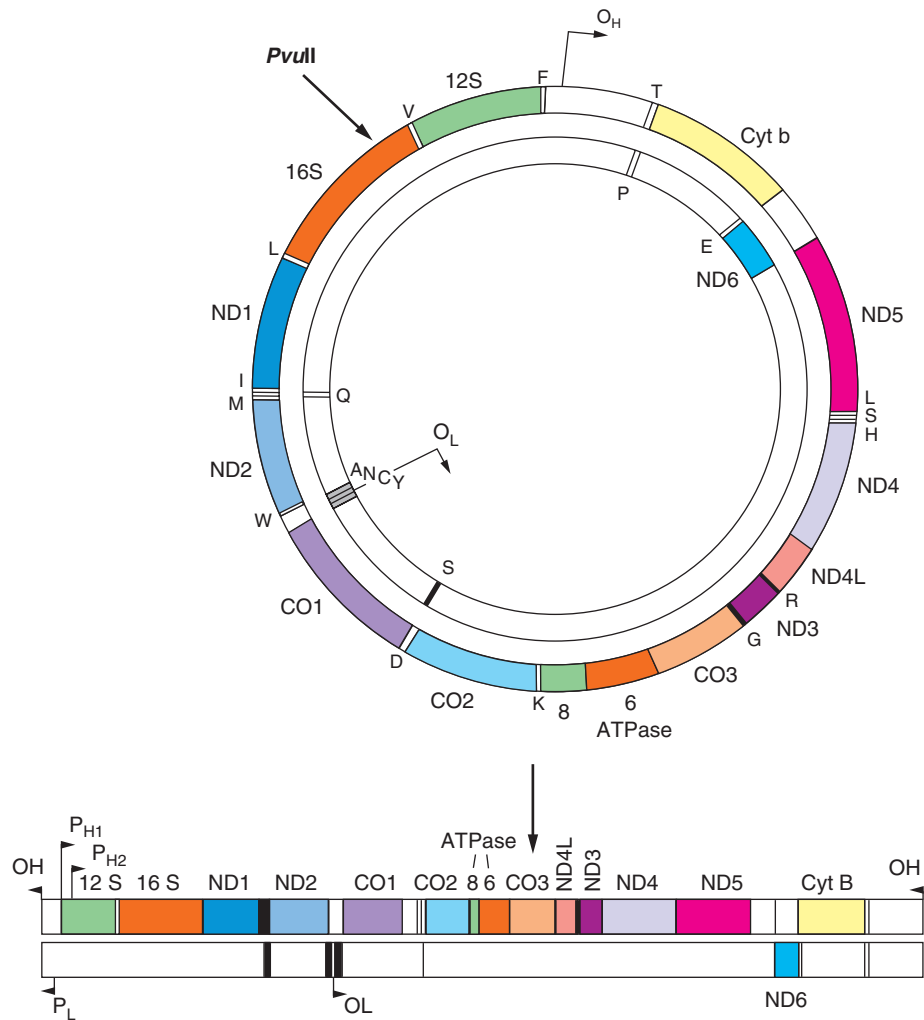

The normal mitochondrial genotype is considered *homoplasmic* if all mtDNA genomes are identical. Conversely, the genotype is *heteroplasmic* if the genomes represent a mixture of wild type and mutated type. The phenotype is determined by the proportion of mutated genomes. When this proportion exceeds a threshold, the biologic behavior of the cell, of the tissue, and of a human individual changes, reflecting the impaired energy state. However, a supersensitive, next-generation sequencing study shows low-level changes (0.2% to 2.0% coexistence of mutated mtDNAs) present in blood and skeletal muscle of clinically unaffected individuals, a phenomenon termed “universal heteroplasmy” (Payne et al., 2013). The *threshold effect* is a relative concept influenced by several factors such as the age of the patient and the energy demands of any specific tissue or organ. For example, brain and muscle cells have high energy demands, as do tissues of the developing child. In these situations, the threshold for phenotypic expression of a pathogenic mutation is lower.

Replicative or *mitotic segregation* is a biologic concept that refers to the stochastic redistribution of the mtDNA genomes during mitochondrial and cell divisions. The random segregation of the mitochondrial genomes during replication influences the oxidative capability of the cellular progeny. The concepts of threshold effect and replicative segregation have provided theoretic explanations for the variable phenotypic expression of maternally transmitted human diseases.

## CLASSIFICATION OF MITOCHONDRIAL DISEASES

Several classification schemes of mitochondrial diseases were based on differing criteria. The original classification scheme which attempts to classify mitochondrial diseases by clinical or morphologic criteria was unsatisfactory. The phenotypic heterogeneity of mitochondrial diseases complicated the clinical classification efforts. Similarly, the lack of histopathologic uniformity undermined the morphologic classification efforts.

In 1988, primary mutations of the mitochondrial genome were particularly relevant to respiratory chain defects because this metabolic pathway is under the dual genetic influence of the mitochondrial and nuclear genomes. In recent times, the term “mitochondrial diseases” has been increasingly restricted to defects of one metabolic pathway, the respiratory chain, and further subgrouped as nuclear DNA defects and mtDNA defects.

**Figure 42-1.** The mitochondrial respiratory chain (bottom) and the mitochondrial DNA (top). Genes and corresponding gene products are similarly color-coded. ND denotes the subunits of NADH-CoQ oxidoreductase (complex I); *cyt b* + cytochrome *b*; subunits of cytochrome *c* oxidase (complex IV) are labeled CO in both renditions; A6 and A8 denote subunits 6 and 8 of ATP synthase (complex V). The 22 tRNA genes are identified by one-letter amino acid nomenclature; 12S and 16S denote ribosomal RNAs (rRNAs).  $O_H$  and  $O_L$  are the origin of heavy- and light-strand replication; HSP and LSP are the promoters of heavy- and light-strand transcription. ADP = adenosine diphosphate; ATP = adenosine triphosphate. Mitochondrial DNA contains 16,569 base pairs and 37 genes. These genes include two ribosomal RNA, 22 transfer RNA, and 13 structural reading frames. Digestion of human mtDNA with a single endonuclease (*Pvu* II) cleaves the circular molecule in one place and produces a linearized version. CO, cytochrome *c* oxidase; CYT, cytochrome;  $O_L$ ,  $O_H$ , origin of replication for L- and H-strands; ND, NADH-CoQ reductase;  $PH_{1,2}$ , primary transcripts of the H-strand starting at H1, H2;  $PL$ , light (l-strand promoter). (With permission from DiMauro, S., 2013. *Mitochondrial Encephalomyopathies—fifty years on. Neurology* 81, 281–291.)

One of the many exciting features of mitochondrial diseases is the pattern of inheritance of these diverse conditions. The unique dual influence of the nuclear and mitochondrial genomes on respiratory chain function has captivated students of mitochondrial biology. A biochemical defect involving the respiratory chain may be transmitted either by Mendelian or by non-Mendelian patterns. The strictly maternal inheritance of mitochondria determines the pattern of vertical transmission of mtDNA mutations.

Clinical conditions related to mtDNA point mutations are transmitted from the mother to all her male and female progeny, but only the daughters pass the condition to succeeding generations. This genetic profile is reminiscent of Mendelian inheritance, including autosomal-dominant and X-linked patterns, but both genders are equally affected, and there is no father-to-child transmission. Expression of the maternally inherited genetic defect is determined by replicative segregation and by the threshold effect. These biologic principles are

demonstrated in several neurologic diseases associated with mtDNA mutations, including Leber hereditary optic neuropathy (LHON), MERRE, MELAS, and the syndrome of neuropathy, ataxia, retinitis pigmentosa/maternally inherited Leigh syndrome (NARP/MILS).

Single deletions of mtDNA generally occur sporadically, as with Kearns-Sayre syndrome (KSS), PEO, and Pearson syndrome (PS). A multicenter retrospective study of 226 KSS cases has shown that the risk of a carrier woman to have affected children is very small but finite (1 in 24 births) and disproves the idea that the risk increases with maternal age.

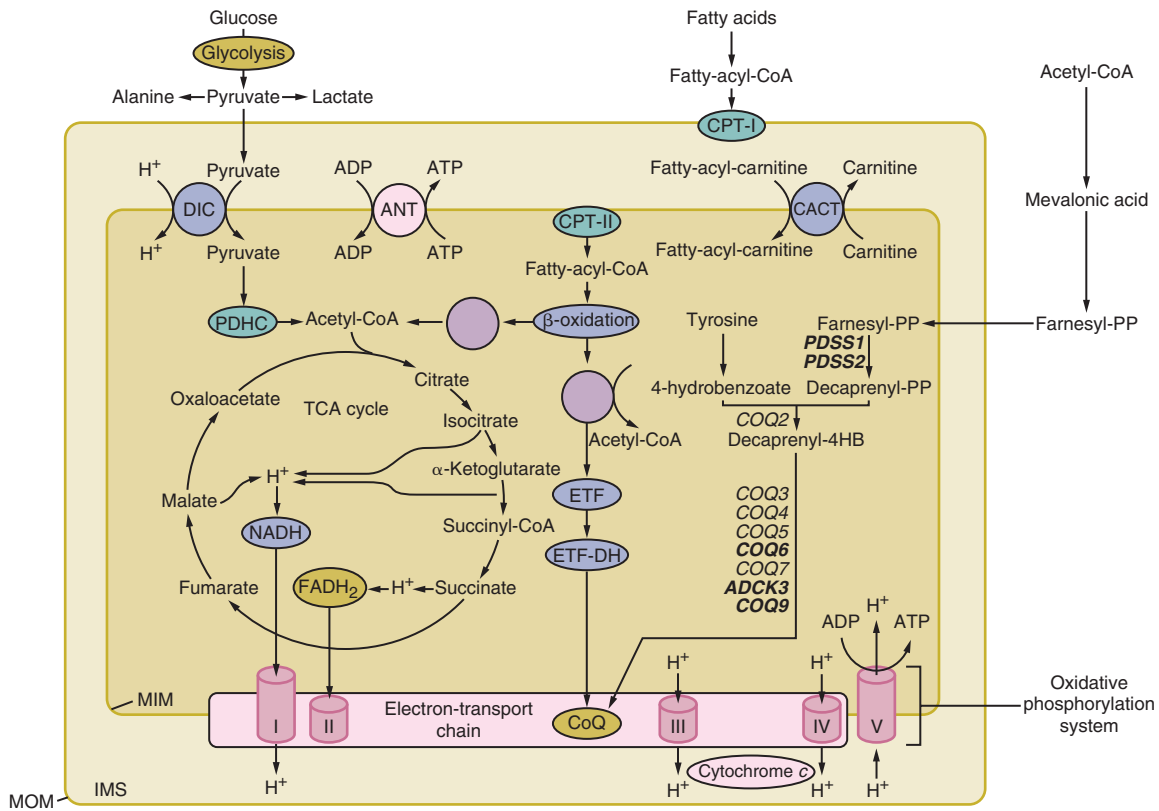

However, the pattern of inheritance for most mitochondrial diseases is not maternal. Rather, classic Mendelian inheritance patterns apply to six main groups of disorders affecting the respiratory chain.

