**TABLE 140-1** Motor Neuron Disease Plus Syndromes (Continued)

Clinical Patterns	Disease	Symptoms	Genes	Inheritance	Diagnostic Testing
Arthrogryposis	LCCS1	Onset: in utero Hydrops fetalis, arthrogryposis multiplex congenita Pulmonary hypoplasia Fractures	<i>GLE1</i> ; 9q34	AR	
	LCCS2	Chest wall deformities Onset: birth Multiple joint contractures Markedly distended bladder Single family of Israeli-Bedouin origin	<i>ERBB3</i> ; 12q13	AR	Anterior horn cell atrophy on autopsy
	SMA-LED	Onset: birth Contractures	<i>DYNC1H1</i> ; 14q32.31	AD	
	X-linked SMA with arthrogryposis (XL-SMA, SMA <sub>X2</sub> )	Onset at birth or infancy Pattern of weakness similar to classic SMA Proximal and finger contractures Myopathic facies Respiratory insufficiency Dysmorphic features Death less than 2 years of age	<i>UBE1</i> ; Xp11.3	X-linked recessive	

AD, autosomal-dominant; AR, autosomal-recessive; CK, creatine kinase; CMAP, compound muscle action potential; CRDs, complex repetitive discharges on EMG; EMG/NCS, electromyography and nerve conduction study; LCCS, lethal congenital contracture syndrome; SMA, spinal muscular atrophy; SMA<sub>X2</sub>, spinal muscular atrophy with respiratory distress; SNAP, sensory nerve action potential.

evaluation for pontocerebellar hypoplasia (PCH). Three types of PCH have been associated with an SMA-like phenotype: PCH1A (*VRK1*), PCH1B (*EXOSC3*), and PCH1C (*EXOSC8*). Children generally present at birth or in infancy with variable contractures and cerebellar hypoplasia. An MRI of the brain will identify cerebellar abnormalities. Electrophysiologic testing can demonstrate the presence of an axonal sensorimotor polyneuropathy.

A few of the genetic motor neuron disorders can have associated movement disorders. Patients with leukoencephalopathy with dystonia and motor neuropathy can present in childhood with progressive distal weakness as well as cerebellar and extrapyramidal symptoms. Whereas the infantile form of hexosaminidase A deficiency is primarily characterized by CNS manifestations, the juvenile onset form may have an associated progressive motor neuropathy characterized by muscle atrophy with fasciculations, muscle cramping, and proximal greater than distal weakness in addition to a movement disorder with ataxia, dysarthria, and dystonia. Patients with achalasia-addisonism-alacrima syndrome (triple A syndrome) may present in childhood with intellectual disability, developmental delay, spasticity, and a progressive axonal motor neuropathy. The associated gastrointestinal, endocrine, skin, and autonomic dysfunction makes identification relatively straightforward.

There are few genetic motor neuron disorders associated with seizures. When myoclonic seizures are present in a patient with suspected motor neuron disease, mutations of *ASAH1* should be sought. Symptoms typically are seen between 3 and 5 years of age with progressive weakness of the legs, arms, and then respiratory muscles.

### Motor Neuron Diseases With Predominant Bulbar Weakness

Bulbar symptoms are often part of the presentation of many neurodegenerative disorders. However, when dysphagia, dysphonia, and dysarthria are the dominant presenting features, childhood progressive bulbar syndromes should be considered. Brown-Vialetto-Van Laere (BVVL) disease and Fazio-Londe (FL) disease are two distinct clinical entities

recognized to be allelic conditions and present along a phenotypic spectrum. The major features of BVVL disease are pontobulbar palsy, neuronopathy, respiratory insufficiency, and sensorineural hearing loss, presenting in the first or second decade of life. The course is generally progressive, but may appear episodic with worsening with illness. In contrast, FL disease is not associated with hearing loss, and onset is in the first to third decades of life. Patients may present initially with repeated respiratory infections and stridor, with progression to weakness, wasting, hypotonia, and decreased reflexes. In both BVVL and FL, patients often die of respiratory failure. The identification of biochemical abnormalities suggested a multiple acyl-CoA dehydrogenase deficiency (MADD)-like disorder and the finding of decreased plasma flavin levels in these patients indicated that riboflavin transporters could play a role. Subsequently, two genes were identified in patients with BVVL and FL. Solute carrier family 52, riboflavin transporter, member 3 (*SLC52A3*, previously known as *C20orf52*) encodes intestinal human riboflavin transporter 3, which is necessary for riboflavin absorption, and *SLC52A2* (previously G protein-coupled receptor 172A) encodes human riboflavin transporter 2 (RFVT2, previously human riboflavin transporter 3 [hRFT3]). Although with both mutations a MADD-like biochemical profile is seen, plasma flavin levels are normal in patients with *SLC52A2* mutations, likely because the encoded transporter is responsible for transport of riboflavin from blood into target cells. Because the *SLC52A3*-encoded transporter is responsible for uptake of riboflavin from food, flavin levels are low. Therefore acylcarnitine levels taken at birth should be interpreted with these differences in mind if BVVL or FL is suspected.

Recognition that riboflavin transport is affected in these patients is an important advance in the management of these children. Treatment with high-dose riboflavin (10 mg/kg per day) appears to result in significant and sustained clinical and biochemical improvements. The recommendation is for treatment early in the disease course in suspected cases to maximize response.

Spinal and bulbar muscular atrophy (SBMA, or Kennedy's disease) is an X-linked motor neuron disease typically presenting in adult men in the 3rd to 5th decades. The classic presentation is of slow progression of proximal weakness, bulbar

weakness including asymmetric or symmetric facial weakness, and gynecomastia. However, some patients may complain of exercise-induced muscle cramps and hand tremors several years before weakness develops, as early as the second decade of life. Weakness and atrophy of the bulbar musculature is striking and may include an atrophied, furrowed tongue and atrophy of the face and jaw. Facial fasciculations around the mouth and chin are striking clinical features best elicited by having the patient whistle or blow out the cheeks. There are no signs of spinal cortical tract dysfunction, and deep tendon reflexes are diminished or normal. EMG/NCS findings and an unusually elevated CK are supportive findings, and should prompt testing for expanded CAG trinucleotide repeats in the androgen receptor gene (*hAR*).

### Motor Neuron Disease With Arthrogryposis

Arthrogryposis at birth can occur because of many causes, but in the context of motor neuron disease, this finding indicates severe and early motor neuron dysfunction. Lethal arthrogryposis with anterior horn cell disease (LAAHD) and X-linked spinal muscular atrophy (SMAX2) are the most severe forms of motor neuron disease. The clinical phenotype includes severely decreased fetal movements, severe multiple contractures at birth, hypotonia, chest wall deformities, pulmonary hypoplasia, and bony fractures. In both LAAHD and SMAX2, patients have severe respiratory insufficiency and die by age 2 years. LCCS2 is a rare disorder described in one family, presenting with multiple contractures at birth and markedly distended bladders. Spinal muscular atrophy with lower extremity predominance (SMA-LED) associated with *DYNC1H1* mutations typically presents in early childhood, but has been associated with contractures at birth, from mild talipes to severe generalized arthrogryposis.

### Motor Neuron Disease With Distal Weakness

The diagnosis of a distal motor neuropathy or neuronopathy can be difficult, particularly if the presentation occurs later in adulthood (Drew et al., 2011). The phenotypic spectrum is wide and varies from a CMT-like presentation to juvenile amyotrophic lateral sclerosis (ALS) and hereditary spastic paraparesis with associated mild sensory abnormalities and upper motor neuron signs, respectively (Table 140-2). Electrophysiologic studies are one of the most helpful means of distinguishing between these diagnostic possibilities. This section will focus on those disorders presenting with lower motor neuron disease in childhood. They are characterized by a slowly progressive length-dependent weakness, starting in the first 2 decades of life, with distal weakness and atrophy, absent reflexes, and electrophysiologic findings of chronic distal denervation. Bulbar involvement, with the exception of vocal cord weakness, is unusual.

The phenotypic variability of these disorders can complicate diagnostic workup of these disorders. The simplest method to approach the diagnosis is by organization by inheritance pattern and by the dominant weakness (Figure 140-2B). However, even with this approach, the diagnostic yield is low, with genotypic characterization in 20% of patients. Of these disorders, SMA with lower extremity predominance (SMA-LED) type 1 caused by *DYNC1H1* mutations can be easily recognized by the unusual waddling gait and disproportionate weakness of the legs compared with the arms. Patients may present at birth with multiple contractures, but many of the patients present with delayed walking in childhood and a slowly progressive weakness and gait abnormality. Intellectual disability and migrational abnormalities have been noted in some patients as well. Interestingly, mutations of *BICD2*, which functions as an adaptor of the dynein molecular motor,

result in SMA-LED2 with similar weakness and gait abnormalities as SMA-LED1. In both, obtaining a complete family history is important in identifying other affected family members and the autosomal-dominant inheritance pattern.

Although mutations of *TRPV4* can present with leg-predominant weakness, a distinguishing feature that can identify the presence of this gene mutation is a hoarse voice resulting from vocal cord paralysis. Mutations of *DCNT1* can also cause vocal cord paralysis, but the clinical picture is more variable. The lower motor neuron phenotype is more suggestive of ALS or SMA than a length-dependent neuropathy. Symptoms typically begin in adulthood with face-arm weakness first, with leg weakness presenting later. Some patients can present with pyramidal signs, as can patients with mutations of *BSCL2* and *HSPB1*.

### Amyotrophic Lateral Sclerosis With Onset in the First Two Decades of Life

ALS represents a spectrum of motor system degeneration involving the corticospinal and corticobulbar pathways and motor neurons associated with the cranial nerves and anterior horn cells of the spinal cord. Onset may be as early as early childhood, although the majority present after the fourth decade of life. Dysfunction of upper and lower motor neurons produces clinical manifestations of both spasticity and muscular atrophy.

To date, more than 25 genes have been associated with ALS or ALS associated with frontotemporal dementia (<http://neuromuscular.wustl.edu/synmot.html#Hereditaryals>). The first causative gene described for ALS in adults (*ALS1* is *SOD*, a gene that encodes a cytosolic Cu/Zn-binding superoxide dismutase, is causative in *ALS1*).

There are six recognized ALS syndromes with onset in the first two decades of life (Table 140-3). First, *ALS 2* is an autosomal-recessive disease caused by mutations in the *Alsin* gene. *Alsin* is a member of the guanine nucleotide exchange factors for the small guanosine triphosphatase, *RAB5*, and plays a role in endosomal trafficking. Children present in the first decade of life with spasticity involving face and limbs, and may develop pseudobulbar affects. Symptoms are very slowly progressive, with difficulty walking after age 40. Two allelic conditions, infantile-onset ascending paralysis and primary juvenile lateral sclerosis (OMIM 606353) are well recognized. More recently, another allelic variant with ALS and generalized dystonia was described. *Alsin*-deficient mice experience progressive axonal degeneration in the lateral spinal cord but lower motor neurons were preserved.

The second juvenile-onset form of ALS is *ALS 4*, an autosomal-dominantly inherited distal motor neuronopathy with pyramidal symptoms. *ALS 4* is allelic to recessively inherited oculomotor apraxia type 2 (*AOA2*). Symptoms of *ALS 4* begin in the second decade of life with difficulty walking, and examination indicates both upper and lower motor neuron involvement. Bulbar symptoms are infrequent. Electrophysiology confirms localization to the anterior horn cell. The clinical course is slowly progressive, with use of wheelchair by fifth or sixth decade and a normal life span. The senataxin protein plays an essential role with DNA damage response.

The third form of ALS with childhood onset is *ALS 5*. *ALS 5* is recessively inherited and is caused by mutations in the *SPG11* gene, which encodes spatacsin and is allelic with *SPG11*. The age of onset is 7 to 23 years, with a mean age of 16 years. Spasticity of limbs, face, and bulbar is present with amyotrophy and weakness. The course is slowly progressive with survival duration of 27 to 40 years.

To date, three other genetic forms of juvenile ALS have been determined by small, informative families. They include *ALS6* secondary to *FUS*, *ALS 16* secondary to sigma-1 receptor, and

**TABLE 140-2** Distal Forms of SMA

Disease	Symptoms	Genes	Inheritance	Diagnostic Testing
Distal SMA, X-linked 3 (SMA3)	Onset: 1–61 years Early weakness of legs with slow progression; remain ambulatory Pes cavus Temperature sensitivity with worsening in cold Variable reflexes	<i>ATP7A</i> ; Xp21.1	X-linked recessive	CK normal EMG/NCS: reduced or absent CMAP, normal SNAPs; widespread denervation on EMG
DSMA1 Distal infantile SMA with diaphragm paralysis SMARD1 (HMN6)	Distal SMA weakness at age 1 year with progression but variable onset of respiratory failure	<i>IGHMBP2</i> ; 11Q13.3	AR	
DSMA 2 Jerash type	Onset 6–10 years Distal weakness in legs and then arms within 2 years Atrophy of hands and feet Brisk reflexes at knees, absent at ankles	9p21.1-p12	AR	EMG/NCS: small CMAPs, normal SNAPs Normal CK
DSMA 3	Onset age 9 months to early adulthood Weakness of feet great than hands Diaphragmatic weakness with childhood onset	11q13.3	AR	EMG/NCS: normal nerve conduction studies; denervation on EMG
DSMA 4	Onset 2–11 years Proximal = distal weakness Scapular winging Progressive respiratory failure Contractures of the hips, elbows, hands Hyperlordosis Allelic with CMTR1C	<i>PLEKHG5</i> ; 1p36.31	AR	EMG/NCS normal nerve conduction studies; denervation on EMG
DSMA 5 (distal motor neuropathy with young adult onset)	Onset age 16–23 years Foot drop Legs great than hands Absent reflexes Edema in legs Progressive to wheelchair Allelic with CMT 2T	<i>DNAJB2</i> ; 2q35	AR	EMG/NCS: small CMAP, especially in legs, normal SNAPs
SMA, lower extremity predominant 1 (SMA-LED)	Onset: birth to early childhood Late walking Slowly progressive Weakness legs great than arms, quadriceps, psoas, and hip abductors typically weak out of proportion to rest of muscles Waddling gait	<i>DYNC1H1</i> ; 14q32.31	AD	MRI legs: early involvement of the vastus lateralis and sartorius MRI brain: occasionally see polymicrogyria, cobblestoning
SMA, lower extremity predominant 2	Onset: in utero, infancy, young adulthood Delayed walking Weakness of legs great than arms, like in SMA-LED1 Contractures of ankles, knees Sleep disordered breathing Slow progression Normal sensation, bulbar function, and cognition	<i>BICD2</i> ; 9q22.31	AD	MRI legs: early involvement of vastus lateralis and intermedius, rectus femoris; spares semitendinosus, medial adductors EMG/NCS: chronic denervation on EMG
DSMA-calf predominant (HMN2D)	Onset 13–48 years Presentation with difficulty standing or walking Weak calves Triceps also weak Fasciculations present	<i>FBXO38</i> ; 5p31.1	AD	EMG/NCS: reduced amplitudes of CMAPs, normal SNAPs, fibrillation potentials
SMA, congenital nonprogressive of the lower limbs	Onset: congenital Weakness of legs only, proximal and distal Nonprogressive Some with vocal cord paralysis Contractures of knees and ankles	<i>TRPV4</i> ; 12q24.11	AD	Mildly elevated CK EMG/NCS: giant motor units; normal motor and sensory NCSs
DSMA: upper extremity predominance (HMN5C)	Onset: 15 years (2–40 years) Weak hands (thenar great than first dorsal interosseous) Foot deformities Peroneal weakness Brisk DTRs Decrease vibration in legs	<i>BSCL2</i> ; 11q12.3	AD	EMG/NCS: small CMAPs, normal or mildly decreased motor NCVs; large MUPs on EMG
DSMA: upper extremity predominance (HMN5A, SMAD1)	Onset: second decade Weakness of thumb and first dorsal interosseous Lower extremity involvement in 50% in 2 years Slow progression Rare pyramidal involvement	<i>GARS</i> ; 7p14.3	AD	

**TABLE 140-3** Genetic Forms of ALS Associated With Presentation in Childhood

Name	Inheritance Gene; Loci	Protein	Onset (Years)	Inheritance	OMIM
ALS 2	AR <i>ALS2</i> ; 2q33	Alsin	1–3	AR	#20511
ALS 4	AD <i>SETX</i> ; 9q34	Senataxin	6–21	AD	#602433
ALS 5	AR <i>ALS5</i> ; 15q21	Spataccin	5–23	AR	#610844
ALS 6 variant	Sporadic <i>FUS</i> ; 16p11	Fusion	17–22	Sporadic	#608030
ALS 6–21	AR 6p 25; 21q22	Unknown	4–10	AR	
ALS 16	AR <i>SIGMAR1</i> ; 9p13	Sigma-1 receptor	1–2	AR	#614373

*AD*, autosomal-dominant; *ALS*, amyotrophic lateral sclerosis; *AR*, autosomal-recessive; #, OMIM gene identified.

a third form currently linked to 6p25 and 32q22. ALS6 is autosomal recessive, is caused by heterozygous mutations in the *FUS* gene, and can present with or without frontotemporal dementia. Although most present in the third and fourth decade, a juvenile form has been reported with onset between age 17 and 22 and may have rapid progression. It is allelic with familial essential tremor-4 caused by heterozygous mutations (*ETM4*). A single family has been found to have autosomal-recessive childhood ALS (ALS16) with onset at age 1 to 2 years because of sigma-1 receptor mutations (*SIGMAR1*). Progression in 2 of the 6 children led to wheelchair use by age 20 but no respiratory or bulbar weakness. Finally, another single family with four affected children has been shown to have autosomal-recessive ALS linked to 6p25 and 21q22.

## OTHER ATYPICAL AND ACQUIRED MOTOR NEURON DISORDERS

If weakness occurs acutely, acquired causes of motor neuron disease should be diagnostic considerations. Infectious, para-infectious, autoimmune, vascular, and traumatic etiologies can result in acute muscle weakness without sensory changes.

## INFECTIONS

With the introduction of the polio vaccine, poliovirus as an infectious cause of acute flaccid weakness has virtually been eradicated. However, recent resurgences of children with flaccid weakness remind us that viruses remain an important etiology to consider when suspecting an acquired cause of motor neuron disease.

Poliovirus was one of the most common causes of acquired motor neuron disease. Typically acquired via the fecal-oral route, the virus is stable in the gastrointestinal tract, and can be detected in the throat and stool before the onset of illness. Less than 1% of all polio infections result in flaccid paralysis. Onset is usually indicated by upper respiratory tract symptoms with accompanying malaise, muscle pain, and stiffness. The patient may experience some degree of nuchal rigidity and a low-grade fever as the disease progresses. Paralytic symptoms generally begin 1 to 10 days after prodromal symptoms and progress for 2 to 3 days. Poliomyelitis is characterized by a triad of fever, nuchal rigidity, and spasm of the back, and may be mistaken for typical meningitis. Typically once the temperature normalizes, no further paralysis occurs. Patients with more rapid progression have more severe involvement, typically with respiratory and bulbar weakness. The weakness

is typically asymmetric, associated with decreased reflexes, and reaches a plateau without change for days to weeks. There is no accompanying sensory loss or changes in cognition. Although some persons with paralytic poliomyelitis recover completely, those with weakness present after 12 months will have permanent weakness.

Cerebrospinal fluid (CSF) pleocytosis with mononuclear cells and a normal or slightly elevated protein concentration supports this diagnosis. Complete blood cell count show that polymorphonuclear cells may predominate early in the course. Poliovirus may be recovered from the stool or pharynx. Isolation of the virus from the CSF is diagnostic, but it is rarely found. Treatment is supportive, and typically requires prolonged rehabilitation as some degree of motor deficits persists after the acute infection. Postpolio syndrome may begin two or more decades after the illness, with progressive loss of strength and atrophy of an already affected limb.

Through widespread use of the polio vaccine, the incidence had been drastically reduced in most parts of the world. Most sporadic cases of a polio-like syndrome are no longer associated with the poliovirus but are the results of other viral infections, including Epstein-Barr, enterovirus 71, enterovirus D68, echo 4 virus, and coxsackie virus (Solomon et al., 2014).

## Vascular Etiologies

The anterior spinal artery originates from where the vertebral arteries meet and traverses the anterior median sulcus over the entire course of the spinal cord. The radicular arteries are divided into anterior and posterior radicular arteries. Blood from the anterior radicular arteries that enter with the nerve roots between the third cervical and third lumbar segments flows into the anterior spinal artery (Figure 140-5). The anterior spinal artery is then separated further into several sulcal branches that pierce the central gray matter, perfuse the anterior horn cells, and form numerous small penetrating vessels that supply the white matter of the anterior and lateral columns. The anterior spinal artery is vulnerable between the T4 and T8 regions because the radicular artery that supplies it (artery of Adamkiewicz) has poor anastomoses and is effectively an end artery. The anatomic relationship between the two posterior spinal arteries provides a very different vascular pattern for the posterior cord compared with the anterior spinal arteries do for the anterior cord. The posterior circulation enjoys a more extensive collateral system. Therefore occlusion of the posterior spinal arteries usually does not cause severe clinical dysfunction.

Occlusion or hypoperfusion of the anterior spinal artery results in weakness below the level of occlusion, loss of pain, and temperature at or below the level because of involvement of the lateral spinothalamic tracts, and autonomic dysfunction such as loss of bowel and bladder function. The posterior columns mediating proprioception and vibratory sense remain intact. Patients often complain of a diffuse, radicular, or girdle-like pain. Occasionally a partial syndrome is seen in which the gray matter of the spinal cord is preferentially affected, with preserved sensation and bowel and bladder control. In children, the most common etiology is iatrogenic, caused by aortic surgery such as during repair of a coarctation of the aorta. Other causes can include anemia, polycythemia, sickle cell disease, paradoxical embolism from a patent foramen ovale, atlantooccipital dislocation, cervical spondylosis, cervical spinal trauma or sprain, cocaine use, or infections such as tuberculosis.

Although arteriovenous malformations of the spinal cord are rare, they should be considered in a child with acute, subacute, or chronic symptoms of back or radicular pain, sensorimotor changes, or bowel or bladder dysfunction. The most common presentation of a vascular malformation in the spinal cord in children is with weakness. Sudden focal pain may occur with an acute hemorrhage, whereas subacute symptoms that worsen and then improve with gradual deterioration over time may indicate alterations in blood flow because of venous hypertension or repeated hemorrhages. Typically, however, sensory changes are also present, as are changes in bowel and bladder function, suggesting a diagnosis other than primary motor neuron dysfunction. Over time, the acute flaccid paralysis evolves into spasticity. Imaging is key to the diagnosis, and conventional angiography may be required to adequately visualize the malformation to develop a surgical plan. Surgical options include microsurgical exclusion and/or endovascular embolization, but the neurologist should be aware that transient neurologic deficits can occur postoperatively.

## Trauma

There are rare case reports of adults and children who develop a delayed upper and lower motor neuron syndrome after exposure to an electrical injury or lightning. In children, electrical injuries typically occur in the household from putting electrical cords in the mouth or from wall outlets. Transient neurologic deficits immediately after an electrical shock are well described and usually recover after hours to several days. A persistent and progressive motor neuron syndrome has been described, developing at variable time intervals after the initial injury, but the relationship between electrical injury and a motor neuron syndrome is controversial.

Trauma to the spinal cord may follow birth trauma, falls, motor vehicle accidents, or blows to the spinal column, resulting in incomplete or total transection of the spinal cord. However, impairment localized only to the anterior horn cells is unlikely unless the anterior spinal arteries are primarily affected.

## Unknown Etiologies

Monomelic amyotrophy is a rare form of motor neuron disease with clinical deficits limited to a restricted number of myotomes. Most cases are sporadic though a familial form has been reported and susceptibility genes have been identified. Many names have been used for this disorder, including juvenile muscular atrophy of a unilateral upper extremity, benign focal amyotrophy, juvenile segmental muscular atrophy, and Hirayama's disease. Symptoms typically present in the second or third decade of life, with a male

preponderance of 5:1 to 10:1, male-to-female ratio. Most cases are limited to the arm, with insidious, painless weakness and atrophy of the hand muscles that progresses to the forearm. Of note, the brachioradialis and extensor carpi radialis are usually spared. No preceding injury or infection is typically identified. Progression is typically slow, over 1 to 3 years, and there may be atrophy of the other arm, though it is typically less marked and more confined to isolated muscles. The etiology of the disorder is unknown.

## TREATMENT

Other than the potentially riboflavin-responsive BVVL and FL, there are no specific treatments for either the inherited or the acquired motor neuron disorders. The mainstays of treatment remain physical therapy, orthotic support, and orthopedic procedures to protect joints and maximize mobility. Orthopedic procedures performed on patients with arthrogryposis often provided sufficient alignment and stability of the legs to allow independent ambulation. Talcotomy before walking ability is acquired may prove beneficial. Scoliosis may be a prominent problem and may require surgical correction. Some improvement in arm and hand function is usually possible with physical therapy and exercise. Anesthesia for these patients requires special consideration. Otolaryngologic management may be necessary for poor suck reflex, omega-shaped epiglottis, airway compromise, achalasia, and micrognathia.

## DEFINITION

This chapter focuses on those hereditary neuropathies present in the pediatric population. Inherited neuropathies are often referred to collectively as Charcot-Marie-Tooth (CMT) disease, an eponym used in recognition of the three men who initially described the disorder. CMT is, however, an umbrella term that encompasses a wide variety of inherited sensory and/or motor neuropathies. These inherited neuropathies also include other closely related neuropathies such as hereditary neuropathy with liability to pressure palsy (HNPP); distal hereditary motor neuropathy (dHMN), also known as distal spinal muscular atrophy (dSMA); and hereditary sensory neuropathy (HSN). HSN is sometimes referred to as hereditary sensory and autonomic neuropathy (HSAN). Collectively, CMT represents the commonest group of inherited neuropathies observed in the pediatric population and therefore is the main focus of this chapter.

## PREVALENCE AND CLASSIFICATION

CMT is the most common inherited neurologic condition, with a prevalence of around 1 : 2500. It is divided into subtypes based on the pattern of inheritance and by neurophysiological studies. Subtypes include AD demyelinating (CMT 1), AD axonal (CMT 2), AR (CMT 4) and X-linked (CMTX) (Harding, 1980a). CMT 1 typically has slow nerve conduction velocities (less than 38m/s in the upper extremities) and pathologic evidence of a hypertrophic demyelinating neuropathy whereas CMT 2 has relatively normal nerve conduction velocities with evidence of axonal degeneration (Harding and Thomas, 1980b). Because most forms of CMT have both motor and sensory involvement, CMT 1 and 2 are often known as hereditary motor and sensory neuropathy (HMSN) type I or II. Another subtype has emerged, known as CMT Intermediate, with nerve conduction demonstrating intermediate velocities (less than and greater than 38 m/s).

Each type of CMT is now subdivided according to the specific genetic cause of the neuropathy (see Table 141-2). For example, the most common form of CMT1, termed CMT1A, is caused by a duplication of a fragment of chromosome 17 containing the peripheral myelin protein 22-kD (PMP22) gene, whereas CMT1B is caused by mutations in the myelin protein zero (MPZ) gene. Currently, mutations in more than 80 genes have been identified as causes of CMT neuropathies.

## CLINICAL SEQUELAE OF INHERITED NEUROPATHY

Symptoms of inherited peripheral neuropathy include weakness, sensory loss, abnormal balance, and autonomic dysfunction. Weakness is often said to be “length dependent” (i.e., distal and more severe in the legs than the arms). Deep and superficial muscles that are innervated by the peroneal nerve often cause more symptoms than muscles innervated by the

tibial nerve, such as the gastrocnemius. As a result, tripping on a carpet or curb and ankle sprains are frequent symptoms. Foot drop can ensue over time. In the hands, symptoms typically involve fine movements, such as using buttons or zippers and inserting and turning keys in locks. Cramping, the painful knotting of a muscle, frequently occurs with motor or sensorimotor neuropathies.

The sensory symptoms of neuropathy reflect disease of small, thinly myelinated or nonmyelinated fibers serving in pain and temperature sensation and large myelinated fibers serving in position sense. Common symptoms of small-fiber sensory neuropathy include feeling as though the feet are “walking on pebbles” or “ice cold” and difficulty determining whether bath water is hot or cold with the foot. Painful dysesthesias are also associated with small-fiber abnormalities. Large-fiber sensory loss usually impairs balance, which may be worse at night when vision cannot overcome the loss of proprioception. Loss of proprioception is also frequently length dependent, so a patient may improve balance by lightly touching a wall with the hand to improve proprioceptive input to the brain.

Autonomic symptoms may occur in the HSN group and various metabolic neuropathies. Symptoms include postural hypotension, cardiovascular incompetence, impaired sweating, urinary retention or incontinence, impotence, and constipation alternating with diarrhea. Often patients will not volunteer autonomic symptoms because they are not aware these symptoms could originate from a neuropathy, and so these particular symptoms need to be specifically addressed when assessing patients.

Despite phenotypic variability, the typical clinical course of CMT1 and CMT2 patients includes normal development before weakness and sensory loss appear gradually within the first 2 decades of life. This is often referred to as the *classical phenotype*. This term is based on the original description by Harding and Thomas. Affected children are often slow runners and have difficulty with activities that require balance (e.g., skating, walking along a log across a stream) but have usually walked on time (i.e., before 15 months). Ankle-foot orthotics (AFOs) are frequently required by the third decade. Generally, hands are rarely as affected as the feet. Most patients remain ambulatory throughout life and have a normal lifespan.

Patients with distal hereditary motor neuropathies (dHMNs) sometimes have mild sensory abnormalities, and patients with hereditary sensory neuropathies (HSNs) usually have some weakness. Indeed, the same mutation in the same gene can cause both CMT and dHMN within the same family (e.g., glycyI-tRNA synthetase or GARS mutations can cause both CMT2D and hereditary motor neuropathy type V).

## PATHOPHYSIOLOGY

Most of the genes mutated in CMT are involved in maintaining the structure or function of the peripheral nervous system. The first genes identified to cause CMT express proteins that are essential for compact (peripheral myelin protein 22

[*PMP22*] and myelin protein zero [*MPZ*] and noncompact (gap junction protein beta 1 [*GJB1*]) myelin, and their altered expressions cause demyelination or dysmyelination. Gene-protein dosage has been shown to be important in some forms of CMT; too much *PMP22* (i.e., with a duplication) causes CMT1A; too little (as seen with a deletion) causes HNPP. Abnormal expression of *MPZ* also causes demyelination, although in this case it is usually a result of point mutations in the *MPZ* gene.

At a pathologic level, dysmyelination, demyelination, remyelination, and axonal loss are characteristic features of the various demyelinating forms of CMT1. In Dejerine-Sottas neuropathy, myelin may never have formed normally, which is referred to as dysmyelination. In CMT1, onion bulbs of concentric Schwann cell lamellae are usually present on nerve biopsies, with loss of both small- and large-diameter myelinated fibers and sometimes axons. Focal, sausage-like thickenings of the myelin sheath (tomaculae) are characteristic of hereditary neuropathy with liability to pressure palsies (HNPP) but may also be found in other forms of CMT1, particularly CMT1B.

## NEUROPHYSIOLOGY

Nerve conduction velocity (NCV) testing will differentiate between demyelinating and axonal neuropathies. In clinical practice, approximately 60% of CMT patients have CMT1, and approximately 20% have CMT2 (Saporta et al., 2011). Neurophysiology is also useful to detect sensory involvement that often is unreported by patients. It can also aid in the classification of axonal inherited neuropathies further into mixed motor and sensory axonal neuropathy (CMT2), pure motor axonal neuropathy (dHMN), and pure sensory axonal neuropathy (HSN/HSAN).

Most CMT1 patients, particularly those with CMT1A, have a uniformly slow nerve conduction velocity of about 20 m/sec. However, asymmetric slowing, which is characteristic of hereditary neuropathy with liability to pressure palsies, may be found in patients with missense mutations in *PMP22*, *MPZ*, *EGR2*, and, particularly in females, *GJB1*. CMT1X, caused by mutations in *GJB1*, comprises about 15% of all CMT patients. Males with CMT1X usually have NCVs in the “intermediate” range of 30 to 45 m/s. NCVs in women with CMT1X are often normal.

Virtually all forms of CMT1 have axonal loss and demyelination. In cases where the motor and sensory responses are absent, it is worthwhile looking at proximal nerve conduction (e.g., axillary nerve latency) to fully investigate the possibility of a severe demyelinating rather than an axonal pathology.

## GENETIC TESTING AND DIAGNOSTIC STRATEGIES

Molecular testing—performed after the family history, neurologic examination, and neurophysiologic testing have suggested the probable candidate genes—is the “gold standard” for the diagnosis of inherited neuropathies. Strategies for focused genetic testing based on inheritance and clinical phenotype are in common use, with the choice of genes tested reflecting the specific population tested. For example, in Northern European and Northern American populations, most patients have dominant inheritance even if the cases are sporadic. Autosomal-recessive (AR) CMT is observed in less than 10% of these cases. However, in populations with high rates of consanguinity AR-CMT is likely to be much more common, even reaching levels of 40%.

An algorithm based on the North American population utilizes neurophysiological data, clinical information, and inheritance patterns to guide testing. Flow charts incorporating the clinical phenotype and electrophysiology findings, illustrated in Figures 141-2 and 141-3, guide the clinician on selection of appropriate testing strategies. With the use of such tools, most CMT clinics will reach a genetic diagnosis in approximately two-thirds of their total CMT population (Murphy et al., 2011). Approximately 90% of patients found to have a genetic diagnosis will have mutations in one of only four genes: *PMP22*, *GJB1*, *MPZ*, and *MFN2*. Therefore, the flow charts emphasize the need for considering these particular genes first. Mutations that alter the amino acid sequence of *PMP22*, *GJB1*, and *MPZ* almost always cause clinical neuropathy, whereas *MFN2* and most other CMT genes can also have benign mutations in which the coding sequences are altered without causing disability. This is important to consider when interpreting genetic testing results. Once genetic testing has been done in a proband, other family members do not usually merit genetic testing and instead are identified by clinical evaluation and neurophysiology.

The landscape of genetic testing is rapidly changing with the introduction of next-generation sequencing (NGS) into clinical practice in some areas, which enables sequencing of either the entire genome or exome (only the protein coding sequences) in days. However advanced genetic interrogation will require careful interpretation. Many genes, such as *periaxin* and *MFN2*, have a high number of polymorphisms that are not pathogenic. Currently, genetic testing is in a transition phase with both traditional Sanger sequencing and NGS (whole-genome sequencing/whole-exome sequencing [WGS/WES]) technology being used by most dedicated CMT clinics.

## SPECIFIC FORMS OF CMT

### CMT1: Autosomal-Dominant Demyelinating Neuropathies

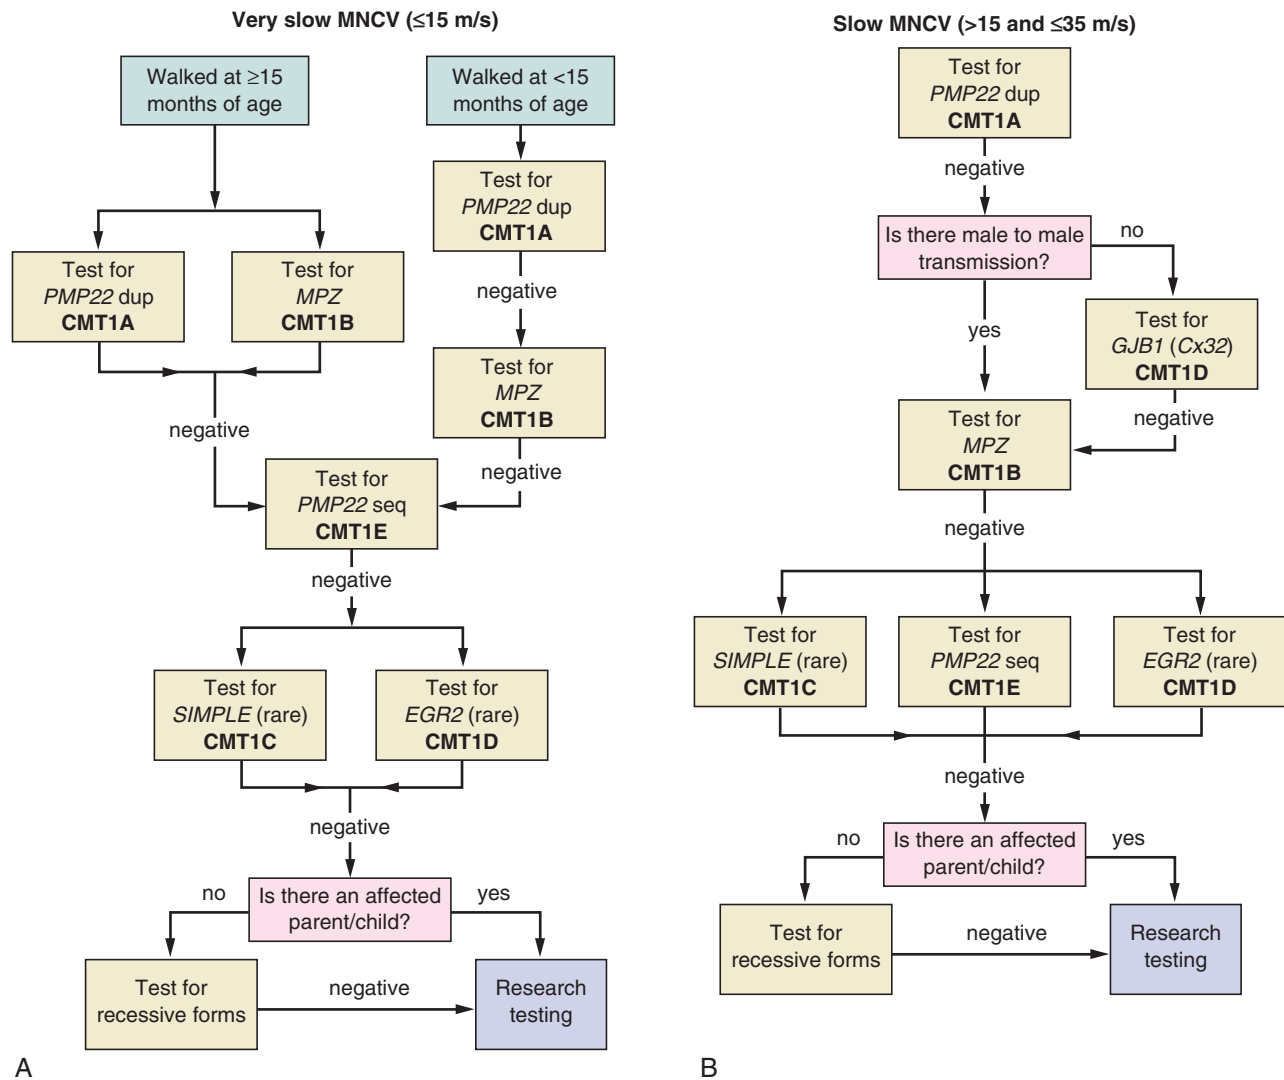

CMT1 is the most common subtype of CMT and is caused primarily by mutations in four genes: *PMP22*, *MPZ*, *LITAF*, and *EGR2*. These genes are essential to formation of the myelin sheath and also Schwann cell function.