Most subunits of respiratory chain complexes are encoded by nDNA genes directly ("direct hits") or are assembled by nuclear proteins ("indirect hits"). A third dysfunction of

the respiratory chain identifies a group of disorders due to altered mtDNA translation. A fourth category includes changes of phospholipid composition of the IMM. A fifth group of mitochondrial diseases is due to altered dynamics (mitochondrial motility, fusion, fission). Interestingly, the sixth disease category (defects of mtDNA maintenance) is due to faulty communication between the two genomes, usually called defects of intergenomic signaling (DiMauro et al., 2013). For example, syndromes of PEO with multiple deletions of mtDNA are inherited as autosomal-dominant or, more rarely, as autosomal-recessive traits. The nuclear gene defects in these cases apparently alter the biologic integrity of the mitochondrial genome and predispose the patient to multiple mtDNA deletions that characterize these clinical syndromes. Another defect of intergenomic signaling is due to a quantitative defect of mtDNA (mtDNA depletion). Syndromes due to mtDNA depletion may affect predominantly one tissue (infantile myopathy or hepatopathy) or multiple tissues (hepatocerebral syndrome) and are due to nuclear gene mutations impairing mtDNA replication.

## METABOLIC DISTURBANCES

The principal function of mitochondria is the oxidation of substrates and the synthesis of adenosine triphosphate (ATP) (Fig. 42-2). The primary oxidizable substrates include pyruvate, fatty acids, ketone bodies, and amino acids. Mitochondria also play a role in the intracellular sequestration of calcium and in the detoxification of ammonia in the urea cycle. Biochemical defects involving these pathways are associated with distinctive metabolic disturbances. A biochemical defect altering pyruvate metabolism directly or indirectly leads to an elevation of pyruvic acid. Pyruvate is in equilibrium with lactate and alanine. As a result, there is lactic acidosis proportionate or disproportionate to the elevation of pyruvate, depending on the associated effect of the biochemical defect on the oxidation-reduction potential. If the oxidation-reduction potential is unaffected by the biochemical defect, the lactate and pyruvate elevations are proportional and the lactate/pyruvate ratio is normal (less than 20). In contrast, if the oxidation-reduction potential is disturbed by a primary

**Figure 42-2. Schematic view of mitochondrial metabolism.** The respiratory chain is highlighted in red. Electrons from dehydrogenases in the Krebs cycle and in  $\beta$ -oxidation spirals are passed “horizontally” along four protein complexes and two small carriers (the electron-transport chain) that are embedded in the MIM. The electrons travel from complex I (an NADH dehydrogenase) and complex II (a succinate dehydrogenase) to CoQ10 (a small mobile electron carrier also known as ubiquinone), then to complex III (ubiquinone oxidoreductase), cytochrome c (another small mobile electron carrier), and complex IV (cytochrome c oxidase), ultimately producing water. Concomitant with this horizontal flow of electrons, there is a “vertical” vectorial transport of dehydrogenase-derived protons from the matrix across the MIM into the intermembrane space. This process creates an electrochemical proton gradient across the MIM that is used to drive complex V ( $F_0F_1$  ATP synthase), a tiny “turbine” that converts ADP to ATP. Conventionally, the five complexes comprise the oxidative phosphorylation system. The biosynthetic pathway of CoQ10, beginning with acetyl-CoA, is shown. (Abbreviations: ANT, adenine nucleotide translocator; CACT, carnitine-acylcarnitine translocase; CoA, coenzyme A; CoQ10, coenzyme Q10; CPT, carnitine palmitoyltransferase; DIC, dicarboxylate carrier; ETF, electron-transfer flavoprotein; ETF-DH, ETF dehydrogenase; FAD, flavin adenine dinucleotide; IMS, intermembrane space; MIM, mitochondrial inner membrane; MOM, mitochondrial outer membrane; PDHC, pyruvate dehydrogenase complex; TCA, tricarboxylic acid.) (With permission from DiMauro, S., 2013. *The Clinical Maze of Mitochondrial Neurology*. *Nat Rev Neurol* 9, 429–444.)

defect involving the respiratory chain, the lactate values are disproportionately elevated and the lactate/pyruvate ratio is increased (greater than 20). Patients with pyruvate dehydrogenase (PDH) deficiency typically have elevated lactate, pyruvate, and alanine concentrations and a normal lactate/pyruvate ratio. In contrast, patients with cytochrome *c* oxidase (COX) deficiency have elevated lactate, pyruvate, and alanine concentrations, but the lactate/pyruvate ratio is increased. These metabolic observations serve as clues to the underlying biochemical defect and may be helpful when all other clinical and metabolic factors are considered simultaneously.

Defects of fatty acid oxidation (FAO) include a variety of mitochondrial defects, but they are considered separately (see Chapter 149) from the more typical mitochondrial encephalomyopathies, which are associated with respiratory chain defects.

## HISTOPATHOLOGIC DISTURBANCES

The tissue reactions in mitochondrial diseases may be informative and direct the clinician's attention to the primary metabolic defect, even if they may be modest or absent in some mitochondrial disorders. A muscle biopsy is considered a gold standard for the diagnosis of mitochondrial disease.

Ragged-red fibers (RRF) or, more commonly SDH-intensely positive ("ragged-blue" fibers) and COX-negative fibers have been considered clues to many respiratory chain diseases, including most mtDNA-related disorders. In many nDNA-related disorders, histochemical abnormalities are often seen but not as common or as intense as in mtDNA-related diseases. However, defects of mtDNA maintenance (intergenomic signaling), although unequivocally Mendelian disorders, share many features of mitochondrial genetics, including mtDNA heteroplasmy and the threshold effect. Muscle biopsies often show a checkerboard pattern of ragged-blue and COX-negative fibers.

The brain pathology is distinctive in many mitochondrial diseases. Three patterns are common. The first is a widespread insult to the brain tissue with resulting microcephaly and ventricular dilatation. This pattern is seen in defects of the urea cycle, several defects associated with congenital lactic acidosis, and some of the defects associated with fatty acid metabolism. Malformations also may be seen, including agenesis of the corpus callosum, ectopic displacement of the olivary nuclei, and cystic destruction of the basal ganglia. This pattern is particularly striking in infants with pyruvate dehydrogenase E1 alpha-subunit deficiency. The second pattern is best typified by the neuropathology associated with Leigh syndrome (LS). These patients have a symmetric subcortical distribution of tissue injury with a particular predilection for the basal ganglia, thalamus, brainstem, and cerebellar roof nuclei. Microscopic features include loss of brain cells, proportionate loss of myelin, reactive astrocytosis, and proliferation of the cerebral microvessels. In some patients, particularly those with MELAS, multifocal encephalomalacia develops. This pathologic condition typically is located in the posterior aspect of the cerebral hemisphere. The third pattern is a spongy encephalopathy with loosening and rarefaction of the neuropil. The spongy encephalopathy is the histopathologic counterpart of a defect in cerebral energy metabolism and is commonly seen in patients with KSS. MRI may reflect these patterns of brain tissue injury with a hyperintense signal of the central white matter on the T2-weighted image (Fig. 42-3). Stroke-like lesions in the posterior cerebral hemisphere are typical of MELAS. Signal hyperintensities involving the putamen, globus pallidus, and caudate nuclei are characteristic of Leigh syndrome. A diffuse signal abnormality involving the central white matter is typical of Kearns-Sayre syndrome. Intracranial

calcifications also are seen in these conditions. Basal ganglia calcifications are most commonly associated with KSS and MELAS.

## Defects of the Krebs Cycle

Pyruvate is the end product of glycolysis. This metabolite can be reduced to lactate or transaminated to alanine in the cytoplasm. Otherwise, pyruvate is translocated across the mitochondrial membrane (Fig. 42-2). In the mitochondrial matrix, pyruvate is carboxylated to oxaloacetate or decarboxylated and activated to acetyl coenzyme A (acetyl-CoA). The first reaction is catalyzed by pyruvate carboxylase (PC), and the second is catalyzed by the pyruvate dehydrogenase complex (PDHC) (Fig. 42-4). The two reaction products—oxaloacetate and acetyl-CoA—condense to form citrate as the primary reactant in the Krebs cycle. Defects of pyruvate metabolism involve the PDHC, PC, or several enzymes in the Krebs cycle.

Fumarase deficiency is a progressive infantile encephalopathy with failure to thrive, hypotonia, microcephaly, and fumaric aciduria. This condition may be associated with enlarged cerebral ventricles and polyhydramnios in utero.

Succinate dehydrogenase is a critical step in the Krebs cycle and the first component of complex II in the respiratory chain. Before the molecular era, several patients were described with defects of complex II and progressive encephalomyopathy. A mutation in the flavoprotein subunit of succinate dehydrogenase was identified in two sisters with Leigh syndrome, the first example of a nuclear DNA mutation affecting respiratory chain disorder. A few more cases of Leigh syndrome were later associated with mutations in the same gene.

Homozygous mutations in the gene *ACO2*, which encodes the mitochondrial isozyme of aconitase, the Krebs cycle enzyme that interconverts citrate to isocitrate, have been described in infants with a neurodegenerative disorder characterized by optic nerve and retinal atrophy, psychomotor retardation, truncal hypotonia, athetosis, and seizures.

Compound heterozygous *ACO2* mutations can cause either isolated optic neuropathy or syndromic presentations of optic neuropathy plus encephalopathy and cerebellar atrophy.