#### CMT1A

CMT1A is the most common form of CMT in most populations, affecting 55% of genetically determined CMT and 36% of all CMT. It accounts for 80% to 90% of CMT1 cases. Patients usually present with the “classical CMT phenotype.” Patients usually will walk on time. Lifespan is not affected. Although patients frequently require ankle-foot orthotics, they rarely require wheelchairs for ambulation. Conduction velocities from the median and ulnar nerves are below 38 m/s and are typically in the 20s. The sensory action potentials are either reduced or absent. Nerve biopsy is not required but if performed reveals demyelination and onion bulb formation. Because there is a de novo mutation rate of 10%, children and adolescents without a family history with ulnar motor nerve conduction velocities (MNCVs) less than 35 m/s should first be screened for CMT1A before proceeding with other genetic testing. CMT1A is caused by a 1.4-Mb duplication on chromosome 17p11.2 in the region that carries the *PMP22* gene.

#### CMT1B

CMT1B is the fourth most common type of CMT and clinically is associated with three distinct phenotypes: (1) an early-infantile-onset severe phenotype with delayed walking and NCV less than 10 m/s, often referred to as Dejerine-Sottas

**Figure 141-2.** Algorithm for the genetic diagnosis of patients with Charcot-Marie-Tooth disease and very slow (A) or slow (B) upper extremity motor nerve conduction velocities. Dup, duplication; Seq, sequencing. (With permission from Saporta AS et al. *Ann Neurol* 2011; 69 [1]: 22-33.)

disease; (2) less commonly, a classic phenotype as described for CMT1A with normal early milestones but progression throughout the first 2 decades of life; and (3) a much later, milder phenotype with onset at around age 40 and NCV of around 40 m/s. CMT1B is caused by point mutations in the *MPZ* gene.

### CMT1C

CMT1C is clinically indistinguishable from CMT1A, presenting in the second decade with the classical phenotype. It is a rare cause of CMT, accounting for less than 1% of the CMT population.

### CMT1D

The CMT1D phenotype is severe, with patients typically presenting in infancy with possible hypomyelination (hypotonia), delayed motor milestones, and MNCV less than 10 m/s. In addition, scoliosis and cranial nerve involvement may be features. This is a rare phenotype of CMT and is caused by mutations in *EGR2*, a member of the early growth response family. Autosomal-recessive inheritance has also

been described, with *EGR2* mutations (known as CMT4E) causing a very similar clinical phenotype.

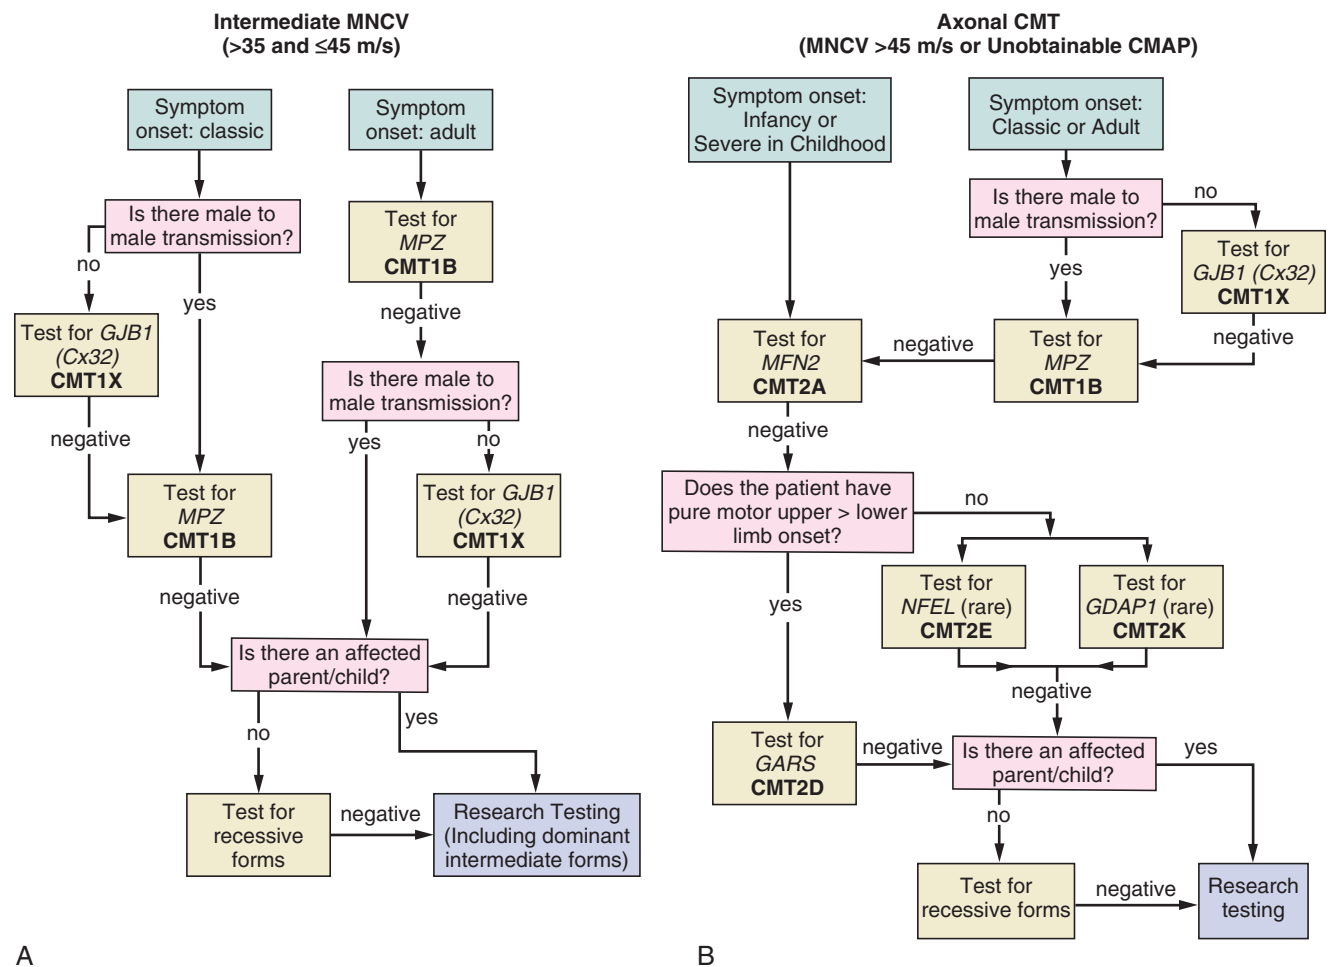

### CMT1E

CMT1E is caused by point mutations in the *PMP22* gene. Often these patients have an earlier onset with a more severe phenotype, sometimes associated with deafness, compared with CMT1A patients. Onset within the first 2 years of life with a delay in walking is not uncommon; however, the clinical phenotype is variable, and onset may be later. The disease severity depends on the particular *PMP22* mutation, and some cases can be very mild or even resemble HNPP.

### HNPP

HNPP is the third most common type of CMT and is an autosomal-dominant disorder, with patients typically presenting with recurrent neuropathies occurring at sites of entrapments. The age of onset is similar to that in CMT1A, although one larger study suggests that over half of HNPP cases have an earlier onset, typically presenting with delay in walking. The literature suggests a wide range of onset, from early childhood

**Figure 141-3.** Algorithm for the genetic diagnosis of patients with Charcot-Marie-Tooth disease and intermediate (A) or normal (B) upper extremity motor nerve conduction velocities. (With permission from Saporta AS et al. *Ann Neurol* 2011; 69[1]: 22-33.)

through adulthood. Motor NCVs can be normal but are usually slowed around sites of entrapment such as the fibular head, carpal tunnel, and medial epicondyle. Usually, there is a history of recurrent focal mononeuropathies that are transient, lasting from hours to days or weeks and occasionally longer. HNPP is usually caused by a deletion of *PMP22* or, less commonly, by point mutations in the *PMP22* gene.

### CMTX: X-Linked CMT

CMT1X is the main X-linked form of CMT and is caused by mutations in *GJB1* gene, which encodes the protein connexin32 (Cx32) (Ouvrier, Geevasingha, and Ryan, 2007). This is the second most common form of CMT accounting for approximately 10% to 15% of CMT. Despite the fact that there are a huge number of mutations described in *GJB1*, the phenotype in males is virtually the same in all affected males, including those with entire gene deletions, suggesting that mutations lead to a loss of function of the protein. The majority of males will start to have symptoms in childhood, but approximately 20% will have a later onset.

Males are typically more severely affected and tend to have marked atrophy of the intrinsic hand muscles and all compartments of the calf muscles. Males with CMT1X often display a "split hand syndrome," with the abductor pollicis brevis being weaker and more wasted than the first dorsal interosseus. Females with *GJB1* will usually have abnormalities on neuro-

logic examination or nerve conduction testing. Typically, males with CMTX have MNCVs between 25 and 45 m/s, whereas women have MNCVs in the normal or nearly normal range. Therefore, the presence of nearly normal to intermediate MNCVs in females and slow to intermediate MNCVs in males in families with an absence of male-to-male transmission should prompt the clinician to consider CMT1X.

### CMT2: Autosomal-Dominant Axonal Neuropathies

CMT2 is suggested by neurophysiology demonstrating NCVs of greater than 38 m/s in the context of small motor and/or sensory amplitudes. Clinical and electrophysiological data should enable axonal neuropathies to be classified further into pure or predominant sensory form (HSN/HSAN), the mixed motor and sensory form (CMT2), or the pure motor form (dHMN). It is more challenging to obtain a genetic diagnosis in CMT2 because there are many genes known to cause axonal CMT (see <http://www.molgen.ua.ac/cmtmutations/>), with each gene accountable for only a very small proportion of cases, with the notable exception of *MFN2*. Because disease-causing CMT genes account for the minority of CMT2 patients (around 35%), most CMT2 patients still await an exact genetic diagnosis. Because the number of patients with CMT2 with a genetic diagnosis is, as yet, small, it is difficult to be accurate

about exact genotype–phenotype correlations, in particular with regard to age of onset. However, with the advent of improved molecular techniques, it is likely that the number of genetic causes of CMT2 will significantly increase over the next few years. We will discuss only CMT2A, the most common subtype seen. For descriptions of other subtypes, the reader is referred to the online version of this chapter.

## CMT2A

CMT2A is the most common type of CMT2, accounting for approximately 20% to 25% of patients with CMT2. This is mostly severe, with onset in infancy or early childhood and with many patients requiring a wheelchair to ambulate by the age of 20. CMT2A is caused by mutations in the nuclear-encoded *MFN2* gene. Often these patients have unrecordable CMAP amplitudes and nerve conduction studies (NCSs) even in the upper extremities, leading to the suggestion to test for *MFN2* mutations as the initial genetic test in such patients. There are a high number of polymorphisms encountered in *MFN2* genetic testing, so care must be taken when ascertaining whether the patient has disease-causing mutations. Most disease-causing mutations are in the GTP-ase domain, coiled-coil domains, or in other evolutionarily conserved regions of the protein. Rarely, some patients present later in life (during childhood, adolescence, or even adulthood) with a milder phenotype.

## CMT4: Autosomal-Recessive Neuropathies

CMT4 includes all forms of autosomal-recessive CMT. Typically, demyelinating conduction velocities are seen, although axonal forms of CMT4 exist. CMT4 mostly presents in infancy and should be considered when multiple family members in one generation are affected or if there is a history of consanguinity. We discuss the demyelinating forms first.

### CMT4A

CMT4A is caused by mutations in the *GDAP1* gene. This is a severe early-childhood-onset neuropathy with weakness starting in the distal lower extremities and affecting the distal upper extremities within the first decade of life. Progression to wheelchair use is not uncommon, and there may be additional clinical features, such as vocal cord paralysis or hoarseness.

### CMT4B1/B2/B3

CMT4B1 neuropathy is characterized by an onset in early childhood with symmetric weakness in all four limbs, with patients typically becoming wheelchair dependent by adulthood (Parman et al., 2004). Additional clinical features of scoliosis and diaphragmatic and facial weakness may be present. CMT4B2 is a similar form with a slightly later age of onset, but symptoms typically begin by age 5 with NCVs around or below 20 m/s. CMT4B1 and CMT4B2 are caused by mutations in myotubularin-related proteins 2 (*MTMR2*) and 13 (*MTMR13*), respectively. *MTMR13* is also called set-binding factor (*SBF-2*). CMT4B3 is caused by AR mutations in *SBF1* and also has a similar phenotype, including focally misfolded myelin, a pathologic feature of all the CMT4Bs.

### CMT4C

CMT4C is a recessive neuropathy of slightly later onset, with childhood-adolescent onsets reported. Scoliosis is a particularly common feature and may precede other findings. Occasional additional clinical findings include movement disorders (ataxia and tremors), facial and bulbar weakness, sensorineural deafness, and respiratory insufficiency. Caused by mutations

in the SH3 domain and tetratricopeptide repeat domain 2 (*SH3TC2*) gene, it is the most common of the AR-CMTs in North American and Northern European populations.

### CMT4F

CMT4F is caused by mutations in the *periaxin* gene. Characteristically, patients have demyelinating conduction with a severe early onset neuropathy. Often patients have predominant sensory findings on examination, including sensory ataxia. As with *MFN*, there are a large number of polymorphisms in *periaxin*, and care should be taken to ensure that mutations segregate with the neuropathy in a family and that the phenotype is appropriate before concluding that mutations are disease causing.

**CMT4: Autosomal-Recessive Axonal Neuropathies (Also Known as AR-CMT2).** A small number of genes have been found to cause axonal forms of CMT4, also known as AR-CMT2.

**Distal Hereditary Motor Neuropathies.** The dHMNs are very similar to CMT in that they are inherited length-dependent and slowly progressive neuropathies with onset usually starting in the first 2 decades (Rossor, Kalmar, Greensmith, and Reilly, 2012). They are defined by being exclusively motor in nature. However, many forms have minor sensory abnormalities, and there is a degree of overlap between CMT2 and dHMN in that the same mutation in the same gene can cause both phenotypes within a family, which can be defined as being either CMT or dHMN. Bulbar involvement in dHMN apart from the recurrent laryngeal nerve is rare. Clinical examination confirms distal weakness and wasting with reduced or absent reflexes. Neurophysiology testing reveals reduced motor amplitude potentials with no sensory abnormalities, and electromyography (EMG) testing may reveal a predominantly distal pattern of denervation. Table 141-3 outlines this group of disorders. For many of the dHMNs, the exact genetic mutation remains to be elucidated. The reader is referred to the online version of the chapter for further details of this group of neuropathies.

**Hereditary Sensory Neuropathies.** The hereditary sensory neuropathies (HSNs) group includes hereditary neuropathies primarily affecting sensory neurons and includes the subtypes of hereditary sensory and motor neuropathies and hereditary sensory and autonomic neuropathies. With HSN, the sensory loss can range from distal numbness with or without loss of proprioception to a complete inability to experience pain and subsequent risk of painless injuries and foot ulcerations. The more severe sensory neuropathies associated with loss of pain can lead to an abnormal mechanical loading in the distal weight-bearing joints; consequent to that, there is significant risk of neuropathic arthropathy and spontaneous fractures. Despite the name of this subtype of neuropathy, motor involvement is commonly observed in patients. The hereditary sensory neuropathies are classified according to their genetic cause and clinical phenotype; however, the majority of these remain genetically unresolved. Table 141-4 summarizes this group of neuropathies. The reader is referred to the online version of the chapter for further details of this group of neuropathies. It is noteworthy that because some of these subtypes (e.g., HSN IV-VII) are both newly described and rare, the range of clinical phenotypes observed in some particular subtypes is unknown (Auer-Grumbach, 2008).

**Neuropathies Associated With Inherited Metabolic Disease.** It is important to be aware that neuropathies can present as part of a more complex disorder as a result of an inherited metabolic deficit. These conditions are generally

**TABLE 141-3** Classification of the Distal Hereditary Motor Neuropathies (HMNs)

Type	Inheritance	Gene/Locus	Specific Phenotype
<b>HMN I</b>	AD	<i>HSPB1/HSPB8/GARS/DYNC1H1</i>	Juvenile-onset (2-20 years) dHMN
<b>HMN II</b>	AD	<i>HSPB1/HSPB8</i>	Adult-onset typical dHMN/CMT2F or dHMN/CMT2L
<b>HMN III</b>	AR	11q13	Early onset (2-10 years), slowly progressive
<b>HMN IV</b>	AR	11q13	Juvenile onset (months to 20 years), diaphragmatic involvement
<b>HMN V</b>	AD	<i>GARS</i>	Juvenile onset (5-20 years), upper limb onset, slowly progressive/CMT2D
<b>HMN V</b>	AD	<i>BSCL2</i>	Upper limb onset, +/- spasticity lower limbs/Silver syndrome
<b>HMN VI</b>	AR	<i>IGHMBP2</i>	Spinal muscle atrophy with respiratory distress (SMARD1), infantile-onset respiratory distress
<b>HMN VIIA</b>	AD	2q14	Adult onset, vocal cord paralysis
<b>HMN VIIB</b>	AD	<i>DCTN1/TRPV4</i>	Adult onset, vocal cord paralysis, facial weakness
<b>HMN/ALS4</b>	AD	<i>SETX</i>	Early onset, pyramidal signs
<b>HMN-J</b>	AR	9p21.1-p12	Juvenile onset, pyramidal features, Jerash origin
<b>Congenital distal SMA</b>	AD	<i>TRPV4</i>	Antenatal onset, arthrogryposis

AD, autosomal dominant; AR, autosomal recessive; *HSPB1*, heat-shock protein B1; *HSPB8*, heat-shock protein B8; *GARS*, glycyl-tRNA synthetase; *BSCL2*, Berardinelli-Seip congenital lipodystrophy 2 (Seipin); *DYNC1H1*, cytoplasmic dynein heavy-chain 1; *IGHMBP2*, immunoglobulin mu binding protein 2; *DCTN1*, dynactin1; *TRPV4*, transient receptor vallanoid 4; *SETX*, sentaxin; *SMA*, spinal muscular atrophy. (Adapted from Reilly MM, Shy ME. J Neurol Neurosurg Psychiatry 2009 80 (12) 1304-14. Copyright 2009. From BMJ Publishing Group Ltd)

much rarer than the more common “umbrella” group of CMT. The neurologic examination needs to be extensive, and the clinician must search extensively for additional neurologic signs, such as ataxia and pyramidal and extrapyramidal deficits. Ophthalmologic involvement and deafness should be specifically investigated. In addition, a good systemic general examination should be performed to look for cutaneous involvement and organomegaly. If a metabolic disorder is suspected, then brain magnetic resonance imaging (MRI) should be done to ascertain if there is brain involvement.

The history is also important. If there are recurrent episodes of neurologic deficit, then specific diagnoses can be considered (e.g., recurrent ataxia with axonal neuropathy in pyruvate dehydrogenase deficiency and acute axonal neuropathy or pure motor neuropathy in porphyria). The main metabolic neuropathies associated with neuropathy are outlined in Table 141-5. These metabolic disorders are discussed more extensively in Chapters 41 through 43. Other genetic neuropathies, such as giant axonal neuropathy and neuroaxonal dystrophy, are discussed in the online version of this chapter.

**Differential Diagnosis.** Inherited neuropathies must be distinguished from acquired neuropathies (see Chapter 142). Additionally, genetic disorders of the central nervous system (CNS), such as hereditary spastic paraplegia, may mimic inherited neuropathies by causing length-dependent weakness, sensory loss, and foot deformities such as pes cavus; these patients will frequently have upper motor neuron signs, such as increased reflexes or Babinski’s signs and do not have neurophysiologic evidence of neuropathy. Neuropathies may present as part of a more multisystem metabolic disorder, such as the leukoencephalopathies, or as part of a more widespread neurologic disorder, such as Friedrich’s ataxia or the spinocerebellar ataxias. Hence, the importance of accuracy in clinical phenotyping is paramount.

**Treatment Strategies.** Despite the great improvement in our biologic understanding of inherited neuropathies, there is still no treatment available for any type of CMT. Physical therapy, occupational therapy, and a few orthopedic

procedures are still the cornerstone of all inherited neuropathy treatment. A detailed family history and often examination of family members will be required for prognosis and genetic counseling.

A dedicated multidisciplinary rehabilitation team can significantly contribute to the management of patients with inherited neuropathy and improve functionality and quality of life. Physical therapy strategies to maintain muscle strength and tone, prevent muscle contractures, and improve balance are a common need for most patients. Orthotic aids are an important component of treating these patients, providing support and improving balance for ambulation. Occupational therapy focused on developing tools and strategies to help patients with activities of daily living will benefit patients with inherited neuropathy, especially those with hand weakness. Tendon lengthening and tendon transfers can benefit a subset of patients with muscle contractures and tendon shortening and patients with significant weakness in functionally relevant muscles, respectively; however, the optimal timing of such procedures is still controversial. Foot surgery is sometimes offered to correct inverted feet, pes cavus, and hammertoes. This surgical intervention may improve walking, alleviate pain over pressure points, and prevent plantar ulcers. However, foot surgery is generally unnecessary and does not improve weakness and sensory loss.

Two new technologies recently developed hold huge potential in the search for compounds to treat inherited neuropathy: cellular reprogramming and high-throughput drug screening. Cellular reprogramming is a technique that allows the generation of specific cell types (including stem cell-like cells, neurons, and glia) by genetically modifying readily available somatic cells such as fibroblasts or lymphocytes to generate patient-specific cell lines. These patient-specific cell lines will be particularly useful when combined with high-throughput screening of drug libraries containing thousands of compounds. In these highly automated platforms, the process of identifying compounds capable of correcting certain disease-related cell phenotypes is streamlined, allowing for a faster target selection of compounds to be tested in phase I animal studies.

TABLE 141-5 Inherited Metabolic Disorders Associated With Neuropathy

Category	Disease	Stored Material	Age of Onset	Neurophysiology	Neuropathic Features
1. Lysosomal • Mucopolysaccharidoses	Hurler	Dermatan/heparan sulfate	Infantile	Slowing at entrapment sites	Entrapment neuropathy
	Hunter	Dermatan/heparan sulfate	Infantile	Slowing at entrapment sites	Entrapment neuropathy
	Sanfilippo A-D	Sulfate	Infantile	Slowing at entrapment sites	Entrapment neuropathy
	• Spingolipidoses	Heparan sulfate Galactosylceramide Trihexosylceramide Sulfatide	Infantile to adult Adolescence Late infancy>adolescence	NCVs < 10 in young onset Small-fiber function abnormal NCVs < 10	Schwann cell inclusions and segmental demyelination Lamellar inclusions (perineural cells) and axonal loss Schwann cell ↑ sulfatide and segmental demyelination
• Glycoproteinoses	Fucosidosis α and β mannosidosis	Oligosaccharides Oligosaccharides	Infantile Infantile to adolescence	Slowing at entrapment sites Slowing at entrapment sites	Entrapment neuropathy Axonal inclusion
	Sialidosis I and II Schindler disease	Oligosaccharides Oligosaccharides	I = juvenile II = infantile Infantile	II = Slowing at entrapment sites Marked axonopathy	Schwann cell vacuoles and axonal inclusions Axonal spheroids
	Adrenomyeloneuropathy Refsum disease Hyperoxaluria	VLCFA Phytanic acid Calcium oxalate	Variable: childhood-adult Childhood/adolescence <5 years	Axonal or demyelinating Slow NCVs Axonal or demyelinating	Schwann cell inclusions and segmental demyelination Schwann cell inclusions, onion bulbs and segmental demyelination Axonal degeneration and segmental demyelination
3. Lipid disorders	Cerebrotendinous xanthomatosis	Cholesterol	Late childhood/adolescence	Clinical symptoms mild; slow NCVs	Axonal loss and Schwann cell vacuoles
	Tangier disease	Cholesterol esters	Childhood/adolescence	Sensory neuropathy; slow NCVs	Axonal loss and Schwann cell vacuoles
	Abetalipoproteinemia		Birth but neuropathy develops in childhood	Sensory neuropathy; sensory CVs prolonged	Axonal degeneration and segmental demyelination
4. Mitochondrial	LCHAD	3-Hydroxy dicarboxylic aciduria	Early infancy	Axonal or demyelinating	Axonal loss and segmental demyelination
	Leigh	Lactate/pyruvate	Early infancy/childhood	Slow NCVs	Segmental demyelination
	NARP	Lactate/pyruvate	Usually adolescence	Sensory demyelinating neuropathy	Segmental demyelination
5. Other	Acute intermittent porphyria	δ = aminolevulinic acid	Usually after puberty	Can be a pure motor axonal picture	Axonal degeneration and segmental demyelination

LCHAD, long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency; NARP = neuropathy, ataxia and retinitis pigmentosa; NCVs = nerve conduction velocities; VLCFA = very-long-chain fatty acids.

Vital to clinical trials in inherited neuropathy is the establishment of solid outcome measures. This can be challenging with neuropathies that progress slowly over many years. To this end, a validated scoring system based on symptoms, signs, and neurophysiological data has been developed for adults that has excellent inter- and intraobserver correlations and can detect changes over 1 year. A more sensitive pediatric scoring system exists for those patients between the ages of 3 and 21, which takes into account growth-related changes and should prove useful in future clinical trials. Sequential yearly MRI of limb muscles looking at progressive replacement of muscle with fatty tissue may also prove to be a valuable outcome measurement and is currently under investigation in a cohort of CMT1A patients.

## CONCLUSION

We have entered an exciting period in the study of inherited neuropathy. Investigating CMT has led to the description of several key genes and proteins together with the functional relevance of many others, leading to a better understanding of normal peripheral nerve function and the development of treatment strategies in some of the more common demyelinating inherited neuropathies. Significant challenges remain to be overcome, however, to develop and test treatments to modify disease progression in this heterogeneous group of genetic neuropathies.

# 142 Acquired Peripheral Neuropathies

Stephen A. Smith

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Acquired peripheral neuropathies are caused by a number of infectious, toxic, or metabolic conditions. They may be acute or chronic and classified by the type of peripheral nerve involved—primarily motor, sensory, or autonomic. Pathologically, neuropathies are demyelinating or axonal, depending on whether the main disruption involves the axon or the myelin sheath supported by the Schwann cell. This chapter discusses acquired toxic and metabolic neuropathies occurring in children.

## ANATOMY

The peripheral nervous system consists of cranial nerves III through XII, the spinal roots, the nerve plexuses, the peripheral nerves, and the autonomic ganglia. Neuronal cell bodies subserving the nerves in the peripheral nervous system reside in the brainstem; anterior horn cells of the spinal cord; intermediolateral cell column, where the autonomic system originates; and the dorsal root ganglia for afferent sensory function. Peripheral nerves innervate all skeletal muscles via large myelinated nerve fibers. Sensory input from skin, joints, and muscles is transmitted via a combination of unmyelinated and myelinated nerve fibers from the periphery to the central nervous system (CNS).

Evaluation of peripheral nerve diseases includes obtaining a clear history of the distribution and rate of progression of the condition; conducting an appropriate examination; obtaining an electromyogram with nerve conduction velocities, amplitudes, and latencies plus indicated muscle needle electrode study; and, in some instances, performing a sural nerve biopsy. A search for toxins, such as heavy metals, or doing diagnostic tests for metabolic conditions may be indicated. Acquired peripheral neuropathies are not familial or inherited.

## FACIAL NERVE PARALYSIS (BELL'S Palsy)

Acute dysfunction of cranial nerve VII, caused by lesions of the facial nerve nucleus in the pons or axial or extraaxial facial nerve, is called Bell's palsy. The result is partial or complete paralysis of the upper and lower facial muscles. Bell's palsy most often results from edema and inflammation of the nerve as it traverses the facial canal within the temporal bone. Lesions involving the facial nerve nucleus or nerve distal to the nucleus result in paralysis of upper (forehead) and lower facial muscles.

### Clinical Features

The incidence of Bell's palsy is 2.7 per 100,000 below the age of 10 years, and 10.1 per 100,000 during the second decade of life. Female and male incidence is equal. Ear pain near the mastoid process is the first manifestation of impending facial nerve involvement half of the time. Unilateral inability to close the eyelid and maintain normal facial movement is the initial indication of motor involvement. Facial weakness develops

rapidly over several hours to 3 days, resulting in paresis to complete paralysis. Bell's palsy commonly follows an upper respiratory tract infection, indicating possible postinfectious demyelination. Drinking and eating are impaired because of the inability to close the mouth on the involved side.

The differential diagnosis of facial paralysis includes infections, both acute and chronic infections of the inner ear (Özkale et al., 2015), herpes simplex infection, herpes zoster (Ramsay Hunt syndrome), *Mycoplasma pneumoniae* infection, Epstein-Barr virus infection, and Lyme disease (*Borrelia* spp. infection), tumor, acute myeloid leukemia, chemotherapy toxicity, trauma, hypertension, and hypertension secondary to Guillain-Barré syndrome.

Bilateral, congenital facial paralysis, usually in conjunction with ophthalmoplegia involving cranial nerve VI, presents in the newborn as Möbius's syndrome. The condition is the result of aplasia or hypoplasia of cranial nerves and nuclei VI and VII.

Simple asymmetry of facial expression when infants and children are crying is common. The majority of children with asymmetric crying facies are normal.

### Laboratory Findings

Uncomplicated facial palsy that resolves relatively quickly does not need detailed evaluation. Palsy that persists or seems atypical requires study. Magnetic resonance imaging (MRI) often reveals gadolinium enhancement of the facial nerve in typical cases of Bell's palsy. MRI can be used in children to find rare tumors invading or compressing the facial nerve.

### Treatment and Prognosis

The prognosis for recovery in children is good. Most children do not need drug therapy. A number of drugs have been used, particularly steroids of limited, if any, benefit. Surgical decompression has been recommended in some patients when progressive paralysis and nerve degeneration occur, but benefit is difficult to prove (Zandian et al., 2014). Prednisone is the most widely used drug; it is given in high dosage for 1 week, followed by slow withdrawal of the drug in the second week. The degree to which steroid therapy can alter the natural history of Bell's palsy is unknown, although it appears to be more helpful in completely paralyzed than paretic individuals. Most children recover completely without treatment. Recovery usually begins within 2 to 4 weeks, reaching its maximum within 6 to 12 months and most within 3 months. In meta-analyses comparing steroids to antiviral treatment, usually acyclovir, there is no added advantage in adding antiviral treatment to steroid treatment.

## BRACHIAL PLEXUS

Nerve roots from the fifth cervical through the first thoracic nerves form the three primary trunks of the brachial plexus. Once formed, they divide promptly into anterior and posterior divisions. The posterior divisions join to form the posterior

cord, which gives rise to the upper and lower subscapular, thoracodorsal, axillary, and radial nerves. The anterior divisions of the fifth, sixth, and seventh nerves form the lateral cord, and the anterior divisions of the eighth cervical and first thoracic nerves form the medial cord. The lateral cord subsequently gives rise to the musculocutaneous nerve and a branch to the coracobrachialis. The medial cord gives rise to the ulnar, medial antebrachial cutaneous, and medial brachial cutaneous nerves. Additional branches from the lateral and medial cords unite to form the median nerve.

## METABOLIC NEUROPATHIES

### Diabetes Mellitus

It has been known for a long time that up to 10% of children with insulin-dependent diabetes mellitus have symptoms and signs caused by peripheral neuropathy associated with diabetes. These bilaterally symmetric changes, especially in the lower extremities, include mild distal weakness, loss of touch and pain sensation, and decreased ankle tendon reflexes. Despite good management of diabetes, impaired nerve function occurs.

Subclinical diabetic neuropathy is now estimated to occur in half of all children with type 1 diabetes after 5 years of known disease. Reduced motor nerve excitability determined by compound muscle action potential (CMAP) measurements is reduced early in type 1 diabetes mellitus, probably before irreversible axonal damage occurs.

It is clear that careful clinical and electrophysiologic follow-up is required to monitor altered peripheral and autonomic nerve function in childhood-onset diabetes mellitus (Höliner et al., 2013). Blood sugar control, as measured by hemoglobin A1c, and duration of diabetes are significant in the causation of diabetic peripheral neuropathy. The importance of strict metabolic control is helpful in slowing the development and progression of diabetic neuropathy. Peripheral neuropathy is common in young, insulin-dependent diabetics.

### Uremic Neuropathy

Uremic neuropathy is rarely diagnosed in children. When recognized, it is characterized by burning sensations in the feet and a symmetric motor sensory neuropathy with progressive muscle weakness. Motor nerve and sensory nerve conduction velocities are decreased early in the course of the disease, often before clinical symptoms appear. Electrophysiologic findings in an adolescent showed a primary axonal sensorimotor polyneuropathy. Sural nerve biopsy showed focal loss of myelinated axons along with axonal degeneration. The facial nerve is a sensitive indicator of uremic neuropathy.

### Acute Intermittent Porphyria

This rare inborn error of metabolism, inherited on an autosomal-dominant basis, is caused by mutations in the hydroxymethylbilane synthase (HMBS) gene on chromosome 11q23.3. Acute intermittent porphyria (AIP) is diagnosed on the basis of characteristic clinical symptoms, elevated levels of urinary porphyrin precursors aminolevulinic acid (ALA) and porphobilinogen (PBG), and a decreased erythrocytic HMBS activity, although an identifiable HMBS mutation provides the ultimate proof for AIP. Gene carriers are at risk of developing potentially fatal neurogenic attacks if exposed to precipitating factors, including certain medications like tricyclic antidepressants, barbiturates, halothane, valproic acid, sulfonamides, estrogens, and alcohol. Axonal damage, observed on both

sural nerve biopsy and autopsy evaluation, suggests that the neuropathy is primarily axonal. The neuropathy is predominantly motor, with associated abdominal pain, dysautonomia, and CNS involvement. It has been made worse with exposure to antiepilepsy medications, phenytoin and carbamazepine, but not clonazepam.

Acute, severe, colicky abdominal pain is a typical manifestation of an acute episode, accompanied by CNS and peripheral nervous system impairment. Peripherally, motor weakness is most striking, but sensory impairment may also occur.

### Vitamin Deficiency

Classic thiamine deficiency in children causes peripheral neuropathy, encephalopathy, and high-output cardiac failure. Infantile beriberi disease has been described in infants born to mothers with thiamine deficiency (Renthal et al., 2014).

Thiamine deficiency can develop secondary to anorexia nervosa in adolescents producing a peripheral neuropathy and Wernicke encephalopathy.

Vitamin E (alpha-tocopherol) deficiency may be associated with peripheral neuropathy and ataxia. It may also occur in children with cystic fibrosis, chronic cholestasis, abetalipoproteinemia, short bowel syndrome, and intestinal malabsorption states.

### Congenital Pernicious Anemia

Two forms of pernicious anemia in children are associated with peripheral neuropathy. One occurs as a congenital or early onset disease in children. Congenital pernicious anemia occurs before age 5 years as a result of a vitamin B<sub>12</sub> deficiency caused by isolated absence of gastric intrinsic factor that may produce a severe and irreversible neuropathy (Dobrozi et al., 2014). A later-onset form of pernicious anemia resembles that seen in adults. This is histamine-fast achlorhydria associated with gastric mucosal atrophy and the presence of antibodies to parietal cells and intrinsic factor in the serum. These children may experience a variety of endocrinologic disorders. Pathologic changes develop in spinal cord and, less commonly, in peripheral nerve and brain.

Infants who are breastfed by strictly vegetarian mothers or who have undiagnosed pernicious anemia are at risk for developing a megaloblastic anemia because of a deficiency of vitamin B<sub>12</sub>.

### Abetalipoproteinemia

Abetalipoproteinemia, known as Bassen-Kornzweig syndrome, is a rare condition characterized by progressive ataxic neuropathy, retinitis pigmentosa, steatorrhea, hypolipidemia, deficiency of fat-soluble vitamins, failure to thrive, and acanthocytosis. The disease results from mutations in the gene encoding microsomal triglyceride transfer protein (MTTP) located on chromosome 4q24. Affected individuals are unable to make beta-lipoproteins to carry fats, cholesterol, and fat-soluble vitamins A, D, E, and K in the blood, and therefore fat absorption is impaired. Sufficient levels of fats, cholesterol, and vitamins are necessary for normal growth and development. Nerve cells and the retina are particularly vulnerable.

### Pathology

Degeneration of posterior columns, spinal cerebellar pathways, and cerebellum, caused by vitamin E deficiency, is the major pathologic change. Loss of anterior horn cells is found in the spinal cord. Posterior column degeneration leads to abnormal somatosensory-evoked potentials. Sural nerve

biopsy shows decreased numbers of large myelinated fibers and clusters of regenerating fibers. The posterior fundus of the eye shows a loss of photoreceptors, loss or attenuation of pigment epithelium, and preservation of submacular pigment epithelium, with an excessive accumulation of lipofuscin. Macrophage-like pigmented cells invade the retina.

### Clinical Characteristics

The most significant neurologic finding is a progressive ataxia that may be present as early as 2 years of age but certainly by age 6. Generalized weakness, ptosis, and extraocular muscle weakness develop. The lower cranial nerves may be involved, with facial and tongue weakness plus twitching movements. A progressive peripheral sensory neuropathy causing hypesthesia, hypalgesia, and proprioceptive loss is associated with absent tendon reflexes. Generalized muscle weakness and wasting may be severe. Intestinal malabsorption produces bulky, foul stools and leads to a delay in normal growth.

### Alpha-Lipoprotein Deficiency (Tangier Disease)

Tangier disease is an uncommon autosomal recessive disorder of lipoprotein metabolism, notable for the absence of normal high-density lipoprotein (HDL) from plasma and the accumulation of cholesterol esters in multiple organs. Extremely low plasma cholesterol levels are present. Physical examination shows patches of yellow-orange lymphoid tissue in the tonsils and pharynx, and hepatosplenomegaly. Yellow patches are present on the surface of the liver, and liver biopsy specimens contain cholesterol esters. Fiberscopic rectal examination shows orange-brown spots present throughout the rectum. Foam cells are present in lymphoid tissues. Onset is between age 2 and 67 years. Sural nerve biopsy shows a reduction of smaller myelinated and unmyelinated fibers, and abnormalities in the paranodal regions. There is lipid deposition, redundant myelin foldings, myelin splitting and vesiculation, and small tomacula. Abnormal lipid storage is found in Schwann cells of unmyelinated fibers. Conduction block is present on electrophysiologic nerve study.

### Clinical Characteristics

Recurrent neuropathy occurs in children with fluctuating asymmetric sensory involvement, mostly in the lower extremities, sometimes accompanied by progressive development of weakness of both distal and proximal muscles. Complaints of numbness and tingling in the distal extremities are early symptoms, followed by signs of the neuropathy and weakness. A dissociated loss of pain and temperature sensation may occur.

### Krabbe's Disease (Globoid Cell Leukodystrophy)

Galactosylceramide lipidosis, known as Krabbe's disease or globoid cell leukodystrophy, is an autosomal-recessive neurodegenerative disorder that presents most often in infants of 3 to 5 months of age. The clinical profile is a highly irritable infant with spasticity, optic atrophy, intellectual delay, and polyneuropathy, which may be the initial presentation. Children have gross motor delay, absent tendon reflexes, elevated CSF protein levels, and delayed motor nerve conduction velocities before neurodegenerative disease is evident.

### Metachromatic Leukodystrophy

Metachromatic leukodystrophy is a recessively inherited disease affecting children and adults caused by mutations in

the *ARSA* or *PSAP* genes resulting in a failure of the catabolism of sulfatide, the sulfate ester of galactose cerebroside. Infants may present with cranial neuropathy and multiple cranial nerve enhancement on MRI.

Clinically, in the infantile form of metachromatic leukodystrophy, the infant acquires normal milestones until 1 to 2 years of age and then begins to show signs of the disease. An unsteady gait is an early sign, accompanied by loss of language, intellectual deterioration, and, later, spasticity. Spinal fluid protein is elevated, and nerve conduction velocities are slowed. The juvenile form of the disease occurs after several years of age, again with gait disturbance followed by intellectual deterioration.

### Refsum's Disease (Heredopathia Atactica Polyneuriformis) and Peroxisome Biogenesis Disorders

Refsum's disease is a recessively inherited condition caused by a deficiency of phytanoyl-coenzyme A hydroxylase allowing the accumulation of phytanic acid in body tissues. Retinitis pigmentosa and anosmia are early signs of the disease that is carried on chromosome 10 as a result of *PHYH* gene mutations.

Refsum's disease is one of the peroxisomal disorders, Zellweger's syndrome and neonatal adrenoleukodystrophy being the other two. They are characterized by absence of catalase-positive peroxisomes and general impairment of peroxisomal functions. Presentations include anorexia, ataxia, ichthyosis, and sensorineural hearing loss with malabsorption and steatorrhea presenting early on. Clinical characteristics can be divided into three groups: congenital abnormalities, such as skeletal deformities; retinitis pigmentosa, which develops slowly; and lesions, including neuropathy, rash, and cardiac arrhythmias, which can deteriorate or improve according to plasma phytanic acid level.

Phytanic acid, a branched chain fatty acid, is present in a wide range of foodstuffs, including dairy produce, meat, and fish. There is toxic accumulation of phytanic acid in blood, fat, and neurons. Normally, phytanic acid levels are virtually undetectable in plasma. However, patients with Refsum's disease have extremely high levels with phytanic acid accounting for 5% to 30% of their total fatty acids.

## TOXIC NEUROPATHIES

### Diphtheria

Diphtheria is an uncommon disease in the Western Hemisphere because most individuals are immunized with diphtheria-pertussis-tetanus vaccine. The disease occurs in unimmunized children and in adults who have lost immunity. An exotoxin produced by *Corynebacterium diphtheriae* infection in the throat produces cardiomyopathy and neuropathy. A systemic radiculoneuropathy may develop, with onset 1 to 16 weeks after infection and marked by sensory loss.

### Neuropathy of Serum Sickness

Serum sickness is a systemic illness resulting from hypersensitivity to an injected foreign protein, such as tetanus or diphtheria antisera, producing encephalomyelitis, neuropathy, or brachial plexus neuropathies. Fever, joint swelling, abdominal pain, diarrhea, and cutaneous eruptions develop within days of receiving foreign protein. Deposition of antigen-antibody complexes is associated with disease.

## Antibiotic-Induced Neuropathy

A number of antibiotic, antifungal, and antituberculous drugs have been known to cause peripheral neuropathy in a small percentage of cases. For example, chloramphenicol can cause mild, primarily sensory, peripheral neuropathy after long-term use at relatively high doses. Nitrofurantoin may produce a polyneuropathy of sudden onset on rare occasion. Isoniazid causes an axonal neuropathy responsive to pyridoxine therapy in 1% to 2% of patients. The primarily sensory neuropathy begins with paresthesias.

There have been a number of reports of peripheral neuropathy, mainly in adults, associated with the use of fluoroquinolones, ciprofloxacin and levofloxacin, ofloxacin, lomefloxacin, and trovafloxacin.

## Pyridoxine-Induced Polyneuropathy

Pyridoxine is an essential cofactor in the metabolism of proteins, carbohydrates, fatty acids, and brain amines. Pyridoxine taken in large doses can cause a sensory neuropathy, with paresthesias, diffuse sensory loss, sensory ataxia, and autonomic dysfunction. Prescribing 50 mg/day or greater amounts for prolonged periods is discouraged.

Pyridoxine deficiency causes a sensory neuropathy, unless severe when motor nerve fibers may also be involved along with CNS dysfunction. Treatment is straight forward with increased dietary pyridoxine intake from foods high in pyridoxine such as vegetables, potatoes, eggs, and dairy products.

## Nitrous Oxide–Induced Polyneuropathy

Severe myeloneuropathy and macrocytic anemia associated with a low vitamin B<sub>12</sub> level are reported after prolonged exposure to nitrous oxide. B<sub>12</sub> supplementation alone does not result in improvement, but the addition of methionine does arrest the progression of neuropathy. Chronic nitrous oxide exposure inhibits methionine synthetase activity, which remains suppressed after nitrous oxide exposure has ended, underscoring the need for treatment with methionine. Continuous exposure to nitrous oxide for longer than 3 hours causes neuropathy, especially in B<sub>12</sub>-deficient individuals (Richardson, 2010).

## Chemotherapeutic Agent–Induced Neuropathy

Peripheral neuropathy may develop after the use of chemotherapeutic agents to treat neoplasms. Painful sensorimotor peripheral neuropathy may develop after high-dose cytosine arabinoside therapy, and is manifested pathologically by axonal degeneration and scattered destruction of myelin sheaths. The neuropathy is marked by dysesthesias, muscle aching, and progressive weakness. Cytosine arabinoside neuropathic pain may respond to carbamazepine.

Vincristine is often used in children to treat acute lymphoblastic leukemia and may cause acute axonal sensorimotor neuropathy. Less commonly, it may cause autonomic and cranial nerve neuropathy.

## Vaccine-Induced Polyneuropathy

The diphtheria-pertussis-tetanus vaccine may rarely produce segmental demyelination and axonal neuropathy from the tetanus toxoid component. Although very rare, demyelinating symmetric neuropathy, when it does occur, responds to immunomodulatory therapy. Rare transient postvaccination polyneuropathy has been reported with complete recovery. CDC

(<http://www.cdc.gov/flu>) recommendations for people who should receive influenza vaccinations are as follows:

Children aged 6 months and older.

Pregnant women

People 50 years of age and older

People of any age with certain chronic medical conditions such as chronic lung, heart, liver, or kidney diseases; blood disorders; and diabetes mellitus

People who live in nursing homes and other long-term care facilities

People who live with or care for those at high risk for complications from influenza

Healthcare workers

Household contacts of persons at high risk for complications from influenza

Household contacts and out-of-home caregivers of children less than 6 months of age. Hepatitis B vaccination has been associated with neuropathy in case reports from adults. Acute sensory neuropathy has been reported in a 13-year-old after bacille Calmette-Guérin (BCG) vaccination.

## Heavy Metal Neuropathy

Excessive exposure to various forms of lead, both organic and inorganic, produces an axonal neuropathy. It is rare in children but presents typically with foot drop but also with weakness of wrist and finger extensors.

Arsenic is a metalloid element, and high-dose exposure can cause severe systemic toxicity and death. The *NALP2* polymorphism is associated with increased risk of tissue and chromosomal damage from arsenic exposure. Arsenic is an essential ultratrace element in animals. Rare instances of arsenic poisoning, often intentional, have been reported, producing an axonal, sensory-predominant neuropathy.

One source of toxic methylmercury (MeHg) is from the consumption of marine fish and mammals. There is concern for potential neurodevelopmental effects from early life exposure to low levels of MeHg. Continuing exposure may include development of peripheral neuropathy. The European project DEMOCOPHES analyzed mercury (Hg) in hair in 1799 mother-child pairs from 17 European countries comparing results to marine fish and seafood consumption. Eating marine fish and seafood once per week had mercury levels well below health-based limit values established by USA-EPA and WHO. Concern is raised for higher exposures given the presence of mercury in the environment for many years to come and the bioaccumulation in aquatic food chains. The study recommends continuing monitoring of methylmercury exposure (Bora et al., 2014).

## VASCULITIC NEUROPATHIES

Cryoglobulinemia may present with a sensory neuropathy and painful dysesthesia because of small-fiber axonal involvement usually in adults, and often in the context of hepatitis C. Rare instances of cryoglobulinemia are reported in children. One child had lower-extremity and one-hand vasculitis, non-hepatitis C, M-spike disease with presumed nerve involvement responsive to steroids. Fever is more common in children with cryoglobulinemia than in adults. Demyelinating neuropathy after vaccination is a rare event with distally predominant sensory symptoms with no or mild distal weakness. Immunomodulatory therapy is effective for treatment. In a study in infants to investigate immune responses to influenza vaccine after two doses of trivalent inactivated influenza vaccine 4 weeks apart, no findings for neuropathy were reported (Hwang et al., 2014).

Organophosphorus pesticides are used as insecticides in agriculture and as eradication agents for termites around homes. Organophosphate intoxication causes cholinergic symptoms early and subsequently a neuropathy with axonal degeneration producing muscle cramping and calf pain along with tingling and burning sensations in the feet. Distal muscle weakness may develop. Neuropsychological assessment of healthy school-aged children exposed to organophosphate pesticides has demonstrated cognitive impairment.

# 143 Inflammatory Neuropathies

Malcolm Rabie, Stephen Ashwal, and Yoram Nevo

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Inflammatory neuropathies are important causes of peripheral nerve disease in childhood because of their relative frequency and response to treatment. Their main etiologies in childhood are acute and chronic immune-mediated polyradiculoneuropathies. Other etiologies such as collagen vascular diseases, rheumatoid arthritis, systemic lupus erythematosus, or mixed connective tissue disease are rare in children.

Acute and chronic immune-mediated polyradiculoneuropathies are acquired autoimmune-mediated disorders in which peripheral nerves become inflamed leading to varying degrees of weakness. They are not exclusively demyelinating; axonal forms responding favorably to immunotherapy also occur. Current data suggest that loss of immunologic tolerance to myelin or axonal antigens trigger autoreactive T-cells and circulating autoantibodies (cellular and humoral factors) either independently or in concert with each other, which then play a fundamental role in the cause of these immune-mediated neuropathies (Dalakas, 2015). Nodal, paranodal, and juxtaparanodal regions of the node of Ranvier may present antigenic targets in some of these disorders, causing nerve conduction failure and rapid recovery (Dalakas, 2015).

Acute onset immune-mediated polyradiculoneuropathy or Guillain-Barré syndrome (GBS) is the most common acquired immune-mediated peripheral neuropathy, and the most frequent cause of acute flaccid paralysis worldwide, constituting one of the serious neurologic emergencies (Yuki and Hartung, 2012). However, GBS is an uncommon disorder and is less frequent among children than in adults. GBS typically has been linked to inflammatory destruction of myelin sheaths in peripheral nerves and roots, termed *acute inflammatory demyelinating polyradiculoneuropathy* (AIDP). The categorization of GBS has evolved. For many years GBS was considered synonymous with AIDP, the demyelinating form most commonly encountered in the Western world, until axonal forms were defined in 1986 and in the 1990s in East Asia (northern China and Japan). In 2001 this led to the division of GBS based on whether motor or sensory nerve fibers are involved and whether myelin sheaths or axons are predominantly affected. Four main subtypes are described: (1) acute inflammatory demyelinating polyradiculoneuropathy (AIDP) (motor and sensory nerve fibers involved); (2) acute motor axonal neuropathy (AMAN); (3) acute motor and sensory axonal neuropathy (AMSAN); and (4) Miller Fisher syndrome (MFS/FS). Additional GBS variants with atypical features are rare (Table 143-3) (Yuki and Hartung, 2012).

Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), although rare in childhood, is the second most common cause of chronic sensorimotor peripheral neuropathy in children. This slow onset immune-mediated disorder presents with either a monophasic subacute course that later relapses, or a slowly progressive course. CIDP patients have proximal and distal symmetric weakness, paresthesias, and hyporeflexia or areflexia. In both GBS and CIDP, high CSF protein with a normal cell count is present.

Evidence-based data regarding the efficacy of GBS and CIDP immunotherapy in children are lacking, relying on retrospective data, open-label studies on small numbers of

children, and data derived primarily from adult trials. Immunotherapy (intravenous human immunoglobulin [IVIg] or plasma exchange [PE]) shorten GBS recovery time with most children recovering completely. Childhood CIDP usually responds to corticosteroids, IVIg, and PE. CIDP children who become resistant to corticosteroids or IVIg, or who become steroid dependent, present a therapeutic challenge. Childhood CIDP prognosis is mostly favorable.

## GUILLAIN-BARRÉ SYNDROME

GBS is a descriptive clinical entity, presenting as a monophasic, nonfebrile, postinfectious illness characterized by acute or subacute progression lasting up to 28 days, a variable plateau phase, and then recovery over weeks to months or in some cases over a more prolonged period. Weakness beginning distally in the legs; ascending rapidly, progressively, and symmetrically to the arms, face, and muscles of respiration, with or without sensory disturbances, hyporeflexia, or areflexia; and a high cerebrospinal fluid (CSF) protein with normal cell count (albuminocytologic dissociation) are the hallmarks for its diagnosis in children and adults. GBS usually remits spontaneously. The spectrum of GBS presents either typically (classic GBS) or atypically (Figure 143-1), with prominent differences in geographic distribution (Asbury, 2000).

## Epidemiology

GBS incidence worldwide is reported as 0.16 to 4/100,000/year. A systematic literature review estimated overall GBS incidence in children aged 0 to 15 years as 0.34 to 1.34/100,000/year from Latin America, Middle East, USA, Finland and Taiwan. It affects all ages, genders, and races, and is rare in children younger than age 2 years or in adults greater than age 80 years. Men are about 1.5 times more likely to be affected than woman (Hughes and Cornblath, 2005). AIDP is the most common GBS subtype in North America, Europe, and Australia affecting all ages (Asbury, 2000). In northern China, Japan, Asia, Latin America, and the developing world, axonal forms occur more frequently (Hughes and Cornblath, 2005; Yuki and Hartung, 2012). Atypical cases such as polyneuritis cranialis and MFS are much less common.

## Antecedent Events

Initial GBS symptoms usually present 1 to 6 weeks after antecedent respiratory or gastrointestinal infections, or vaccinations in about 26% to 85% of children and approximately 60% of adults, suggesting that a range of bacteria and viruses trigger the syndrome (Box 143-1) (Hughes and Cornblath, 2005; Korinthenberg, 2013). *Campylobacter jejuni* infection may be followed by any subtype of GBS but is more frequent with axonal forms (Hughes and Cornblath, 2005).

GBS declined with USA influenza vaccination campaigns between 1990 and 2003; however, a very small increased risk of GBS (1 per million above background incidence) occurred with influenza vaccinations between 1992 and 1994. Rabies

**TABLE 143-3** Guillain-Barré Syndrome Subtypes and Rare Variants Described in Childhood

	Relative Frequency	Associated IgG-Antiganglioside Antibodies
<b>SUBTYPES</b>		
Acute inflammatory demyelinating polyradiculoneuropathy (AIDP)	Common (more in Western world)	None/GM1 (~10%)
Acute motor axonal neuropathy (AMAN)	Common (more in developing countries)	GM1, GD1a
Acute motor and sensory axonal neuropathy (AMSAN)	Rare	GM1, GM1b, GD1a
Miller Fisher syndrome (MFS/FS)	Uncommon	GQ1b, GT1a
<b>VARIANTS</b>		
Bickerstaff brainstem encephalitis (BBE)	Rare	GQ1b, GT1a
Polyneuritis cranialis (PC)	Rare	GQ1b, GT1a
Pharyngeal-cervical-brachial variant (PCB)	Rare	GT1a > GQ1b >> GD1a
Acute sensory neuropathy	Very rare	GQ1b, GT1a
Acute pandysautonomia	Very rare	
Acute ophthalmoparesis	Very rare	GQ1b, GT1a
Paraparesis	Very rare	

vaccine has a GBS risk of about 1 in 1000 individuals. The risk of GBS or CIDP relapse after immunization is low. However, precaution is required when there is a history of GBS or CIDP, and specifically if they occurred within 6 weeks after a vaccination. For specific vaccination guidelines after immune-mediated neuropathies, the *Red Book* published by the American Academy of Pediatrics should be consulted. Rarely, GBS can be the presenting manifestation or develop during the course of lymphoma or systemic lupus erythematosus.

### Clinical Features of AIDP (GBS)

AIDP appears similar in children and adults, except children recover faster with fewer residua. The main presenting feature is initial rapid bilateral relatively symmetric ascending weakness beginning in the legs and progressing to the arms, face, and respiratory muscles within  $\leq 4$  weeks before a plateau is reached. Eighty percent of children reach maximum severity with inability to walk unaided within 2 weeks after onset, and 90% to 98% of children and adults reach maximum severity by 4 weeks (Hughes and Cornblath, 2005). Early generalized hyporeflexia or areflexia is typical. Cranial nerve involvement occurs early in about 30% of children, and later on in nearly 50%. The facial nerve is the most common cranial nerve affected, often bilaterally. After 7 to 10 days about 60% of children and adults are unable to walk, and respiratory compromise occurs in about 17% to 30% of adults (Hughes and Cornblath, 2005) and about 15% (4.4% to 24%) of children. Respiratory insufficiency and need for artificial ventilation correlate with severe upper limb involvement, degree of disability at nadir (disease peak), and dysautonomias in childhood GBS (Korinthenberg, 2013). Pain is a very prominent early complaint in about 50% to 79% of children and adults at the peak of the disease, and precedes the weakness in some children. In preschool children, weakness and pain often present with gait disturbances or refusal to walk (Asbury, 2000).

Transient dysautonomias, including arrhythmias and labile blood pressure, may be life-threatening and are reported in about 20% of adults and 3.7% to 77% of children with GBS. Transient bladder dysfunction occurs in 15% to 19.5% of childhood GBS. Children with a more severe acute phase may need catheterization and bladder decompression. Impaired swallowing, gastroesophageal dysmotility, pseudoobstruction, hypotension, urinary incontinence/retention, bowel incontinence/constipation, hyperhidrosis, and vasomotor instability may occur in GBS. Rarely cardiac arrest secondary to autonomic dysfunction is described in children. **Box 143-2** outlines the classic GBS clinical presentation in children.

### BOX 143-2 Classic Guillain-Barré Syndrome Presentation in Children

- Symmetric ascending paralysis
- Diminished or absent reflexes
- Often severe pain—may lead to a delay in diagnosis

### Acute Motor Axonal Neuropathy

Initially AMAN described a summer epidemic of acute ascending paralysis in children in northern China, strongly associated with prior *Campylobacter jejuni* infections (Asbury, 2000). Compared with AIDP, AMAN patients less frequently have cranial nerve involvement and generally have pure motor neuropathy involving only motor axons with sparing of the sensory axons. Around 10% of patients with AMAN have normal or exaggerated tendon reflexes throughout the disease, which could cause a diagnostic delay (Yuki and Hartung, 2012). AMAN patients have little or no dysautonomias, more rapid progression, and an earlier disease peak than AIDP (Hughes and Cornblath, 2005; Yuki and Hartung, 2012). Differences between AIDP and AMAN in childhood are outlined in Table 143-4.

### Other Subtypes and Variants of GBS

Several clinical subtypes of GBS have been characterized and are discussed online (Table 143-3) (Yuki and Hartung, 2013).

### Diagnostic Challenges of GBS in Childhood

Pain and walking difficulties may cause misdiagnosis of this potentially life-threatening disease in children. Presentation early in life may be less classic, with acute severe hypotonia, and may raise concerns of an encephalopathic process with meningismus, vomiting, and headache. Back pain and Babinski sign in an uncooperative child early on in GBS make differentiation from a spinal cord process difficult. Less commonly, weakness starting proximally may be confused with muscle disease. Occasionally botulism with weakness in the face and arms may cause diagnostic confusion.

### GBS Diagnostic Criteria

GBS diagnostic criteria and exclusionary features (Asbury, 2000) are outlined in **Box 143-3**.

**BOX 143-3** Clinical and Laboratory Features in the Diagnosis of Guillain-Barré Syndrome**I. REQUIRED FOR DIAGNOSIS**

- Progressive motor weakness of more than one limb
- Areflexia—loss of ankle-jerk reflex and diminished knee and biceps reflexes suffice, if other features are consistent with the diagnosis

**II. STRONGLY SUPPORTIVE OF THE DIAGNOSIS**

- Progression—weakness may develop rapidly but cease to progress after 4 weeks; roughly 50% will plateau within 2 weeks, 80% by 3 weeks, and 90% after 4 weeks
- Relative symmetry
- Mild sensory symptoms or signs
- Cranial nerve involvement; facial weakness develops in about half of patients
- Autonomic dysfunction
- Absence of fever at the onset of neurologic symptoms
- Recovery—usually recovery begins 2 to 4 weeks after progression ceases; it may be delayed for months
- Variants
  - Fever at onset of symptoms
  - Severe sensory loss with pain
  - Progressive phase longer than 4 weeks
  - Lack of recovery or major permanent residual deficit
- Sphincter dysfunction—sphincters are usually spared, although transient bladder paralysis may occur
- CNS involvement

**III. FEATURES CASTING DOUBT ON THE DIAGNOSIS**

- Marked persistent asymmetry in motor function
- Persistent bowel or bladder dysfunction
- Bowel or bladder dysfunction at onset of symptoms
- Discrete sensory level

**IV. FEATURES THAT EXCLUDE THE DIAGNOSIS**

- History of recent hexacarbon abuse
- Evidence of porphyria
- Recent diphtheria
- Features consistent with lead neuropathy and evidence of lead intoxication
- A pure sensory syndrome
- Definite diagnosis of an alternate paralytic disorder

(With permission of Asbury AK, Cornblath DR. Assessment of current diagnostic criteria for Guillain-Barré syndrome. *Ann Neurol* 1990;27:S21.)

**Differential Diagnosis**

A variety of other peripheral and occasional CNS disorders can be confused with GBS. These are outlined in [Box 143-4](#) and the reader is referred to the specific chapters discussing these conditions.

**Laboratory Findings Supportive of GBS****Cerebrospinal Fluid**

Characteristically the CSF has albuminocytologic dissociation, with a raised protein and no significant evidence of inflammation (<10 mononuclear cells/mm<sup>3</sup>) ([Asbury, 2000](#); [Yuki and Hartung, 2012](#)). Protein elevation is present in <50% of patients during the first week of illness, increasing to 75% in the third week ([Yuki and Hartung, 2012](#)). Significant CSF pleocytosis (>50 mononuclear cells/mm<sup>3</sup>) or polymorphonuclear leukocytes raise doubt about the diagnosis. In a

**BOX 143-4** Differential Diagnosis of Guillain-Barré Syndrome**CEREBRAL**

- Bilateral strokes
- Hysteria

**CEREBELLAR**

- Acute cerebellar ataxia syndrome (multiple etiologies)
- Posterior fossa structural lesion

**SPINAL**

- Poliomyelitis
- Compressive myelopathy
- Transverse myelitis
- Anterior spinal artery syndrome

**PERIPHERAL NERVE**

- CIDP
- Toxic neuropathy:
  - *Drugs*: amitriptyline, dapsone, glutethimide, hydralazine, isoniazid, nitrofurantoin, nitrous oxide, incrusting
  - *Toxins*: acrylamide, glue sniffing, fish toxins, heavy metals (lead, arsenic, mercury, thallium), insecticides, N-hexane and other solvents, organophosphates, snake venom
- Critical illness neuropathy
- Vasculitis
- Diphtheria
- Tick paralysis
- Porphyria

**NEUROMUSCULAR JUNCTION**

- Botulism
- Myasthenia gravis
- Neuromuscular-blocking agents

**MUSCLE DISEASES**

- Acute viral myositis
- Acute inflammatory myopathies (polymyositis, dermatomyositis)
- Metabolic myopathies (multiple types)
- Periodic paralysis
- Hypo- or hyperkalemia
- Critical illness myopathy

pediatric series, CSF protein levels range from 80 to 200 mg/dl (normal <40 mg/dl).

**Electrodiagnosis**

In the vast majority of children with GBS in the Western world, nerve conduction studies (NCS) show demyelinating features such as conduction slowing (prolonged distal latencies, slowed conduction velocities, prolonged F-wave minimal latencies, prolonged H-reflex minimal latencies) or conduction block over focal nerve segments (Figure 143-2, *A* and *B*). The electrophysiologic criteria outlined by the 88th European Neuromuscular Center (ENMC) for childhood CIDP ([Box 143-5](#)) ([Nevo and Topaloglu, 2002](#)) can be used to diagnose demyelination in childhood GBS. With more advanced disease, there may also be low-amplitude compound muscle action potentials (CMAPs). NCS performed early in the course or in mild cases may be nonspecific. In Asia, primary axonal subtypes of GBS show low-amplitude CMAPs in AMAN, and low-amplitude CMAPs and sensory nerve action potentials in AMSAN. Mild nerve conduction slowing secondary to axonal damage may occur.

## Magnetic Resonance Imaging

Gadolinium lumbosacral MRI is sensitive but not specific for acute demyelinating GBS, showing cauda equina root enhancement in 95% of adults and adolescents 13 days (mean) after onset. This was confirmed in 95% of Turkish pediatric GBS cases.

## GBS Pathogenesis

 This is discussed online.

## GBS Treatment

### Supportive Care

The potential mortality rate of <5% in children and 4% to 15% in adults necessitates hospitalization and regular monitoring for dysautonomias and respiratory compromise until maximal disability is reached. With supportive care alone, recovery usually starts within 2 to 4 weeks after the weakness stops progressing (Asbury, 2000).

Rapid progression, inability to flex the arms or head, bulbar weakness, inability to cough, dysautonomia, or children with a CSF protein >800 mg/dl are more likely to require mechanical ventilation. Indications for intubation are impending respiratory failure, oropharyngeal paresis, and severe dysautonomia. Respiratory failure in children is characterized by paradoxical breathing, lethargy, reduced alertness (hypoxemia until proven otherwise), or hypoxemia diagnosed by pulse oximetry or arterial blood gases. Infants and children with severe respiratory muscle weakness may lack the classical clinical signs of rapid respiratory effort and retractions, having only anxiety and tachycardia. In adults, vital capacity <20 ml/kg warns of imminent respiratory arrest. Weaning from the ventilator should be guided by improved strength, pulse oximetry, or serial arterial blood gases.

Dysautonomias, including arrhythmias and labile blood pressure, may be life-threatening and should be sought. Endotracheal suction or medications may trigger autonomic dysfunction. Adynamic ileus, urinary retention, and hyponatremia must be regularly sought and treated.

Early management involves nasogastric tube feeding for significant dysphagia to avoid aspiration, nutritional support, and positioning the child to avoid pressure palsies and aid pulmonary drainage. Nonsteroidal antiinflammatory drugs, carbamazepine and gabapentin, are useful in pain control. Opioids provide pain relief but may aggravate autonomic bowel dysmotility. Attention for complications such as immobilization hypercalcemia, infections, and gastrointestinal hemorrhage/dysfunction is required. The adult GBS risk of deep vein thrombosis is low in children (Korinthenberg, 2013).

### GBS Immunotherapy

Intravenous immunoglobulin (IVIg) and PE are treatment options in severe childhood GBS. Started promptly within the first 2 weeks, IVIg/PE in adults reduces median time to independent walking from 83 to 43 days (PE) and to 51 to 55 days (IVIg). A Cochrane review (Hughes RA, Swan AV, van Doorn PA. 2014, Intravenous immunoglobulin for Guillain-Barré syndrome. Cochrane Database Syst Rev;9:CD002063) of adults and children showed moderate evidence that IVIg started within two weeks from severe GBS onset, hastens recovery as much as PE. In children, IVIg probably hastens recovery compared with supportive care alone (low quality evidence). Small trials in children show a trend towards more improvement with high-dose compared with low-dose IVIg,

and no significant difference when the standard dose was given over two days rather than five days. IVIg is preferred in childhood because of less invasiveness and rarer complications than PE. Combined IVIg and PE is not more effective than either alone. Relapse rates (about 10%) within the first 3 weeks are similar for IVIg and PE, responding to retreatment. PE improved time to independent walking from 60 to 24 days in one small pediatric study, confirmed by other small series. Three randomized pediatric GBS trials compared IVIg with supportive treatment or placebo, suggesting IVIg significantly hastens recovery compared with supportive care. Of these, Korinthenberg et al. (2005) (randomized open study) had two groups: (1) early treatment of mild GBS (walk 5 m unaided) in 21 children—half the usual dose of IVIg (0.5 g/kg/day over 2 days) had significantly faster improvement (median 8 days) compared with supportive treatment (median 32 days); (2) severe GBS (unable to walk 5 m unaided) in 51 children (all treated with IVIg). In this treated cohort no side effect difference or significant differences in primary or secondary outcome measures were found between IVIg 1 g/kg/day over 2 days versus 0.4 g/kg/day over 5 days (median time to unaided walking: 19 days vs. 13 days), except for more early relapses (21.7%) after the 2-day regimen ( $p = 0.049$ ). IVIg side effects are discussed elsewhere. IVIg treatment should be started promptly according to clinical indications. However, IVIg is contraindicated where there is hypersensitivity to human immunoglobulin, severe renal, or severe cardiovascular disease. In patients with IgA deficiency (prevalence about 1:1000), IgA-poor IVIg or alternative therapies may be used to prevent anaphylaxis; however, the risk of anaphylaxis is not completely eliminated with IgA-poor preparations. Avoid PE with marked dysautonomia.

### Corticosteroids in GBS

Corticosteroids alone should not be used in GBS treatment. A minor synergistic effect of intravenous methylprednisolone with IVIg on short-term outcome cannot be excluded.

### Potential GBS Therapies

These are discussed online.

## Childhood GBS Outcome

About 90% to 95% of children with GBS recover completely within 6 to 12 months independent of therapeutic intervention (Asbury, 2000) compared with 20% of adults who have persistent disability. Mean maximal Hughes GBS disability scale of hospitalized children is grade 3.5 (walk 5 m with support) to 4 (bed/chair bound). After IVIg therapy childhood AMAN and AMSAN recover slower than AIDP. All have favorable outcomes at 12 months except for a worse prognosis in some AMAN and AMSAN cases. AMAN does not have the same long-term consequences in children as it does in adults (Korinthenberg, 2013). Children not recovering completely are usually functionally independent with minor residua. Long-term symptoms (paresthesias, pain, severe fatigue) possibly leading to psychosocial/school problems later in life occurred in a Dutch childhood GBS study.

Factors predictive of delayed recovery and long term weakness in children following GBS, include young age, maximum disability score at presentation, quadriplegia at day 10, need for ventilator support, cranial nerve involvement, and absent or unexcitable motor nerve responses on nerve conduction testing (Korinthenberg, 2013). Poor adult prognosis occurs with advanced age, severe GBS, rapid onset, need for assisted ventilation, other serious medical conditions, *C. jejuni* enteritis, recent cytomegalovirus infection, anti-GM1 antibodies,

and marked reduction of compound motor action potentials when first measured (Asbury, 2000; Hughes and Cornblath, 2005). A small percentage of children go on to develop CIDP (Korinthenberg, 2013).

## CHRONIC INFLAMMATORY DEMYELINATING POLYRADICULONEUROPATHY

### Epidemiology

The estimated prevalence is 0.48 per 100,000 children compared with 1 to 1.9 per 100,000 adults, with a male preponderance in children and adults. Onset occurs from birth, with most childhood cases occurring before 10 years of age (Hughes and Cornblath, 2005).

### Antecedent Events

These occur in 23% to 53% of children, including infection or immunization during the month before CIDP onset (Nevo, 1998).

### Diagnostic Criteria and Clinical Features

The 88th ENMC consortium on childhood CIDP research mandatory clinical criteria are (1) progression of proximal and distal weakness of upper and lower extremities >4 weeks, or rapid progression (GBS-like presentation) followed by relapsing or protracted course (>1 year), and (2) areflexia or hyporeflexia (Box 143-5) (Nevo, 2002). ENMC "confirmed CIDP" criterion require mandatory clinical plus both electrodiagnostic and CSF features. The "Confirmed CIDP" criterion does not require nerve biopsy. "Possible CIDP" requires mandatory clinical plus only one of three laboratory findings (electrophysiologic, CSF, or nerve biopsy). Children with CIDP present mainly with lower limb weakness and/or ataxia, and younger children, with developmental delay. Proximal and distal weakness occurs in most patients. A minority of children have sensory symptoms on presentation, but sensory findings occur in most patients during the disease course (touch and vibration deficits being the most common). Facial weakness occurs in 20% to 33% of children and other cranial nerve dysfunction is uncommon. Deep tendon reflexes are either absent or decreased. Pes cavus and enlarged nerves has been noted in several childhood CIDP cases and tremor is infrequent. In general, the pattern and distribution of weakness and the presence of sensory symptoms are similar to adults. Subacute onset and relapses are more common in childhood. Presentation may be monophasic with complete recovery, relapsing remitting, slowly progressive, or stepwise progressive, and should be distinguished from acute immune neuropathies and hereditary motor and sensory neuropathies (Box 143-6).

ENMC childhood CIDP mandatory research criteria were revised to include progressive muscle weakness over at least 4 weeks (instead of 8 weeks) defining a shorter progression time, as childhood onset is more often acute/subacute than adults, evolving over 2 to 3 months, or in the case of rapid progression (i.e., GBS-like presentation) followed by relapse or protracted course >1 year (Nevo, 2002).

In adults subacute inflammatory demyelinating polyneuropathy (SIDP) is intermediate between GBS and CIDP, reaching nadir between 4 and 8 weeks with no relapse. SIDP has more antecedent infections than CIDP, a high rate of full recovery (64% to 100%), and is set apart from GBS by steroid responsiveness. SIDP cases have been described in children. However, because childhood CIDP is defined as starting from >4 weeks, SIDP is therefore included in CIDP in childhood.

## CIDP Laboratory Evaluation

### Cerebrospinal Fluid and Electrodiagnosis

Most children and adults with CIDP have an elevated CSF protein with <5 cells/mm<sup>3</sup>. Electrophysiologic criteria for childhood CIDP are outlined by the 88th ENMC international workshop on childhood chronic inflammatory demyelinating polyneuropathy (Box 143-5) (Nevo, 2002).

### CIDP Pathology and Pathogenesis

Reviewed online.

### CIDP Magnetic Resonance Imaging

Spinal MRI may show intrathecal and intraforaminal root, and brachial or lumbosacral plexus enhancement or enlargement (Ware et al., 2014).

## Childhood CIDP Immunotherapy

In practice, CIDP should be diagnosed clinically, and appropriate therapy should be started as soon as the diagnosis is made even if research diagnostic criteria are not entirely fulfilled. CIDP usually responds to corticosteroids within approximately 2 months; however, there is considerable variability. Starting with either daily oral prednisone or high-dose pulse corticosteroids or IVIg is effective in both children and adults. First-line choice depends on cost, side effects, and personal preference. Resistance to therapy and steroid dependence present a therapeutic challenge. Newer agents offer second-line therapy for treatment-resistant cases.

### First-Line CIDP Treatments

**Corticosteroids.** Corticosteroids induced short-term improvement in 65% to 95% of adults and 71% to 100% of children in small series (Nevo, 1998; Connolly, 2001). The best regimen in children is not known. Initially 1 to 2 mg/kg/day oral prednisone (maximum 60 to 80 mg) usually results in improvement within 1 to 4 weeks. Slow tapering is begun after significant improvement, but not before 4 to 6 weeks. Relapses are frequent with rapid tapering; therefore, a slow reduction by 5 mg every 2 weeks in adults and equivalent slow tapering in children is recommended after a clinical response (Nevo, 1998). Deterioration may occur within days of starting corticosteroids. Intermittent pulse intravenous methylprednisolone may have less corticosteroid side effects over the longer-term than oral corticosteroids.

**Intravenous Immunoglobulin.** IVIg showed good efficacy in 50% to 88% of pediatric CIDP cases, improving disability for 2 to 12 weeks and may be used as initial therapy because of paucity of side effects (Connolly, 2001). A proportion of patients need recurrent treatments (months to years) to maintain improvement. IVIg improves adult CIDP disability for at least 2 to 6 weeks (possibly for 24 to 48 weeks) compared with placebo, with similar efficacy to PE, oral prednisolone, and intravenous methylprednisolone.

**Plasmapheresis/Plasma exchange (PE).** PE, usually a temporary measure, showed good short-term improvement in 50% to 100% of children in small CIDP series (Connolly, 2001). Efficacy lasts for 7 to 14 days (up to 8 weeks). PE should be reduced gradually, repeated, and occasionally used with immunosuppressives because of possible rebound worsening.

## Potential Second-Line Immunosuppressants for Treatment Resistant CIDP

Cytotoxic drugs may improve the therapeutic response in resistant adult CIDP patients and have a corticosteroid sparing effect or reduce the need for IVIg and PE. However, current evidence for their efficacy is insufficient or does not show significant benefit. These agents are discussed in detail online.

**Current Practice in Childhood CIDP Immunotherapy.** Current practice in childhood CIDP immunotherapy as described in case reports and series is as follows: (1) *First-line therapy*: either IVIg 0.4g/kg/day for 5 days repeated every 3 to 4 weeks, or corticosteroids (oral prednisone) 1 to 2 mg/kg/day for 4 to 6 weeks and then slow tapering. (2) *Second-line therapy*: azathioprine 1 to 3 mg/kg/day. (3) *Always consider*: combining therapies, individual adjustments of treatment strategy, and alternative therapies (PE, methotrexate, cyclosporine A, mycophenolate mofetil, cyclophosphamide, monoclonal antibodies, IFN- $\alpha$ ).

**Differentiating Abrupt-Onset CIDP From GBS Fluctuations.** There may be difficulty differentiating monophasic GBS with transient fluctuations from CIDP patients with abrupt symptom onset (McMillan et al., 2013). This is further discussed online.

**Clinical Variants Not Meeting CIDP Research Criteria.** There are clinical variants in which CIDP research criteria cannot be met, but respond to immune-modulating therapy. Infants with CD59 deficiency and chronic hemolysis were reported with a relapsing immune-mediated polyneuropathy mimicking CIDP.

This is discussed online.

## Childhood CIDP Outcome

CIDP has complete remission in about 70% to 100% of children compared with adult response rates of 65% to 70% with more severe residua. Simmons et al. (1997), Korinthenberg (1999), and Rossignol et al. (2007) showed very good outcomes in 83% to 85%, with no correlation between rapid onset and outcome. McMillan et al. (2013) found that 87% of CIDP children had a favorable long-term outcome; however, on long-term follow-up some had minimal focal weakness, and 1 child had restricted activity. Nevo et al. (1996) described two outcome groups: short progression (1 to 3 months) with complete resolution in 75%, and mild residua in 25%. Children with longer progression (>3 months) had mild residua in 78%, and severe residua in 22%. Hattori et al. (1998) showed the above short- and long-progression groups. Ryan et al. (2000) identified two populations with very good long-term outcome in general, and mild persistent deficit in cases with progressive deterioration.