Combined deficiency of two Krebs cycle enzymes, SDH and aconitase, in skeletal muscle, was described in a young Swedish man with recurrent episodes of exercise-induced myoglobinuria. The etiology of the double enzyme defect is due to the lack of iron-sulfur (Fe-S) cluster proteins, prosthetic groups present in the three complexes (I, II, and III), and in the Krebs cycle enzyme aconitase. Homozygosity mapping revealed a pathogenic mutation in the *ISCU* gene, which encodes iron-sulfur cluster proteins in three Swedish families. Decreased amount of ISCU protein in muscle was associated with decrease of iron regulatory protein (IRP12) and with intramuscular iron overload.

## Mendelian Defects of the Respiratory Chain

The respiratory chain contains five functional units or complexes that are embedded in the IMM (see Fig. 42-2). The five complexes contain approximately 80 polypeptides, 13 of which are encoded by mtDNA. Complex II, unlike the other four complexes, is solely under the control of the nuclear genome. The function of the respiratory chain is to transfer electrons from the reduced pyridine nucleotides and flavoproteins to molecular oxygen, with the resulting oxidation of reduced nicotinamide-adenine dinucleotide phosphate and flavin adenine dinucleotide and the production of water. Biochemical defects of the respiratory chain are associated with lactic acidosis. However, unlike defects of pyruvate metabolism, respiratory chain defects are associated with a disturbed

**Figure 42-3. Characteristic brain MRI abnormalities in mitochondrial encephalomyopathies.** **A**, These T2-weighted images show bilateral putaminal hyperintensities in a child with cytochrome c oxidase (COX)-associated Leigh syndrome; **B**, Bilateral globus pallidus hyperintensities in a child with a familial Leigh syndrome phenotype; **C**, A left posterior cerebral hyperintensity in a child with MELAS; **D**, bilateral white matter hyperintensities in a child with Kearns-Sayre syndrome (KSS). (With permission from DeVivo, D.C., DiMauro, S., 2011. *Mitochondrial diseases*. In: Swaiman, K.F., Ashwal, S., Ferriero, D.M., editors. *Pediatric Neurology: Principles and Practice*, 5th edition. Philadelphia: Mosby Elsevier. p. 452–467.)

cellular oxidation-reduction potential manifested by an elevated lactate/pyruvate ratio (greater than 20). Respiratory chain defects are complicated by the diversity of clinical presentations. Many patients have neurologic or neuromuscular symptoms and are grouped together in the neurologic literature reports as examples of mitochondrial encephalomyopathies. Others have nonneurologic symptoms, including dysfunction of the liver, heart, kidney, bone marrow, pancreas, and/or gastrointestinal tract. The specific clinical syndromes associated with the six groups of disorders are discussed later in the chapter.

### 1. Respiratory Chain “Direct Hits”

Pathogenic mutations that directly affect nDNA-encoded respiratory chain subunits have been identified in all five complexes, but more abundantly in the gigantic complex I and relatively rarely in complex II, complex III, complex IV, and complex V. Mendelian direct hits (most of which are recessive) generally manifest at or soon after birth and are severe or lethal in infancy. The most common clinical presentation is Leigh syndrome that reflects the detrimental energy shortage on the developing nervous system. Leigh syndrome is defined

ubiquinone-binding protein (QP subunit or subunit VII) was identified in an 8-month-old girl with modest hepatomegaly, hypoglycemia, and lactic acidosis. At age 4 years, the child was normal, although the activity of complex III was decreased in liver, lymphocytes, and fibroblasts. A homozygous mutation of *UQCRB* was associated with a severe encephalomyopathy but was compatible with long survival in 20 members of an Israeli-Bedouin family. They developed psychomotor retardation and extrapyramidal signs, including dystonia, athetoid movements, ataxia, and dementia.

**Complex IV.** Mutations in the nDNA-encoded 11 subunits of complex IV (COX) are extremely rare, and confined to one subunit, *COX6B1*. A mutation in *COX6B1* was associated with severe cavitating leukodystrophy in two brothers, one of whom died at 10 years of age: both had failure to thrive but normal psychomotor development until late childhood, when they developed muscle weakness, cognitive impairment, visual problems, and lactic acidosis.

**Complex V.** Only one patient harbored a direct hit in one complex V subunit, *ATP5E*. A homozygous mutation in *ATP5E* affected a girl at birth, with poor suck, small size, respiratory distress, lactic acidosis, and 3-methyl-glutaconic aciduria. She had metabolic crises, which improved by 5 to 6 years of age, and she was able to complete school. At age 17 years, she presented with mild ataxia, horizontal nystagmus, exercise intolerance, axonal and demyelinating neuropathy, and mild left ventricular hypertrophy.

## 2. Respiratory Chain “Indirect Hits”

All nuclear encoded subunits of the respiratory chain have to be translated, imported into mitochondria, and directed to the MIM, where they are then assembled together with their mtDNA- and nuclear DNA-encoded counterparts, acquire prosthetic groups, multimerize, or further assemble into supercomplexes.

**Complex I.** There are as many indirect as direct hits affecting the assembly of this giant complex, and the encephalopathic phenotypes are similar in the two groups of disorders. Although indirect hits explain many cases of Leigh syndrome, frequently they impair white matter more than gray matter and give rise to leukodystrophies. Cardiomyopathy more commonly is observed in indirect hits, and is often a dominating feature when presenting in infancy or childhood, leading to death or manifesting a fluctuating course (Calvo et al., 2010).

**Complex III.** A rapidly fatal infantile disorder observed in Finland and termed GRACILE (growth retardation, aminoaciduria, cholestasis, iron overload, lactic acidosis, and early death) syndrome was associated with mutations in an assembly protein (*BCS1L*) needed for the correct synthesis and function of complex III. Mutations in the same nuclear gene (*BCS1L*) have also been found in children with Leigh syndrome.

**Coenzyme Q10 Defects.** Coenzyme Q (CoQ10) serves as an electron shuttle among complexes I and II and complex III. Coenzyme Q deficiency is associated with three clinical presentations, all autosomal recessive CoQ10 deficiencies. The first presentation, a *myopathic form* first described in 1989 in two sisters, has been reported in three more patients. It is characterized by the triad: (I) myopathy with recurrent myoglobinuria; (II) muscle biopsy with ragged-red fibers (RRF) and lipid storage; and (III) CNS dysfunction, with seizures, ataxia, or mental retardation. The second presentation is an ataxic form dominated by cerebellar ataxia and cerebellar atrophy, inconsistently accompanied by seizures, pyramidal signs, and mental retardation. The third

presentation, an *infantile encephalomyopathic form*, was described in two families with severe brain involvement and renal disease. These syndromes are important to be considered because all patients (especially those with the myopathic and the infantile forms) respond rather dramatically to oral CoQ10 supplementation.

A new group of disorders attributed to deficiency of coenzyme Q10 (CoQ10) can be related to indirect hits, mutations in a cascade of biosynthetic enzymes that result in deficiency of the relatively simple component, CoQ10, which is an integral part of the respirasome, where it shuttles electrons from complex I and complex II to complex III, acts as an antioxidant, and modulates apoptosis. Molecular defects in genes encoding CoQ10 biosynthetic enzymes (*PDSS2* and *COQ2*) were initially discovered in 2006, but mutations in other biosynthetic genes (*PDSS1*, *COQ6*, *ADCK3*, and *COQ9*) followed.

**Complex IV.** Leigh syndrome was a well known defect of COX activity, and there was a chase to identify direct hit mutations, to no avail, affecting nuclear genes encoding the 11 COX subunits. COX-deficient Leigh patients were clinically asymptomatic during early infancy but systemic and neurologic symptoms developed after age 6 months, and patients died by 4 to 5 years. They had a protracted clinical course associated with deceleration of head growth and peripheral neuropathy with rare seizures. In 1998 the first search for the molecular basis of COX-deficient Leigh syndrome led to simultaneous discovery of a mutant COX assembly gene, *SURF-1*, by two independent groups of investigators. Finding the genetic basis of this condition has greatly improved genetic counseling and has made prenatal diagnosis possible. Mutations in several other ancillary proteins required for COX assembly have been found in children with Leigh-like encephalopathy with involvement often of one other tissue, either liver, heart, or kidney. Thus mutations in the *SCO2* gene cause cardioencephalopathy, when generally the cardiopathy predominates and causes early death, but a few cases presented as spinal muscular atrophy (SMA) with cardiopathy. Mutations in *COX15* also cause cardioencephalopathy, whereas mutations in *SCO1* cause hepatic encephalopathy, and mutations in *COX10* cause nephrotic encephalopathy. The reasons for the selective involvement of specific tissues and organs in addition to the brain remain unclear.

**Complex V.** The first nuclear defect leading to impaired complex V function has been described. It involves a gene (*ATP12*) encoding an assembly protein, which is accompanied by congenital lactic acidosis and a fatal infantile multisystemic disease.

“Indirect hits” in complex V are rather frequently associated with mutations in the gene *TMEM70*, resulting in defective assembly of ATP synthase. Most patients harboring *TMEM70* mutations were severely affected with neonatal hypotonia, apneic spells, psychomotor delay, hypertrophic cardiomyopathy, and profound lactic acidosis; however, a minority presented additionally with infantile-onset cataracts, early onset gastrointestinal dysfunction, and multiple joint contractures.

## Defects of Protein Importation

The protein importation process is energy-dependent and requires that proteins be unfolded before traversing mitochondrial membranes and then refolded before reaching their final destination. This requires a complex machinery, involving leader peptides, chaperonins, translocases in the outer and inner membranes, and proteases (Bolender et al., 2008). Relatively few human diseases have been attributed to dysfunction

of mitochondrial protein import, possibly because of the devastating consequences that would disrupt the general import machinery. Most of these mutations involve leader peptides. One of these mutations affected methylmalonyl-CoA mutase and accounted for one form of methylmalonic aciduria. A second mutation affected the leader sequence of the E1 alpha-subunit of the pyruvate dehydrogenase complex in a child with PDH deficiency and Leigh syndrome. Two disorders have been associated with mutations in components of the transport machinery. The first is an X-linked disease called *deafness-dystonia syndrome* (Mohr-Tranebjaerg syndrome), characterized by neurosensory hearing loss, dystonia, cortical blindness, and psychiatric symptoms due to mutations in the *TIMM8A* gene, which encodes the deafness-dystonia protein (DDP1), a component of the transport machinery. The second disorder is an autosomal dominant form of hereditary spastic paraplegia due to mutations in the chaperonin HSP60.