## OTHER CAUSES OF IMMUNE-MEDIATED NEUROPATHIES IN CHILDREN

These rare causes of inflammatory neuropathy in childhood are discussed online.

# 144 Congenital Myasthenic Syndromes

Duygu Selcen and Andrew G. Engel

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Congenital myasthenic syndromes (CMS) are inherited disorders of neuromuscular transmission associated with abnormal weakness and fatigability on exertion. CMS were described as early as 1937 but received little attention until the autoimmune origin of acquired myasthenia gravis in the late 1970s and of the Lambert-Eaton syndrome in the 1980s were described. Then it became apparent that myasthenic disorders occurring in a familial or congenital setting must have a different etiology. By the first decade of this century, clinical, ultrastructural, in vitro microelectrode, and molecular genetic studies of CMS patients revealed a phenotypically and genetically heterogeneous group of disorders.

## CLINICAL MANIFESTATIONS

Some patients with CMS can present as early as in fetal life by decreased motility. Patients harboring mutations in rapsyn (Ohno et al., 2002), in the AChR delta subunit, in the fetal AChR gamma subunit (Hoffmann et al., 2006), in ChAT, or in SNAP25B (Shen et al., 2014) can have multiple joint contractures at birth. In the neonatal period, most patients are hypotonic with a weak cry, poor suck, and symmetric eyelid ptosis; they may also have stridor, choking spells, respiratory insufficiency, or apneic episodes. The symptoms are worsened by crying or activity and increase by the end of the day. Motor milestones are delayed, and most patients never learn to run or climb stairs well. They fatigue abnormally on exertion and cannot keep up with their peers in sports. Many have impaired eye movements. Small muscle bulk and spinal deformities can become apparent in later life but in some patients, severe scoliosis is present in infancy. The slow-channel CMS and the CMS caused by mutations in DOK7, GFPT1, and DPAGT1 are slowly progressive and can lead to severe disability in later life. Low-expressor mutations in nonepsilon AChR subunits are associated with a severe clinical phenotype; by contrast, most low-expressor mutations in the AChR epsilon subunit have a mild and static course because expression of the fetal gamma subunit can partially substitute for the defect in the epsilon subunit. The mildest forms of CMS present with fatigable oculobulbar or limb muscle weakness later in life.

The edrophonium or neostigmine test can be positive in some but not in all CMS such as in endplate acetylcholinesterase deficiency, in some cases of the slow-channel syndrome, or in Dok-7 myasthenia. Box 144-1 lists generic and specific clinical features of the various CMS.

## DIAGNOSIS

A generic diagnosis of CMS can be made on the basis of classical clinical manifestations, a positive family history, and a decremental electromyographic response. The differential diagnosis of CMS is broad and includes various neuromuscular conditions.

The physical examination should include detailed manual muscle testing as well as tests for fatigable weakness such as measuring the arm and leg elevation time, the number of

times a patient can rise from squatting or from a low stool, whether eyelid ptosis increases with sustained upward gaze, and the number of steps the patient can climb or the distance the patient can walk before having to rest. Respiratory muscle strength can be evaluated by measuring the maximal inspiratory and expiratory pressures and the vital capacity.

The EMG examination should include repetitive stimulation of nerves at 2 to 3 Hz in search of a decrease of the amplitude or area of the fourth, compared with the first, evoked compound motor action potential in multiple muscles, and especially in muscles that are significantly weak. The repetitive compound muscle action potential (CMAP) typical in the slow-channel syndrome and endplate acetylcholinesterase deficiency is detected by a repetitive CMAP elicited by a single nerve stimulus. A decremental EMG response is frequently present in facial and trapezius muscles when it cannot be detected in other muscles. If repetitive nerve stimulation studies fail to show a decremental response, then single fiber EMG (SFEMG) is needed to exclude a defect of neuromuscular transmission. However, the SFEMG can also be abnormal in patients with myopathies.

Antiacetylcholine receptor, antimuscle specific tyrosine kinase (MuSK), and antivoltage-gated P/Q type calcium channel antibodies should be searched in sporadic patients whose symptoms present after the age of 1 year, and anti-AChR antibodies should be searched both in mother and the infant with arthrogyrosis and weakness to exclude autoimmune myasthenia. Infantile botulism may need to be excluded if the clinical features suggest acute- or subacute-onset fatigable weakness, ptosis, dry mouth, dilated pupils, and loss of light reflex and accommodation.

The genetic diagnosis of a specific CMS is important as it guides the therapy. Identification of the culprit gene is greatly facilitated when clinical and EMG studies point to a candidate gene (Box 144-3).

Testing for CMS mutations in previously identified CMS genes is now commercially available and offered as a panel of tests. In recent years, whole exome sequencing has also been used to identify CMS mutations. If a novel CMS disease gene is discovered, then expression studies with the genetically engineered mutant protein should be used to confirm its pathogenicity.

Deeper insights into disease mechanisms and clues to etiology can be obtained by in vitro analysis of neuromuscular transmission and structural studies of the neuromuscular junction. They are important for identifying direct effects of the mutations on neuromuscular transmission, characterizing novel CMS, and providing clues for therapy.

## PRESYNAPTIC CONGENITAL MYASTHENIC SYNDROMES

### 1. Endplate Choline Acetyltransferase (ChAT) Deficiency

ChAT catalyzes the resynthesis of ACh by transfer of an acetyl group from acetyl-CoA to choline in cholinergic neurons.

**BOX 144-1** Generic Clinical Features of the Congenital Myasthenic Syndromes**GENERIC FEATURES**

- Fatigable weakness involving ocular, bulbar, and limb muscles since infancy or early childhood
- Similarly affected relative
- Decremental EMG response at 2–3 Hz stimulation
- Negative tests for anti-AChR antibodies, MuSK, and P/Q type calcium channels

**EXCEPTIONS AND CAVEATS**

- In some congenital myasthenic syndromes, the onset is delayed
- There may be no similarly affected relatives
- The symptoms can be episodic
- EMG abnormalities may not be present in all muscles, or are present only intermittently
- Weakness may not involve cranial muscles

**BOX 144-3** Clinical Clues Pointing to a Specific Congenital Myasthenic Syndrome or Disease Protein

- Dominant inheritance: slow-channel CMS, SNAP25 and synaptotagmin
- Refractory or worsened by AChE inhibitors: ColQ, Dok-7, MuSK, Agrin, LRP4, plectin, and laminin- $\beta$ 2
- Repetitive compound muscle action potential (CMAP) evoked by single nerve stimuli: slow-channel CMS and ColQ deficiency
- Delayed pupillary light response: some patients with ColQ deficiency
- Congenital contractures: rapsyn, AChR  $\delta$  or  $\gamma$  subunit, ChAT, SNAP 25
- Greater than 50% decrease of CMAP amplitude after subtetanic stimulation at 10 Hz for 5 min followed by slow recovery over 5–10 minutes: ChAT deficiency
- Sudden apneic episodes provoked by fever or stress: ChAT, rapsyn, sodium channel myasthenia
- Limb-girdle and axial distribution of weakness: Dok7, GFPT1, DPAGT1, ALG2, ALG14, LRP4, and occasionally rapsyn and ColQ
- Selectively severe weakness and atrophy of distal limb muscle: slow-channel syndrome and in some patients with agrin deficiency
- Tubular aggregates of the sarcoplasmic reticulum in muscle fibers: GFPT1, DPAGT1, ALG2
- Autophagic myopathy: GFPT1 and DPAGT1
- Stridor and vocal cord paralysis in neonates or infants: Dok-7
- Nephrotic syndrome and ocular malformations (Pierson syndrome): laminin- $\beta$ 2
- Association with seizures or intellectual disability: DPAGT1
- Intellectual disability and cerebellar ataxia: SNAP25
- Developmental anomalies of eye, brain, and heart: mitochondrial citrate carrier deficiency
- Association with epidermolysis bullosa simplex: plectin deficiency

Pathogenic mutations, alone or in combination, alter the expression, catalytic efficiency, or structural stability of the enzyme (Ohno et al., 2001). When neuronal impulse flow is increased as during exercise, the decreased rate of ACh resynthesis progressively depletes the ACh content of the synaptic

vesicles, which decreases the amplitude of the EPP and of the CMAP.

Some patients present with hypotonia, bulbar paralysis, and apnea at birth. Others are normal at birth and develop apneic attacks during infancy or childhood precipitated by infection, excitement, or no apparent cause. In some children an acute attack is followed by respiratory insufficiency that lasts for weeks. Few patients are apneic, ventilator dependent, and paralyzed since birth, and some develop cerebral atrophy after episodes of hypoxemia. Others improve with age but still have variable ptosis, ophthalmoparesis, fatigable weakness, and recurrent cyanotic episodes; some complain only of mild to moderately severe fatigable weakness. The symptoms are worsened by exposure to cold because this further reduces the catalytic efficiency of the mutant enzyme.

A useful clinical test is to monitor the EMG decrement and the CMAP amplitude during 10 Hz stimulation over 5 minutes and for 10 to 15 minutes after stimulation. A decrease lower than 50% of the potential from the baseline followed by return to the baseline in 2 to 3 minutes is a nonspecific finding that occurs in different CMS. In contrast, in patients with ChAT deficiency the recovery occurs slowly over 5 to 15 minutes.

Treatment consists of prophylactic therapy with pyridostigmine, which increases the number of AChRs activated by each quantum. The parents should be provided with an inflatable rescue bag and a fitted mask, should be instructed in the intramuscular injection of neostigmine methylsulfate, and are advised to have an apnea monitor.

**2. SNAP25B Myasthenia**

SNAP25B is one of the three essential SNARE proteins required for synaptic vesicle exocytosis. A patient with severe CMS associated with cortical hyperexcitability, ataxia, multiple joint contractures at birth, and intellectual disability harbored a dominant negative mutation in SNAP25B. Treatment with 3,4-diaminopyridine (3,4-DAP), which increases the number of ACh quanta released by nerve impulse, improved the patient's weakness but not her ataxia or intellectual disability.

**3. Synaptotagmin-2 Myasthenia**

Synaptotagmin 2 is a synaptic vesicle-associated calcium sensor. In two kinships, dominant mutations in this gene caused a Lambert-Eaton syndrome-like disorder with lower limb predominant weakness, areflexia, and a motor neuronopathy. They had low amplitude CMAP that were greatly facilitated by exercise (Herrmann et al., 2014).

**SYNAPTIC BASAL LAMINA ASSOCIATED CONGENITAL MYASTHENIC SYNDROMES****1. Endplate Acetylcholinesterase Deficiency**

The EP species of acetylcholinesterase (AChE) is an asymmetric enzyme composed of catalytic subunits encoded by *AChE<sub>T</sub>* and a collagenic structural subunit encoded by *COLQ* that anchors the enzyme in the synaptic basal lamina.

The clinical course of patients with EP AChE deficiency is variable. Patients typically present in the neonatal period or infancy with apnea and generalized weakness that persist through life. In some patients, the ocular ductions are spared and in some the pupillary light reflex is delayed. Milder cases may present later in childhood with limb-girdle weakness. Absence of AChE from the EP prolongs the lifetime of ACh in the synaptic cleft because each ACh binds multiple AChRs

before leaving the synaptic space by diffusion. This prolongs the duration of the MEPP and EPP, and when the EPP outlasts the absolute refractory period of the muscle fiber, it generates a second (or repetitive) muscle fiber action potential, reflected by a repetitive CMAP that is unaffected by edrophonium (Ohno et al., 1998).

Therapy is still unsatisfactory, but ephedrine and albuterol (Liewluck et al., 2011) were noted to have a gradually developing beneficial effect.

## 2. Congenital Myasthenic Syndrome Associated With $\beta$ 2-Laminin Deficiency

$\beta$ 2-Laminin, encoded by LAMB2, is a component of the basal lamina of different tissues and is highly expressed in kidney, eye, and the neuromuscular junction. Synaptic  $\beta$ 2-laminin governs the appropriate alignment of the axon terminal with the postsynaptic region and, hence presynaptic and postsynaptic trophic interactions. Defects in  $\beta$ 2-laminin result in Pierson syndrome with renal and ocular malformations. In a single report, a patient carrying two heteroallelic frameshift mutations in LAMB2 had Pierson syndrome associated with ocular, respiratory, and proximal limb muscle weakness. The renal defect was corrected by renal transplant at age 15 months.

A trial with a cholinesterase inhibitor resulted in profound weakness requiring hospitalization and ventilatory support. The patient responded to treatment with ephedrine but still had significant weakness.

## POSTSYNAPTIC CONGENITAL MYASTHENIC SYNDROMES

Most postsynaptic CMS stem from molecular defects in the muscle form of the nicotinic AChR. The muscle form of nicotinic AChR is a pentameric transmembrane macromolecule with a subunit composition of  $\alpha$ 2 $\beta$  $\delta$  $\epsilon$  at adult EPs, and  $\alpha$ 2 $\beta$  $\delta$  $\gamma$  at fetal EPs and extrajunctional sites. The genes encoding the  $\alpha$  (CHNRA1),  $\delta$  (CHRND), and  $\gamma$  (CHRNA3) subunits are located in chromosome 2q, and those encoding the  $\beta$  (CHRNA1) and  $\epsilon$  (CHRNE) subunits are on chromosome 17p. At the human EP, AChR is concentrated on the crests of the junctional folds.

### 1. Primary Acetylcholine Receptor Deficiency

The clinical phenotypes vary from mild to severe. Patients with recessive mutations in the  $\epsilon$  subunit are generally less affected than those with mutations in other subunits because compensatory expression of the fetal  $\gamma$  subunit can partially substitute for the defective  $\epsilon$  subunit. The sickest patients have severe ocular, bulbar, and respiratory muscle weakness from birth and survive only with respiratory support and tube feeding. They may be weaned from a ventilator and begin to tolerate oral feedings during the first year of life but have bouts of aspiration pneumonia; they may need intermittent respiratory support during childhood and adult life. Motor milestones are severely delayed; they seldom learn to negotiate steps and can walk for only a short distance. Older patients close their mouth by supporting the jaw with the hand and elevate their eyelids with their fingers. Facial deformities, prognathism, malocclusion, and scoliosis or kyphoscoliosis become noticeable during the second decade. Muscle bulk is reduced. The tendon reflexes are normal or hypoactive.

The least affected patients pass their motor milestones with slight or no delay and show only mild ptosis and limited ocular ductions. They are often clumsy in sports, and fatigue easily. In some instances, a myasthenic disorder is suspected

only when the patient develops prolonged respiratory arrest on exposure to a curariform drug during a surgical procedure.

Patients with intermediate clinical phenotypes experience moderate physical handicaps from early childhood. Ocular palsies and eyelid ptosis become apparent during infancy. They fatigue easily, walk and negotiate stairs with difficulty, cannot keep up with their peers in sports, but can perform most activities of daily living.

Most patients respond favorably but incompletely to AChE inhibitors. The additional use of 3,4-DAP results in further improvement but the limited ocular ductions, pronounced in most patients with AChR deficiency, are typically refractory to therapy. Recently, albuterol was found to benefit patients responding poorly to pyridostigmine and 3,4-DAP.

## 2. Kinetic Defects in Acetylcholine Receptor

### 2.1 Slow-channel Myasthenia

The slow channel myasthenia is caused by dominant gain of function mutations that either enhances the affinity or the gating efficiency of AChR (Engel et al., 2003). Either mechanism prolongs the duration of the EP potentials and currents. As in EP AChE deficiency, when the length of the EPP exceeds the absolute refractory period of the muscle fiber, it triggers a repetitive CMAP; however, unlike in AChE deficiency, the repetitive response is enhanced by edrophonium.

The onset of symptoms ranges from infancy to early adult life. There is severe selective involvement of the cervical, scapular, and the wrist and finger extensor muscles.

The slow-channel syndromes are refractory to, or are worsened by, cholinergic agonists but are improved by long-lived open-channel blockers of the AChR, such as quinine or quinidine, or by fluoxetine (Harper et al., 2003).

### 2.2 Fast-channel Myasthenia

They are recessively inherited disorders caused by either decreased affinity for ACh or reduced gating efficiency, or by destabilization of the channel kinetics, or by a combination of these mechanisms; they leave no anatomic foot prints. Each of these derangements results in abnormally brief channel openings reflected by an abnormally fast decay of the EP potentials and currents. They are thus physiologic and structural opposites of the slow-channel syndromes.

A fast-channel mutation dominates the clinical phenotype when the second allele harbors a null mutation or if it occurs at homozygosity. The clinical consequences vary from mild to severe; no clinical clues point to the diagnosis of fast-channel myasthenia.

Most patients respond to a combination of 3,4-DAP and pyridostigmine, but some are refractory to therapy.

## 3. Prenatal Congenital Myasthenic Syndrome Caused by Mutations in Acetylcholine Receptor Subunits and Other Endplate Specific Proteins

The first identified prenatal myasthenic syndrome was traced to mutations in the fetal AChR  $\gamma$  subunit. In humans, AChR harboring the fetal  $\gamma$  subunit appears on myotubes around the ninth developmental week and becomes concentrated at nascent nerve-muscle junctions around the sixteenth developmental week. Subsequently, the  $\gamma$  subunit is replaced by the adult  $\epsilon$  subunit and is no longer present at fetal EPs after the thirty-first developmental week. Thus pathogenic mutations of the  $\gamma$ -subunit result in hypomotility in utero during the 16th and 31st developmental week. The clinical consequences at

birth are multiple joint contractures, small muscle bulk, multiple pterygia (webbing of the neck, axilla, elbows, fingers, or popliteal fossa), fixed flexion contractures of the fingers (camptodactyly), rocker-bottom feet with prominent heels, and characteristic facies with mild ptosis and a small mouth with downturned corners. Myasthenic symptoms are absent after birth because by then the normal adult  $\epsilon$  subunit is expressed at the EPs.

A lethal fetal akinesia syndrome is caused by biallelic null mutations in the AChR  $\alpha$ ,  $\beta$ , and  $\delta$  subunits as well as in rapsyn, Dok-7, and MuSK.

#### 4. Sodium-channel Myasthenia

Thus far, only one patient with this syndrome has been identified. The patient had abrupt attacks of respiratory and bulbar paralysis since birth, lasting from 3 to 30 minutes, and was normokalemic. Intracellular microelectrode studies of neuromuscular transmission revealed that suprathreshold EPPs failed to generate muscle action potentials pointing to Nav1.4, encoded by SCN4A, as the culprit. After the defect in Nav1.4 was established, the patient was treated with pyridostigmine, which improved her endurance, and with acetazolamide, which prevented further attacks of respiratory and bulbar weakness.

#### 5. Congenital Myasthenic Syndrome Caused by Plectin Deficiency

Plectin, encoded by PLEC, is a highly conserved and ubiquitously expressed intermediate filament-linking protein. By virtue of its tissue and organelle-specific isoforms, it links cytoskeletal filaments to target organelles in different tissues. Mutations in plectin result in epidermolysis bullosa simplex (EBS), a progressive muscular dystrophy in many patients and a myasthenic syndrome in some. In two patients investigated by the authors, microelectrode studies of intercostal muscle EPs showed low-amplitude MEPPs. Morphologic studies revealed clustering of nuclei, endomysial fibrosis, and focal calcium accumulation in some fibers, as in Duchenne dystrophy. Electron microscopy studies showed degeneration and disarray of muscle fiber organelles, plasma membrane defects accounting for calcium accumulation in the muscle fibers, and extensive degeneration of the junctional folds all attributable to lack of cytoskeletal support. Both patients were refractory to pyridostigmine.

### CONGENITAL MYASTHENIC SYNDROMES CAUSED BY DEFECTS IN ENDPLATE DEVELOPMENT OR MAINTENANCE

To date, mutations in proteins essential for EP development and maintenance have been detected in MuSK, neural agrin, LRP4, Dok-7. Agrin, secreted into the synaptic space by the nerve terminal, binds to the lipoprotein-related protein LRP4 in the postsynaptic membrane. The Agrin-LRP4 complex binds to and activates MuSK. This enhances MuSK phosphorylation and leads to clustering of LRP4 and MuSK. Activated MuSK in concert with postsynaptic Dok-7 and other postsynaptic proteins acts on rapsyn to concentrate AChR in the postsynaptic membrane, enhances synapse specific gene expression by postsynaptic nuclei, and promotes postsynaptic differentiation. Clustered LRP4, in turn, promotes differentiation of motor axons. The agrin-LRP4-MuSK-Dok-7 signaling system is also essential for maintaining the structure of the adult neuromuscular junction.

#### 1. Agrin Myasthenia

Patients with mutations in agrin can present with mild to severe muscle weakness with eyelid ptosis and facial weakness. One patient responded partially to pyridostigmine, but the other two patients did not respond to pyridostigmine or 3,4-DAP.

In one report five patients in three kinships had a distinct phenotype associated with wasting that first affected the lower and later the upper distal limbs, sparing of the axial and cranial muscles, and slowly progressive weakness. The patients responded to albuterol or ephedrine but not to pyridostigmine.

#### 2. LRP4 Myasthenia

The first reported patient was 17-year-old girl with moderately severe fatigable limb-girdle weakness, dysplastic synaptic contacts, and borderline EP AChR deficiency. The patient has two heterozygous missense mutations in the third  $\beta$ -propeller domain of LRP4. Subsequently, two sisters with moderately severe LRP4 myasthenia and a homozygous mutation in LRP4 were found to have structurally and functionally abnormal EPs and EP AChR deficiency. Expression studies revealed that the mutation hinders LRP4 from binding to, activating, and phosphorylating MuSK. Both patients respond partially to albuterol.

#### 3. MuSK Myasthenia

The patients with mutations in MuSK present at birth or early life with eyelid ptosis or respiratory distress. Subsequently, the ocular, facial and proximal limb muscles, and sometimes the bulbar muscles are affected. Pyridostigmine therapy is ineffective or worsens the disease (personal observation). A program of 3,4-DAP therapy improved symptoms in one patient. Importantly, a recent report indicates that therapy with albuterol has been highly effective in two brothers. No clear genotype-phenotype correlations have emerged.

#### 4. Dok-7 Myasthenia

Patients with mutations in DOK7 have limb-girdle weakness with lesser facial and cervical muscle involvement, but a few have severe bulbar weakness and significant oculoparesis (Beeson et al., 2006). Some are initially misdiagnosed as having limb-girdle muscular dystrophy. The clinical course is mild to severe. Type 1 fiber preponderance, type 2 fiber atrophy, mild myopathic changes, and target formations are associated features. Importantly, this CMS is rapidly worsened by pyridostigmine but responds well over a period of time to ephedrine or albuterol.

#### 5. Rapsyn Myasthenia

Most patients with mutations in RAPSN present in the first year and a few later in life. Arthrogryposis at birth and other congenital malformations occur in close to one third of patients. Intercurrent infections or fever can trigger respiratory crises and can cause anoxic encephalopathy. The ocular ducts are intact in most patients. Most patients respond well to pyridostigmine; some derive additional benefit from 3,4-DAP, and some benefit from the added use of ephedrine or albuterol.

There are no genotype-phenotype correlations except that near-Eastern Jewish patients with a homozygous E-box mutation (c.-38A>G) have a mild phenotype with ptosis,

prognathism, severe masticatory and facial muscle weakness, and hypernasal speech.

## CONGENITAL MYASTHENIC SYNDROMES ASSOCIATED WITH CONGENITAL DEFECTS OF GLYCOSYLATION

Glycosylation increases the solubility, folding, stability, assembly, and intracellular transport of nascent peptides. O-glycosylation occurs in the Golgi apparatus with addition of sugar residues to hydroxyl groups of serine and threonine; N-glycosylation occurs in the endoplasmic reticulum in sequential reactions that decorate the amino group of asparagine with a core glycan composed of 2 glucose, 9 mannose and 2 N-acetylglucosamine (GlcNAc). To date, defects in four enzymes subserving glycosylation have been found to cause CMS: GFPT1 (glutamine fructose-6-phosphate transaminase); DPAGT1 (dolichyl-phosphate [UDP-N-acetylglucosamine] N-acetylglucosaminophosphotransferase 1); ALG2 (alpha-1,3/1,6-mannosyltransferase); and ALG14 (UDP-N-acetylglucosaminyltransferase subunit). Tubular aggregates of the sarcoplasmic reticulum (SR) in muscle fibers are a phenotypic clue to the diagnosis but are not present in all patients. Because glycosylated proteins are present at all EP sites, the safety margin of neuromuscular transmission is compromised by a combination of presynaptic and postsynaptic abnormalities.

### 1. GFPT1 Myasthenia

GFPT1 controls the flux of glucose into the hexosamine pathway, and, thus, the formation of hexosamine products and the availability of precursors for N- and O-linked glycosylation of proteins. A defect in GFPT1 predicts hypoglycosylation and, hence, defective function of several endplate-associated proteins. Most patients present in the first decade. As in Dok-7 myasthenia, the weakness affects mainly the limb-girdle muscles. Only a few patients have respiratory complications. The course is relatively benign in most, but one patient whose mutations abrogated expression of the muscle-specific exon of GFPT1 had severe facial, bulbar, and respiratory muscle weakness, and has been quadriplegic since birth. This patient has an autophagic vacuolar myopathy, reduced evoked quantal release, and low MEPP amplitude. Most patients respond to pyridostigmine. Some patients derive additional benefit from albuterol and 3,4-DAP.

### 2. DPAGT1 Myasthenia

DPAGT1 catalyzes the first committed step of N-linked protein glycosylation. DPAGT1 deficiency predicts impaired asparagine glycosylation of multiple proteins distributed throughout the organism, but in the first five patients harboring DPAGT1 mutations only neuromuscular transmission was adversely affected; this was attributed to reduced AChR expression at the EP, but the patient EPs were not examined. As in GFPT1 deficiency, muscle fibers harbor tubular aggregates, and the weakness tends to spare the craniobulbar muscles. A subsequent study of two siblings and of a third patient extended the phenotypic spectrum of the disease. These patients have moderately severe to severe weakness and are intellectually disabled. The siblings respond poorly to pyridostigmine and 3,4-DAP; the third patient responds partially to pyridostigmine and albuterol. Intercostal muscle studies showed fiber type disproportion, small tubular aggregates, and an autophagic vacuolar myopathy.

### 3. ALG2 and ALG14 Myasthenia

ALG2 catalyzes the second and third committed steps of N-glycosylation. ALG14 forms a multiglycosyltransferase complex with ALG13 and DPAGT1 and catalyzes the first committed step of N-glycosylation. These defects are predicted to cause endplate AChR deficiency. Two siblings with mutations in ALG14 have fatigable limb-girdle muscle weakness with sparing of ocular muscles. Both patients benefit from pyridostigmine. Four siblings with mutations in ALG2 presented in infancy or less than age 2 years with hypotonia and delayed motor milestones and never achieved ambulation, one other patient presented at age 4 years with limb-girdle weakness, and responded to pyridostigmine.

## OTHER MYASTHENIC SYNDROMES

### 1. PREPL Deletion Syndrome

The hypotonia-cystinuria syndrome is caused by recessive deletions involving the contiguous genes SLC3A1 and PREPL at chromosome 2p21. The major clinical features are type A cystinuria, growth hormone deficiency, muscle weakness, ptosis, and feeding problems. A patient with isolated PREPL deficiency had myasthenic symptoms since birth, including marked hypotonia, ptosis and facial and bulbar muscle weakness. She had growth hormone deficiency but no cystinuria and responded transiently to pyridostigmine during infancy. She harbors a paternally inherited nonsense mutation in PREPL and a maternally inherited deletion involving both PREPL and SLC3A1; therefore the PREPL deficiency determines the phenotype. PREPL expression was absent from the patient's muscle and EPs.

### 2. Myasthenic Syndrome Associated With Defects in the Mitochondrial Citrate Carrier SLC25A1

The mitochondrial SLC25A1 mediates the exchange of mitochondrial citrate/isocitrate with cytosolic maleate that is cleaved into acetyl-CoA and oxaloacetate by ATP-citrate lyase. Mutations of SLC25A1 were shown to interfere with brain, eye, and psychomotor development. Exome sequencing of two siblings born to consanguineous parents with CMS and intellectual disability revealed homozygous missense mutation in SLC25A1. Another patient harboring two missense mutations in SLC25A1 had hypotonia, severe intellectual disability, epilepsy, postnatal microcephaly, as well hypoplastic optical nerves, agenesis of the corpus callosum, sensorineural deafness and 2-hydroxyglutaric aciduria. At 18 months of age the patient had no spontaneous voluntary movements and was shown to have neuromuscular transmission defect.

### 3. Myasthenic Syndromes Associated With Congenital Myopathies

Eyelid ptosis, ophthalmoparesis, weakness of facial muscles, exercise intolerance, a decremental EMG, and response to pyridostigmine have been documented in patients with centronuclear myopathies caused by mutations in amphiphysin, myotubularin, and dynamin 2, as well as in patients with no identified mutations. Two patients with congenital fiber type disproportion caused by mutation in tropomyosin 3 had mild abnormalities in single fiber EMG, suggesting CMS. Finally, two siblings harboring mutations in ryanodine receptor 1 had fatigable ptosis and facial and generalized weakness, and responded partially to pyridostigmine.

**TABLE 144-2** Treatment of Congenital Myasthenic Syndromes

Type of Congenital Myasthenia	Therapy Options
Choline acetyltransferase deficiency	Pyridostigmine; parental neostigmine sulfate for apneic episodes
SNAP25B-myasthenia	3,4-DAP*
Acetylcholine esterase deficiency	Albuterol or ephedrine
Laminin $\beta$ 2 deficiency	Partial response to ephedrine
Primary AChR deficiency	Pyridostigmine, 3,4-DAP, albuterol can have additional benefit in severe cases
Slow-channel syndrome	Quinine, quinidine, or fluoxetine
Fast-channel syndrome	Pyridostigmine and 3,4-DAP
Agrin-myasthenia	Partial response to ephedrine or albuterol; one patient with partial response to pyridostigmine
LRP4-myasthenia	Partial response to albuterol in two patients
MuSK-myasthenia	Variable response to 3,4-DAP, good response to albuterol in one patient
Dok-7 myasthenia	Albuterol or ephedrine
Rapsyn myasthenia	Pyridostigmine, 3,4-DAP, albuterol
GFPT1, DPAGT1, ALG2, and ALG4 associated myasthenia	Pyridostigmine, 3,4-DAP additional benefit, albuterol in one patient
PREPL deletion syndrome	Pyridostigmine beneficial in infancy
Plectin deficiency	Refractory to pyridostigmine and 3,4-DAP
Na-channel myasthenia	Pyridostigmine and acetazolamide
CMS associated with congenital myopathies	Pyridostigmine with some response

\*3,4-DAP = 3,4-diaminopyridine

## TREATMENT

Current therapies for CMS include cholinergic agonists, namely pyridostigmine and 3,4-DAP, long-lived open-channel blockers of the acetylcholine receptor ion channel such as fluoxetine and quinidine, and adrenergic agonists such as salbutamol and ephedrine. Some agents that can be beneficial in one type of CMS can be harmful in another type. Hence a specific diagnosis is essential for the treatment of these patients. [Table 144-2](#) summarizes the pharmacotherapy of the recognized CMS.

## ACQUIRED DISEASES OF THE NEUROMUSCULAR JUNCTION

Both acquired and inherited disorders of the neuromuscular junction (NMJ) are seen in childhood. As with adults, the most common NMJ disorders are autoimmune and respond to immunosuppressive therapy. These include myasthenia gravis (MG) and, rarely, Lambert–Eaton myasthenic syndrome (LEMS). Botulism, a toxin-mediated disorder of the NMJ, most commonly occurs in infancy. All NMJ disorders have the ability to produce generalized weakness and fatigability, with a propensity for oculobulbar involvement. Electrophysiological studies will detect an impairment of neuromuscular transmission in most of these disorders. Fortunately, most of these disorders are treatable.

### AUTOIMMUNE MYASTHENIA GRAVIS

MG, the best understood autoimmune disease of the nervous system, is most commonly caused by antibodies to acetylcholine receptor (AChRs). Circulating IgG antibodies directed against AChRs bind to the postsynaptic membrane and activate the terminal complement sequence (C5b-9), resulting in lysis of the AChR with complement-mediated muscle endplate degeneration.

AChR-antibody formation has also been shown to block neuromuscular transmission and accelerate turnover of AChR cross-linked by IgG. As a result of these processes, the postsynaptic membrane becomes simplified, with decreased junctional folds.

The process that initiates the immune-mediated NMJ dysfunction is still unknown. The thymus gland may play a role; 75% of MG patients who undergo thymectomy have thymic pathologic findings, with 15% being tumors of the thymus, and the remainder consisting of lymphoid hyperplasia. There may be a hereditary predisposition to develop MG because there is an increased incidence of certain HLA antigens in various MG populations (Meriggioli and Sanders, 2009).

### CLINICAL FEATURES

MG has a prevalence of approximately 125 cases per million population. Approximately 11% to 24% of all MG patients have disease onset in childhood or adolescence (Millichap and Dodge, 1960). Overall, there is a slight female predominance of 3:2, although males predominate in older age groups. The disease can arise at any age, but peaks are observed in the third and sixth decades (Grob et al., 2008).

MG is characterized by weakness and fatigability of ocular, bulbar, and extremity striated muscles. The ocular manifestations are ptosis and diplopia, whereas the bulbar manifestations are dysarthria, dysphagia, dysphonia, and dyspnea. Masticatory weakness presents with jaw fatigue and jaw-closure weakness. Proximal limb and axial muscles tend to be weaker than distal extremity muscles. Symptoms of MG tend to worsen with stress, with illness, with exertion, and as the day

progresses. These temporal symptoms, however, may be difficult to elicit in many patients. Myasthenic crisis, characterized by respiratory weakness and the inability to handle secretions or swallow, may punctuate a more stable clinical course in some children.

### CATEGORIES OF MYASTHENIA GRAVIS IN CHILDHOOD

Autoimmune MG in children is most commonly divided into neonatal transient and juvenile types.

Neonatal transient MG occurs in infants of myasthenic mothers. Placental transfer of AChR-antibody or immunocytes results in transient impairment of neuromuscular transmission in the neonate. Findings such as a weak suck or cry, ptosis, dysphagia, generalized weakness, decreased spontaneous movement, or respiratory distress are usually present in the first few hours of life but may not be evident until the third day (Millichap and Dodge, 1960). The majority of infants have hypotonia or transient weakness, and a very small proportion present with arthrogryposis multiplex congenita. The hypotonia and transient weakness usually resolve in the first 4 weeks but may persist for months and even lead to persistent facial and bulbar manifestations. The severity of the disorder in the infant does not correlate with the degree of maternal involvement, but there is evidence that a higher maternal antibody titer may predict severity. A prior history of neonatal MG in a sibling is the only predictive factor. Fortunately, only 10% to 15% of infants born to myasthenic mothers develop the disorder. Prior thymectomy or remission of disease in the mother does not prevent development of neonatal transient MG but has decreased its likelihood. In terms of treatment, if there is no significant respiratory or swallowing impairment, medications are not necessary. In more severe cases, oral pyridostigmine is given in syrup form (60 mg/5 ml) at an initial dose of 0.5 to 1 mg/kg every 4 to 6 hours. Treatment for 4 to 6 weeks is usually all that is required.

Careful monitoring of pregnant women with MG is critical because there is a 40% chance of disease exacerbation during pregnancy and a 30% risk in the puerperium. Perinatal mortality is approximately 68 per 1000 births, 5 times the risk in uncomplicated pregnancies.

Juvenile MG represents the childhood onset of autoimmune MG seen in adults, but there are differences in the presentation (Chiang, Darras, and Kang, 2009). Onset is usually after 10 years of age, and disease manifestations appear before puberty in half the cases. Onset before 1 year of age is exceptional. Pubertal status might affect the clinical presentation, with higher incidence of ocular MG in prepubertal patients and generalized MG in postpubertal patients. Female predominance was observed only after the age of 10 years.

As with adults, ptosis is the most common clinical finding, frequently accompanied by ophthalmoparesis (Figure 145-2). Ptosis was unilateral at onset in one-third of juvenile MG patients but subsequently spread to the other eye in nearly

**Figure 145-2.** Ptosis of the right eyelid in a young woman with juvenile MG. Hypertropia of the left eye is also present.

90% of cases (Afifi and Bell, 1993). Evidence for ptosis and restriction of eye movement can often be found on careful examination. Facial and oropharyngeal weakness are other common findings, producing dysarthria, dysphagia, and difficulty chewing. Facial weakness without ocular involvement is an unusual but recognized presentation of juvenile MG. Extremity weakness can occur and is usually most prominent proximally. Bulbar weakness characterized by slow chewing, dysphagia, nasal dysarthria, and weak cough develops in up to 75% of patients (Rodríguez et al., 1983). Respiratory failure from either diaphragmatic or intercostal muscle weakness or airway compromise related to bulbar dysfunction produces myasthenic crisis, an exacerbation severe enough to endanger life. As in adults, the disease may be generalized at onset, but isolated ocular involvement is a more common presentation, followed by generalization at a later time. However, children with ocular MG appear more likely than adults to remain with purely ocular disease. As many as 85% of adults with ocular MG later go on to develop generalized disease. In children this percentage is closer to 50% to 75% (Afifi and Bell, 1993; Castro et al., 2013).

## CLINICAL AND LABORATORY TESTS

In most instances the clinician can be confident about the diagnosis of MG based on abnormalities brought out through the neurologic history and examination. However, one or more tests are usually performed to confirm the clinical diagnosis.

### Edrophonium (Tensilon) Test

The intravenous (IV) administration of up to 10 mg of edrophonium is often the first diagnostic test performed in the evaluation of a potential MG patient. However, the edrophonium test has a number of pitfalls. The most common mistake is that the physician performing the test does not have an objective parameter to measure before and after edrophonium administration. The most useful parameter is the degree of ptosis. The best indication of a positive test is a significant increase in the palpebral fissure aperture or the opening of a completely ptotic eye. If no ptosis is present, the edrophonium test may be difficult to interpret even in clear-cut cases of MG. If the patient has a severe restriction of extraocular movement

and edrophonium dramatically improves the motility, the test is considered positive. However, subjective diplopia may not resolve unless edrophonium produces orthophoria in the eyes, which is rare. Significant improvement in dysarthria or in swallowing is another indication of a positive edrophonium test. A mild improvement in limb strength or subjective well-being is not sufficient to claim a positive test. In addition, a positive edrophonium test is not specific because transient subjective improvement is reported in other neurologic disorders, such as motor neuron disease and peripheral neuropathy. Details on how to perform this test are located in the online version of this chapter and elsewhere. Positive results on edrophonium testing are seen in up to 90% of juvenile MG cases (Afifi and Bell, 1993).