### 3. Defects of mtDNA Translation

The mitochondrial genome is transcribed into 13 mRNAs, which are translated by mitoribosomes into the 13 mtDNA-encoded respiratory chain subunits. As described in a comprehensive review, this process can be divided into two phases: a posttranscriptional phase (involving tRNA modifications, aminoacyl-tRNA synthetases, and processing of ribosomal proteins); and a mtRNA translation phase (initiation, elongation, termination, and recycling). Representative examples of defects of each step of the mitochondrial translation process are briefly highlighted (Pearce et al., 2013).

**Abnormal tRNA Modifications.** Pseudouridylation is thought to promote stability and conformation of mitochondrial and nuclear tRNAs. Mutations in pseudouridine synthase 1 (*PUS1*) differentially impair nuclear and mitochondrial tRNA maturation causing mitochondrial myopathy, lactic acidosis, and sideroblastic anemia (*MLASA*). Psychiatric symptoms and facial dysmorphism are likely due to abnormal cytosolic protein synthesis.

The mystery of spontaneous improvement in *infantile reversible COX deficient myopathy* (now, more accurately designated reversible infantile respiratory chain deficiency [RIRCD]) was resolved by elucidation of the tRNA modification processes in this disorder. RIRCD is due to homoplasmic mutations in mt-tRNA<sup>Glu</sup>. Pathogenesis of the disease was noted to be more complex than previously appreciated, when patients in two families were found to harbor mutations in the *TRMU* gene, which modifies a wobble uridine base in mt-tRNA<sup>Glu</sup>. Skeletal muscle from infants in the initial symptomatic phase showed significantly decreased 2-thiouridylation due to defective TRMU activity, which exacerbated the effect of the mtRNA<sup>Glu</sup> mutation and triggered the mitochondrial translation defect, thus demonstrating a nDNA modifying effect on the mtDNA mutation.

**Mutations of Aminoacyl-tRNA Synthetases.** In highly specialized tRNA-charging enzymes, the aminoacyl-tRNA synthetases (ARs), are associated with specific clinical syndromes. Thus pathogenic mutations in the gene *DARS* (encoding aspartyl-tRNA synthetase) cause brainstem and spinal cord involvement and lactate elevation (LBSL). Children from 30 families presented early with cerebellar ataxia, spasticity, dorsal column dysfunction, and mild cognitive decline. Equally severe mutations in the gene *RARS2* (encoding arginyl-tRNA synthetase) have been identified in three patients with severe infantile encephalopathy with *pontocerebellar hypoplasia*. Mutations in *EARS2*, encoding glutamyl-tRNA synthetase, were identified by whole-exome sequencing in a cohort of 11 unrelated cases with symmetric cerebral white matter abnor-

malities and signal abnormalities of the thalami, midbrain, pons, medulla oblongata, and cerebellar white matter. All patients shared an infantile onset and rapidly progressive disease with severe lactic acidosis. Mutations in *MARS2*, encoding the methionyl-tRNA synthetase, were found to be responsible for autosomal recessive *spastic ataxia with leukoencephalopathy* (*ARSAL*), mostly in nine patients from a large French-Canadian family.

Many fewer patients with mutations in *YARS2*, *HARS2*, *AARS2*, *SARS2*, and *FARS2* also have specific clinical phenotypes, including myopathy and sideroblastic anemia (*MLASA*) due to *YARS* (encoding tyrosyl-tRNA synthetase); a *Perrault syndrome* (characterized by ovarian dysgenesis in females, and sensorineural deafness in both genders) due to *HARS* (encoding histidyl-tRNA synthetase); a perinatal or infantile hypertrophic cardiomyopathy; a more common presentation with leukoencephalopathy, childhood or adult-onset ataxia, spasticity, and cognitive decline (associated with the gene, *AARS2*, encoding alanyl-tRNA synthetase); a nonneurologic syndrome dominated by hyperuricemia, pulmonary hypertension, renal failure, and alkalosis in infancy due to *SARS2*, encoding seryl-tRNA synthetase; a form of hepatocerebral dysfunction simulating closely *Alpers syndrome*, due to *FARS2* (encoding phenylalanyl tRNA synthetase). Mutations in *MARS2*, encoding the methionyl-tRNA synthetase, were found responsible for autosomal recessive *spastic ataxia with leukoencephalopathy* (*ARSAL*). This was reported in nine patients from a large French-Canadian family.

### Defects of Mitoribosomes

These have been associated with complex multisystemic disorders; however, in one family with *MPRL3* mutations, four siblings manifested fatal infantile-onset hypertrophic cardiomyopathy and psychomotor retardation. Similarly, patients with abnormal mitochondrial translational elongation factors typically presented with fatal infantile diseases with early hepatic encephalopathy with *GFMI1* (*EFG1*) mutations and macrocystic leukodystrophy and micropolygyria due to *TUFM* (*EF-Tu<sub>mi</sub>*) defects.

### 4. Defects of the IMM Lipid Milieu

Phospholipid metabolism and the lipid composition of the IMM were relatively neglected in the study of mitochondrial diseases, but there was a recent interest in this subject and several new disorders were discovered, thanks in part to whole exome sequencing.

*Barth syndrome* is due to alterations in cardiolipin, the most abundant phospholipid component of the IMM and due to mutations in the *TAZ* gene that encodes the monolysocardiolipin transacylase (Schlame et al., 2002). Barth syndrome is an X-linked disorder characterized by mitochondrial cardiac and skeletal myopathy, cyclic neutropenia, and growth retardation.

*Sengers syndrome*, an autosomal recessive disorder was described in 1975 and consisted of congenital cataracts, hypertrophic cardiomyopathy, skeletal myopathy, exercise intolerance, and lactic acidosis. This syndrome was found to be due to mutations in the gene (*AGK*) encoding acylglycerol kinase, which drives the assembly of adenine nucleotide translocator (*ANT1*) and causes a lack of *ANT1* in the IMM. This finding came about through exome sequencing.

A second disorder of the mitochondrial lipid milieu was identified in 15 patients with a *congenital myopathy* characterized by early-onset muscle weakness, mental retardation, and a protracted clinical course (most patients were alive at the time of publication and only four had died between the ages of 2 1/2 and 28 years). The hallmark of the disease was the

presence of greatly enlarged mitochondria (megaconial disease) in muscle displaced at the periphery of the fibers. The genetic cause was due to mutations in the gene (*CHKB*) encoding choline kinase beta. A new homozygous *CHKB* mutation was found in an American patient, who also had weakness and psychomotor delay and was alive at 2 years.

A genetic alteration of phospholipid metabolism causes a syndrome characterized by 3-methylglutaconic aciduria (3-methylglutaconic aciduria type IV, deafness, and Leigh-like encephalopathy, termed *MEGDEL*). This syndrome was caused by mutations in the phospholipid remodeling gene *SERAC1*, a key player in intracellular cholesterol trafficking and a member of the mitochondria-associated ER membranes (MAM).

Some forms of *primary lateral sclerosis* due to defective gene *ERLIN2* and of *juvenile amyotrophic lateral sclerosis* (ALS) due to defective gene *SIGMAR1* were associated with alterations of the lipid rafts that are part of the MAM.

Another genetic alteration of phospholipid metabolism explained many puzzling cases of recurrent *myoglobinuria in children*. Mutations in the gene (*LPIN1*) encoding the muscle-specific phosphatidic acid phosphatase cause accumulation of phosphatidic acid and lysophospholipids in muscle.

## 5. Defects of Mitochondrial Dynamics

Mitochondria are dynamic organelles forming complex tubular structures in many cells, which require constant fusion of the mitochondrial tubules, balanced by fission. Also, individual mitochondria move in the cell, sometimes covering considerable distances, as in axons propelled by energy-requiring dynamins along cytoskeletal microtubular rails (Burté et al., 2015).

There are a group of disorders due to numerous mutations in fusion proteins and, less commonly, in fission proteins. Mutations in fusion proteins such as *OPA1* result in a dominantly inherited optic atrophy (DOA or Kjer disease), the nDNA-correspondent blindness to the mtDNA-correspondent Leber hereditary optic neuropathy (LHON). Other mutations in fusion proteins such as *MFN2* or *GADP1* result in Charcot-Marie-Tooth neuropathies (types 2A and 4A).

Two infants with distinct mutations in fission genes (*DRP1* and *MFF*) had shown both mitochondrial and peroxisomal abnormalities, and they were severely affected with rapidly fatal encephalopathy and lactic acidosis.

The role of altered mitochondrial dynamics in neurologic diseases is addressed elsewhere.

## 6. Defects of mtDNA Maintenance

Here, we consider the main clinical phenotypes associated with mtDNA depletion syndromes (MDS), with multiple mtDNA deletion syndromes (PEO-plus), and finally – with combined appearance of mtDNA depletion and of multiple mtDNA deletions (Fig. 42-5).

### mtDNA Depletion Syndromes (MDS)

**Myopathic MDS.** Patients usually present in the first year of life with failure to thrive, hypotonia, weakness, and occasionally PEO. Patients typically die in childhood due to pulmonary insufficiency, but severity of weakness and survival vary considerably. The myopathic MDS is most commonly due to mutations in the gene (*TK2*) encoding mitochondrial thymidine kinase. About 20 mutations have been reported in as many patients. Notably, mutations in *TK2* can also cause a phenocopy of spinal muscular atrophy (SMA). It is notable, in this respect, that a *TK2* knockin mouse has more severe involvement of the central nervous system than that of muscle.

It is also of practical importance to sequence the *TK2* gene in patients with SMA but without mutations in the *SMN1* gene.

**Encephalomyopathic MDS.** Two variants of this condition are both due to a defect of succinyl-CoA lyase activity in the Krebs cycle. Mutations in the gene (*SUCLA2*) encoding the ATP-dependent succinyl-CoA lyase (*SUCLA2*) cause severe psychomotor retardation, muscle hypotonia, hearing loss, generalized seizures, knee and hip contractures, mild ptosis, lactic acidosis and methylmalonic aciduria. There is moderate mtDNA depletion (about 30% in muscle, and the brain MRI is suggestive of Leigh syndrome).

Mutations in the gene (*SUCLG1*) encoding the GTP-dependent isoform *SUCLG1* cause a much more severe and rapidly fatal phenotype with mtDNA depletion in both muscle and liver, characterized clinically by dysmorphic features, congenital lactic acidosis, and methylmalonic aciduria. A less dismal course, similar to the *SUCLA2* phenotype, correlates with the degree of residual activity.