## Electrophysiologic Testing

### Repetitive Nerve Stimulation

The classic electrophysiologic demonstration of an NMJ transmission defect is the documentation of a decremental response of the compound muscle action potential (CMAP) to repetitive nerve stimulation (RNS) of a motor nerve. Decrement is attributable to failure of some muscle fibers to reach threshold and contract when successive volleys of ACh vesicles are released at the NMJ. Failure to reach the threshold EPP to achieve muscle contraction is called blocking. The percentage of decrease in amplitude and area is calculated between the first CMAP produced by a train of stimuli and each successive one. In most laboratories, five or six responses are obtained at 2 or 3 Hz, and the maximal percentage of decrement can be measured at the fourth or fifth response. A decrement of greater than 10% is considered a positive RNS study. In some patients, a decremental response can be demonstrated at baseline; in others, it is only observed after a brief period of exercise and improves after rest (Figures 145-3 and 145-4).

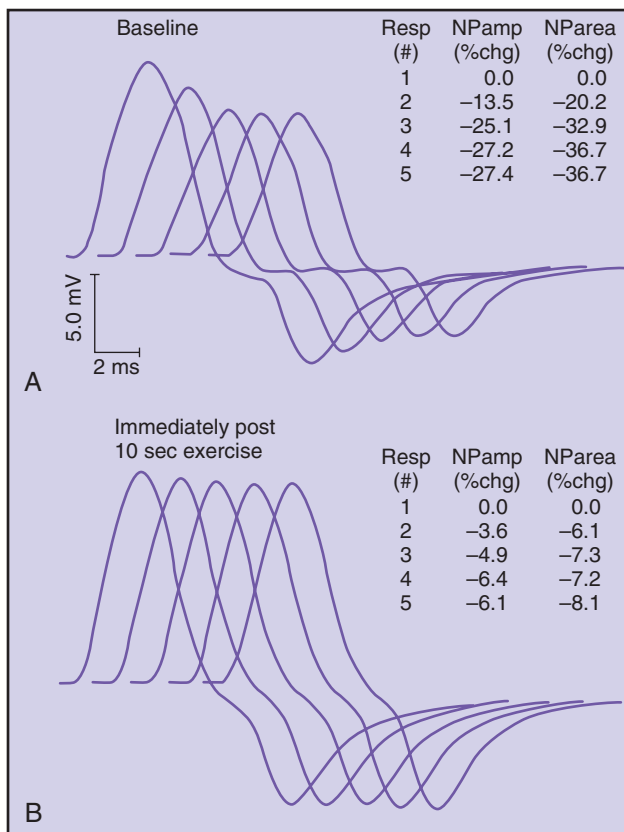

As with the edrophonium test, RNS does not have to be performed on every MG patient if the diagnosis is certain based on clinical findings and a positive AChR-antibody.

### Single-Fiber Electromyography

Single-fiber electromyography (EMG) is a more sensitive measure of neuromuscular transmission than RNS and can be considered in select children. In MG the time required for the EPP at the NMJ to reach threshold is extremely variable. The measurement of this variability in the EPP rise time is known as jitter. The jitter value, calculated in microseconds, is the most important piece of data obtained from single-fiber EMG. Everyone, including healthy individuals, has some degree of jitter. Myasthenic patients have increased jitter values. In addition, blocking occurs in myasthenics if a muscle fiber's EPP never reaches threshold and depolarization does not occur. The frequency of blocking, expressed as a percentage, is also determined with single-fiber EMG. In healthy individuals the percentage of blocking is 0%.

Single-fiber EMG is undoubtedly the most sensitive test for MG in adults. It is abnormal in 94% of generalized and 80% of ocular MG patients. However, single-fiber EMG has several disadvantages. It is a tedious and lengthy study that requires considerable patient cooperation and is poorly tolerated by many children. Stimulated single-fiber EMG can be performed under sedation, requires less patient cooperation, and may be preferred in children, although it is still a lengthy procedure. An abnormal single-fiber electromyographic study is not specific for MG because increased jitter commonly occurs as a result of other neuromuscular diseases, including motor neuron disease, peripheral neuropathy, and many myopathies. Fortunately, it is seldom necessary to perform single-fiber

**Figure 145-3.** Repetitive nerve stimulation (RNS) of the ulnar nerve at 3 Hz, recorded from the adductor digiti minimi. **A**, Baseline, abnormal amplitude decrement of 27%. **B**, Immediately after 10 seconds of exercise the decrement has resolved, demonstrating *repair*. NPamp, negative peak amplitude; NParea, negative peak area; Resp, response.

EMG to diagnose MG in children. It is probably most useful in children who present difficult diagnostic dilemmas and who otherwise have normal laboratory studies for MG.

## Antibody Testing

### Anti-AChR Antibodies

Finding elevated AChR-antibody levels in the serum of a suspected MG patient is the most specific and reassuring diagnostic test. When the AChR-antibody assay is positive, it can be argued that no other diagnostic studies for MG are needed. Thus the clinician who is initially making the diagnosis is often in the position of performing the edrophonium and electrophysiologic tests while awaiting the serologic results.

AChR-antibody levels are not elevated in all MG patients. The assay is most helpful in adult generalized MG; it is positive in 85% of such patients. Ocular MG patients, however, have a measurable AChR-antibody in only 50% of cases. Children represent another group of MG patients who are often antibody negative. In one study, 50% of prepubertal children with autoimmune juvenile MG were seropositive. Seropositive rates of 68% and 91% were observed in peripubertal and postpubertal disease onset, respectively. Similarly, seropositivity was more common in girls with onset of juvenile MG after 11 years of age. Seronegativity was more common in pure ocular forms, mild disease, and remission (Afifi and Bell, 1993).

AChR-antibody titers correlate poorly with MG severity. Indeed, MG patients in clinical remission may still have ele-

vated titers, but this is not an indication to continue immunosuppressive therapy.

### Anti-MuSK Antibodies

Since 2001, IgG from 40% to 70% of seronegative generalized patients has been found to bind to the extracellular domain of muscle-specific receptor tyrosine kinase (MuSK). Marked female predominance with mean age of onset in the fourth decade has been typical, although pediatric cases have been reported. Three main patterns of anti-MuSK MG have been observed; one of them is clinically indistinguishable from anti-AChR generalized MG. The other two patterns are severe oculobulbar weakness and prominent neck, shoulder and respiratory involvement largely sparing ocular musculature. In these two phenotypic variants limb strength is relatively intact. Anti-MuSK antibodies are rarely seen in pure ocular MG. We consider testing for anti-MuSK antibodies in all suspected MG patients who are AChR-antibody negative. Anti-MuSK MG is somewhat more refractory to conventional treatment compared with anti-AChR MG.

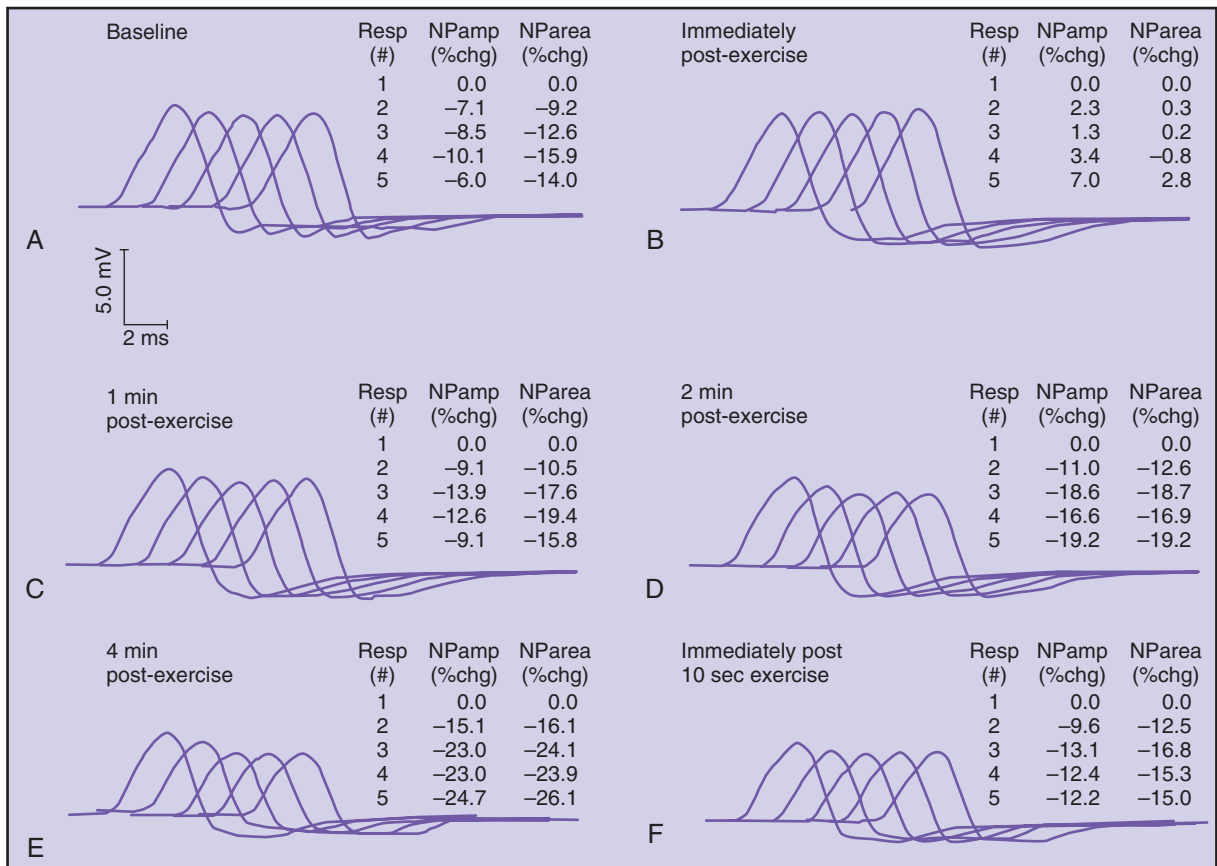

**Treatment.** Most patients with juvenile MG who require maintenance therapy are treated with anticholinesterase agents with or without a variety of immunosuppressive medications. Pyridostigmine is recommended as an initial intervention. As with the adult form of the disease, corticosteroids and other immunomodulatory treatments are used, although few randomized controlled clinical trials have been performed in the pediatric MG population. Thymectomy plays an important role in treating older children at most centers. Plasmapheresis and IV gamma globulin (IVIg) are generally reserved for more refractory patients or for those in myasthenic crisis. Plasmapheresis and IVIg are also used to maximize function before thymectomy. As mentioned previously, short-term supportive care and anticholinesterase agents are usually adequate for neonatal transient MG.

### Acetylcholinesterase Inhibitors

In juvenile MG the aggressiveness of management should be in accordance with disease severity. In general, management attempts should first focus on pyridostigmine. A total daily dose up to 7 mg/kg a day is delivered in 5 to 6 divided doses. Typical doses in older children and adults are 60 mg 3 to 5 times a day. If symptoms are poorly controlled on a pyridostigmine dose exceeding 300 mg/day, it is probably necessary to add immunomodulating therapy. Although weakness, a nicotinic receptor side effect, is relatively uncommon, muscarinic side effects occur frequently. The most common of these are gastrointestinal cramps and diarrhea. Oral hyoscyamine sulfate, glycopyrrolate, and over-the-counter loperamide can be prescribed on an as-needed basis or prophylactically with selected pyridostigmine doses to minimize these side effects.

### Thymectomy

When a child's symptoms can no longer be controlled by anticholinesterase agents alone, a decision must be made regarding whether to pursue thymectomy or immunosuppressive therapy. There is a general consensus that generalized MG patients between puberty and 60 years of age benefit from thymectomy. However, randomized studies of thymectomy that control for medical therapy have never been performed. The use of thymectomy in very young children, in itself, is controversial because of concerns for a subsequent impairment in immune protection or an enhanced risk of cancer. A review of incidental thymectomy and thymectomy as treatment for MG in young children, however, did not find a

**Figure 145-4.** Repetitive nerve stimulation (RNS) of the ulnar nerve at 3 Hz, recorded from the adductor digiti minimi. At baseline (**A**) there is only a borderline decrement at response 4. After exercise, a 12% to 13% decrement develops immediately (**B**) at 1 minute (**C**) postexercise, and this worsens at 2 and 4 minutes (**D** and **E**), demonstrating postexercise exhaustion. After 10 seconds of brief exercise (**F**), the decrement improves. NPamp, negative peak amplitude; NParea, negative peak area; Resp, response.

consistent association between thymectomy and these proposed risks in children older than 1 year.

Thymectomy has been widely used for the treatment of juvenile MG, showing a higher likelihood of remission when performed within 2 years of symptom onset compared with nonsurgical patients. Transsternal, transcervical, and thoracoscopic procedures are all performed and have all demonstrated benefit in clinical trials. Several studies have suggested benefit anywhere from 3 to 10 years after surgery. Favorable predictors for postoperative remission included surgery during the first year after disease onset, bulbar symptoms, onset of symptoms between ages 12 and 16 years, and the presence of other autoimmune disorders.

The presence of a thymoma is, of course, the one absolute indication for thymectomy. All newly diagnosed MG patients must undergo computed tomography or magnetic resonance imaging of the chest to search for thymoma. Routine chest radiographs may not detect up to 25% of thymic tumors. Although there is a consensus among neurologists that thymectomy should be considered in all but the youngest children with generalized MG who are not controlled on anticholinesterase agents alone, there is less enthusiasm for the procedure in pure ocular MG.

### Corticosteroids

Prednisone continues to be used as an immunosuppressive agent of first choice in MG. Despite its many potential side

effects, prednisone is considered by many to be the most effective oral immunosuppressive agent for the treatment of MG. Although corticosteroids can potentially suppress the immune system in a variety of ways, the exact explanation for the beneficial response in MG is unknown.

Typically, oral prednisone is initiated at 1 to 1.5 mg/kg daily. If clinical improvement occurs in the first 4 weeks, the patient can be immediately switched to an alternate-day dose of 1 to 1.5 mg/kg. Daily regimens extending beyond a month must be followed by a slower alternate-day taper. If corticosteroid therapy is initiated at moderate to high doses, an improvement is usually apparent in 2 to 3 weeks. The main concern when initiating prednisone therapy at these doses is the transient worsening that occurs in one-third to one-half of patients. The mechanism may involve a direct effect of corticosteroids to impair NMJ transmission. Thus an advised practice is to admit MG patients to the hospital for 5 to 7 days when initiating high-dose prednisone therapy. If the patient remains stable over this interval, the patient can be safely discharged on oral prednisone.

After significant improvement is observed, there should not be a rush to taper off the prednisone. Most patients remain on alternate-day dose prednisone for at least 6 to 8 months. When beginning the taper, it is best to proceed slowly by reducing the dose no faster than 5 mg every 2 weeks. When the patient's dose has been reduced to 20 mg every other day, tapering at an even slower rate is advisable. Although an attempt should be made to fully taper the patient off

prednisone, it is not uncommon for patients to require low-dose therapy (5–10 mg every other day) for many years or indefinitely.

The side effects of corticosteroids are well appreciated and significant (Andrews, 2004). Children should be closely monitored for cataracts, hypertension, diabetes mellitus, weight gain, growth retardation, and cognitive or affective disturbance. Adverse effects of corticosteroids on early stages of bone mineralization and development are also of concern, emphasizing the need for “steroid-sparing” strategies in children who are refractory to tapering.

### Azathioprine

Azathioprine (Imuran), an antimetabolite that blocks cell proliferation and inhibits T lymphocytes, has been used more frequently in recent years because of the side effects associated with corticosteroids. Most reports describe its use in adults. It is used most often in patients who have a relapse on prednisone or who have been on prednisone for lengthy periods in the hope that the steroid dose can be decreased or eliminated. Azathioprine is also used at times as a first-line immunosuppressive agent instead of prednisone.

Retrospective studies of azathioprine therapy have demonstrated that 70% to 90% of MG patients improve regardless of whether or not it is used as a first- or second-line immunosuppressive drug. However, the clinical response is slow, not appearing for 12 months or more. Thus if a patient already on pyridostigmine is quite weak and a rapid response is required, azathioprine is not a practical choice.

The initial dose of azathioprine in children should be no more than 25 to 50 mg daily for 1 week. If there are no side effects, the dose is increased to a target level of 2 to 3 mg/kg per day. Although azathioprine is generally well tolerated, there are three important and limiting side effects. Approximately 10% of patients have an idiosyncratic systemic reaction within the first several weeks of therapy that consists of fever, abdominal pain, nausea, vomiting, and anorexia. When the drug is stopped, the symptoms resolve quickly. If the patient is rechallenged, the symptoms invariably recur. In addition, patients can develop leukopenia and hepatotoxicity. Blood counts and hepatic enzymes need to be monitored monthly. If the white blood cell count falls below 4000 cells/mm<sup>3</sup>, it is advisable to decrease the dose. If it falls below 3000 cells/mm<sup>3</sup>, medication should be temporarily withheld until the cell count normalizes. Similarly, medication should be temporarily withheld if there is evidence of hepatocellular dysfunction. Although the patient can be rechallenged after the laboratory values normalize, toxicity often recurs, requiring discontinuation of the drug. Patients should be evaluated for thiopurine methyltransferase (TPMT) deficiency because this may lead to severe myelosuppression. Azathioprine dosing needs to be adjusted in hepatic and renal impairment, and potential interactions with other medications should be considered on initiation. Late development of malignancy following chronic use of azathioprine is a concern (Andrews, 2004).

### Cyclosporine

Cyclosporine (Sandimmune, Neoral) is an accepted option for immunosuppressive therapy in adult MG. Data are not available on its use in juvenile MG, although it is frequently used in pediatric transplant patients. Cyclosporine inhibits helper T lymphocytes and allows the expression of suppressor T lymphocytes. It blocks the production and secretion of interleukin-2 by helper T cells. Cyclosporine has been subjected to randomized, double-blinded, placebo-controlled trials in MG. These studies demonstrated that cyclosporine was more effective than placebo in improving MG when a

quantitative MG scale was used as the primary efficacy measure. Corticosteroid doses could be reduced after cyclosporine was initiated.

The onset of clinical benefit for cyclosporine is 1 to 2 months. This is somewhat faster than azathioprine and slower than prednisone. Doses for cyclosporine range between 4 and 6 mg/kg per day in two divided doses. Side effects include hirsutism, tremor, gum hyperplasia, paresthesias, and hepatotoxicity. Hypertension and nephrotoxicity are the main limitations to therapy. Over one-quarter of adult patients taking cyclosporine had serum creatinine levels increase between 30% to 70% above baseline levels, and 11% of them also developed skin cancers. Such high rates of neoplasia have not been reported in other studies. Blood pressure, renal function, and trough plasma cyclosporine levels are monitored monthly. A similar medication, tacrolimus, has also been widely used in adult patients with MG with success.

### Mycophenolate Mofetil

Mycophenolate mofetil (MM; CellCept) is another immunosuppressive agent commonly used in practice at MG centers, having shown initial promise in several uncontrolled, open series demonstrating favorable responses in two-thirds of adult patients. MM had a relatively rapid onset of action, with improvement observed at a mean of 9 to 11 weeks and maximal improvement by approximately 6 months. However, in some subjects the initial response was delayed up to 40 weeks. With its more rapid onset of action and favorable side-effects profile, MM began replacing azathioprine as the first-line “steroid sparer” in many MG centers. Unfortunately, two randomized controlled studies failed to demonstrate additional efficacy for MM when added to prednisone. Study design may have been at fault in these negative trials.

MM blocks inosine monophosphate dehydrogenase, resulting in selective inhibition of B and T lymphocyte proliferation by blocking purine synthesis. It has been well tolerated in the MG population. The most common adult dosing regimen is 1 gm by mouth twice daily, although doses up to 3 gm a day have been used. It is used in the pediatric transplant population at doses of 600 mg/m<sup>2</sup> twice daily. Children with body surface areas greater than 1.5 gm/m<sup>2</sup> are dosed at 1 gm twice daily.

Main side effects are diarrhea, vomiting, increased risk for infection, and leukopenia, which is relatively uncommon. Complete blood counts are checked weekly for the first month and then less frequently. Long-term safety for MM is still in question, but there have been rare reports of primary central nervous system (CNS) lymphoma with use of MM in MG.

### Cyclophosphamide

The use of cyclophosphamide (Cytoxan), a nitrogen mustard alkylating agent that blocks cell proliferation, is mainly reserved for refractory MG patients, but its reported use is limited. One study reported 42 adults who had been treated with cyclophosphamide; 23 were also on prednisone. At the time of the retrospective data analysis, 25 of the 42 patients became asymptomatic, and 12 were in complete remission off all medications. Eight of 10 children with juvenile MG improved when cyclophosphamide was added to regimens including azathioprine and corticosteroids.

The high rate and severity of toxicity are the drawbacks for cyclophosphamide. In one study, alopecia occurred in 75%, leukopenia in 35%, and nausea and vomiting in 25%. The increased risk of bladder and lymphoreticular malignancy with prolonged administration of cyclophosphamide should be of particular concern. As a result, cyclophosphamide should be considered only in the most refractory cases of juvenile MG.

## Plasmapheresis

Plasma exchange is primarily employed in the short-term, acute management of severe disease, including crisis, and in readying weak patients for thymectomy. Plasmapheresis removes pathogenic antibodies from the circulation of MG patients, with improvement measured in several days rather than weeks for corticosteroids and months for immunosuppressive agents. Two other circumstances in which plasmapheresis is considered include the treatment of severely weak patients admitted for initiation of prednisone therapy and as a chronic intermittent therapy in patients with refractory disease. Plasmapheresis has been life-saving in some children.

Generally a course of plasmapheresis consists of four to six exchanges in which approximately 50 ml/kg of plasma are removed at each treatment. Decisions regarding the number of exchanges and total amount removed are largely driven by the status of the patient, including clinical response and tolerability of the hemodynamic shifts from the procedure. Improvement is often seen within 48 hours after the first or second exchange. Treatments are usually administered every other day or on no more than 2 of 3 consecutive days so that a full course is completed in 7 to 10 days (Andrews, 2004).

The main limitations of plasmapheresis are (1) IV access—a double-lumen catheter is required in younger children; (2) complications, including pneumothorax, hypotension, sepsis, and pulmonary embolism; (3) the expense of the procedure; and (4) the relatively brief clinical benefit, which persists for only a few weeks.

## Intravenous Immunoglobulin

Over the last two decades, IVIG has been used by neurologists for various immune-mediated neuromuscular diseases, including MG, in which response rates of approximately 75% were observed in early retrospective series. Although no studies have focused on the pediatric population, children and adolescents have responded favorably to IVIG (Andrews, 2004).

The initial dose of IVIG is usually 2 g/kg. This can be given over 2 to 5 days. When given over the shorter interval, the infusion runs nearly continuously. A common practice is to then schedule two or three subsequent infusions of 0.4 to 1 g/kg at 2- to 4-week intervals. Patients are then reevaluated to determine whether further treatments are needed.

Advantages of IVIG over plasma exchange include relative ease of administration and favorable side-effects profile in both children and adults. Headache, transient flu-like symptoms, and hyperactivity are the adverse events most common to the pediatric population. Migraine patients are prone to develop a severe headache related to aseptic meningitis. Major complications are observed in up to 5% of adults, including cardiovascular, cerebrovascular, and deep venous thrombotic events; congestive heart failure; and acute nephrotoxicity.

## Drugs to Avoid

Children, like adults with MG, are sensitive to nondepolarizing neuromuscular blocking agents. Intermediate-acting nondepolarizing blockers such as atracurium and vecuronium should be used with care. It is advisable to administer small increments of these agents, using neuromuscular monitoring as a guide. Other commonly used drugs known to exacerbate MG or interfere with neuromuscular transmission are listed in Box 145-2.

## Lambert–Eaton Myasthenic Syndrome

Lambert–Eaton myasthenic syndrome (LEMS) is an acquired autoimmune disorder of neuromuscular transmission in

### BOX 145-2 Drugs That May Worsen Myasthenia Gravis or Interfere With Neuromuscular Transmission

#### ANTIBIOTIC AGENTS

which there is an autoimmune attack on voltage gated calcium channels (VGCC) on the presynaptic nerve terminal, ultimately resulting in a reduction in presynaptic release of ACh and defective neuromuscular transmission.

## Clinical Features

LEMS begins gradually and is characterized by fatigability and weakness in a limb-girdle distribution. Unlike MG, patients may note that the weakness is worse soon after awakening, and better later in the day. While exercise can transiently improve strength, persistent exertion causes fatigue. Cranial nerve and respiratory involvement is less common than in MG. Patients also have autonomic involvement including dry mouth and eyes, impotence, blurred vision, and orthostasis (Sanders, 2003). On examination, there is a limb-girdle pattern of weakness and reduced or absent deep tendon reflexes. In only about 50% of patients can one convincingly demonstrate improvement in strength or reflexes after brief exercise. A malignancy is present in approximately 50% of adult LEMS patients. The tumor is usually a small-cell carcinoma of the lung, but other malignancies such as renal cell carcinoma and hematologic tumors occur. Malignancy is more common in men than in women, and is more likely in the setting of chronic smoking or after age 50 years. LEMS can be the presenting manifestation of a small-cell carcinoma, and can precede the detection of the tumor by months. Patients with small-cell carcinoma tend to have a more rapidly

progressive course than those without malignancy, with dysarthria, difficulty chewing, weakness, dry mouth, and impotence appearing earlier in the disease course. LEMS is only rarely described in children.

### Diagnostic Tests

A diagnosis of LEMS is often first suggested by findings on nerve conduction studies and repetitive nerve stimulation (RNS). The classic electrophysiologic triad of LEMS is as follows: (1) low-amplitude compound muscle action potentials (CMAPs) that increase dramatically after brief exercise, (2) decremental response at low rates of RNS (2–5 Hz), and (3) incremental response at high rates of RNS above 20 Hz. Diffusely reduced CMAPs on routine motor nerve conduction studies should raise suspicion of LEMS.

Antibody testing in LEMS for antibodies to P/Q-type VGCC is readily available and is positive in a large majority of patients with this disorder.

### Treatment

As with MG, treatment of LEMS should be individualized, tailored according to clinical severity, underlying disease, and life expectancy. Upon confirmation of the diagnosis, an extensive search for an underlying malignancy is imperative. This should begin with radiologic studies and may require bronchoscopy. Initial treatment should be directed against the malignancy because this may improve neurologic manifestations. When no malignancy is found, repeat screening every 6 to 12 months is advised, especially in patients at greater risk.

Aggressive immunotherapy is easier to justify in LEMS patients without cancer because there is concern that such agents may adversely affect management of malignant disease by interfering with normal immunosurveillance. In general, a trial of pyridostigmine is the first pharmacologic intervention, although it is often of limited benefit. Ideally, drugs that enhance the presynaptic release of ACh vesicles should be used (Sanders, 2003). 3, 4-diaminopyridine (3, 4-DAP) increases the duration of the presynaptic action potential by blocking outward potassium efflux. This indirectly prolongs the activation of VGCC and increases calcium entry in nerve terminals. Most patients tolerate the drug well, and side effects such as paresthesias tend to be minor. There is a risk of seizures when daily doses exceed 100 mg. Usually doses up to 20 mg three times a day are used. Expert recommendations for laboratory monitoring include liver function tests, complete blood count (CBC), blood urea nitrogen (BUN), and creatinine every 3 months for the first year and then less frequently.

There are only a few clinical studies of immunosuppressive therapy in LEMS. Plasmapheresis, corticosteroids, and azathioprine can be effective in both neoplastic and nonneoplastic LEMS. IVIG has also been effective. In general, the regimens and doses for the immunotherapies outlined for MG can be applied to LEMS. Response to immunosuppression tends to be less dramatic for LEMS than for MG.

### Botulism

Botulism is caused by a toxin produced by *Clostridium botulinum*, a gram-positive anaerobic organism found commonly in soil and agricultural products. Eight immunologically distinct toxins have been identified, with most human cases caused by types A, B, or E (Cherington, 2004). Recovery time varies between toxin types; for instance, type A toxin produces more persistent paralysis than types B and E. After binding irreversibly to receptors on presynaptic nerve terminals, the toxin is translocated across the membrane and blocks the calcium-dependent release of ACh. The action of the toxin appears

independent of calcium entry. The impaired release of ACh results in failed neuromuscular transmission. The damage to nerve terminals may be permanent, resulting in a prolonged clinical recovery believed to be dependent on the formation of new neuromuscular junctions. Infantile botulism, first described in 1976, is now the most common form of the disease, representing over 70% of approximately 110 annual cases in the United States.

### Infantile Botulism

Most reported cases of infantile botulism in the United States occur in California, Pennsylvania, and Utah, states with high counts of *C. botulinum* spores in the soil. After spores of *C. botulinum* are ingested, they germinate and propagate in the gastrointestinal tract, producing toxin in vivo. Consumption of honey and corn syrup has been associated with infantile botulism, but in most cases the source of infection is not evident. Infantile botulism typically presents between 6 weeks and 9 months of age, often heralded by the onset of severe constipation. A descending paralysis with cranial nerve palsy, poor suck, feeble cry, and reduced facial expressions ensues, followed by limb weakness. The child appears hypotonic, with ptosis, decreased extraocular motility, sluggish pupillary light responses, facial diplegia, weak suck, and a reduced gag response. Deep tendon reflexes and spontaneous bowel sounds are reduced. There is usually no associated fever. Both respiratory and autonomic compromise may occur. The diagnostic approach should consider other possible etiologies, including systemic infection, tick paralysis, organophosphate poisoning, Guillain-Barré syndrome, congenital myopathies, and autoimmune and congenital myasthenic conditions. Electrophysiologic studies support a presumptive diagnosis of botulism while waiting for the bacteriologic studies to return. Sensory nerve conduction studies are normal. Compound muscle action potential amplitudes are normal to reduced, with preserved motor conduction velocities. Repetitive stimulation will confirm a presynaptic defect in neuromuscular transmission. Decremental responses are variably seen on slow rates of repetitive nerve stimulation, but increments are present at rapid rates (20–50 Hz). Fibrillation potentials are seen on EMG in approximately 50% of infants, and short-duration, low-amplitude motor units in over 90%. Diagnosis is confirmed by isolation of the organism or toxin in stool samples. Toxin isolation is accomplished by the mouse neutralization test, usually performed at state health departments. Polymerase chain-reaction assays are increasingly available. In infantile botulism, the toxin is only rarely found in serum.

Treatment of infantile botulism is generally supportive, with complete recovery requiring several weeks to months. Botulism immune globulin, approved by the U.S. Food and Drug Administration (FDA) in late 2003, reduced the hospital stays for both ventilated and nonventilated children. Overall, median hospital stays fell from 40 to 23 days. Case-fatality rates of hospitalized patients in the United States are below 5%. Nasogastric or parenteral nutrition is needed if the child is unable to drink or eat. Mechanical ventilation may also be required. Aminoglycosides and other agents that impair neuromuscular transmission should be used with extreme caution. The length of hospitalization averages 4 weeks, but some infants may require supportive care for as long as 5 months.

### Foodborne Botulism

The classic form of botulism almost always follows ingestion of food contaminated by preformed toxin. The classic presentation is the development of bulbar symptoms, including blurred vision, diplopia, ptosis, dysarthria, and dysphagia within 12 to 36 hours after ingestion of the contaminated

food. A descending pattern of weakness follows and, in some cases, respiratory paralysis. Supportive care measures have improved survival rates, and nearly full recovery is expected for surviving patients. Treatment with antitoxin mainly plays a role in this form of botulism, but it is not likely to be effective unless administered in the first 24 to 48 hours; the antitoxin does not reverse established paralysis. Beneficial effects are more likely with type E toxin (Cherington, 2004). Use of antitoxin remains controversial because of the lack of efficacy in some cases and the 20% risk of serious allergic side effects related to the equine source. The incidence of hypersensitivity increases further with polyvalent antitoxin. Antitoxin is obtained from the Centers for Disease Control and Prevention (CDC) in Atlanta.

### Wound Botulism

Wound botulism appears 4 to 14 days following infection with *C. botulinum*. Although considered rare, an increasing number of cases have been recognized in drug abusers. Wound botulism can be severe, with ventilatory support required in a majority of patients. The organism can be isolated directly when an obvious wound is present. Wound debridement, appropriate antibiotic therapy, and supportive care are the keys to management.

The muscular dystrophies comprise a clinically and genetically heterogeneous group of disorders, the most common of which are the allelic X-linked recessive disorders, Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD). Both occur because of mutations in the *DMD* gene, encoding the dystrophin protein, and are thus known as dystrophinopathies. In general, the more severe DMD is associated with an absence of the dystrophin protein, whereas the milder BMD is associated with the presence of a partially functional dystrophin protein. Both states result in dystrophic changes in muscle, a term that refers to chronic and severe myopathic changes, including muscle fiber degeneration and regeneration but also fibrosis and fatty replacement of muscle fibers. The severity and tempo of these changes differs between DMD and BMD, but these features play a prominent role in the loss of muscle function, as noted by Guillaume Duchenne de Boulogne when he described *paralysie musculaire pseudohypertrophique ou paralysie myosclérotique*. Despite the association of his name with the syndrome, a compelling case has been made that the English physician Edward Meryon provided an earlier description of the syndrome in 1852, and claim has been made for the primacy of an even earlier description by the Italian physician Gaetano Conte in 1836. The German neurologist Peter Becker first proposed what we now know as BMD as a “benign variant” in 1952.

The more severe DMD is also the more common dystrophinopathy. A DMD incidence of 1 in 3500 live male births is frequently cited, with a citation trail leading to a 1991 estimate of population frequency in a Northern English population. However, newborn screening studies have demonstrated an incidence ranging from around 1:3802 to 1:6391, with an incidence of around 1:5200 found in a recent U.S. study. BMD is about one third as common, with an estimated incidence of around 1 in 18,500 male births. Rarely, *DMD* mutations may result in a third form of dystrophinopathy: X-linked dilated cardiomyopathy (XLDC), in which skeletal myopathy may be entirely absent. As the *DMD* gene is found on chromosome Xp21, the dystrophinopathies typically affect only boys, although rare cases in females occur explained by unusual genetic mechanisms such as balanced chromosomal translocations; most often, carriers are asymptomatic, although exceptions can occur.

### The Dystrophin Protein

The dystrophin protein consists of multiple functional domains. In the 427-kDa muscle-specific isoform (Dp427m), the N-terminus contains an actin-binding domain (ABD1) canonically described as critical to dystrophin function, participating in binding to the filamentous F-actin of the cytoskeleton. A central rod domain consists of 24 spectrin-like repeats, and 4 hinge regions. Within this region are found a second actin-binding domain and a binding site for neuronal nitric oxide synthase (nNOS). A C-terminal cysteine-rich domain mediates binding to  $\beta$ -dystroglycan at the sarcolemmal membrane. Anchored by a complex of four sarcoglycan proteins (mutations in any of which cause a limb-girdle

muscular dystrophy),  $\beta$ -dystroglycan binds the extracellular  $\alpha$ -dystroglycan, which in turn is engaged in glycosylation-dependent binding to extracellular matrix ligands and in particular to laminin  $\alpha_2$ . Distal to the dystroglycan-binding region are binding sites for additional proteins, including dystrobrevin and syntrophin.

Based on this structure, a standard model of dystrophin function has been developed in which it plays a critical role as a stabilizer of the muscle membrane in the setting of significant deformational forces generated by muscle contraction. In the absence of dystrophin, the muscle membrane is damaged, as seen clinically by elevations of the muscle enzyme creatine kinase (CK) in serum. Elevated CK is typically the first biochemical sign of the disease detected by clinicians. Simultaneously, calcium influx into the muscle fiber leads to activation of calcium-dependent proteases, initiating myofiber degeneration, followed by cycles of regeneration and fibrosis and eventual loss of muscle contractile function. However, the presence of binding sites for nNOS, dystrobrevin, and syntrophin suggests that dystrophin has a significant signaling role as well. In contrast to the absence of dystrophin resulting in DMD, the protein resulting from BMD mutations retains some of these functions, resulting in the milder phenotype.

Shorter isoforms utilize promoters found in intronic regions, but generally share the same C-terminal domains. Of particular clinical relevance are the dystrophin isoforms Dp140 and Dp71, which are predominant in brain; as discussed below, mutations that result in absent expression of these isoforms are related to increased cognitive impairment in DMD patients.

### The “Reading Frame Rule”

DMD is nearly always associated with an absence of dystrophin expression, whereas BMD is associated with expression of a partially functional protein (Figure 146-1). At the level of gene mutations, the difference between an absent or a partially functional dystrophin is explained by the concept of the “reading frame rule.” As discussed under Molecular genetic testing, the majority of mutations responsible for dystrophinopathies consist of exonic deletions. The reading frame rule states that the number of exons deleted is not the primary determinant of disease severity. Rather, mutations that disrupt an open reading frame—commonly termed “out-of-frame” mutations—lead to termination of translation, no protein expression, and DMD. In contrast, mutations that maintain an open reading frame—or “in-frame” mutations—lead to BMD (Figure 146-2). Most often, these are single or multiple exon deletions that result in internal deletions of some portion of the central rod domain, and allow translation of the protein that still binds F-actin and  $\beta$ -dystroglycan. As a result, some patients with quite large deletions, particularly of the spectrin repeat-containing central rod domain, can have relatively mild disease.

This rule has proven useful in understanding phenotypic differences, with a sensitivity of 93% to 96% in predicting

DMD in large series (Flanigan et al., 2009). Importantly, it also provides a pathway for therapeutic approaches for DMD. Two examples discussed below include virally mediated microdystrophin gene therapy and antisense oligonucleotide exon-skipping therapy, both of which are directed toward expression of internally deleted dystrophin proteins from in-frame BMD-like transcripts. Exceptions to the rule occur, and are discussed in more detail in the Molecular Diagnostic section below.

## Clinical Features

### Duchenne Muscular Dystrophy

Boys with DMD typically present with symptoms between 2 and 5 years of age. Parents most commonly describe abnormal gait, often as toe walking immediately on gait acquisition, but gait onset may also be delayed. Recent studies show measurable differences in motor function in infants. Symptoms may only be obvious to parents in retrospect—sometimes noted only after a younger sibling is noted to show more rapid motor development—but delayed motor and developmental function can be demonstrated within the first years of life. Delayed language acquisition may be the presenting sign of DMD, and boys with language delay should have a CK level checked as part of their assessment.

By the time of presentation to the specialist, proximal weakness is typically evident to an examiner. At ages when isolated strength testing is unreliable, examination shows difficulty in climbing stairs or hopping. Attempts to arise from the floor typically elicit the Gowers' maneuver (Figure 146-3), which, although not specific (as it may be seen in the setting of any disease causing pelvic girdle weakness), is always eventually seen in DMD: a supine boy will roll over into quadruped, spread his base of support, raise his buttocks into the air before his trunk, and place one hand or both hands on his knees and walk his hands up his thighs to thrust into an upright position. Muscle enlargement is common, particularly in the calves. Originally termed "pseudohypertrophy" by Duchenne, such enlargement is often attributed to increased fibrosis and fatty replacement, but true hypertrophy of the contractile mass of muscle fibers also occurs. At presentation, heel cords are typically tight, and mild lordosis is present. Neck extension strength is often normal but the neck flexors are particularly weak, in contrast to BMD, in which neck flexor strength may be relatively preserved. Given their gait abnormalities, boys with DMD are often first referred to orthopedic physicians, or physical therapists rather than neurologists as part of their diagnostic odyssey.

The clinical course in DMD after diagnosis is stereotyped. Strength may show improvement, and motor function typically improves into the sixth or seventh year, followed by a plateau in function that may last 12 to 18 months. Thereafter, weakness progresses and leads inexorably to wheelchair dependence. This loss of ambulation historically occurred, in the precorticosteroid treatment era, by the age of 12 years (although, steroid treatment has moderately altered the natural history of disease). Wheelchair dependence is followed by progressive arm weakness, which limits independent function. It is also followed by a progressively increased risk of ventilatory insufficiency, scoliosis, and cardiomyopathy, and without supportive ventilatory therapy, death historically occurred by the age of 20 years—a figure altered by current care standards.

Arguably the best predictor of disease severity in an individual patient is the clinical course of an affected male relative carrying the same mutation. Such comparisons must take into

account different treatment practices, but families with significant differences in severity between affected individuals are rare. Few clinical tests help provide prognostic information. Importantly, the level of CK elevation is not predictive of the severity of the phenotype, but rather reflects the phase of the disease process.

In addition to motor symptoms, cognitive impairment is common in DMD patients. IQ is diminished by one standard deviation in comparison to normal controls and in general does not change with age. Language development is delayed, and although the verbal IQ does improve, difficulties with expression may occur. Combined with dysarthria because of tongue hypertrophy, this may make communication challenging with age. Boys with DMD are also at an increased risk of autism, attention-deficit/hyperactivity disorder, and obsessive-compulsive disorder.

Measuring progression of skeletal muscle dysfunction is important both for clinical trials and to predict the loss of function in clinical care (see Ch. 137). In general, boys with DMD improved by most measures until the age of 7 years, after which their function begins to decline. Timed functional tests in common usage include the time to rise from the floor, the time to complete a 10-m walk/run, the time to climb a standard set of 4 stairs, and the distance covered during a 6-minute walk test (6MWT). Among these, the 10-m walk and time to rise from the floor are particularly useful in the clinic setting, as a boy taking greater than 12 seconds to walk 10 m or unable to rise from the floor is highly likely to lose the ability to ambulate independently within 1 year. The 6MWT has become the current de facto standard as both a stratification tool and an outcome measure in clinical trials. A 30-m change on the 6MWT is considered the minimal clinically significant change in the DMD population, and among DMD boys those walking less than 350 m are at a high risk for a significant functional decline within 1 year, and those walking less than <325 m are at risk for loss of ambulation. Another tool used in clinical trials is the North Star Ambulatory Assessment (NSAA), an evaluator-administered scale specifically designed for children with DMD.

### Becker Muscular Dystrophy

BMD is much more clinically heterogeneous than DMD. Half of affected males demonstrate muscle weakness by age 10 years, typically in a limb-girdle pattern, but many without muscle weakness at that age recall myalgias with exertion and calf hypertrophy in childhood. Symptoms may present well into mid-adulthood or late adulthood, and may include prominent or isolated quadriceps involvement. Very mild phenotypes include cramp-myalgia syndromes, exercise-induced myoglobinuria, and asymptomatic hyperCKemia. Although isolated cognitive impairment has been reported as the predominant presenting feature of rare cases of BMD, patients with BMD have a normal IQ distribution. Two thirds of BMD children have behavioral problems, and the frequency of autism and attention-deficit disorders is increased.

Although BMD displays a significant degree of variability, patients at the more severe end of the spectrum do present in childhood, but differ from DMD patients in that they continue to ambulate beyond the age of 13 years. However, as steroid therapies have altered the natural history of DMD, prolonging the age at which loss of ambulation occurs, many clinicians choose to use the categorization of an "intermediate muscular dystrophy" (IMD) phenotype for patients who walk past the age of 12 but stop walking by age 15. In this scheme, the clinical classification of BMD applies to the patient with dystrophinopathy who loses ambulation after age 15. The use of an IMD category is helpful to describe patients who are less

severe than is typical for DMD but more severe than is typical for BMD.

## Laboratory Features

Serum creatine kinase (CK) is increased in both DMD and BMD, and is usually the initial diagnostic test performed when a dystrophinopathy is suspected. In DMD, it is often 50 to 100 times normal at diagnosis. Serum CK levels are generally lower in BMD, and reach a maximum around age 10 to 15 years, reflecting relatively preserved muscle mass and activity in comparison to DMD. Episodes of extremely elevated serum CK leading to myoglobinuria or a diagnosis of rhabdomyolysis have been described, most often in BMD patients at the very mild end of the phenotypic spectrum and likely reflecting the ability of these mildly affected patients to perform vigorous physical activity that leads to such episodes.

Serum CK is elevated at birth, providing a marker for newborn screening. Most such studies utilize a fluorometric CK testing assay from a dried blood spot followed by a confirmatory serum CK and subsequent genomic mutational analysis. However, a two-tiered analysis allows both CK determination and mutational analysis of DNA extracted from the same Guthrie card, improving the feasibility of newborn screening. The CK is often >1000 U/L as a neonate, then typically rises to 20,000+ (>100× normal values) in childhood, but then declines as muscle mass is lost; as a result, the serum CK level may be normal in end-stage disease.

No other clinical laboratory values besides serum CK is particularly useful in making the diagnosis. However, it is very important for clinicians to be aware that the serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels are always elevated in dystrophinopathies, as these enzymes are found in muscle in addition to the liver. In the setting of unexplained transaminase elevations, the serum CK should always be checked before liver biopsy. The serum level of the liver-specific gamma-glutamyl transferase has proven to be a useful marker of liver injury in the dystrophinopathy population. In assessing renal function in the DMD patient, serum creatinine or creatinine clearance may be decreased because of diminished muscle mass, and cystatin C is a more appropriate clinical marker of renal dysfunction.

## Molecular Genetic Testing

**DMD Mutation Analysis.** Mutation analysis of the *DMD* gene has largely replaced muscle biopsy as the first diagnostic test performed after serum CK testing. Testing of genomic DNA derived from lymphocytes is readily available. Detailed mutational analysis now represents the standard of care, not only because it may provide prognostic information, but also because it facilitates genetic counseling and potentially more importantly may determine suitability for specific novel therapies. Notably, DNA confirmation of an obligate carrier status is not required in the setting of a clear X-linked history consistent with that state. However, one third of DMD cases are *de novo* (consistent with the Haldane rule for an X-linked lethal disorder). Genetic counseling is essential, in part to address the risk of germline mosaicism in mothers whose lymphocyte DNA analysis is negative (up to 10%).

The *DMD* gene is, in genomic terms, the largest gene identified. Because it consists of 79 exons spread over 2.2 million bases, mutation analysis has historically been challenging. Eight different promoters have been identified, resulting in a variety of isoforms that share the same C-terminal portion of the protein. The most abundant in muscle is 427 kDa (Dp427m), but other isoforms are found in brain, retina, and in a wide variety of tissues.

Around 65% of all dystrophinopathy mutations consist of a deletion of one or more exons, and because males are hemizygous at the *DMD* locus, a polymerase chain reaction (PCR)-based test can readily detect the absence of exons. As exon lesions are clustered around “hotspots” within the gene, a limited number of exons (25 to 28) could be tested to determine whether there was a deletion. This multiplex PCR test identified 98% of patients with deletions (Beggs et al., 1990), but did not necessarily identify the full extent of the deletion, nor could be used for determining carrier status or identifying duplications. In addition, it could not identify point mutations, such as nonsense mutations, missense mutations, or small insertion/deletion mutations.

This now archaic test has been superseded by methods that interrogate all exons for copy number change, allowing complete characterization of the exon range of all duplication and deletions, as well as identification of carriers of these mutation classes. Several such methods exist, including multiplex ligation-dependent probe amplification, and comparative genomic hybridization. Clinically, the specific method used is not as important as the fact that these methods interrogate all exons, which not only confirms the extent of deletions or duplications but also has the additional benefit of allowing the identification of those rare patients with complex exon duplications or deletions (i.e., affecting noncontiguous blocks of exons). Such modern methods are typically paired with a reflex test for direct sequence analysis of all exons by either Sanger or next-generation sequencing in patients without an exon copy number change to detect point mutations. Nearly all point mutations are individually rare and random mutations, meaning that they do not occur in hotspots and sequencing must be performed across the entire coding region.

The distribution of *DMD* mutation classes varies slightly in different cohorts, but in an unselected clinic cohort of 68 index cases, exonic deletions accounted for 65% of mutations and exonic duplications for 6%; nonsense mutations for 13%; missense mutations for 4%; and small insertions/deletions for 3%. Some reported cohorts are enriched for a single mutation class because of their recruitment design, but a similar distribution of mutation classes is seen in other large aggregate collections of patients.

With these modern methods of mutation analysis, the sensitivity of mutation detection in the peripheral blood-derived genomic DNA samples is approximately 93% to 96%. Patients for whom there is a strong index of suspicion but no detectable mutation on genomic DNA analysis require muscle biopsy. This allows confirmation of the diagnosis of the dystrophinopathy (by analysis of dystrophin expression) and provides muscle tissue for mRNA extraction, necessary for detection of mutations that escape detection by current clinical blood-based assays. The standard mutational methods result in the sequencing of both exons and flanking introns, but many dystrophinopathy patients without detectable mutations within these regions have deep intronic mutations that activate cryptic splice sites and result in the inclusion of intronic sequence as a “pseudoexon” within the mRNA. Sequencing of cDNA generated by reverse transcription PCR is required for diagnosis of pseudoexon mutations and for clarification of other unusual mutations such as exon inversions, for which standard mutational analyses may prove inadequate.

It is important for clinicians to recognize that exceptions to the reading frame rule do exist, and complicate prognostication based on mutation analysis alone. One such example consists of large in-frame deletions that encompass a large part of the ABD1 domain and extend the central rod domain, and may be associated with DMD. More commonly, predicted nonsense mutations—which, by definition, should result in no dystrophin expression—may instead alter exon splice

definition elements, including exon splice enhancer or exon splice suppressor sequences. Among predicted nonsense mutations, 14% are associated with BMD, nearly all of which affect pre-mRNA splicing. These mutations are found within the exons flanked by two exons that would maintain an open-reading frame, typically with the regions spanning exons 23 to 42; the resulting mature mRNA includes some proportion that excludes the nonsense-containing exon, with resultant dystrophin expression. Particularly in the absence of an informative family history regarding the implication of a given mutation, prognostication or phenotypic classification cannot rely solely on the results of mutation analysis, but must take into account the entire clinical picture, including age at presentation, consistency of the examination with the predicted phenotype, and, if available, the results of any dystrophin expression studies on muscle biopsy.

### Genotype-Phenotype Correlations

All mutations that ablate expression of the Dp427m isoform result in skeletal muscle degeneration, and with the exception of some mutations in which some variability of splicing may result in low levels of reading frame restoration, the specifics of the mutation do not significantly influence skeletal muscle phenotype. However, in nonmuscle tissues, mutations may influence symptoms; for example, mutations that ablate expression of the shorter dystrophin isoforms that are expressed in brain (Dp140, Dp71) result in a higher frequency of cognitive impairment (Pane et al., 2012). When a mutation results in an open reading frame, allowing expression of a partially functional dystrophin, symptom severity may be related to the presence or absence of specific domains, such as in BMD because of in-frame rod domain mutations where cardiomyopathy onset occurs earlier in deletions affecting the amino-terminal portion of the rod domain than in those affecting the latter portion of the rod domain.

Observations from patient mutations confirm the importance of the reading frame rule while providing templates for therapeutic approaches. The identification of a mildly affected BMD patient with a very large central rod domain deletion lends credence to the potential of mini- or microdystrophin approaches for viral gene therapies. The large in-frame deletion of exons 45 to 55 may result in X-linked dilated cardiomyopathy (XLDCM) without any significant limb weakness, or may result in relatively mild BMD; either outcome suggests the utility of a therapy directed at inducing exon skipping to result in the equivalent mRNA.

Besides variation caused by underlying alternative splicing, notable exceptions to the reading frame rule can result from alternative translational initiation. Another is the only DMD founder allele mutation described in North American families.

### Muscle Biopsy

The histopathologic features in DMD and BMD are not specific to the dystrophinopathies. The degree of changes depends in part on age of the patient, the muscle sampled, and where the patient lies in the disease course. In DMD patients without dystrophin, myofiber necrosis, phagocytosis, and regeneration are present from an early age, along with fibrosis and fatty replacement leading eventually to end-stage pathology. NF- $\kappa$ B is upregulated in DMD in infancy, before fibrosis becomes evident. In BMD, the degree of pathology is often less severe, particularly in earlier phases of the disease, where more moderate variation in myofiber size may be seen, and fibrosis may be less prominent; however, with time many BMD muscles in older patients appear indistinguishable from

DMD muscles, correlating with weakness rather than a specific clinical classification.

The importance of muscle biopsy in the diagnosis of the dystrophinopathies has declined as robust and complete mutational analysis has become available. Nevertheless, absent or altered dystrophin expression can provide an unequivocal diagnosis, and as previously noted, muscle biopsy is still required to establish the specifics of the mutational mechanism in some patients. Dystrophin protein expression can be assessed by either immunofluorescent (IF) or immunohistochemical (IHC) staining of muscle sections, or by immunoblot analysis of homogenized tissue, or by Western blot (WB) analysis (see Figure 146-1). The standard clinical practice is to perform IF or IHC staining with three antibodies, with one directed to each of the N-terminal, C-terminal, and central rod domains, as utilization of a rod domain antibody alone may give a false result in patients with in-frame deletions of exons coding for the epitope. Reproducible and specific quantification of dystrophin expression is technically challenging, and is routinely performed only in research settings. In routine clinical practice, dystrophin expression is typically expressed qualitatively. Biopsies of DMD muscle frequently demonstrate revertant fibers—found in up to 50% of biopsies—which are clusters of fibers with significant dystrophin expression that occurs because of altered mRNA splicing resulting in some mRNA with an open reading frame, resulting in the expression of dystrophin. Western blotting can provide information regarding protein size, and quantitative estimates, although absolute values as cutoffs of DMD versus BMD have not been rigorously validated.

### Management of DMD and BMD

Although the dystrophinopathies commonly present because of skeletal muscle symptoms, multiple systems are affected. DMD uniformly progresses to include cardiomyopathy, impaired ventilation because of diaphragmatic and thoracic muscle weakness, diminished bone density (exacerbated by corticosteroid therapy), and gastrointestinal dysmotility. Once a boy is wheelchair dependent, cardiac and ventilatory dysfunction become more severe, scoliosis typically supervenes, and the need for adaptive therapies becomes more important. Management may be facilitated by provision of care within a multidisciplinary clinic, and published standards of care describe consensus recommendations (with an updated version in preparation) (Bushby et al., 2010a,b). At a minimum, DMD patients should be seen yearly by a neurologist or rehabilitation physician, a cardiologist, a pulmonologist, physical and occupational therapists, and a nutritionist (see also Ch. 152). Additional input may be required from endocrinologist, orthopedic surgeons, social workers, and palliative care specialists.

### Pharmacologic Management

**Corticosteroids.** The mainstay of medical therapy for DMD is the corticosteroids prednisone and deflazacort. These are the only medications that have been shown to affect the clinical course, with a consensus that treatment with some corticosteroid regimen results in preservation of ambulation by up to 1 to 3 years. Their precise mechanism of their effect is unknown, but postulated effects include membrane stabilization, diminished fibrosis, and decreased inflammatory responses. A seminal randomized placebo-controlled trial of prednisone demonstrated that treatment with 0.75 mg/kg per day resulted in improved muscle strength by 6 months, whereas a dose twice that showed no additional benefit, with significantly more side effects. Deflazacort at an equivalent dose of 0.9 mg/kg per day has equivalent efficacy but a potentially a less

pronounced side effect profile, with less weight gain. However, both drugs are associated with significant side effects, including obesity, gastrointestinal bleeding, osteoporosis (leading to increased vertebral body and long bone fracture, with the latter leading to a risk of fat embolism syndrome), short stature, delayed puberty, Cushingoid features, hypertension, cataracts, glaucoma, and emotional lability. Alternative regimens have been utilized in an effort to minimize side effects, including dosing on a schedule of 10 days on/10 days off or for the first 10 days a month. A small study of weekend dosing at 10 mg/kg per week divided on weekend days suggested efficacy roughly equivalent to daily dosing in terms of efficacy, but showed no significant decrease in side effects. These different regimens have not been well characterized in head-to-head clinical trials, but the ongoing NIH-sponsored multicenter, multiyear FOR-DMD randomized double-blinded trial will likely answer outstanding questions regarding relative efficacy and side effects among these alternate regimens.

Despite decades of use, several issues regarding corticosteroid therapy exist. One is at what age to initiate corticosteroid therapy with treatment. Published recommendations suggest starting therapy between 2 and 5 years of age in boys whose strength has plateaued or is declining, but earlier treatment may be more beneficial. A second concern regards dose adjustments; in common practice most physicians do not adhere strictly to a 0.75-mg/kg dose of prednisone over years but instead allow the per-kilogram dose to drift down depending on tolerance and side effects. A third issue relates to the optimal use of corticosteroids after loss of ambulation, as there is increasing evidence that the use of low-dose steroids in nonambulant boys may result in diminished scoliosis and improved ventilation.

**Cardiac.** All patients with DMD eventually develop cardiomyopathy, the clinical importance of which is arguably increasing as ventilatory and orthopedic care continues to improve. Although a typical age of onset is often described as around 14 to 15 years, the incidence may be as high as 25% by age 6 years and 59% by 10 years. Screening echocardiograms are recommended at diagnosis or by age 6 years, then every 2 years up to age 10, and yearly thereafter. Cardiac MRI is increasingly available, and may demonstrate fibrosis and diastolic dysfunction before systolic dysfunction is noted. Cardiomyopathy is typically treated with afterload reduction, using angiotensin-converting enzyme inhibitors or angiotensin receptor blockers, with evidence that drugs should be initiated even before echocardiographic abnormalities are detected. Cardiac conduction disturbances are frequent, and the use of regular Holter monitoring may be helpful. In BMD, cardiomyopathy is also frequent, and may be severe, even necessitating cardiac transplantation, often when the skeletal muscle phenotype is more modestly affected.

**Pulmonary.** Pulmonary insufficiency remains the major cause of mortality, with impairment in vital capacity and airway clearance frequently leading to significant morbidity. Respiratory therapy and nocturnal ventilatory support have played key roles in extending life expectancy and improving quality of life in patients with DMD (LoMauro et al., 2015). The use of mechanical insufflator/exsufflator devices is associated with decreased pulmonary infections, and their use should be considered routine in this population. Loss of forced vital capacity becomes noticeable after loss of ambulation, and all patients in a wheelchair should be considered for yearly sleep studies and institution of bilevel positive airway pressure support.

### Non-pharmacologic Management

**Spine/Scoliosis.** Scoliosis ultimately affects the majority of boys with DMD, accelerating after loss of ambulation.

Orthopedic consultation should be considered for boys with scoliosis notable on examination, with yearly progression assessed by x-rays. Historical retrospective data from a single clinic suggest that spine stabilization surgeries in appropriate patients, combined with nocturnal ventilation, are sufficient interventions to prolong survival into the fourth decade.

**Contractures.** Early institution of the use of nighttime ankle-foot orthoses (AFOs) decreases the development and progression of heel cord contractures. Dynamic splints may be preferred over fixed AFOs, as they reduce contracture progression by stretching the ankle joint and maintaining ankle position over several hours. A dynamic splint has the potential to provide a passive muscle stretch throughout the night, whereas a solid brace will maintain the ankle in a 90-degree position. Use of daytime ankle bracing is generally not recommended, as they may interfere with gait deviations that are compensatory for pelvic girdle and the extensor weakness. Other muscle groups prone to contracture and targeted for passive stretching are the iliotibial band, hip flexors, hamstrings, and elbow and finger flexors. Surgical release of Achilles tendon contractures is generally not advised when the child is still ambulatory, and may even lead to premature loss of ambulation.

### Recent Advances in Dystrophinopathy Therapeutics

Multiple approaches toward correcting the pathologic features of dystrophinopathy are in development, and some are near or have reached clinical trials. These include therapies directed toward upregulation of the dystrophin surrogate utrophin, toward diminishing fibrosis, or toward modulating nNOS (which is mislocalized in muscle in the absence of dystrophin). Many of the most promising potential therapies that have already reached clinical trials are directed toward correcting the fundamental defect in DMD by inducing expression of a corrective (i.e., at least partially functional) version of the dystrophin protein (Figure 146-4).

*Nonsense suppression* therapies alter ribosomal recognition of premature stop codons, as first demonstrated with gentamicin treatment in the *mdx* mouse, which carries a nonsense mutation in exon 23. Gentamicin treatment of nonsense mutation associated DMD patients—accounting for around 15% of all mutations—is not practical, despite a small proof-of-principle study. The orally available nonsense suppression agent ataluren has demonstrated promising clinical efficacy into early phase clinical trials, and received conditional approval in Europe.

*Exon skipping* therapies are based on the reading frame rule, and seek to alter pre-mRNA splicing such that an exon flanking an out-of-frame exonic deletion excluded from the mature mRNA resulted in an in-frame transcript encoding a BMD-like protein. Targeting of a given exon may restore the reading frame for several different out-of-frame mutations; for example, exclusion of exon 51 will restore the reading frame for deletions of 13 to 50, 29 to 50, 43 to 50, 45 to 50, 47 to 50, 48 to 50, 49 to 50, 50 alone, 52 alone, and 52 to 63. Because of the clustering of exon deletions around the central rod domain deletion hotspot, targeting a limited number of exons will allow restoration of an open reading frame for a relatively large number of patients. For example, skipping of only four exons would be beneficial to around 35% of patients, including exon 51 (13.0% of patients), exon 45 (8.1%), exon 53 (7.7%), and exon 44 (6.2%), and skipping of up to two exons corrects 83% of DMD mutations.

Such skipping has been brought to human trials using antisense oligonucleotides based on two different chemistries,

2'-O-methyl phosphorothioate (2'-O-Me) antisense oligonucleotides or phosphorodiamidate morpholino oligomers (PMO), in each case with exon 51 as the lead target. Treatment of 12 patients with the PMO eteplirsen resulted, at 48 weeks, in a significant difference in the distance walked in the 6MWT between patients treated with the compound at the start of the study and those who initially received a placebo for 24 weeks before receiving active drug, and at 3 years in a difference between treated patients and historical controls. Similarly, treatment of 53 patients with the 2'-O-Me drisapersen for 48 weeks resulted in a significant increase in 6MWT distance walked at 25 weeks in those patients treated with continuous treatment, rather than intermediate treatment or placebo. In 2016, the US Food and Drug Administration granted approval for Eteplirsen and denied approval for drisapersen. Studies targeting other exons are underway.

*Gene transfer* is directed toward the delivery of a functional version of the gene to skeletal muscle, and ultimately as well to the heart and diaphragm. Delivery of the full-length *DMD* gene in naked plasmid form proved inefficient. In contrast, various serotypes of adeno-associated viruses (AAV) show significant tropism for muscle, and can deliver transgenes that remain in the cell as episomal DNA. Because AAVs are limited in the size of transgene they can encapsidate (with a maximum capacity of around 5 kb), microdystrophin transgenes lacking large portions of the central rod domain have been developed. Although an initial trial with an early microdystrophin vector version did not show significant dystrophin expression after intramuscular injection, improved AAV vectors are in development and are reaching clinical trials.

*Other approaches:* In addition to these gene-directed therapies, a variety of other approaches are in or have reached clinical trials, although none have yet gained regulatory approval. Treatment with idebenone, a benzoquinone antioxidant that inhibits lipid peroxidation and stimulates mitochondrial electron flux and cellular energy production, has been shown to slow the decline in peak expiratory flow as percentage predicted, forced vital capacity, and peak cough flow in nonambulant DMD patients. Inhibition of myostatin has been shown to ameliorate disease severity in animal models of DMD. This has led to trials of myostatin inhibition by antibodies or by expression of a transgene expressing the competing protein follistatin, and studies have been published in BMD or are underway in DMD. Another approach is the use of phosphodiesterase type 5 (PDE5) inhibitors such as

tadalafil or sildenafil to increase nNOS activity in skeletal muscle. Although this has been shown to be promising in animal models and can alter measures of muscle ischemia in DMD patients, it has not yet been shown to have a clinical benefit. Upregulation of the dystrophin paralog utrophin is beneficial in mouse models, and clinical development of a small-molecule upregulator is underway. Other new therapeutics are directed toward antiinflammatory pathways or membrane stabilization.

Altogether the breadth of these approaches allows the clinician to offer some optimism to the parents of a child with a new diagnosis, and can appropriately claim that the dystrophinopathies are the subject of intense clinical research with the prospect of meaningful therapies on the horizon.

# 147 Congenital, Limb Girdle and Other Muscular Dystrophies

Richard S. Finkel, Payam Mohassel, and Carsten G. Bönnemann

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Muscular dystrophies (MDs) are prototypic neuromuscular disorders that often present in childhood and are characterized by progressive weakness and loss of motor function. In addition, there is often related cardiac, pulmonary, and musculoskeletal morbidity, and survival may be shortened. All MDs are caused by mutations in genes responsible for the production of proteins essential for contractile, cytoskeletal, signaling, or enzymatic function within the muscle fiber or extracellular matrix. The explosion in molecular genetics over the past three decades has brought a greater understanding of the biologic basis for these disorders and the appreciation that multiple genes, when mutated, can cause a similar phenotype. Conversely, mutations in one gene can cause very different phenotypes. Chapter 135 discusses normal muscle development and the pathophysiologic processes involved in MDs. Common themes to MDs are features of muscle fiber degeneration with inadequate cellular repair, leading to atrophy of these fibers and replacement by fat and connective tissue. As a consequence, muscles lose contractile force and become flaccid, stiff, atrophic, or hypertrophied. This results in loss of function and joint contractures in skeletal muscle, and in some instances impaired cardiac and intestinal (smooth muscle) function. Each MD has distinctive features, for reasons not well understood, where some muscles are more vulnerable and others more resistant to the intrinsic pathologic processes that cause the progressive muscle fiber deterioration. As such, patterns of muscle involvement have been identified over nearly two centuries, and this has led to the current nomenclature. Figure 147-1 presents a classification of the MDs within the overall context of muscle disorders. Chapter 137 discusses more general principles of neuromuscular disorders and Figure 137-2 illustrates the more common MDs. Duchenne and Becker MD (“dystrophinopathies”) are discussed in Chapter 146. Myotonic dystrophies, a distinct category of muscle disease, are discussed in Chapter 151. This chapter discusses the other common MDs with an emphasis on pediatric presentation:

- Limb-Girdle MD (LGMD): proximal > distal weakness involving the lower > upper extremities
- Congenital MD (CMD): early onset dystrophic process, often with brain and ophthalmologic involvement, abnormal brain myelination, or extracellular matrix collagen abnormality
- Facioscapulohumeral MD (FSHD): principal involvement of the facial, scapular, humeral, peroneal, and abdominal muscles
- Emery-Dreifuss MD (EDMD): scapular, humeral, and peroneal involvement with early onset of joint contractures and often cardiac involvement
- Oculopharyngeal MD (OPMD): ocular, bulbar, and variable proximal shoulder and hip girdle involvement (onset of OPMD is typically in the adult years)

To grasp how these conditions are interrelated, it is useful to understand how the various genes and gene products (proteins) function within the muscle fiber as illustrated in

Figure 147-2. Table 147-1 categorizes these disorders based on the clinical phenotype and related genes, mode of inheritance, and name of the gene product. Each subsection below will address the relevant genes, proteins, mechanisms, and pathophysiology. The inheritance patterns—autosomal dominant, autosomal recessive, and X-linked recessive—are also discussed. Three websites listed in the selected references are particularly useful when a focused search is desired. In addition, the Online Mendelian Inheritance in Man ([www.omim.org](http://www.omim.org)) and the Orphanet ([www.orpha.net](http://www.orpha.net)) websites provide a broad overview of all genetic conditions. The Gene Tests website ([www.genetests.org](http://www.genetests.org)) provides a comprehensive resource of genetic testing laboratories, by country, where testing for these disorders can be pursued.

## DYSTROPHINOPATHIES (DUCHENNE AND BECKER MUSCULAR DYSTROPHIES AND CLINICAL VARIANTS)

The dystrophinopathies are reviewed in Chapter 146.

## LIMB-GIRDLE MUSCULAR DYSTROPHIES

### Definition

The limb-girdle MDs (LGMDs) consist of a diverse group of disorders within the broader field of genetic muscle diseases.

LGMD is defined as a muscular dystrophy presenting with predominantly proximal weakness, sparing facial, extraocular, and distal extremity muscles (at least early in the course of the disease). Muscle biopsy is of great importance for inclusion into this group and shows dystrophic features, including degeneration and regeneration, increased internalized nuclei, fiber size variability, increased endomysial fibrosis, and fatty replacement. However, just mild, nonspecific myopathic changes may also be seen still be consistent with the diagnostic category. Autosomal-recessive LGMDs (type 2) are more common than the autosomal-dominant (type 1) counterparts and will be discussed first in this chapter. Currently, 8 forms of type 1 and 19 forms of type 2 have been described and assigned a number and are summarized in Table 147-1.

### Autosomal-Recessive Limb-Girdle Muscular Dystrophies

Classic autosomal-recessive LGMDs include the sarcoglycanopathies (LGMD 2C-F), calpainopathy (LGMD 2A), and dysferlinopathy (LGMD 2B). This order reflects their average age of onset from younger to older. Two additional more common autosomal-recessive LGMDs are attributed to mutations in the  $\alpha$ -dystroglycanopathy gene fukutin-related protein (FKRP) (LGMD 2I), with a broad range of age of onset, and anoctamine-5 (LGMD 2L), a primarily adult-onset disease that resembles dysferlinopathy. There are a number of additional recessive LGMD forms.

**Figure 147-2.** Schematic diagram illustrating a muscle fiber and the cellular localization of the gene products for the limb-girdle and congenital muscular dystrophies, with their associated disorders. DG, dystroglycan; SG, sarcoglycan. (Reproduced, with permission, from Wicklund MP, Kissel JT. *The limb-girdle muscular dystrophies*. *Neurol Clin* 2014;32:729–49.)

### Sarcoglycanopathies (LGMD 2C-F)

Sarcoglycanopathies were first described as autosomal-recessive disorders resembling Duchenne muscular dystrophy (DMD). In addition to the autosomal-recessive pattern of inheritance, the immunohistochemical presence of dystrophin on muscle biopsy differentiated sarcoglycanopathies from DMD. While initially referred to as SCARM (for severe childhood autosomal-recessive muscular dystrophy), many patients with milder presentations were subsequently identified and the term SCARM is no longer widely used.

Sarcoglycanopathies account for 20% to 25% of all patients with muscular dystrophy but comprise roughly 50% to 60% of the more severe LGMDs as opposed to 10% to 20% of the milder forms.

**Pathophysiology.** See online chapter for discussion.

**Genetics and Mutations.** Mutations in all four major sarcoglycan genes cause four genetically separate forms of autosomal-recessive LGMD with almost indistinguishable clinical phenotypes. The majority of milder cases in sarcoglycanopathies are related to  $\alpha$ -sarcoglycan mutation, including almost asymptomatic patients with high CK levels and lordosis.  $\beta$ - and  $\gamma$ -sarcoglycan mutations have a higher proportion of severe early childhood cases, although significant intrafamilial variability occurs.  $\delta$ -Sarcoglycan mutations generally are more severe.

**Clinical Features.** Clinical features of the four sarcoglycanopathies overlap. They predominantly affect young children with a median age of onset around 6 to 8 years.

**Time Course and Distribution of Motor Symptoms.** The first symptoms generally relate to pelvic muscle weakness, evidenced by a waddling gait, which limits running, getting up from the floor, or climbing stairs. Primary toe walking may be present. Muscle cramps, pain, and exercise intolerance with or without myoglobinuria can occur. The distribution of weakness is reminiscent of dystrophinopathies. However, unlike dystrophinopathies, anterior and posterior compartments of the thigh may be equally affected. Shoulder girdle weakness ensues. Deltoid, infraspinatus, and biceps muscles are involved early in the disease. Scapular weakness tends to be more pronounced compared with dystrophinopathies (Figure 147-3). Facial and extraocular muscles are spared. Late in the disease, distal muscles may be involved. In later stages and similar to DMD, neck flexor weakness may occur. Loss of independent ambulation may occur around 12 to 16 years of age, although there is variability. CK levels are elevated 10- to 100-fold early in the course of the disease.

**Cardiac Features.** Cardiac involvement occurs although clinically overt dilated cardiomyopathy is only seen in a minority of patients. Cardiac failure or sudden cardiac death may occur and cardiac transplantation may become necessary. Dilated cardiomyopathy may be more common in  $\gamma$ - and  $\delta$ -sarcoglycanopathies but cardiac involvement is reported in all sarcoglycanopathies. Subclinical cardiac involvement is more common and noticeable on electrocardiography and echocardiography.

**Pulmonary Features.** Symptomatic respiratory failure is not an early feature of sarcoglycanopathies. Some patients with severe early onset muscle weakness develop severe restrictive

lung disease. Clinically relevant respiratory failure does not manifest while the patient is still ambulant.

**Contractures and Other Signs and Symptoms.** Other associated signs include calf hypertrophy and macroglossia. Achilles tendon shortening tends to be the first sign of contractures and lordosis may occur early in the course, and so toe walking can be an early manifestation. Later, more contractures involving the hip flexors, lateral tractus, and knee flexors may develop. Progressive scoliosis may worsen respiratory compromise later in the disease. Intellectual impairment is not seen.

**Diagnosis.** Sarcoglycanopathies can be suspected based on clinical grounds. The probability of an autosomal-recessive LGMD in boys with a Duchenne-like phenotype is 6% to 8%.

Definitive histologic diagnosis requires immunohistochemical stains with antibodies against muscle sarcoglycans and dystrophin (Figure 147-4). Histology usually shows marked degeneration and regeneration and severely dystrophic muscle. Dystrophin immunoreactivity is expected to be normal, although it can be reduced similar to BMD or female carriers of a dystrophin mutation. Western blot analysis usually shows dystrophin with a normal molecular weight and quantities within 10% of normal.

**Treatment.** No specific therapies are available for sarcoglycanopathies but unlike dystrophinopathies, sarcoglycanopathies are more amenable to gene therapy as discussed in the online chapter.

## Disorders of $\alpha$ -Dystroglycan Glycosylation

### Limb-Girdle Muscular Dystrophy 2I: Fukutin-Related Protein Deficiency

Fukutin-related protein (FKRP) belongs to the growing list of genes underlying the group of  $\alpha$ -dystroglycanopathies, characterized by abnormal O-mannosyl glycosylation of  $\alpha$ -dystroglycan, which more typically are associated with forms of CMD (Congenital Muscular Dystrophies, below). Mutations in *FKRP* cause an extremely wide spectrum of phenotypes: ranging from severe Walker-Warburg syndrome (WWS), transitional phenotypes of CMD with variable central nervous system involvement or normal brain imaging, to less severe LGMDs with Duchenne to Becker MD-like like severities that are referred to as LGMD2I. LGMD2I is one of the more common forms of LGMD, representing from 11% to 19% of all cases of LGMD in different series.

**Clinical Features.** The LGMD phenotype of *FKRP* mutations can present with severity and distribution of muscle weakness similar to DMD, with early loss of ambulation even before 10 years of age. There is a pronounced predilection for axial muscles, neck flexors, and proximal limb muscles with prominent lordosis. Predominant weakness is typically seen in shoulder adduction and internal rotation, elbow flexion, hip flexion and adduction, knee flexion, and ankle dorsiflexion. Hamstrings are generally more involved than the quadriceps. Mild facial weakness can be seen. Scapular winging is not common. There can be tongue, calf, and brachioradialis hypertrophy.

Dilated cardiomyopathy can occur even before the loss of ambulation, whereas respiratory failure necessitating nocturnal ventilatory support manifests after loss of ambulation.

**Diagnosis.** LGMD 2I may be clinically suspected based on features such as the peculiar hypertrophy of brachioradialis muscle and tongue and the pattern of muscle weakness. Muscle MRI may demonstrate a distinctive pattern of involvement, similar to LGMD2A (calpain-3 deficiency). Muscle biopsy shows prominently reduced  $\alpha$ -dystroglycans and also

mild reduction of laminin  $\alpha_2$ . Although these are not specific, they can be helpful in suggesting appropriate genetic analysis of the *FKRP* gene.

**Management.** No specific treatments are available at this time. Similar to other MDs with a predilection for cardiomyopathy and respiratory failure, recognition, evaluation, and treatment of these complications is of utmost importance.

### Other $\alpha$ -Dystroglycanopathies

See online chapter for discussion.

### Calpainopathy (LGMD2A)

**Background and Epidemiology.** Calpainopathy or LGMD 2A is likely the most common juvenile onset form of LGMD and may account for 40% to 50% of all LGMD patients.

**Pathophysiology, Genetics, and Mutations.** *CAPN3*, the gene mutated in LGMD 2A, encodes calpain-3, a calcium-activated protease that localizes to the cytoplasm and nuclei of the cells.

**Clinical Features.** Calpainopathies have a characteristic clinical phenotype although variations and atypical presentations do occur. The age of onset is later than sarcoglycanopathies, between 8 and 15 years of age, with a wide range from 2 to 40 years.

**Time Course and Distribution of Motor Symptoms.** The first symptoms generally relate to pelvic girdle muscle weakness. Later, shoulder girdle and arm weakness becomes apparent. Minimal facial weakness is reported very late in the disease, and facial, extraocular, and pharyngeal muscles are otherwise spared. Overall, a rather thin-appearing muscle profile, with gluteus maximus and hip adductor weakness, scapular winging and high riding scapulae, wide stance, biceps atrophy, and lax abdominal muscles, is the most typical clinical appearance of patients with calpain-3 mutations (Figure 147-5). The course of the disease is progressive. Loss of independent ambulation occurs around 14 years of age or later. CK concentrations in the serum are significantly elevated. In comparison to sarcoglycanopathies or dysferlinopathies, CK levels tend to be lower on average.

**Cardiac Features.** No primary cardiac involvement has been attributed to *CAPN3* mutations. However, right bundle branch block has been reported.

**Pulmonary Features.** Respiratory failure is rare, occurring only in patients with severe and very advanced disease. Mild restrictive lung disease evidenced by reduced forced vital capacity is quite prevalent and usually asymptomatic.

**Contractures and Other Signs and Symptoms.** Contractures appear in the Achilles tendons and may involve the elbows and spine. In some patients, contractures may be severe earlier in the course, mimicking EDMD. Early lordosis may be seen.

**Diagnosis.** The clinical features can strongly suggest calpainopathy but further studies are needed for confirmation. Muscle imaging may reveal the characteristic distribution of muscle disease with selective involvement of the posterior compartment of the thigh and hip adductors, but such testing should be interpreted with caution. Muscle biopsy may show dystrophic features and type 1 fibers may appear lobulated on the oxidative stains such as NADH. Direct immunohistochemistry for calpain-3 with the current antibodies is not reliable but Western blot analysis can be informative with the calpain-3 level reduced or absent in muscle biopsy immunoblots in most patients. Mutation analysis is the most specific test.