Patients with mtDNA depletion may harbor mutations in *RRM2B* (encoding the small subunit, p53R2, of the p53-inducible ribonucleotide reductase protein). Infants are hypotonic, and children are weak. The presentation consists of renal involvement and central nervous system involvement with microcephaly, seizures, and developmental delay.

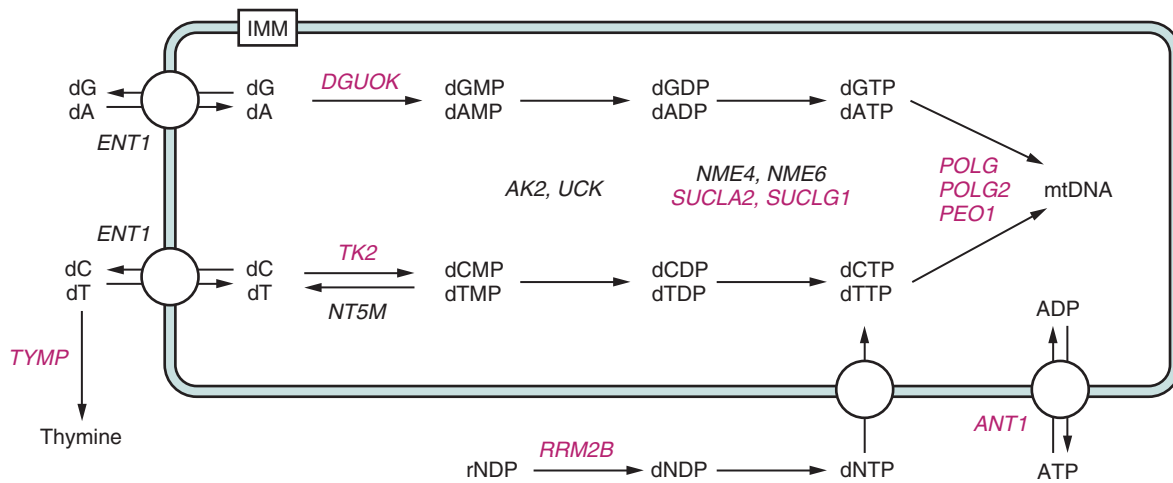

**Hepatocerebral MDS.** Mutations in three other genes, *DGUOK*, *MPV17*, and *POLG*, also cause liver and brain involvement. Mutations in *DGUOK*, encoding the mitochondrial deoxyguanosine kinase (dGK), were first reported in 2001, and by 2007, 15 different mutations had been identified in 12 kindreds. Severe mutations cause fatal infantile hepatopathy and brain involvement whereas milder mutations cause isolated liver disease and are compatible with longer survival.

Mutations in *MPV17*, which encodes a small mitochondrial membrane protein of unknown function, cause a rather typical hepatocerebral syndrome in Caucasian children but is associated with a peculiar neurohepatopathy in the Navajo population. Navajo neurohepatopathy (NNH), which has a prevalence of 1 in 1600 live births, was attributed to mtDNA depletion and is due to a homozygous *MPV17* mutation. The clinical features of NNH include peripheral and central nervous system involvement, acral mutilation, corneal scarring or ulceration, liver failure, and immunologic derangement.

Alpers-Huttenlocher syndrome (AHS) is the classical form of hepatocerebral MDS, and it has been attributed to mutations in *POLG*. AHS is defined as a disorder of childhood by the tetrad of refractory seizures, episodic psychomotor regression, cortical blindness, and hepatopathy with micronodular cirrhosis. It is important not to expose these children to the antiepileptic drug valproic acid, which often precipitates fulminant hepatic failure. This interaction of gene and environment contributes to the extreme clinical heterogeneity associated with *POLG* mutations.

### Syndromes Due to Multiple mtDNA Deletions

**Mutations in *ANT1*.** Mutations in the gene for one isoform of the adenine nucleotide translocator (*ANT1*) have been identified in patients with autosomal dominant PEO, sometime associated with psychiatric disorders. In a seminal paper, multiple mtDNA deletions were most abundant in brain, followed by cardiac and skeletal muscle. Sporadic PEO also may be due infrequently to mutations in *ANT1*; the association of mitochondrial myopathy and cardiomyopathy, even in patients with recessive inheritance and without PEO, should raise the question of *ANT1* mutations.

**Figure 42-5.** Schematic representation of the mitochondrial nucleotide pool, showing the genes whose mutations have been associated with multiple mtDNA deletions, those associated with mtDNA depletion, and those associated with both mtDNA multiple deletions and mtDNA depletion. (dA, deoxyadenosine; dC, deoxycytosine; dT, deoxythymidine; dG, deoxyguanosine; dAMP, deoxyadenosine monophosphate; dCMP, deoxycytosine monophosphate; dGMP, deoxyguanosine monophosphate; dTMP, deoxythymidine monophosphate; dADP, deoxyadenosine diphosphate; dCDP, deoxycytosine diphosphate; dGDP, deoxyguanosine diphosphate; dTDP, deoxythymidine diphosphate; dATP, deoxyguanosine triphosphate; dCTP, deoxycytosine triphosphate; dGTP, deoxyguanosine triphosphate; dTTP, deoxythymidine triphosphate; AK2, adenylate kinase 2; ANT1, adenine translocator 1; dGK (DGUOK) deoxyguanosine kinase; ENT1, equilibrative nucleoside transporter 1; NME4, nucleoside diphosphate kinase D; NME6, nucleoside diphosphate kinase 6; NT5M, 5' nucleotidase, mitochondrial; PEO1, mtDNA helicase; POLG, polymerase gamma, catalytic form; POLG2, polymerase gamma, accessory form; RRM2B, ribonucleoside diphosphate reductase subunit M2 B; TK2, thymidine kinase 2; TYMP, (TP) thymidine phosphorylase; SUCLA2, succinate CoA ligase (ADP forming) beta subunit; SUCLG1, succinate CoA ligase (GDP forming) alpha subunit; UCK, uridine-cytidine kinase.) (With permission from De Vivo, D.C., Paradas, C., DiMauro, S., 2015. *Mitochondrial encephalomyopathies*. In: Darras, B.T., Royden Jones Jr., H., Ryan, M.M., De Vivo, D.C., editors. *Neuromuscular Disorders in Infancy, Childhood, and Adolescence, A Clinician's Approach*, 2nd edition. London: Academic Press of Elsevier. p. 796–823.)

**Mutations in PEO1.** In 2001, autosomal dominant PEO with multiple mtDNA deletions was associated with mutations in the gene (*PEO1*), encoding a mitochondrial helicase called Twinkle, an essential factor for mtDNA maintenance and for the regulation of mtDNA copy number. A review of 33 patients from 26 families showed that the most common symptoms were ptosis (97%) and ophthalmoparesis (94%), followed by exercise intolerance (52%) and mild proximal weakness (33%). Central nervous system involvement was infrequent and included visual impairment, migraine, lethargy, hearing loss, and epilepsy. Cardiac problems were noted in 24% of the patients. The relatively benign, long-term progression also was noted in another large family with autosomal dominant PEO.

**Mutations in POLG.** Mutations in the gene encoding the only mitochondrial polymerase, polymerase  $\gamma$  (*POLG*) have emerged as major causes of a vast array of mitochondrial disorders. Over 150 mutations have been described in all three domains of the gene—exonuclease, linker, and polymerase—and may cause either autosomal dominant or autosomal recessive PEO, a syndrome comprising autosomal recessive sensory ataxic neuropathy, dysarthria, and ophthalmoparesis (SANDO), mitochondrial recessive ataxia syndrome (MIRAS), or parkinsonism with or without PEO.

**Mutations in OPA1.** One unexpected gene was recently added to those described previously and associated with myopathy and PEO, *OPA1*. Why unexpected? It was unexpected because mutations in *OPA1* were initially associated with a purely ophthalmologic condition, dominant optic atrophy (DOA) or Kjer disease and because the gene product was a mechanoenzyme associated with mitochondrial fusion rather than with mitochondrial maintenance.

However, a syndromic disorder, often termed DOA-plus, has emerged. This condition was characterized more or less sequentially by optic atrophy with visual failure, sensorineural

deafness, ataxia, myopathy, axonal sensory-motor polyneuropathy, and PEO. Muscle biopsy in these patients shows scattered ragged-blue, COX-negative fibers and multiple mtDNA deletions are demonstrable by long-range PCR. Interestingly, the proportion of COX-negative fibers is much higher in patients with DOA-plus than in those with nonsyndromic DOA. The relationship between this defect of mitochondrial dynamics and altered mitochondrial maintenance is intriguing. Two explanations have been proposed: decreased ability by the organelles to repair stress-induced mtDNA damage or accelerated accumulation of preexisting age-associated somatic mtDNA mutations.

### Coexistence of mtDNA Depletion and mtDNA Multiple Deletions

**Mitochondrial Neurogastrointestinal Encephalomyopathy (MNGIE).** One of the disorders in which the coexistence of multiple mtDNA deletions and mtDNA depletion was first recognized is MNGIE. This autosomal recessive multisystemic syndrome is characterized by mitochondrial myopathy with ptosis and PEO, peripheral neuropathy, gastrointestinal dysmotility causing severe cachexia, and leukoencephalopathy without cognitive impairment. MNGIE is due to mutations in the gene (*TYMP*) encoding thymidine phosphorylase (TP), resulting in elevated levels of thymidine and deoxyuridine in plasma and tissues. The disease starts in young adults and is relentlessly progressive, with an average age of death at 37 years. Molecular analysis has shown over 50 *TYMP* mutations resulting in mtDNA multiple deletions, depletion, and site-specific somatic mtDNA point mutations in multiple tissues. It has been suggested that the increased levels of thymidine and deoxyuridine lead to imbalance of the mitochondrial deoxynucleotide triphosphate pool, resulting in mtDNA instability.

**Infantile onset spinocerebellar ataxia (IOSCA)** was described in the 1970s in Finland. Between 9 and 18 months of age, children develop acutely or subacutely ataxia, hypotonia, athetosis, and areflexia; by teenage years, they lose independent ambulation. Additional symptoms include PEO, optic atrophy, sensorineural hearing loss, cognitive impairment, sensory neuropathy, and autonomic nervous system dysfunction. In 2005 this autosomal recessive disorder was attributed to mutations in *PEO1*. MRI revealed cerebellar atrophy. Although no mtDNA alteration was initially identified, it was subsequently found that both brain and liver harbored mtDNA depletion. An early-onset hepatocerebral presentation similar to Alpers-Huttenlocher syndrome has also been associated in two siblings with recessive *PEO1* mutations and mtDNA depletion in liver.

Mutations in *TK2* can also cause adult-onset myopathy with mtDNA depletion and even late-onset PEO with multiple mtDNA deletions rather than mtDNA depletion.

Mutations in *RRM2B* can also be associated with autosomal dominant or recessive PEO and multiple mtDNA deletion. One such case had multisystem involvement mimicking KSS.

Exome sequencing revealed *DGUOK* mutations in five adult patients with PEO and mitochondrial myopathy with multiple mtDNA deletions: only one of these patients had a history of liver problems in childhood.

Mutations in *MPV17* were identified in a 65-year-old man with axonal sensorimotor peripheral neuropathy, PEO and ptosis, diabetes mellitus, exercise intolerance, hepatic steatosis, depression, parkinsonism, and gastrointestinal dysmotility, and with multiple mtDNA deletions in his muscle.

## Defects of Oxidation-Phosphorylation Coupling

**Luft disease** (nonthyroidal hypermetabolism) is the singular example of a defect in this pathway. Only two cases have been reported, both female, sporadic, and with negative family histories. Onset is in adolescence with fever, heat intolerance, profuse perspiration, polyphagia, polydipsia, resting tachycardia, and exercise intolerance. Both women died in middle age. Numerous ragged-red fibers were present in skeletal muscle, but the underlying molecular defect has not yet been elucidated.

## Diseases Due to Primary mtDNA Mutations

(Fig. 42-4)

**Complex I:** Patients with complex I deficiency can be subclassified as examples of a myopathy or a multisystem disorder. The myopathy may develop in childhood or early adult life and is manifested by exercise intolerance and limb weakness. These patients have sporadic “somatic mutations” in mtDNA-encoded genes of complex I—that is, spontaneous *de novo* mutations in the mitochondrial genome occurring in the oocyte or in the embryo but affecting myoblasts after germ-layer differentiation.

Recently, attention has been drawn to mutations in mtDNA-encoded complex I (ND) subunits, especially mutations in the *MTND3* or *MTND5* genes, which appears to be hotspots; these mutations have been associated with maternally inherited Leigh syndrome or with overlap syndromes of Leigh syndrome and MELAS syndrome.

**Complex III** (coenzyme Q-cytochrome c oxidoreductase): Complex III contains 11 subunits, one of which is encoded by mtDNA (*MTCYB*). Defects involving complex III are subdivided into a generalized multisystem disorder manifested by limb weakness, exercise intolerance, and various neurologic signs or a tissue-specific syndrome manifested either as a pure

myopathy with onset in childhood or adolescence or as a pure cardiopathy (“histiocytoid cardiomyopathy”) manifesting in early infancy. Some patients with the myopathic phenotype and without apparent maternal inheritance have mutations (“somatic” mutations—see previous mention) in the cytochrome *b* gene (*MTCYB*) of mtDNA.

**Complex IV (cytochrome c oxidase):** Somatic mutations in mtDNA genes encoding subunits I or III (*MTCOI* or *MTCOIII*) can cause exercise intolerance and recurrent myoglobinuria.

Since 1988, no less than 11 clinical syndromes have been associated with defects of the mitochondrial genome. Three conditions can be subdivided into sporadic disorders associated with single large-scale rearrangements of mtDNA, which include Kearns-Sayre syndrome (KSS), progressive external ophthalmoplegia (PEO), and Pearson syndrome (PS).

## KSS

Kearns-Sayre syndrome (KSS) is the prototype of this group of diseases. Males and females are affected in roughly equal number, and there are no documented examples of familial KSS. The dominant clinical features include progressive eye signs such as ptosis, progressive external ophthalmoplegia, and pigmentary retinopathy. Neurologic symptoms include cerebellar ataxia, intellectual disability, and episodic coma. Seizures are infrequent and are usually associated with hypoparathyroidism. Brain MRI shows diffuse white matter hyperintensity. Complete heart block may lead to sudden death and insertion of a pacemaker is lifesaving. Short stature and hearing loss are common. Endocrine disturbances include diabetes mellitus, hypoparathyroidism, and isolated growth hormone deficiency.

Ragged-red fibers (RRF) are found in almost all affected patients. Calcification of the basal ganglia usually occurs in the setting of hypoparathyroidism. The surprisingly rare incomplete forms of KSS demonstrate PEO as an invariant clinical sign. Some cases have unusual clinical presentations such as renal tubular acidosis, whereas others may overlap with clinically distinct syndromes such as MELAS.

**Pearson syndrome** is a nonneurologic disorder of infancy characterized by pancytopenia, disturbed pancreatic exocrine function, and liver abnormalities. The few survivors of this infantile condition may later develop clinical features of KSS. The phenotypic transformation from Pearson syndrome to KSS is an example of tissue-specific modifications of mitochondrial heteroplasmy (mitotic segregation).

Six clinical conditions are maternally inherited and associated with point mutations in mtDNA protein-coding genes.

Leber hereditary optic neuropathy (LHON) and neuropathy, ataxia, and retinitis pigmentosa (NARP) affect structural genes in the mitochondrial genome. Lactic acidosis is usually absent in LHON and may be absent in NARP. Ragged-red fibers are conspicuously absent in skeletal muscle biopsies from patients with both conditions.

**LHON** is dominated clinically by the sudden onset of visual loss in a young adult and, more commonly, a man. The peak age of onset is between 20 and 24 years, although children as young as 5 years have reported bilateral visual loss. In most cases, although the condition may first develop in one eye, it is followed by involvement of the second eye in weeks or months. The presentation is a retrobulbar neuropathy, often associated with disc edema and subtle alterations of retinal vessels. The male predominance suggests an X-linked factor that modulates the expression of the mtDNA point mutation, but this remains to be documented. A more likely explanation for the predominant male involvement seems to be an

epigenetic factor—that is, a protective effect of estrogens in women.

The condition is relatively static after the subacute visual loss. Other neurologic and psychiatric symptoms have been described in patients and their family members, signifying the global nature of the molecular defect. Variable findings have included hyperreflexia, Babinski sign, incoordination, peripheral neuropathy, and cardiac conduction abnormalities. Three primary mutations are capable of causing LHON alone. All of these genes encode subunits of complex I (m.3460G>A in ND1, m.1178G>A in ND4, and m.14484T>C in ND6).

*NARP* affecting an mtDNA structural gene results in neuropathy, ataxia, and retinitis pigmentosa (NARP). It was described in four family members of three successive generations with a variable combination of retinitis pigmentosa, ataxia, developmental delay, dementia, seizures, proximal limb weakness, and sensory neuropathy. This maternally transmitted condition was associated with an mtDNA point mutation involving the gene for subunit 6 of mitochondrial ATPase (*MTATP6*). The most severely affected family member was a 3-year-old girl. She had had a history of reduced fetal movement, developmental delay, and a pigmentary retinopathy. Additional features included limb hypertonia, hyperreflexia, bilateral Babinski sign, and generalized ataxia. The m.8993T>G mutation in the ATPase 6 gene of mtDNA has been recognized as one important cause of Leigh syndrome. Curiously, a different mutation at the very same nucleotide (m.8993T>C) causes a milder clinical phenotype and a less severe impairment of ATP synthesis in mitochondria isolated from cultured fibroblasts. Mutations in the ATPase 6 gene of mtDNA appear to be associated with various syndromes characterized by the neuroradiologic features of Leigh syndrome or bilateral striatal necrosis.

There are now more than 250 pathogenic point mutations affecting synthetic genes but only two distinct and frequent clinical conditions that are maternally inherited and associated with mtDNA point mutations affect tRNA genes. These two conditions are MELAS and MERRF.

*Mitochondrial encephalopathy with lactic acidosis and stroke-like episodes (MELAS)* was first described in 1984 and is the most common mtDNA-related disease. Most patients become symptomatic before age 40 years, and 90% to 100% of patients have normal early development followed by the onset of exercise intolerance, stroke-like episodes, seizures, and dementia. Almost all patients have lactic acidosis and ragged-red fibers in biopsied skeletal muscle. Recurrent migraine-like headaches preceded by nausea and vomiting are common, as is hearing loss, short stature, learning difficulties, hemiparesis, hemianopia, and limb weakness. The cerebrospinal fluid protein concentration is normal in half of the patients and only mildly elevated in the other half. One third of patients have basal ganglia calcifications. Seizures are common and often (or always) precede the stroke-like events. Progressive external ophthalmoparesis was noted in approximately 10% of cases. The m.3243A>G mutation in the tRNA<sup>Leu(UUR)</sup> gene (*MTTL*) of mtDNA is responsible for about 80% of MELAS patients worldwide. Several other mutations in the same gene have been associated with MELAS, as well as increasing numbers of mutations in structural genes of mtDNA.

*Myoclonic epilepsy and ragged-red fibers (MERRF)* was first described in 1980. The major clinical features include cerebellar syndrome, generalized convulsions, myoclonus, dementia, hearing loss, impaired deep sensation, and a positive family history consistent with maternal inheritance. In 1990 Shoffner and colleagues described a point mutation (m.8344A>G) involving the mtDNA gene for tRNA<sup>Lys</sup> (*MTTK*). Two more mutations in the same gene (m.8356T>C and m.8363G>A)

are less frequent causes of typical MERRF. One mutation in a different gene (m.611G>A in the tRNA<sup>Phe</sup>) gene (*MTTF*) has been reported to cause typical MERRF.

## THERAPY

No panacea for respiratory chain dysfunction and no universal therapy for mitochondrial disorders currently exist. Nevertheless, symptomatic pharmacologic treatments (for example, antiepileptic drugs) and surgical interventions (such as blepharoplasty) are useful in prolonging and improving the lives of patients with these conditions. Exercise therapy has been demonstrated to improve exercise tolerance and quality of life in patients with mitochondrial diseases. Several strategies aimed at curing (or even preventing) mitochondrial diseases have shown promise *in vitro* or in animals, or have produced encouraging preliminary results in humans (Viscomi et al., 2015).