**Treatment.** No specific therapies are available for calpainopathies. Findings of eosinophilic inflammation in the muscle

in some LGMD2A patients have raised some interest in the use of immunosuppressive therapies. In mouse models, adenovirus-mediated gene transfer has been successful.

### Dysferlinopathy (LGMD 2B)

Linkage studies have identified mutations in *DYSF*, the gene coding for dysferlin, the protein affected in LGMD 2B on chromosome 2p. *DYSF* mutations are associated with a number of distinct clinical phenotypes: a typical LGMD, a distal muscular dystrophy known as Miyoshi myopathy, and a third phenotype with early anterior tibial compartment weakness. Even in the limb-girdle phenotype, the phenotypic spectrum is broad. The majority of patients first develop weakness in late adolescence and early adulthood. However, some patients develop a congenital myopathy and some remain only mildly affected well into adulthood.

 **Pathophysiology.** (see online)

 **Genetics and Mutations.** (see online)

**Clinical Features.** Compared with sarcoglycanopathies and calpainopathies, dysferlinopathies begin later in life with weakness starting around 18 to 20 years of age but congenital disease or mild adult onset disease have been reported. Weakness is slowly progressive and ambulation is usually preserved typically into the fourth decade.

**Time Course and Distribution of Motor Symptoms.** In the limb-girdle dysferlinopathy (LGMD2B), the first motor symptoms occur in the pelvifemoral distribution, in particular the quadriceps, and later involve the arms. However, one can detect gastrocnemius and soleus muscle wasting and weakness early in the limb-girdle phenotype as well, causing early inability to walk on toes even in the LGMD phenotype. This unique feature, which can be demonstrated with muscle imaging, can be diagnostically helpful. The pattern of weakness in the arms is usually mild at first and involves the distal biceps. Deltoid and periscapular muscles are often spared and as a result, in contrast to sarcoglycanopathies and calpainopathy, scapular winging is not a usual feature. As in other LGMDs, facial and extraocular muscles are preserved. In the Miyoshi phenotype, the gastrocnemius and soleus muscles are affected first, manifesting as the inability to walk on toes. In the upper extremities, the muscles of the forearms are quite weak, yet the intrinsic muscles of the hand are spared. The proximal muscles are affected as the disease progresses.

CK levels tend to be very high during the early, 20 to 150 times the upper limit of normal; in the presymptomatic patients it may only be mildly elevated.

**Cardiac and Pulmonary Features.** Dysferlinopathies do not feature conductive or functional cardiac disease or restrictive lung.

**Contractures and Other Signs and Symptoms.** Contractures are not a usual feature of dysferlinopathy.

**Diagnosis.** The characteristic clinical presentation includes the following features: age of onset around 18 to 20 years, highly elevated CK levels, proximal lower extremity weakness in conjunction with inability to walk on toes, relative sparing of the periscapular muscles, and early gastrocnemius muscle involvement on muscle imaging. However, the significant phenotypic variation, even among family members, can be misleading.

Muscle biopsy usually shows dystrophic features but inflammation may be prominent and delay the accurate diagnosis by suggesting myositis. Immunostains for dysferlin are usually absent. However, secondary reductions and staining abnormalities for dysferlin in other dystrophic conditions are not uncommon. Likewise, calpain level may be secondarily reduced or absent in dysferlinopathy. Western blot analysis is

a more specific diagnostic test and can also be attempted and yield diagnostic information. Mutation analysis is the most specific test.

**Treatment.** No specific treatments are available. Judicious use of orthotics can provide help in maintenance of ambulation in many patients.

### Anoctaminopathy (LGMD2L)

Recessive mutations in *ANO5* on chromosome 11, the gene encoding anoctamine-5, have recently been linked with a group of adult patients with limb-girdle muscular dystrophy. See online chapter for discussion. 

### Other Rare Autosomal-Recessive Limb-Girdle Muscular Dystrophies

Telethoninopathy (LGMD 2G), LGMD 2H, and titinopathy (LGMD 2J) are rare forms of LGMD that may present in childhood. Further information on these disorders can be found on the resources listed at the beginning of this chapter.

### Autosomal-Recessive Conditions Presenting as LGMD

**Partial Laminin  $\alpha_2$  Deficiency.** This condition is allelic to primary laminin  $\alpha_2$  deficiency, the form of CMD related to severe deficiency of laminin  $\alpha_2$ , the heavy chain of the heterotrimer laminin 211 (merosin). Primary mutations in the *LAMA2* gene on chromosome 6q are responsible. In case of complete deficiency the clinical phenotype is that of a severe CMD. MRI of the brain may show supratentorial white matter T2 hyperintensities and some children develop seizures. The clinical presentation may be that of a milder CMD or may resemble LGMD with proximal weakness only, in which case, walking may be achieved. Joint contractures can be prominent and resemble EDMD. In these cases, only a partial deficiency of laminin  $\alpha_2$  on muscle biopsy specimen is seen. Western blot analysis is a more sensitive measure. Patients with partial laminin  $\alpha_2$  deficiency almost always show subtle alterations of white matter signal on T2-weighted MRIs. Patients with the LGMD phenotype usually have a missense mutation or an in frame deletion.

### X-Linked Recessive Conditions Presenting as LGMD

Some patients with emerin mutations, the protein mutated in classical X-linked EDMD, discussed below, may present with an LGMD-like presentation without cardiac involvement.

### Autosomal-Dominant Limb-Girdle Muscular Dystrophies

Autosomal-dominant LGMDs are generally less common and constitute about 10% of LGMDs. They occur later in comparison to autosomal-recessive LGMDs and have a milder or moderate course. Commonly, a positive family history is evident; however, de novo mutations and germline and/or somatic mosaicism account for some patients.

In this section we will divide autosomal-dominant LGMDs into two groups: one without cardiac involvement (LGMD 1A, 1C, and 1D) and the other with cardiac involvement (LGMD 1B).

### Autosomal-Dominant LGMDs Without Cardiac Involvement

**Myotilinopathy-LGMD 1A.** Myotilinopathy LGMD 1A mutations have been implicated in myofibrillar myopathy-3—a distal, adult-onset, autosomal-dominant myopathy.

**Pathophysiology and Mutations.** (see online) 

**Clinical Features.** Onset usually is in adulthood (late 20s) with slowly progressive symptoms involving proximal leg and arm weakness. Patients have a particular nasal speech quality and dysarthria. Achilles tendon contractures may be seen. CK values may be raised 1.6- to 10-fold the upper limit of normal. Cardiac and pulmonary involvement is not a typical feature.

**Diagnosis.** The peculiar clinical feature of nasal speech quality in the setting of an autosomal-dominant LGMD with mildly raised CK values can suggest this diagnosis. Muscle biopsy shows dystrophic features and in some cases autophagic vacuoles; Z-line streaming and disorganization as well as rod-shaped accumulations similar to nemaline myopathies have been reported on electron microscopy. Immunohistochemistry and Western blot analysis usually show normal levels of myotilin. Mutation analysis is usually necessary.

**Treatment.** No specific therapies are available.

### Caveolinopathy (LGMD 1C)

**Pathophysiology and Genetics.** Caveolin-3 mutations, the muscle-specific form of caveolin, result in LGMD 1C as well as other phenotypes. Caveolae contribute to sarcolemmal integrity, regulate ion channels, and play a role in signal transduction among other roles. Most mutations resulting in the limb-girdle phenotype are missense or microdeletions. There is significant reduction of caveolin-3 immunoreactivity in muscle biopsy specimens of heterozygous patients.

**Clinical Features.** Four different muscle disease phenotypes are recognized: LGMD, rippling muscle disease, asymptomatic CK elevation, and a distal myopathy. There is significant overlap. There is also significant intrafamilial variability without a typical clinical phenotype. Some patients develop weakness in early childhood, whereas others remain asymptomatic. Myalgias and cramping with exertion have been reported. Some patients have calf hypertrophy (Figure 147-6). Definite cardiac or pulmonary involvement is not typically seen.

**Diagnosis.** Immunohistochemistry of muscle biopsy tissue shows reduced caveolin-3 immunoreactivity. Genetic confirmation is necessary in suggestive cases.

**Treatment.** Supportive management can be helpful to patients.

**LGMD 1D.** This particular muscular dystrophy has been genetically linked to chromosome 7q in several families with DNAJB6 mutations. See online chapter.

### Autosomal-Dominant LGMDs With Cardiac Involvement

Autosomal-dominant LGMDs with cardiac involvement have a close relationship to autosomal-dominant EDMD. Desmin mutations can also present with LGMD-like phenotype (LGMD 1E) and cardiac involvement; however, they are better described as myofibrillar myopathy.

**Laminopathy (LGMD 1B).** This LGMD is allelic with autosomal-dominant EDMD.

**Pathophysiology and Genetics.** (see online)

**Clinical Features.** Whereas the EDMD and CMD forms have onset in earlier childhood, the LGMD presentation of laminopathy usually occurs in the late teens and early adulthood. Most patients develop weakness in the pelvic girdle muscles. Mild facial weakness and mild anterior tibial compartment weakness may be seen. Progression is slow, and biceps and Achilles tendon contractures may develop. CK values are usually mildly elevated, 1.5- to 3-fold.

**Cardiac Features.** Cardiac problems may manifest in the third and fourth decades with first-degree atrioventricular (AV) block that progresses to complete AV block. Similar to the EDMD and CMD presentations of LMNA mutations, sudden

cardiac death is a prominent risk and may be its first and only manifestation. Dilated cardiomyopathy only rarely occurs.

**Diagnosis.** Diagnosis is based on suggestive clinical features, the cardiac manifestations, as well as the presence of contractures and an autosomal-dominant hereditary pattern. Muscle biopsy evaluation is not particularly helpful as lamin A/C immunoreactivity appears normal even in the presence of mutations; however, it is helpful to rule out other causes of LGMD. Genetic analysis should be initiated when LGMD 1B is suspected.

**Treatment.** No specific treatments are available. Careful cardiac evaluation and monitoring is important to evaluate for the need for intracardiac defibrillator placement to prevent fatal cardiac arrhythmias.

### Autosomal-Dominant Conditions That May Present as LGMD

#### Facioscapulohumeral Dystrophy (FSHD, See Below).

FSHD is the single most important entity to consider in patients with an LGMD-like presentation, especially those with an autosomal-dominant pattern of inheritance.

**Myotonic Dystrophy (DM) Types 1 and 2.** Myotonic dystrophy, discussed in Chapter 152, is one of the most common MDs. Patients with myotonic dystrophy, especially DM type 2, may present with a limb-girdle pattern of muscle weakness.

**Collagen VI-Related Dystrophies.** Collagen VI-related dystrophies constitute a spectrum of severities from the mild Bethlem myopathy, via intermediate severity to the more severe Ullrich CMD. For the differential diagnosis of LGMD, Bethlem myopathy is the most important to consider. Bethlem myopathy is an autosomal-dominant and rarely also a recessive disorder caused by mutations in one of three genes coding for alpha chains of collagen type VI, COL6A1 and A2 on chromosome 21q22.3 or COL6A3 on chromosome 2q37.

Ullrich CMD is characterized by severe weakness concomitant with joint hyperlaxity and contractures at birth. Respiratory insufficiency, which may begin before loss of independent ambulation, also worsens over time. As a result, early detection and treatment with noninvasive bilevel positive airway pressure ventilation may be required. There are also patients presenting with phenotypes of intermediate severity (Figure 147-7). Patients in this intermediate phenotype also experience progressive respiratory insufficiency, frequently leading to the need for nighttime noninvasive ventilator support.

Diagnosis is clinically suspected based on congenital weakness and concomitant severe contractures and joint laxity. Skin findings with prominent keratosis pilaris of the extensor surfaces of the arms and legs and abnormal keloid formation may be seen (Figure 147-8). Muscle imaging may show a characteristic pattern of muscle degeneration beginning adjacent to the fascia, resulting in the typical rimming of muscles and the "central cloud" in the rectus femoris along its central fascia. Molecular testing is similar for all collagen VI-related phenotypes.

Most patients with Bethlem myopathy develop symptoms in childhood and some may have congenital weakness/hypotonia, torticollis, or foot deformities. Weakness is usually more predominant in the proximal muscles. Early on, there may be no contractures, and joint hyperlaxity may be present. Contractures usually occur at the end of the first decade, involving the deep finger flexors and proximal joints (Figure 147-8), and when absent or minor, the phenotype can resemble LGMD. Diagnosis is usually secured by showing mutations in one of the three genes encoding one of the alpha chains of collagen type VI. Sanger sequencing as well as next-generation sequencing is available to screen for mutations in the collagen type VI genes and arrive at a specific diagnosis.

## EMERY-DREIFUSS MUSCULAR DYSTROPHY

Emery-Dreifuss MD (EDMD) is characterized by a clinical triad of early contractures, muscle wasting, and weakness in a humeroperoneal distribution, and cardiomyopathy. Considerable phenotypic variability exists regarding age at onset and rate of progression. X-linked transmission and autosomal-dominant transmission are recognized. Five genes have been identified (Table 147-1). EDMD is included in this section on LGMD because of the phenotypic similarity. Mutations in *FHL1* or *STA* genes also cause EDMD (see online chapter).

### Pathophysiology and Genetics

Both X-linked and autosomal-dominant EDMD result from mutations in genes coding for nuclear envelope proteins. See online chapter.

Autosomal-dominant EDMD and, very rarely, autosomal-recessive EDMD result from mutations of the *LMNA* gene, located on 1q21, which encodes two nuclear envelope proteins, lamins A and C, discussed above.

### Clinical Features

Although X-linked EDMD and autosomal-dominant EDMD usually share a similar phenotype, wide clinical variation with poor genotype-phenotype correlation has been documented in both.

The onset of contractures occurs early in the disease, in the first or second decade, and often precedes weakness. Contractures are most prominent at the elbows, Achilles tendons, and posterior cervical muscles. Upper-extremity contractures often precede axial and lower extremity deformities. The arms are held in a semiflexed position. The feet are set in talipes equinus, often in association with toe walking. Posterior cervical contractures preclude full neck flexion (Figure 147-9). Contractures usually remain disproportionate to the degree of weakness and may be the major factor in functional impairment. Muscle weakness is relatively mild and slowly progressive. The distribution of motor deficits is humeroperoneal, with upper-extremity weakness (in biceps, triceps, and spinatus muscles) occurring earlier than leg weakness (in tibialis anterior and peroneal muscles). Pseudohypertrophy is not seen, and its absence helps differentiate X-linked EDMD from dystrophinopathy (BMD) clinically.

Cardiac symptoms may include palpitations, syncope, and diminished exercise tolerance. Supraventricular dysrhythmias, AV conduction block, ventricular dysrhythmias, and restrictive or dilated cardiomyopathy may evolve.

### Diagnosis

The diagnosis of EDMD is suspected based upon the clinical phenotype, especially the early onset of joint contractures relative to the degree of weakness, and confirmed by genetic testing for mutations in the *LMNA*, *FHL1*, or *STA* genes.

### Management

Treatment is based largely on symptoms. The high incidence of cardiac dysfunction mandates early and regular cardiology evaluations. ICD rather than pacemaker should be considered for the arrhythmogenic component of the cardiomyopathy. Mothers and sisters of males with X-linked EDMD should also receive cardiology consultation. Orthopedic interventions may be helpful in addressing limb contractures. In the late stage of EDMD, respiratory aids, including cough-assistive devices and noninvasive nocturnal respiratory support, may be helpful.

## Summary and Approach to LGMD Patients

### Clinical Features

Because of the significant genetic and phenotypic variability of the different LGMDs, a careful family history and examination of family members that may or may not be aware of symptoms can play an important role in narrowing the differential diagnosis. Certain diagnostically helpful clinical features need to be evaluated fully:

1. Age of onset and speed of progression may provide an important clue in patients with suspected LGMD. Earlier onset and a more severe course with elevated CK are suggestive of mutations in the sarcoglycan complex or FKRP. With later childhood-onset symptoms, calpainopathy become more likely. If symptoms first appear in adolescence or early adulthood, a dysferlinopathy should be suspected, especially if the CK levels are extremely elevated. Adult-onset symptoms that are mild with significantly elevated CK may suggest anoctaminopathy, or myotilinopathy if the CK is close to normal.
2. The distribution of muscle weakness, presence or absence of contractures, or muscle groups that are spared can be important clues. Radiologic imaging such as MRI can be helpful in discerning the distribution of myopathy. For a summary of the specific clinical features in the commonly encountered LGMDs, please refer to [Table 147-2](#).
3. The presence or absence of cardiac features can be an important clue, especially in autosomal-dominant LGMDs.

### Muscle Biopsy and Protein Studies

In LGMD patients, muscle biopsy with routine histochemical stains usually shows dystrophic features with fiber size variability, increased endomysial fibrosis, fatty replacement, as well as myofiber degeneration and regeneration. Immunohistochemistry, in addition to Western blot analysis, can be helpful in many cases. Although assessment against many antibodies can be done, these methods are at best semiquantitative and should be interpreted with caution. Major patterns of immunohistochemical reduction of expression in different LGMDs are summarized in [Table 147-2](#).

### Molecular Genetic Testing

It is preferable that all diagnoses of genetic LGMDs be confirmed by molecular genetics when available. Availability of whole-exome sequencing and simultaneous sequencing of multiple genes at relatively low cost using next-generation technology has recently provided an alternative to traditional methods and costly panels. However, some mutations with large deletions or duplications are not amenable to detection using this approach. In addition, variations of unknown significance complicate the interpretation of the results in the absence of functional data. As a result, these approaches should be used as a complement to the clinical findings and the molecular and clinical features carefully correlated. It is always important to adequately consider metabolic etiologies, for example, Pompe disease, and acquired muscle diseases as the treatment and genetic implications are so different.

### Diagnostic Algorithm

The American Academy of Neurology published an evidence-based guideline in 2014 for the diagnosis and treatment of LGMD and distal MDs. The three algorithm tables for autosomal-dominant, autosomal-recessive, and X-linked LGMDs and distal MDs are reproduced as [Figure 147-10](#).

**TABLE 147-2** Characteristic Clinical and Biopsy Findings in the Limb-Girdle Muscular Dystrophies

Helpful Clinical Features		Immunohistochemistry and Western Blot
<b>A. Autosomal-Dominant LGMD</b>		
LGMD 1A (myotilinopathy)	Late onset and milder disease Nasal speech quality Early contractures of the Achilles tendons	Usually normal
LGMD 1B (laminopathy)	Contractures mimicking EDMD but can be minimal Conductive cardiac disease and AV block Early childhood onset possible Common de novo mutations	Usually normal
LGMD 1C (caveolinopathy)	Highly variable May present with isolated elevated CK with none to minimal weakness	Majority of cases with reduced or absent protein
<b>B. Autosomal-Recessive LGMD</b>		
LGMD 2A (calpainopathy)	Juvenile onset (~10 yrs) Early periscapular weakness Muscle wasting and atrophy Hamstrings weakness Sparing of the hip abductors	IHC is not available but WB shows reduction in the majority of cases. Secondary reduction in dysferlin occurs. Eosinophilic myositis has been reported.
LGMD 2B (dysferlinopathy)	Late adolescent onset (~18 yrs) Can present with proximal and/or distal weakness Early gastrocnemius involvement, esp. on MRI Spared periscapular muscles CK levels extremely high	Possible by IHC but WB is more specific. Secondary reductions in calpainopathy occurs. Intramuscular vessels may show amyloid deposits.
LGMD 2C-F (sarcoglycanopathies)	Early childhood onset (6–8 yrs) Similar pattern to DMD/BMD except early scapular weakness Calf hypertrophy very common CK levels very high Cardiomyopathy in a subset	IHC and WB are possible. Pattern of absence of all sarcoglycan proteins may be helpful.
LGMD 2G (telethoninopathy)	Variable clinical phenotype Early anterior tibial weakness and foot drop	IHC and WB are possible.
LGMD 2H	Variable clinical phenotype LE > UE weakness Trapezius and deltoid affected	Not possible
LGMD 2I	Typically mild but early childhood onset seen Weakness in the neck flexors and axial muscles UE > LE weakness Brachioradialis, tongue, and calf hypertrophy Cardiopulmonary disease possible	IHC may show reduced $\alpha$ -dystroglycan and laminin $\alpha_2$ but not specific.
LGMD 2L (anoctaminopathy)	Adult onset Knee flexor and extensor weakness Medial gastroc, hamstring, and quadriceps atrophy, esp. vastus medialis	Not possible Intramuscular vessels may show amyloid deposits.

AV, atrioventricular; BMD, Becker's muscular dystrophy; DMD, Duchenne's muscular dystrophy; EDMD, Emery-Dreifuss muscular dystrophy; IHC, immunohistochemistry; LE, lower extremity; LGMD, limb-girdle muscular dystrophy; UE, upper extremity; WB, Western blot.

The Jain Foundation website ([www.jain-foundation.org](http://www.jain-foundation.org)) provides a computer-based “automated LGMD diagnostic assistant,” which is a useful resource to narrow the focus of diagnostic considerations in an individual patient.

## FACIOSCAPULOHUMERAL MUSCULAR DYSTROPHY

Facioscapulohumeral MD (FSHD) is inherited as an autosomal-dominant disorder with high penetrance and variable expression. Between 10% and 30% of cases represent new mutations. Prevalence is estimated at  $2$  to  $4.5 \times 10^{-5}$  (refer to Table 137-2 in Chapter 137). Clinical signs and symptoms are usually present before age 20 years and are manifested by

weakness of the facial muscles, fixators of the scapula, and dorsiflexors of the ankle. Although skeletal muscle symptoms dominate the clinical picture, other systems are often involved, which implies a more widespread developmental/degenerative process.

## Molecular Genetics

FSHD maps to chromosome 4q35. More than 95% of patients with FSHD have a reduced number of 3.3-kilobase tandem repeat sequences termed *D4Z4*. See online chapter for additional discussion. Testing for the number of *D4Z4* tandem repeats on chromosome 4q35 is the most specific and sensitive diagnostic test for FSHD. Subtelomeric translocations

between chromosomes 4q35 and 10q26 occur relatively frequently in the general population and may complicate molecular diagnosis.

## Clinical Features

Clinical diagnostic criteria have been established by the Facioscapulohumeral Muscular Dystrophy Consortium. Inclusion criteria specify autosomal-dominant inheritance; bifacial weakness; and weakness of the scapular stabilizer muscles, ankle dorsiflexor muscles, or both. Supporting criteria include asymmetry of motor deficits (a finding far more common in FSHD than any other muscular dystrophy); sparing of deltoid, neck flexor, and calf muscles; and involvement of wrist extensors and abdominal muscles. Hearing loss involving high frequencies and retinal vasculopathy (Coats disease) are additional supportive findings. Exclusion criteria include eyelid ptosis, extraocular muscle weakness, skin rash, elbow contractures, cardiomyopathy, sensory loss, neurogenic changes documented in muscle biopsy, and myotonia or neurogenic motor unit potentials documented on needle electromyography.

Weakness is usually appreciated first in the facial muscles. Patients have difficulty with puckering the lips, whistling, sipping through a straw, or blowing up balloons because of weakness of the orbicularis oris muscle. Most patients have a transverse smile and limited facial expression. Weakness of the orbicularis oculi is usually asymptomatic, but the examiner can recognize facial muscle weakness by observing incomplete burying of the eyelashes with forced eyelid closure and the ease with which the closed eyelids can be pried apart. A history of sleeping with the eyes open may be offered by a parent or spouse. Facial weakness may be asymmetric (Figure 147-11).

Weakness of scapular fixation is evidenced by scapular winging, accentuated by arm extension. The scapulae ride high on the back, producing the illusion of hypertrophied trapezius muscles. Arm abduction is impaired in the presence of normal power and bulk of the deltoid muscles. Wasting of the biceps and triceps with preservation of deltoid and forearm muscles yields a "Popeye" configuration to the arms. Wasting of the clavicular head of the pectoral muscles produces a reversal of the axillary folds with a deep upward slope. Weakness of lower abdominal muscles may result in a "pot belly" when standing and a positive Beever sign (cephalad movement of the umbilicus with neck flexion) when the patient lies supine.

Lower-extremity weakness is usually evident first in the ankle dorsiflexors, with compromised heel walking or overt footdrop. Atrophy is most prominent in the tibialis anterior muscle. Preservation or hypertrophy of the extensor digitorum brevis muscle clinically excludes a neurogenic etiology of the footdrop. Axial paraspinous muscle weakness may result in marked lumbar lordosis, especially in patients with childhood-onset FSHD.

Motor deficits are slowly progressive. Most patients remain functionally independent throughout life.

Sensorineural hearing loss is frequently documented, especially in children presenting before 10 years of age, and can often be asymptomatic. Retinal vasculopathy with telangiectasia and retinal detachment (Coats disease) may develop. Symptomatic cardiac disease is infrequently encountered. Restrictive lung disease may be seen in patients with more severe FSHD. Congenital onset of FSHD has been associated with mental retardation and epilepsy in children with the largest D4Z4 deletions. The congenital-onset, or infantile, phenotype is often severe and rapidly progressive, accompanied by sensorineural hearing loss and Coats disease. Profound weakness of facial muscles is typical (Figure 147-11).

## Laboratory Findings

Creatine kinase determinations are either normal or slightly elevated; creatine kinase levels exceeding five times the laboratory norms are suggestive of an alternative diagnosis. Genetic testing has largely replaced electrodiagnostic and muscle biopsy evaluations in persons with suspected FSHD.

## Diagnosis

The American Academy of Neurology published an evidence-based guideline in 2015 for the evaluation, diagnosis, and treatment of FSHD (reference below) (Figure 147-12).

## Treatment

There is no definitive treatment for FSHD. Results of therapeutic trials of corticosteroids and the  $\beta$ -adrenergic agonist albuterol have been disappointing. Trials of the calcium blocker diltiazem and an industry-sponsored trial of monoclonal antibody directed against human myostatin failed to increase strength or function.

## OCULOPHARYNGEAL MUSCULAR DYSTROPHY

Oculopharyngeal MD (OPMD) is an adult-onset, autosomal-dominant disorder, manifesting after 50 years of age, that maps to chromosome 14q11.2 and is caused by a small trinucleotide GCG repeat expansion. See online chapter.

## CONGENITAL MUSCULAR DYSTROPHIES

The CMDs are a diverse group of genetically based disorders characterized by early onset of progressive hypotonia, weakness, and a variable degree of muscle contractures. There may be associated dysmorphic or dysmyelinating brain abnormalities and structural eye abnormalities. Signs and symptoms are typically evident in the neonatal period, but may present within the first year of life, before ambulation is achieved. Serum creatine kinase levels are usually elevated. Muscle biopsy abnormalities typically show features of a dystrophic process, with variation in muscle fiber size, degenerating and regenerating fibers, and an increase in endomysial and perimysial connective tissue (refer to Chapter 135). Milder myopathic changes can also be seen initially. Biopsies are also useful to exclude congenital structural or metabolic myopathies. Biopsies from suspected CMD patients should be analyzed in specialized muscle histopathology laboratories that can perform the detailed immunohistochemical staining and interpretation necessary to identify features of dystroglycanopathies, merosinopathy, and collagen type VI disorders. The CMDs are autosomal recessive, with the exceptions of de novo dominant mutations in the lamin A/C gene, and the majority of cases of Ullrich CMD.

There is no clear separation of the CMDs from the LGMDs. The latter, in a general sense, have onset after ambulation has been achieved and after 24 months of age. Different mutations within genes causing CMD can also cause LGMD (i.e., allelic heterogeneity). Additional mutations and range of related phenotypes are likely to be discovered that will blur the boundary between the CMDs and the LGMDs.

The CMDs are rare disorders, having an estimated overall prevalence of approximately 0.8 to  $5.46 \times 10^{-5}$  (refer to Table 137-2 in Chapter 137).

The CMD syndromes have been classified in several ways. An earlier classification of CMDs into two groups of "merosin-negative" and "merosin-positive" is no longer used as the latter group has been better characterized by the identification

of several genes that comprise this clinical cluster. CMDs can be considered as those with dysmorphic brain and eye changes (“syndromic”) and those with a pure muscle phenotype (“nonsyndromic”). Current classification schema combine clinical features and cellular localization of the gene product into five categories, discussed in more detail below and summarized in Table 147-1:

1. Dystroglycanopathies: 15 glycosyltransferase genes that affect glycosylation of  $\alpha$ -dystroglycan, and *DAG1*
2. Basil lamina disorders: 4 genes—laminin  $\alpha_2$  (merosinopathy), integrins  $\alpha_7$  and  $\alpha_9$ , and also incorporating the dystroglycanopathies
3. Extracellular matrix (collagenopathies): 3 collagen type VI genes
4. Nuclear envelope proteins: 2 genes—lamin A/C (*LMNA*) and nesprin
5. Endoplasmic reticulum: selenoprotein 1 (*SEPN1*)

### Abnormalities of $\alpha$ -Dystroglycan

The dystroglycan complex, discussed above in the LGMD section, structurally links the intracellular dystrophin-cytoskeleton complex to the extracellular matrix (Figure 147-2). Here the discussion will focus on  $\alpha$ -dystroglycan (ADG) and its role in CMD. CMD patients with mutations in the dystroglycan gene (*DAG1*) are extremely rare, as it is believed that most of these mutations result in an embryologic lethal condition. The vast majority of ADG-related CMDs are caused by mutations in glycosyltransferase genes responsible for the glycosylation of ADG and are termed *dystroglycanopathies*. Fifteen such genes have been identified to date (Table 147-1).

### Clinical Presentations of the Dystroglycanopathies

Current classification in OMIM divides the dystroglycanopathies into three syndromic categories:

1. Muscle-eye-brain phenotypes. This includes WWS, muscle-eye-brain (MEB) disease, and Fukuyama CMD. Brain abnormalities involve migrational disorders of the cortex (lissencephaly, polymicrogyria, pachygyria), gross structural defects (absence of the corpus callosum, or vermis of the cerebellum, ventriculomegaly without hydrocephalus), and posterior fossa defects (cerebellar cysts, cerebellar and brainstem hypoplasia). Eye abnormalities range from microphthalmia, retinal degeneration, cataracts, glaucoma, and anterior chamber malformation to mild myopia.
2. CMD with posterior fossa abnormalities but having normal supratentorial structures. These CMD patients may have intellectual disability.
3. LGMD and CMD phenotypes with normal brain MRI.

Unlike several of the other CMDs and LGMDs, the responsible gene cannot be inferred from the phenotype as many of these glycosyltransferase genes can present with a similar phenotype. Conversely, some of these genes can present with a broad range of phenotypes; for example, *FKRP* can cause CMD with a severe WWS phenotype or a milder LGMD type 2I.

### Muscle Biopsy Features

See online chapter.

### Fukuyama Congenital Muscular Dystrophy

Fukuyama CMD is the second most common form of muscular dystrophy in Japan, where the carrier frequency is estimated at 1 in 90. The disease is uncommon outside of Japan. Fukuyama CMD is caused by mutations in the *FKTN* gene coding

for fukutin, a protein localized to the basement membrane of muscle. Fukutin deficiency is associated with decreased immunostaining for  $\alpha$ -dystroglycan and merosin, with preservation of the dystrophin-related complex.

Hypotonia and generalized muscle weakness are usually present before 9 months of age, and 50% of affected infants manifest a poor suck and weak cry. Facial weakness and a tented upper lip are frequent findings. Calf hypertrophy is often present. Gross motor milestones are severely delayed. Affected children often achieve independent sitting, but never gain independent ambulation. Contractures are not marked at birth, but develop by 1 year of age and involve the hips, knees, ankles, and elbows.

Mental retardation is often severe. Seizures occur in approximately 40% of affected children. Ocular abnormalities are common but not universal, and include myopia, cataracts, optic disc pallor, and retinal detachment.

Creatine kinase levels are increased. Electrophysiologic studies reveal myopathic potentials on electromyography; nerve conduction velocities are normal. Brain imaging studies and postmortem studies reveal brain malformations, including polymicrogyria, pachygyria, and agyria of the cerebrum and cerebellum (type II cobblestone lissencephaly), with a lack of normal lamination of the cerebral cortex.

### MDC1C (Fukutin-Related Protein Deficiency)

MDC1C is allelic to LGMD2I, discussed above, caused by mutations in the *FKRP* gene coding for fukutin-related protein. Symptoms usually manifest at birth or in the first few weeks of life, with hypotonia and leg muscle hypertrophy. Creatine kinase values are greatly increased (1000 to 10,000 IU/L). Children follow a regressive course that may include cardiomyopathy. Routine histochemical analysis of muscle biopsy specimens does not differentiate these patients from children with merosin-negative CMD, but immunohistochemical staining reveals partial merosin deficiency and severely reduced glycosylated  $\alpha$ -dystroglycan.

### Muscle-Eye-Brain Disease

The first description of patients with the muscle-eye-brain phenotype were from Finland but the syndrome has now been seen worldwide. Initial reports suggested that *POMGNT1* was the gene causing muscle-eye-brain disease. It is now evident that this phenotype may be the result of mutations in other genes along the  $\alpha$ -dystroglycan O-mannosyl-glycosylation pathway (Table 147-1). The clinical phenotype may be severe, dominated by neonatal hypotonia, profound developmental delay with psychomotor retardation, and ocular abnormalities. Affected children may attain independent ambulation by age 4 years. Visual failure is in the form of severe myopia, followed by retinal degeneration, glaucoma, and cataracts. Seizures are common. Central nervous system dysgenesis includes lissencephaly type II (cobblestone complex), frontal pachygyria, cerebellar hypoplasia, and occipital micropolygyria. There is severe disorganization of the cerebral and cerebellar cortices. The associated myopathy may be overshadowed by central nervous system and ocular abnormalities. Creatine kinase levels are increased, especially after the first year of life, and electromyography studies show myopathic abnormalities.

### Walker-Warburg Syndrome

WWS has no ethnic predominance. The clinical stigmata are dominated by the most severe brain malformations seen in any CMD syndrome, including lissencephaly type II, hydrocephalus, occipital encephalocele, fusion of the cerebral

hemispheres, absence of the corpus callosum, and hypoplasia of the cerebellum and brainstem. Ocular findings have included congenital cataracts, microphthalmia, buphthalmus, and Peter's anomaly. At birth, affected children are blind, markedly hypotonic, and poor feeders. Myopathy is manifest by mild elevations of the creatine kinase level and variable abnormalities on muscle biopsy. All affected infants manifest profound psychomotor retardation, and the median length of survival is only 4 months. Epilepsy is a common comorbidity. It is now felt that WWS and muscle-eye-brain disease represent a clinical spectrum secondary to multiple mutations in multiple genes rather than distinct diseases.

### MDC1D: LARGE

Ⓢ CMD caused by *LARGE1* gene mutations (MDC1D) is a very rare disorder and is discussed in the online chapter.

### Congenital Muscular Dystrophy With Integrin $\alpha_7$ Deficiency

Ⓢ Integrins are transmembrane heterodimeric ( $\alpha/\beta$ ) receptors crucial in establishing linkages between the extracellular matrix and muscle cytoskeleton. Deficiency of integrin  $\alpha_7$  is a very rare disorder and is discussed in the online chapter.

## Abnormalities of Extracellular Matrix Proteins

### MDC1A: Laminin- $\alpha_2$ (Merosin)-Negative Congenital Muscular Dystrophy ("Nonsyndromic Congenital Muscular Dystrophy")

**Genetics.** The *LMNA* gene encodes the extracellular matrix protein laminin  $\alpha_2$  (merosin). Laminin  $\alpha_2$ -negative CMD (MDC1A) is the most commonly diagnosed of the CMD disorders and accounts for about one-quarter of cases of nonsyndromic autosomal-recessive CMDs.

**Clinical Features.** Patients with complete absence of merosin present as neonates with significant hypotonia and generalized trunk and limb weakness, and may have multiple joint contractures. The upper limbs are often more affected than the lower limbs, which may exhibit muscle hypertrophy. Feeding and respiratory function is usually preserved initially. Small, slow gains in motor function are expected over the first year or two, with maximal milestones usually no better than independent sitting, and occasionally standing with support, but independent ambulation would be exceptional. Flexion contractures develop initially and are followed by a progressive rigid kyphoscoliosis that often necessitates surgical correction. Feeding tubes and noninvasive ventilation support are often needed because of development of dysphagia with aspiration and respiratory insufficiency, respectively. Most patients exhibit normal brain structure, although cystic lesions have been described, and cognitive development is generally preserved. Epilepsy occurs in approximately 30% of patients.

**Diagnosis.** Serum creatine kinase levels are usually elevated in the neonatal period in excess of 1000 U/L but tend to decrease over years.

Characteristic changes are seen in brain MRI scans of merosin-negative CMD patients. These findings may not be evident at birth but invariably become evident by age 6 months. White-matter hyperintensity is most prominent on T2-weighted images and principally involve the centrum semiovale, while sparing other myelinated structures in the corpus callosum, internal capsule, cerebellum, and brainstem. These MRI scans are often misinterpreted as a leukodystrophy. Focal cortical dysplasia of the occipital lobes occurs in some

cases with concurrent intellectual impairment, but the extensive neuronal migration abnormalities characteristic of patients with syndromic CMD are not seen.

Electrodiagnostic studies yield nonspecific myopathic findings on electromyography. Nerve conduction studies reveal slowing of conduction velocity.

Muscle biopsy demonstrates changes consistent with a dystrophic process. Absence of immunohistochemical staining for the laminin  $\alpha_2$  chain on frozen muscle biopsy or skin biopsy tissue provides confirmation of the diagnosis of merosin deficiency. Genetic testing is necessary to confirm the diagnosis.

Partial merosin deficiency has been reported in patients with a less severe childhood-onset or young adult-onset LGMD phenotype. See online chapter. Ⓢ

### Merosin-Positive, Nonsyndromic Congenital Muscular Dystrophies

This category is no longer used.

### Ullrich Congenital Muscular Dystrophy and Bethlem Myopathy

They are allelic disorders caused by mutations in any of three collagen 6 genes (*COL6A1*, *COL6A2*, and *COL6A3*). Ullrich CMD and Bethlem myopathy are discussed above in the LGMD section.

### Congenital Muscular Dystrophy With Early Rigid Spine Syndrome

Ⓢ Rigid spine syndrome (RSS) is characterized by contractures of the paraspinal muscles, which limit spine flexion, especially in the thoracolumbar segments. Onset of RSS in infancy is caused by mutations in the *SEPN1* gene. Rigid spine can be seen in other muscle disorders, including EDMD and Ullrich CMD. Infants with *SEPN1*-related CMD present initially with mild hypotonia and weakness, followed by development of rigid spine and joint contractures, especially the Achilles tendons (Figure 147-13). Despite the spine rigidity, scoliosis typically evolves and may need surgical correction. A thin body habitus with generalized decrease in muscle bulk is typical. Motor milestones are delayed but most children with *SEPN1*-related CMD eventually achieve and maintain independent ambulation. Restrictive lung disease evolves later in the course and cardiac involvement has not been described.