### Mitochondrial Replacement Therapy (MRT)

For mtDNA-related diseases, many of which are devastating and undiagnosable prenatally, the ultimate goal is to prevent their occurrence altogether via mitochondrial replacement. In this approach, the nucleus of an oocyte from an mtDNA mutation carrier is transferred to an *in vitro*-fertilized enucleated oocyte from a normal donor, resulting in the embryo having the nDNA of the biological parents but the mtDNA of a normal mitochondrial donor. In nonhuman primate experiments using oocyte spindle-chromosomal complex transfer, the offspring were healthy and devoid of original maternal mtDNA. The same technique was applied to fertilized and unfertilized but parthenogenetically activated human oocytes, and the cells were found to develop into normal blastocysts and containing virtually exclusively donor mtDNA (Paull et al., 2013). Moreover, only donor mtDNA was detected after stem cell lines from blastocysts were differentiated into neurons, cardiomyocytes, and  $\beta$ -cells. Similar results were obtained in the United Kingdom after pronuclear transfer in abnormally fertilized human oocytes developed up to the blastocyst stage. Despite some concerns, the stage appears to be set for approval of this technique for therapeutic application both in the United Kingdom and the United States.

### Shifting Heteroplasmy

For mtDNA-related disorders, an obvious but challenging goal is to shift heteroplasmy in patients, thereby lowering the mutation load to subthreshold levels. When deprived of glucose and exposed to ketogenic media, cybrids harbouring single mtDNA deletions shifted their heteroplasmy level and recovered mitochondrial function, probably through selective mitochondrial autophagy (mitophagy). A genetic approach to heteroplasmic shifting involves use of restriction endonucleases to eliminate specific pathogenic mutations.

### Enhancement of Respiratory Chain Function

The most obvious therapeutic approach to mitochondrial disorders is to enhance respiratory chain function, thereby mitigating both energy crisis (ATP deficit) and oxidative stress (toxic build-up of ROS). The compound is used almost universally in patients with mitochondrial disease is CoQ10, given the pivotal role of this molecule in electron transport, its antioxidant properties, and its safety even at high doses. Two synthetic analogs of CoQ10—idebenone and parabenzoquinone—seem more promising. Idebenone, a short-chain benzoquinone, has shown positive results in two studies of patients with LHON. The second compound,

a parabenzoquinone labeled EPI-743, has so far been tested only in open studies; this compound reversed vision loss in four of five patients with LHON produced clinical improvement in 12 children with various mitochondrial disorders and arrested or reversed disease progression in 13 children with genetically proven Leigh syndrome.

### Elimination of Noxious Compounds

The second logical therapeutic approach to mitochondrial disease is to eliminate the noxious compounds that accumulate in these disorders. To decrease brain lactate in patients with MELAS, we used dichloroacetate (DCA), which stabilizes pyruvate dehydrogenase in the active form and favors lactate oxidation. Unfortunately, this agent, DCA, had unacceptable neurotoxicity and treatment had to be discontinued. A more promising “detoxifying therapy” may be allogeneic hematopoietic stem-cell transplantation (AHSCT) aimed at restoring sufficient thymidine phosphorylase activity in patients with MNGIE to normalize the circulating toxic levels of thymidine and deoxyuridine. As of 2012, 9 of 24 patients with MNGIE who had undergone AHSCT were alive and had normal blood thymidine phosphorylase activity, virtually undetectable levels of thymidine and deoxyuridine, and mild clinical improvements. A safety study of AHSCT in patients with MNGIE is under way to assess whether transplants can be performed with low morbidity in mildly to moderately affected individuals.

### Alteration of Mitochondrial Dynamics

Mitochondrial dynamics could be exploited therapeutically in two opposing ways. Mitochondrial fission could be enhanced, thereby favoring mitophagy, a natural “quality control” function that sequesters and eliminates dysfunctional mitochondria, perhaps sensing their abnormally low membrane potential. Alternatively, enhancement of mitochondrial fusion and “networking” would allow complementation of “bad” and “good” mitochondria and normalization of overall mitochondrial function.

Although natural mitochondrial proliferation (e.g., RRF) is a futile compensatory mechanism, preliminary studies indicate it may be possible to improve on nature’s strategy by enhancing mitochondrial biogenesis through activation of the transcriptional coactivator PGC-1 $\alpha$ , AMPK pathway, or Sirtuin1. The advantage over disease-induced mitochondrial proliferation, which appears to favor mutated mtDNAs, is that

upregulation of mitochondrial biosynthesis increases numbers of all mtDNAs, allowing wild-type genomes to compensate for mutated ones. Encouraging results have been obtained in four mouse models of COX deficiency.

## Peroxisomal Disorders

Gerald V. Raymond, Kristin W. Barañano, and S. Ali Fatemi

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Disorders of the peroxisome—organelles found in all eukaryotic cells—are characterized by alterations in their unique metabolic functions in the cell and tissues. The pervasive presence of the peroxisome leads to far-reaching consequences of these genetic disorders. Peroxisomal disorders are divided into two major categories. In the first, the organelle fails to develop normally, leading to disruption of multiple peroxisomal enzymes. The second category consists of those disorders in which the peroxisome structure is normal but functioning of a single peroxisomal enzyme is defective. [Box 43-1](#) lists the known peroxisomal disorders; their combined incidence is estimated at 1 in 25,000 or higher. Because peroxisomal disorders are genetically determined with a majority readily identifiable by biochemical means, including prenatal testing, and nearly all affecting the nervous system, knowledge of these diseases is important. As the pathophysiology of these disorders is better understood, novel therapeutic strategies may be developed, which gives new hope for advances not only in the diagnosis but also in the management and outcome of peroxisomal disorders ([Vamecq et al., 2014](#)).

### STRUCTURE AND FUNCTION OF PEROXISOMES

The peroxisome is bound by a single membrane and contains a fine granular matrix. Histologically, these organelles are identified by the presence of catalase, are present in all human tissues except mature erythrocytes, and demonstrate variation in size and number. They do not contain DNA and appear to be devoid of glycoproteins. The membrane is 6.5 to 7 nm thick and has a trilaminar appearance and a unique protein composition. The peroxisomal membrane contains four ATP binding cassette (ABC) proteins. These proteins have important intracellular roles in transport. As discussed later on, the ABC protein, ABCD1, is defective in X-linked adrenoleukodystrophy, the most prevalent peroxisomal disorder.

The process of peroxisomal biogenesis is highly conserved in all eukaryotic organisms, which has permitted the study of yeast to identify the cellular mechanism for the assembly of the organelle and targeting of proteins to the developing vesicle. Peroxisomal proteins are encoded by nuclear genes, synthesized on free polyribosomes, and discharged into the cytosol in the mature form. Work in yeast has identified more than 20 genes labeled PEX whose products, peroxins, are required for the incorporation of peroxisome membrane proteins and matrix protein importation. Peroxins are required for the proper importation and have roles in receptor docking, stability, and translocation across the membrane.

Targeting information directing matrix proteins into the peroxisomes is inherent in the mature polypeptide. A majority of proteins destined for the peroxisome use peroxisome targeting sequence 1 (PTS1), which consists of a terminal tripeptide of serine-lysine-leucine (-SKL) that is recognized by the soluble receptor Pex5p. Not all matrix proteins contain the carboxyl-terminal PTS1 signal. The peroxisomal enzymes, 3-ketoacyl-coenzyme A (CoA) thiolase and phytanoyl-CoA hydroxylase, have a different peroxisomal targeting sequence (PTS2). PTS2

consists of a nine-residue signal located at the amino terminus. It directs the import of a smaller number of proteins using the soluble receptor Pex7p ([Wanders, 2014](#)).

### METABOLIC FUNCTION OF PEROXISOMES

Peroxisomes were named for the presence of hydrogen peroxide and catalase, which decomposes the hydrogen peroxide. It is now known that more than 40 enzymatic functions are found in the peroxisome. Some peroxisomal activities such as oxidation of fatty acids and cholesterol synthesis can occur in other cellular compartments as well. Certain reactions, however, occur exclusively in the peroxisome. These reactions include oxidation of very long-chain fatty acids and pipecolic acid and certain steps in the synthesis of plasmalogens and bile acids. These reactions are abnormal in many peroxisomal disorders. The composition of enzymes within the peroxisome varies among species and within tissues in a species, as well as with maturation, metabolic state, and environmental factors.

### CLASSIFICATION OF PEROXISOMAL DISORDERS

Peroxisomal disorders may be divided into two categories:

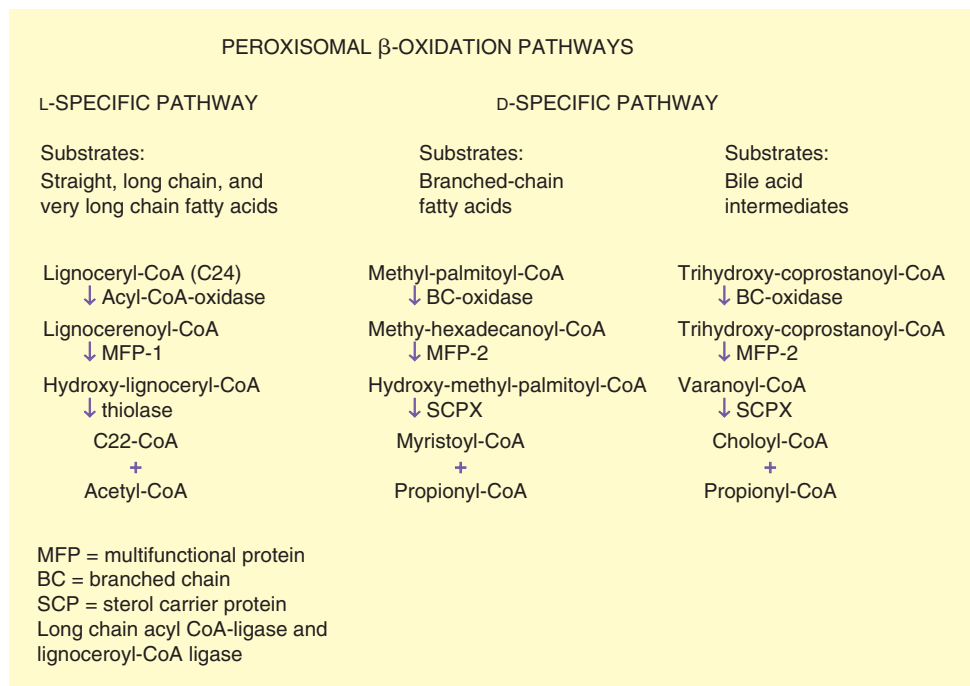

1. Disorders of peroxisome assembly or biogenesis
2. Single-enzyme defects

In the first, the peroxisome fails to form, and abnormalities of multiple peroxisomal functions are present. It is understood that these disorders are defects in protein importation using the PTS1 and PTS2 targeting sequences or membrane incorporation. This group of biogenesis disorders can be further divided by their clinical and biochemical features into the Zellweger spectrum disorders and rhizomelic chondrodysplasia punctata. The second major group consists of a growing number of disorders in which a genetically determined abnormality of a single peroxisomal enzyme is present and peroxisomal structure is intact.

All of these disorders are, in actuality, single-gene and, ultimately, single-protein deficiencies, but the downstream consequences of the first group affect more than one peroxisomal pathway, resulting in multiple diagnostic abnormalities. With the emergence of DNA-based diagnosis, the utility of this division may require reassessment. An overview of diagnostic evaluation of peroxisomal disorders is provided in [Figure 43-2](#).

### CONDITIONS RESULTING FROM DEFECTIVE PEROXISOME BIOGENESIS

Conditions resulting from defective peroxisome biogenesis are listed in [Box 43-1](#); Zellweger syndrome and rhizomelic chondrodysplasia punctata are the respective prototypes. Clinical and biochemical variation between these two types of assembly defects still makes it useful to discuss them separately, although it is important to recognize that these disorders were

**Figure 43-1.** Activation and subsequent  $\beta$ -oxidation of very long-chain fatty acids, branched-chain fatty acids, and bile acid intermediates by the l- and d-specific pathways in peroxisomes. CoA, coenzyme A.

### BOX 43-1 Peroxisomal Disorders

#### DISORDERS OF PEROXISOME BIOGENESIS

##### Zellweger Spectrum

- Zellweger syndrome
- Neonatal adrenoleukodystrophy
- Infantile Refsum disease

##### RHIZOMELIC CHONDRODYSPLASIA PUNCTATA (RCDP)

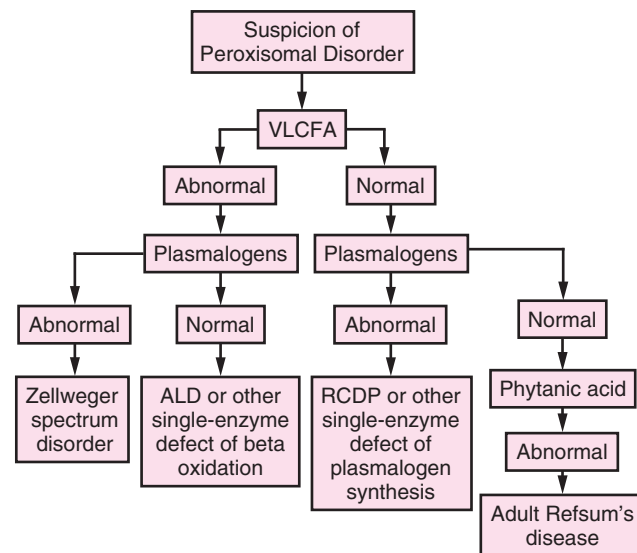

- Refsum disease secondary to PEX7 mutation

#### DISORDERS OF SINGLE PEROXISOMAL ENZYMES

##### X-Linked Adrenoleukodystrophy

- CADD5
- Acyl CoA-oxidase deficiency
- Bifunctional enzyme deficiency
- DHAP acyltransferase deficiency
- Alkyl DHAP synthase deficiency
- Hyperoxaluria type 1
- Adult Refsum disease
- Acatalasemia
- Mulibrey nanism

CADD5, contiguous ABCD1 DXS1357E deletion syndrome; CoA, coenzyme A; DHAP, dihydroxyacetone phosphate.

**Figure 43-2.** Diagnostic evaluation of peroxisomal disorders. Confirmatory genetic or biochemical testing may be required. ALD, adrenoleukodystrophy; RCDP, rhizomelic chondrodysplasia punctata; VLCFA, very long-chain fatty acid.

described on a clinical basis before details of the cell and molecular biology of peroxisomal disorders was known; hence, they were assigned names based on the clinical features, pathologic findings, or biochemical defects that identified them.

## MOLECULAR ETIOLOGY OF DISORDERS OF PEROXISOME ASSEMBLY

These disorders result from defects in the PEX genes. A complex interaction of peroxins is necessary for the biogenesis

of peroxisomes, and a defect in any of these proteins impairs the process. The final common pathway is peroxisomal dysfunction, with the respective clinical syndromes. Zellweger spectrum disorders are secondary to PTS1-mediated pathways including PEX5, and that rhizomelic chondrodysplasia punctata is secondary to mutations in PEX7, the receptor for PTS2 proteins (Braverman et al., 2013). The most common causes of Zellweger spectrum disorders are mutations in either PEX1 or PEX6, although to date, 13 PEX genes have been identified as potential causes of these disorders. PEX1 and PEX6 encode AAA ATPases. The clinical spectrum is seen in PEX1.

For example, a single base-pair deletion results in a severe phenotype and the common missense mutation G843D allows a milder phenotype (Braverman et al., 2013).

## ZELLWEGER SPECTRUM DISORDERS

Zellweger syndrome (cerebrohepatorenal syndrome) was first described by Bowen and associates. Subsequently, the disorders neonatal adrenoleukodystrophy and infantile Refsum disease were described as separate entities. Although classic Zellweger syndrome is the most severe form with a characteristic phenotype, clinical overlap exists between it and the other forms. All of the Zellweger spectrum disorders share morphologic and biochemical abnormalities, and genetic understanding of the underlying mutations has been obtained in many cases. In view of this overlap, it appears prudent at this time to retain a portion of this clinical nomenclature and refer to the group as Zellweger spectrum disorders.

### Clinical and Pathologic Features

#### Zellweger Syndrome

Zellweger syndrome is a multiple congenital anomaly syndrome characterized by craniofacial abnormalities, eye abnormalities, neuronal migration defects, hepatomegaly, chondrodysplasia punctata, and near-complete absence of peroxisomes. The craniofacial features include a high forehead, hypoplastic supraorbital ridges, epicanthal folds, midface hypoplasia, and a large fontanel (Fig. 43-3). The head circumference usually is normal. Reported ocular abnormalities include cataracts, glaucoma, corneal clouding, Brushfield spots, optic nerve hypoplasia, and pigmentary retinal abnormalities. Severe weakness and hypotonia manifest in the newborn period, often accompanied by seizures and apnea. Most affected infants have oromotor dysfunction and require

tube feeding. Little psychomotor development ensues, and the average life span is limited, with most affected children surviving for 12 to 24 months. The facial appearance, Brushfield spots, and profound hypotonia may lead to a consideration of Down syndrome, although the chromosomal determination will eliminate that as a consideration.

Striking abnormalities of neuronal migration unique to Zellweger syndrome are evident in the cerebral hemispheres as areas of pachygyria or polymicrogyria localized to the opercular region. In the cerebellum, the Purkinje cells form scattered heterotopias throughout the cortex and in the granule cell layer. Laminar discontinuities involving the olivary nucleus are noted, which also are unique to Zellweger syndrome.

Multiple other abnormalities have been reported. The eyes demonstrate loss of retinal ganglion cells and gliosis of the optic nerve. Retinal pigmentary degenerative changes are associated with absent electroretinograms. Hepatomegaly with periportal fibrosis may result in significant cholestasis and jaundice, micronodular cirrhosis, and hypoprothrombinemia. Renal cortical cysts of varied sizes are present in 97% of patients studied pathologically but may be missed by ultrasound analyses. The adrenal gland demonstrates changes similar to those in X-linked adrenoleukodystrophy, with cytoplasmic lamellar inclusions consisting of cholesterol esterified with very long-chain fatty acids. Skeletal abnormalities include clubfoot, thumb rotation, and stippled chondral calcification of the patella and acetabulum in 50% of patients.

#### Neonatal Adrenoleukodystrophy and Infantile Refsum Disease

We now have a clear understanding that alteration in PEX genes may result in clinical phenotypes that are less severe than in Zellweger syndrome previously termed NALD and IRD. Even in the milder forms, patients generally have

**Figure 43-3.** Cerebrohepatorenal syndrome of Zellweger. **A**, Note the prominent forehead, large fontanel, hypertelorism, epicanthal folds, hypotonia, and hepatomegaly. **B**, Milder form of generalized peroxisomal disorder: 10-year-old boy with ataxia, significant mental retardation, visual loss secondary to retinitis pigmentosa, absence of speech, and sensorineural hearing loss. Liver biopsy showed micronodular cirrhosis and very few, abnormally small peroxisomes.

intellectual disability, sensorineural hearing loss, retinal degeneration, and motor handicaps. Dysmorphism is less severe than in Zellweger syndrome; renal cysts may be absent, and no radiographic stippling of the cartilage is seen. Although neonatal adrenoleukodystrophy and infantile Refsum disease have in the past been split into distinct clinical presentations, this division can no longer be supported in light of more recent information on the genetic mechanism. This was already apparent from the clear clinical overlap between Zellweger syndrome and neonatal adrenoleukodystrophy and infantile Refsum disease. Attempts to differentiate between these milder phenotypes, either genetically or biochemically, do not reliably predict the clinical course.

Patients with milder forms may present in the neonatal period with mild to moderate dysmorphism, hypotonia, poor feeding, and hepatomegaly. Motor and cognitive development usually is delayed. Even with hypotonia, patients may be able to walk, although gait often is ataxic. Retinal pigmentary degeneration may not become evident until the age of 4 to 6 months and often results in visual loss in the first years of life. Electroretinograms show profound abnormalities in nearly all affected persons and do not correlate well with vision in this population. Sensorineural hearing loss is associated with limited language development. Adrenal dysfunction may develop with age. Liver dysfunction often is present and detectable by persistent elevation of liver enzymes. A bleeding diathesis that responds to vitamin K also may develop; in several children, esophageal varices were observed, consistent with portal hypertension. Optic atrophy and retinitis pigmentosa may be seen in patients. The association of retinal pigmentary degeneration and sensorineural hearing loss has led to misdiagnosis as Usher syndrome.