**Diagnosis.** Classic features of *SEPN1*-CMD can lead the clinician directly to request genetic testing for mutations in the *SEPN1* gene. The creatine kinase level is typically normal and the muscle biopsy can have subtle dystrophic features or have multiminicores, fiber-type disproportion, or myofibrillar changes with Mallory body-like inclusions. These findings may erroneously focus attention on other congenital myopathies.

**Treatment.** Management of *SEPN1*-CMD is supportive.

## Lamin A/C-Associated Congenital Muscular Dystrophy

The broad spectrum of neuromuscular and nonneuromuscular disorders caused by mutations in the lamin A/C gene (*LMNA*) has been outlined earlier in the section describing Emery-Dreifuss MD. A CMD phenotype has also been identified with de novo mutations of the *LMNA* gene. See online chapter for further discussion. Ⓢ

## Nesprin-Associated Congenital Muscular Dystrophy

 This entity is discussed in the online chapter.

### Approach to the Patient With an LGMD, FSHD, EDMD, and CMD

#### Clinical Assessment

The following clinical features should be considered when evaluating the patient with a suspected MD: age at symptom onset, distribution and extent of weakness, contractures, rigid spine, muscle atrophy or hypertrophy, microcephaly, eye abnormalities, and seizures. Feeding, respiratory, and cardiac status also should be evaluated. It is important to obtain a careful family history.

#### Diagnostic Studies

Diagnostic testing to consider includes creatine kinase level, electromyography, and nerve conduction studies; muscle biopsy, MR brain, and muscle imaging; and ophthalmology evaluation. The algorithms presented here and in Chapter 137 (Figure 137-1) can then be used to help focus on a small number of diagnoses and guide confirmatory genetic testing.

#### Treatment

 Management of these patients is supportive and discussed in more detail in the online chapter. Chapters 152 and 160 provide additional information on these issues.

As the molecular genetic basis and related cellular pathophysiology of these disorders become better understood, targeted treatment strategies are likely to be developed. The age of precision medicine for the MDs as with other childhood neurologic disorders is now emerging and offers some hope to these patients.

#### Acknowledgments

Drs. Diana M. Escolar and Robert T. Leshner contributed the chapter on muscular dystrophies to the prior edition of this textbook. We thank them for use of portions of their chapter and some figures that have been retained here.

# 148 Congenital Myopathies

Jahannaz Dastgir, Hernan D. Gonorazky, Jonathan B. Strober, Nicolas Chrestian, and James J. Dowling

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Congenital myopathies are a clinically and genetically heterogeneous group of neuromuscular diseases. The most common clinical presentation is in the neonatal period as the floppy infant. However, congenital myopathies can present at essentially all life stages, making them an important diagnostic consideration in all individuals with muscle weakness. The prevalence of congenital myopathies is incompletely defined. The most accurate pediatric estimate (from a North American study) is approximately 1:26,000, though this is likely a significant underestimation given the increasing recognition of the condition and the delineation of an expanded range of clinical phenotypes considered under the congenital myopathy umbrella (North et al., 2014).

Historically, congenital myopathies have been diagnosed and defined based on features observed on muscle biopsy. The first congenital myopathy described, central core disease (CCD), was by Shy and Magee in 1956. The most common histopathologic subtypes are nemaline myopathy (NM), centronuclear myopathy (CNM), core myopathy, and congenital fiber-type disproportion (CFTD). With significant improvements in the cost, availability, and diagnostic accuracy of genetic testing, a gene-based definition of congenital myopathies has recently taken shape. At present, the most accurate and parsimonious categorization for congenital myopathies incorporates clinical features, muscle biopsy findings, and genetic information.

All congenital myopathies, with very rare exceptions, are assumed to have a genetic underpinning. To date, mutations in 20+ genes have been identified as causes of congenital myopathies (Table 148-1). These genes explain disease in approximately two thirds of all cases; in other words, about one third of the genetic burden of disease remains to be solved (Colombo et al., 2015). Inheritance can be autosomal dominant, autosomal recessive, and X-linked. Although a positive family history is often elicited, many cases are sporadic, and dominant mutations in particular often present (because of the severity of symptoms) as de novo.

At present, no therapies have been defined for congenital myopathies that have been tested in controlled clinical trials (Wang et al., 2012). Therefore management has largely been symptomatic, with a strong focus on respiratory management, surgical correction of orthopedic complications, and application of physical and occupational therapy services to maximize motor function. For a select few congenital myopathies, cardiac management is also necessary. A handful of drugs, all of which seem to provide modest clinical benefit at best, have hinted at efficacy based on case-controlled studies. In addition, several candidate therapeutics have been developed in preclinical studies and are now on the cusp of assessment in the clinical arena. Efforts to evaluate these drug targets will hopefully usher in a new era of therapy for a group of previously untreatable and devastating diseases.

## DIAGNOSTICS

In general, congenital myopathies are considered in the setting of low muscle tone, depressed or absent reflexes, and extremity

muscle weakness, often of a long-standing nature, that exhibits limited active progression. Facial weakness is often a key additional clue (Fig. 148-1). Ultimately, the diagnosis of congenital myopathy, regardless of clinical presentation, is established through a compatible muscle biopsy result and/or through positive genetic testing. The diagnostic strategy for assessing patients with neonatal hypotonia in whom congenital myopathy is suspected follows logically from the differential diagnoses (spinal muscular atrophy (SMA) DM1, congenital myasthenic syndromes, congenital muscular dystrophies, and Prader-Willi syndrome). Studies should include serum CPK levels (typically normal to maximum two to three times elevated in congenital myopathies), chromosomal microarray, genetic testing for SMA and congenital DM1, and (where available) electromyography and nerve conduction studies (EMG/NCS) (with repetitive stimulation) to evaluate for congenital myasthenic syndrome. Muscle magnetic resonance imaging (MRI) can also provide useful data in many cases. As mentioned, the diagnosis of congenital myopathy is only truly established through a consistent muscle biopsy and/or via positive genetic testing (see below under muscle biopsy and genetics sections). Similar strategies for diagnosis should be considered in the older child, keeping in mind that there will be a shift in consideration of potential alternative diagnoses based on age. A diagnostic algorithm that highlights some discriminative clinical and biopsy features is presented in Figure 148-2.

## DIAGNOSTIC TESTING FOR CONGENITAL MYOPATHIES

### Muscle Biopsy

The muscle biopsy has long been the definitive diagnostic study for congenital myopathies. In fact, congenital myopathies are defined and named by the characteristic observations seen by muscle pathology analysis. Each subtype of congenital myopathy is defined as follows (Dowling et al., 2015):

*Centronuclear myopathy* (Jungbluth et al., 2008): The basic definition of CNM is the presence of centrally located nuclei in >25% of the muscle fibers. This number can be quite variable, and truly there is no specific threshold for establishing CNM. Central nuclei are best seen with hematoxylin/eosin (H/E) staining (Fig. 148-3, A), though can also be appreciated with Gomori trichrome. The diagnosis of CNM is thus usually established not only by the presence of central nuclei but also by other histopathologic features. These features include myofiber hypotrophy, type I fiber predominance, and central accumulation of staining product with oxidative stains.

*Nemaline myopathy*: NMs are defined on biopsy by the presence of nemaline rods or nemaline bodies. Rods are composed primarily of proliferations of Z-band lattices. By light microscopy, rods are best visualized on Gomori trichrome staining, where they appear as eosinophilic aggregates (Fig. 148-3, B). The signature rod-like appearance from which the disorder derives its name is best appreciated by electron microscopy. In most cases, light microscopy is sufficient for

Could present rigid spine syndrome, and severe arthrogryposis.

**TABLE 148-1** Classification of Congenital Myopathies by Genes (Continued)

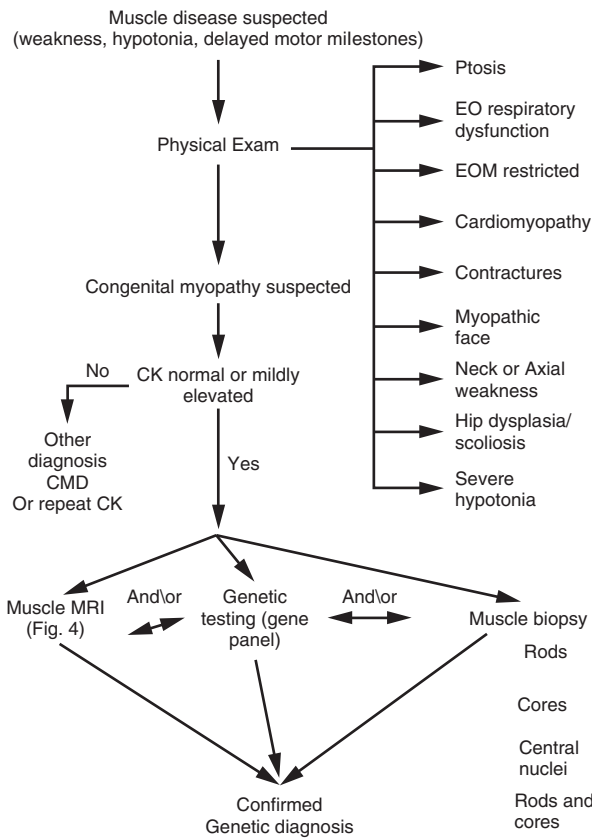

Gene	Subtype	Inheritance Pattern	Protein	Features
<i>STAC3</i>	• Native American myopathy	AR	SH3 and cysteine rich domain containing protein 3	Lumbee Indians in North Carolina. Congenital onset, dysmorphic features (telecanthus, cleft palate, downslating palpebral fissures, low ear set, ptosis), short stature, arthrogryposis proximal weakness, MHS.
<i>SEPN1</i>	• Multiminicore myopathy • Congenital fiber-type disproportion	AR AR	Selenoprotein N1	Onset birth to childhood. Predominant axial muscle involvement, poor head control, rigid spine, scoliosis at the age of 10 years, nocturnal hypoventilation central apnea during paradoxical sleep.
<i>CCDC78</i>	• Centronuclear myopathy	AD	Coiled coil domain containing protein 78	Congenital onset, distal involvement with slow progression, excessive fatigue mild to moderate cognitive impairment.
<i>BIN 1</i>	• Centronuclear myopathy	AR, AD	Amphiphysin	Variable onset. Severe forms present at birth or childhood. Proximal and lower facial weakness with marked bulbar involvement, ophthalmoparesis and ptosis, could present cardiomyopathy (dilated)
<i>DNM2</i>	• Centronuclear myopathy	AD	Dynamamin 2	Variable onset. Distal muscle weakness, exercise induce myalgias, ophthalmoparesis, ptosis, lower facial weakness and marked bulbar involvement, slow progression hypertrophy of paravertebral muscles absent or reduce tendon reflexes, distal limb, contractures, scoliosis cardiomyopathy.
<i>MTM1</i>	• Myotubular myopathy	XR	Myotubularin 1	Onset; prenatal. Polyhydramnios, macrosomia, proximal and distal weakness with severe respiratory involvement at birth, lower facial weakness with marked bulbar involvement, usually early death, other features, bleeding diathesis, liver and gastrointestinal complications.
<i>SPEG</i>	• Centronuclear myopathy with dilated cardiomyopathy	AR	SPEG complex locus	Onset at birth, proximal weakness with lower face and bulbar involvement, ophthalmoplegia, hip contractures cardiomyopathy.
<i>PTPLA</i> (= <i>HCD1</i> )	• Congenital myopathy related to PTPLA	AR	Protein tyrosine phosphatase-like (3-hydroxyacyl CoA dehydratase)	Onset birth. Lower facial and proximal weakness. Absent or reduce deep tendon reflexes. Severe presentation at onset with progressive improvement.
<i>TTN</i>	• Centronuclear myopathy • Congenital myopathy with fatal cardiomyopathy	AR AR	Titin	Onset, birth or infancy. Proximal and distal weakness with facial involvement. Could present asymmetric ptosis. Some with scapula-peroneal syndrome. Pseudohypertrophy of thighs and calves. Ambulation could be achieved in most of the cases. Scoliosis and absent reflexes. Cardiomyopathy (dilated)
<i>MYH7</i>	• Myosin storage myopathy • Myosin storage myopathy with cardiomyopathy • Congenital fiber-type disproportion	AD AR AD	Myosin, heavy chain 7, cardiac muscle	Onset at infancy or early childhood, distal weakness predominant, and weak toe extensor (hanging big toe), scapular winging, mild facial involvement, cardiomyopathy (dilated or hypertrophic)
<i>MYH2</i>	• Myosin IIa myopathy	AD, AR	Myosin, heavy chain 2, skeletal muscle	Onset at birth, contractures, ophthalmoplegia, ptosis, mild to moderate proximal weakness
<i>MEGF10</i>	• Early onset myopathy, areflexia respiratory distress and dysphagia • Minicores	AR AR	Multiple EGF-like domains 10	Prenatal onset with reduced fetal movements. Proximal and distal weakness, distal contractures, scoliosis, areflexia, bulbar involvement, respiratory distress.

AD, autosomal dominant; AR, autosomal recessive; XR, X linked.

(Adapted from Kaplan JC, et al. The 2015 version of the gene table of monogenic neuromuscular disorder. *Neuromuscul Disord* 2014;24:1123–53.)

**Figure 148-1. The “myopathic” facies.** One of the characteristic clinical observations in many children with congenital myopathies is the so-called “myopathic” facial appearance. This can include both upper and lower facial weakness, as illustrated in these photomicrographs. *Left panel:* The patient depicted demonstrates ptosis, ocular misalignment caused by ophthalmoparesis, an inverted C-shape to her upper lip, and prominent lower facial weakness resulting in an open mouth appearance. The ultimate diagnosis in this case was nemaline myopathy caused by recessive mutation in the *LMOD3* gene. Patients with nemaline myopathy often have particularly striking lower facial weakness. *Middle panel:* This individual has ptosis, ophthalmoparesis, and moderate lower facial weakness. He has *DNM2*-related centronuclear myopathy. Note also the muscle atrophy present in his chest and shoulders. *Right panel:* Photograph of a young boy with myotubular myopathy caused by *MTM1* mutation. He has the characteristic long face with bilateral ptosis and ophthalmoparesis.

establishing the diagnosis; however, there are instances where the rods are either poorly appreciated or else not seen at the light level and only revealed through electron microscopic analysis. In addition, there are histopathologic variants that are included within the nemaline umbrella. These include cap myopathy (where there is an accumulation of myofibrillar material sitting as a cap at the periphery of the myofiber) and zebra body myopathy (Dowling et al., 2015).

**Core myopathy (Jungbluth, 2007a,b):** Core myopathies are typically subdivided into CCD and multimincore myopathy. Cores are best appreciated on light microscopy with oxidative stains such as SDH and NADH (Fig. 148-3, C). They are defined as areas devoid of reactivity for these enzymes and reflect areas in the myofibers that lack mitochondria. Central cores are longitudinal and often traverse the entire length of the myofiber. Mincores are typically transverse in location and usually small. Core myopathies are often also seen in the context of type I fiber predominance and type I fiber hypotrophy, both features best seen with ATPase staining. Electron microscopy is often required for evaluation of core myopathies. This is because there are other conditions that can result in absence or change of SDH/NADH staining. Most prominent among them is the targetoid staining pattern seen with neurogenic lesions. On EM, cores appear as areas of myofibril disorganization that lack mitochondria. At times there will be a ring of mitochondria around the area of disorganization (referred to as a structured core).

**Congenital fiber-type disproportion:** CFTD is defined by two biopsy features. The first is relative hypotrophy of type I fibers compared with type II fibers. The second is numerical predominance of type I fibers over type II fibers. The general criterion for calling CFTD is a 25% reduction in type I fiber size. Such a reduction is relatively nonspecific and can be seen in a range of disease, many of which are not primary myopathies. "True" CFTD, or CFTD caused by mutations in congenital myopathy genes, is usually characterized by much more significant reduction in type I fiber size (to <50% that of type IIs) and clear type I predominance (often >75% of fibers). CFTD can be seen by H/E staining, but is best diagnosed and evaluated using stains for fiber type (Fig. 148-3, D). These include enzymatic reactions (ATPase at acid pH [4.3 to 4.6] to stain type I fibers and at basic pH [9.4 to 10.2] to mark type II fibers) or immunostaining with myosin antibodies (slow myosin for type I and fast myosin for type II).

## Genetics

All pediatric-onset (and most adult-onset) congenital myopathies are considered to have a genetic underpinning. It is important to establish a genetic diagnosis, even when a child has a consistent muscle biopsy, because knowledge of the specific genetic subtype greatly contributes to understanding of specific clinical features, anticipatory care requirements, and prognostication (Wang et al., 2012; North et al., 2014). Mutations in congenital myopathies span the range of inheritance patterns (X-linked, autosomal recessive, autosomal dominant) and often are caused by sporadic/de novo variants. To date, mutations in 20 genes have been identified as causal in patients with congenital myopathy (see Table 148-1). The interplay between clinical presentation, biopsy diagnosis, and genetic subtype is complex. In particular, there are several genetic causes for each histopathologic grouping (e.g., mutations in 10 genes are associated with NM), and each genetic cause can result in a variety of clinical presentations and histopathologic diagnoses (e.g., *RYR1* mutations have been described in every histopathologic subtype) (North et al., 2014). Of note, it is critically important that genetic counseling be offered to all patients with congenital myopathies and to their families,

ideally starting at the time that genetic testing is first considered (Wang et al., 2012).

## Muscle Imaging (MRI or Ultrasonography)

Muscle imaging is an emerging modality for the diagnosis and care of patients with a range of neuromuscular disorders. For congenital myopathies it is used primarily as an adjunct diagnostic tool, though in the future may aid in assessment of disease status and progression. Muscle ultrasonography is the fastest and least expensive technique and offers the potential of application in the outpatient clinic and/or inpatient setting, though requires an experienced user for interpretation. Muscle MRI is widely available and does not require any particular advanced training to obtain or analyze; the downside is expense and the fact that some children (particularly those under age 5 years) may require sedation. The diagnostic value of muscle imaging lies in the fact that different genetic subtypes of myopathy present with different imaging patterns of muscle involvement. The pathognomonic patterns are best characterized with lower extremity imaging, though the value of whole-body MRI for diagnosis (particularly in the young child) is increasingly being recognized. Representative examples of muscle MRI and a diagnostic flow chart describing its application are presented in Figure 148-4.

## SPECIFIC SUBTYPES OF CONGENITAL MYOPATHY

### Centronuclear Myopathies

Centronuclear myopathies, even though clinically heterogeneous (particularly in terms of symptom onset and severity), often feature prominent eye muscle weakness (ptosis and ophthalmoparesis) in addition to lower facial and extremity weakness (Jungbluth et al., 2008). In infancy and childhood, these features can appear like those seen in congenital myasthenic syndromes. The extremity weakness may have significant distal involvement, including distal predominance in some individuals.

There are six established genetic causes of CNM. Mutations in myotubularin (*MTM1*) are associated with the distinctive, severe, neonatal-onset X-linked condition myotubular myopathy (XLMTM or MTM) (Das et al., 1993). Mutations in dynamin-2 (*DNM2*) are the most common cause of dominant CNM; patients typically present either in the first year or two of life (with de novo mutations) or in late childhood. Recessive causes of CNM include mutations in *RYR1*, *BIN1*, *TTN*, and *SPEG*. *RYR1* mutations are the most common and can present in infancy in a manner resembling MTM. *BIN1* mutations typically cause childhood-onset CNM, though one particular homozygous splice mutation results in a rare, rapidly progressive form. There is also a late-onset CNM in some families with dominant *BIN1* mutations. *SPEG* mutations cause a rare, severe form of CNM that also includes cardiomyopathy.

There are currently no therapies that have been proven to be efficacious for CNM. There is mounting evidence, however, including several case reports and compelling preclinical data, that acetylcholinesterase inhibitors such as pyridostigmine provide modest but definitive improvement in clinical symptomatology. Patients with mutations in *RYR1*, *DNM2*, and *MTM1* have all been reported in these case series. In terms of experimental therapies, there is considerable excitement concerning both gene therapy and enzyme replacement therapy for MTM. These strategies have shown robust disease correction in the MTM mouse model, and gene therapy

additionally has been effective in a spontaneous dog model of the disease.

## Nemaline Myopathies

NMs are characterized in general by the presence of significant bulbar dysfunction (because of lower face and neck flexor weakness) in the setting of additional and variable extremity weakness (North et al., 2014). The disease is noted to have significant clinical variability and has thus been classically subdivided into groups based on age of onset and clinical severity: (1) severe congenital NM (16% of NM cases), (2) intermediate congenital NM (20%), (3) typical congenital NM (46%), (4) childhood-/juvenile-onset NM (13%), and (5) adult-onset NM (4%) (North and Ryan, 1993). There is considerable overlap between the groups, though the distinctions can be helpful (e.g., individuals with severe congenital NM have a high risk of death in infancy, whereas those with typical congenital NM tend to show stabilization and even improvement).

There are 10 known genetic causes of NM. Mutations in *ACTA1* are the most common dominant/de novo cause (25% of all NM), whereas those in nebulin (*NEB*) are the most common autosomal-recessive cause (~50% of all NM). Mutations in *ACTA1* are associated with a tremendous variability in age of presentation and clinical expression, not only between different mutations in the gene but also among family members with the same mutation. They are the most common cause of severe congenital NM (severe weakness, reduced or absent fetal/neonatal movements, respiratory failure, and often death in infancy). Mutations in *NEB* are most frequently encountered with typical congenital NM (neonatal hypotonia, weakness, feeding difficulties, ability to eventually ambulate, static/slowly progressive course).

The specific breakdown in terms of relative prevalence of the other genetic subtypes is otherwise not well established. Some are associated primarily with specific clinical groupings. *LMOD3* and *KLHL40* mutations are seen almost exclusively with severe congenital NM. Dominant mutations in *TPM2* and *TPM3* are associated with symptoms ranging from typical congenital to mild childhood (with *TPM2* mutations usually milder), whereas rare recessive mutations in *TPM3* are associated with severe disease. *TPM2* mutations can additionally been seen in the absence of overt weakness with distal arthrogryposis syndromes. Dominant mutations in *KBTBD13* are seen with childhood-onset NM and characteristic slowness of movements. Recessive mutations in *TNNT1* (Amish NM) and *CFL2* (severe or typical congenital) are extremely rarely encountered. Of note, ophthalmoparesis is infrequently observed in NM (with the exception of *LMOD3* mutations), and may serve as a means of distinguishing NM from other congenital myopathies.

At present, there are no specific therapies that have proven efficacious for NM. L-tyrosine has been examined in a mouse model of *Acta1* and shown to increase muscle strength; a limited patient case series examining L-tyrosine found that it improves some bulbar symptoms and specifically sialorrhea. Its impact on disease course is likely limited, and true efficacy awaits more systematic clinical study. There are no other therapies currently in the clinical pipeline, though a few are at the stage of preclinical assessment.

## Core Myopathies

Core myopathies can be subdivided into CCD and multiminicore disease (MmD). CCD is caused by *RYR1* mutations (usually dominant/de novo) in approximately 90% of cases (Jungbluth, 2007a). The other well-described cause

is dominant *MYH7* mutation. Minicore disease, along with the more general categorization of myopathy with cores, has several genetic causes (Jungbluth, 2007b). Most classically, it is caused by mutations in either *SEPN1* (MmD without ophthalmoparesis) or *RYR1* (MmD with ophthalmoparesis). Other genetic causes include *ACTA1*, *TTN*, *MEGF10*, and *CCDC78*; biopsies in these settings typically include additional histopathologic abnormalities (such as rods or protein aggregates). In addition, there can be both cores and rods in the same biopsy (termed “core-rod” myopathy), with known causes, including *TPM2*, *NEB*, *RYR1*, *ACTA1*, and *KBTBD13*.

## *RYR1*-Related Myopathies

Myopathies caused by mutations in the skeletal muscle ryanodine receptor (*RYR1*) are the commonest group of nondystrophic muscle conditions. These are also termed “*RYR1*-related myopathies,” and encompass a broad clinical spectrum that spans the entire gamut of histopathologic subtypes. *RYR1*-related myopathies are subdivided primarily either by mode of inheritance (recessive vs. dominant/de novo) or by histopathology (CCD, MmD, CNM, etc.), though there are distinctive clinical conditions that do not classically fall into a specific grouping (e.g., axial myopathy, malignant hyperthermia, exertional rhabdomyolysis, isolated ophthalmoparesis).

CCD associated with *RYR1* mutation is almost entirely caused by dominant mutations (Jungbluth, 2007a). The typical pediatric presentation for CCD is one of neonatal hypotonia, muscle hypotrophy, and extremity muscle weakness, often accompanied by significant skeletal abnormalities such as chest wall deformities, scoliosis, joint contractures, and hip dysplasia. Respiratory failure is present in some instances, though rarely requires tracheostomy and often improves. The course of disease is typically quite stable, and, although delayed, individuals often acquire all motor developmental milestones. Of note, there may be some mild facial muscle involvement, including ptosis and lower facial weakness, but ophthalmoparesis is rarely encountered. There is also a milder CCD presentation that includes minimal weakness that may only be recognized in adulthood; there are also several cases of dominant mutations causing late-onset axial myopathy. Rarely, heterozygous de novo mutations can present with extreme weakness in the perinatal period that results in death in infancy. The mutations in *RYR1* that cause CCD are enriched in the C-terminal aspect of the gene. Some are additionally associated with malignant hyperthermia susceptibility (MHS), a pharmacogenetic condition of hypermetabolism and muscle breakdown in response to exposure to volatile anesthetics.

The other histopathologic subtypes (MmD, CNM, core-rod myopathy, and CFTD) are most commonly seen with recessive *RYR1* mutations. The most frequently encountered recessive subtype is minicore disease, which typically presents with diffuse weakness in combination with ophthalmoparesis. Onset is usually in the neonatal period or in early childhood, and can be severe enough to result in respiratory failure with chronic ventilator support and wheelchair dependence. As with CCD, skeletal abnormalities (particularly joint contractures and scoliosis) are quite frequently encountered. These are often accompanied by severe facial weakness that can include ophthalmoparesis. Axial muscle involvement can also be quite pronounced.

At present, there are no specific treatments for *RYR1*-related myopathies. Salbutamol has been shown in a small case-control series to improve strength and motor function. This result has not been followed up with additional clinical trials, and the medication is not widely used in *RYR1* patients. An intriguing candidate drug class is the RyCals; RyCals interact with RyR1 and augment its ability to release calcium. RyCals

have yet to be tested for efficacy in patients, and have not been examined in any preclinical models of *RYR1* myopathy. One drug that has shown promising results in animal models and in patient cells is the antioxidant N-acetylcysteine (NAC). NAC is currently being evaluated in a placebo-controlled clinical trial in ambulant *RYR1* myopathy patients. Of note, dantrolene is the standard therapy for treating MH. It has yet to be tested in other dynamic *RYR1*-related phenotypes such as rhabdomyolysis. Because it reduces RyR1 calcium release, it is unlikely to be effective in the majority of instances of *RYR1* mutations that cause static muscle weakness.

### SEPN1-Related Myopathies

Recessive mutations in *SEPN1* were first described in a rare muscular dystrophy subtype called rigid spine muscular dystrophy. However, *SEPN1* mutations are most typically found associated with multimimicore disease; they are also seen with other histopathologic patterns, including CFTD and Mallory Body myopathy. Regardless of histopathologic phenotype, patients with *SEPN1* mutations present a relatively uniform clinical picture. This picture includes early onset hypotonia and axial muscle weakness with relative sparing of the extremity muscles. It also includes spinal rigidity; severe, progressive scoliosis; and potentially lethal, progressive respiratory failure. These severe axial symptoms are not matched by corresponding limb weakness, with the resulting appearance often one of an ambulant patient with ventilator dependence. Patients do not have ophthalmoparesis, a distinguishing feature from *RYR1* mutations.

*SEPN1* encodes selenoprotein N1 (SelN1), a selenocysteine-containing protein located in the endoplasmic reticulum. The functions of SelN1 in relation to muscle structure and function have been relatively elusive, though it seems clear that one of its major roles is to regulate oxidative stress. Based on this, the consequences of *SEPN1* mutations (which in general result in loss of SelN1 expression and/or function) are predicted to be increased basal oxidative stress, susceptibility to the consequences of oxidative species, and ultimately impaired redox related RyR1 function. As with *RYR1* myopathies, the antioxidant NAC protects *SEPN1*-patient-derived myotubes from oxidant-related death, and is now being considered for clinical trial in *SEPN1*-related myopathy patients.

### Congenital Fiber-Type Disproportion

CFTD is a diagnosis applied in the context of clinical symptoms of myopathy and fiber-type disproportion on biopsy (significantly smaller type I fibers, usually type I predominance) (Clarke, 2011). The biopsy observation of CFTD often precedes or is accompanied by other pathologic features (rods, cores, etc.); in such cases, the individual is typically described as having the diagnoses corresponding to the other biopsy features (e.g., NM when rods are present). Some individuals, however, do have “pure” CFTD (usually considered when type I fibers are >40% smaller). When this occurs, the recognized genetic causes are mutations in *TPM3*, *TPM2*, *RYR1*, *SEPN1*, and *ACTA1*. The clinical presentations in these cases are primarily dictated by the underlying genetic cause; for example, patients with CFTD caused by *TPM3* mutations resemble those with similar mutations and NM on biopsy.

## GENERAL MANAGEMENT OF CONGENITAL MYOPATHIES

General management guidelines for congenital myopathies are based on practical experience, expert opinion, and inferences from other similar neuromuscular conditions. These

guidelines are summarized here, and also found in extensive detail in the recently published standards of care for congenital myopathies (Wang et al., 2012).

### Respiratory

Respiratory dysfunction is the likeliest cause of morbidity and mortality in children with congenital myopathies. This relates to the fact that the diaphragm and intercostal muscles are often weakened in these conditions, leading to poor rib excursion, impaired mucus expectoration and airway clearance, and sleep apnea. The recognition of early respiratory compromise (often identified via sleep study or pulmonary function testing in both the seated and supine positions) leads to early intervention via noninvasive ventilation, typically first at night and then during daytime in more severe or progressive cases. Identifying a weak cough in patients is also an important predictor of how a child may respond to an upper respiratory infection. A weak cough can predispose to mucus plugging and bronchiectasis and hence cause risk for fatal pneumonias. This can be prevented with the use of a cough assist device (either while sick or best also when healthy) as a form of pulmonary physical therapy. A thairvest, which employs chest vibration to loosen mucus, may also be used, though it is imperative that this treatment is followed by cough assist regimen. This is so that the mucus that is loosened as a result of this procedure can actually be expectorated and not actually make things worse by being left to plug the airways.

### Nutrition, Gastrointestinal, and Oromotor Management

Nutritional management guidelines for congenital myopathies are essentially nonexistent despite the fact that poor nutrition and growth are inherent to many of these conditions. Weakness in oromotor function is a contributing factor, particularly in nemaline and centronuclear myopathies. Efforts should be made to monitor patient weight and height (either erect or via ulnar length) in conjunction with calorie intake. If calorie intake is limited, or the risk of aspiration pneumonia is high, the placement of a gastrostomy tube should be discussed with families early in the disease course. Improved nutritional status has been related to improved growth and decreased respiratory problems. Yearly assessments of calcium and vitamin D levels should also be made in order to address bone health, as osteopenia is a concern in any individual with long-standing muscle weakness.

Gastrointestinal dysmotility is also a frequent problem in children with congenital myopathies. Dysmotility may present as gastroesophageal reflux, which can be managed with medication (e.g., proton pump inhibitors, H2 blockers, and antacids), nonpharmacologically (e.g., thickening of formula and adjusting feeding positions), and/or surgically (e.g., with Nissen fundoplication). Dysmotility can also present with delayed gastric emptying and constipation, symptoms that can be treated with diet modification, stool softeners/laxatives, and the use of prokinetic drugs (erythromycin or metaclopramide).

Excessive oral secretions are often a significant problem in congenital myopathies. This is related to bulbar and facial weakness and particularly seen in nemaline and CNM. Speech and occupational therapy can be used to address this, primarily through facial muscle-strengthening exercises. If this is not successful, anticholinergic drugs may be administered systemically (e.g., robinul and scopolamine), though they are not without systemic side effects (e.g., constipation). A small study has also found evidence that L-tyrosine supplementation may

be helpful with sialorrhea in NM. Botulinum toxin injections and surgical management are considered in very rare circumstances when secretions are particularly debilitating, though such strategies are controversial.

## Cardiac

The majority of congenital myopathy subtypes are not associated with primary cardiac involvement. Baseline and periodic follow-up cardiac evaluations, however, should be provided to all patients with congenital myopathy until the specific genetic cause has been identified. This is because certain gene mutations, such as those in *TTN*, *MYH7*, *SPEG*, and (more rarely) *ACTA1*, can cause cardiomyopathy. In addition, continued cardiac screening is indicated in settings (*SEPN1*-related myopathy, for example) where secondary right-sided heart failure is of concern because of chronic respiratory compromise.

## Orthopedic

Scoliosis is a pervasive problem in these conditions and should be monitored from the initial presentation of symptoms. This can initially be done via clinical examination (with the patient assessed in forward flexion at the hip), but once any curvature is noted, routine x-rays should be obtained. Once scoliosis has been diagnosed, patients should be referred to orthopedics for the management of the progressive curvature with either a conservative (e.g., bracing/casting) or invasive/surgical approach. The management of scoliosis is essential for maintaining respiratory function.

Joint contractures are a concern for the majority of congenital myopathy patients, and may in fact be the presenting sign of patients in some individuals. Ankle contractures are typically managed with physical therapy, passive stretching, and ankle-foot orthoses, which are used in the ambulant patient to slow contracture progressive and to improve gait, and in the nonambulant patient to aid in comfort and wheelchair positioning. Surgery to release contractures is rarely indicated, as it often does not appreciably improve range of motion and can potentially worsen muscle weakness. Exceptions include contractures that significantly hinder ambulation (in the setting of relatively preserved strength) and those that cause considerable discomfort (in the nonambulant patient).

## Physical Therapy/Exercise

Physical therapy is mainstay of management in children with congenital myopathy. It helps with strengthening and improves range of motion. It should be utilized regularly and in a manner that matches the child's pattern of weakness. Assist devices can complement therapy services, and include gait trainers and stationary bikes.

The impact of exercise on muscle strength and motor function in congenital myopathies has yet to be formally addressed, though there is anecdotal evidence that exercise in children with myopathies is safe and potentially of benefit. Further work is necessary to establish this as a formal recommendation.

## SUMMARY

Congenital myopathies represent a clinically and genetically heterogeneous group of childhood muscle disorders. With

improvements in clinical recognition and genetic testing, it is now clear that these disorders represent a significant portion of childhood genetic neuromuscular disease. The availability of gene panels and whole-exome sequencing has improved diagnostics, has enabled the discovery of new myopathy genes, and has greatly broadened the genotype-phenotype spectrum of these disorders. It has also presented challenges related to disease classification and genetic variants of unknown clinical significance; in addition, the genetic cause in many individuals still remains elusive. Currently there are few, if any, therapies available for these often devastating disorders; however, work using preclinical model systems has identified several promising candidates for translation into the clinical arena. One of the key challenges in the future will be effectively translating these drugs, and factors related to disease natural history and clinical trial readiness are becoming of paramount importance as the field moves forward toward hopefully identifying meaningful therapies.

# 149 Metabolic Myopathies

Ingrid Tein

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## UTILIZATION OF BIOENERGETIC SUBSTRATES IN EXERCISE

Symptoms in muscle energy defects are directly related to a mismatch between the rates of adenosine triphosphate (ATP) utilization (energy demand) relative to the capacity of the muscle metabolic pathways to regenerate ATP (energy supply). This energy supply-demand mismatch impairs energy-dependent processes that power muscle contraction (weakness, exertional fatigue), mediate muscle relaxation (muscle cramping, tightness), and/or maintain membrane ion gradients necessary for normal membrane excitability (fatigue, weakness) and muscle cell integrity (muscle pain, injury, myoglobinuria). In metabolic myopathies, the specific metabolic mediators of premature fatigue, cramping, pain, and muscle injury are complex and vary among the different metabolic disorders. Disorders of glycogen, lipid, or mitochondrial metabolism may cause two main clinical syndromes in muscle: (1) acute, recurrent, reversible muscle dysfunction with exercise intolerance and acute muscle breakdown or myoglobinuria (with or without cramps), for example, mitochondrial disorders, and (2) progressive weakness, for example, fatty acid oxidation (FAO) defects and mitochondrial enzyme deficiencies (Box 149-1). Progressive weakness and recurrent myoglobinuria can also occur together in a given disorder.

Defects of energy metabolism may profoundly disrupt the function of muscle and other highly energy-dependent tissues, such as brain, nerve, heart, kidney, liver, and bowel. The limits of energy utilization in skeletal muscle are set by the adenosine triphosphatases (ATPases) that couple muscle contraction (myosin ATPase) and ion transport (calcium and sodium, potassium ATPases) to the hydrolysis of ATP to adenosine diphosphate (ADP) and inorganic phosphate (Pi). ADP and Pi in turn activate energy-producing reactions that regenerate ATP. Without this, ATP stores would be exhausted in seconds. The substrates that are used to replenish ATP are determined by the intrinsic properties of these fuels and by the intensity and duration of exercise that modulates fuel selection. The creatine kinase (CK) reaction and anaerobic glycogenolysis are the major anaerobic sources of ADP phosphorylation. Increases in ADP and AMP that occur in heavy exercise are primarily buffered by the coupled adenylate kinase (myokinase), adenylate deaminase (myoadenylate deaminase) reactions. Anaerobic glycogenolysis and phosphocreatine hydrolysis support muscle energy production with two- to fourfold higher rates than those supported by oxidative metabolism. Anaerobic energy is crucial for rapid bursts of exercise and to fuel the transition from rest to exercise. The acceleration to high rates of energy production occurs instantly for ATP, in less than a second for phosphocreatine, and within seconds for anaerobic glycogenolysis. In contrast, maximal oxidative power requires from 3 minutes (with glycogen as the oxidative substrate) to 30 minutes (for peak FAO). Anaerobic fuels are rapidly depleted and lead to the accumulation of metabolic end products such as protons and Pi that promote fatigue.

If exercise needs to be sustained for more than a few minutes, then oxidative phosphorylation is necessary and provides the most abundant source of ATP synthesis. Glycogen is the major endogenous oxidative fuel of skeletal muscle, whereas blood glucose and free fatty acids (FFA) are the major exogenous fuels. A small percentage of muscle energy needs are supplied by amino acids, predominantly branched chain amino acids, which are oxidized to a limited extent. Oxidative metabolism provides higher yields of ATP per mole of substrate, rising from 2 to 36 for glucose and from 3 to 37 per glycosyl unit of glycogen metabolized anaerobically versus oxidatively. Furthermore, the metabolic end products of oxidative metabolism, namely, CO<sub>2</sub> and water, are easily removed from working muscle and do not promote fatigue. The most abundant and critical fuel for the support of prolonged, moderate exercise is lipid. Carbohydrate stores in the form of muscle and hepatic glycogen and blood glucose (derived mainly from hepatic glycogenolysis) are limited and can support high-intensity exercise for only 1 to 2 hours. However, carbohydrate, particularly muscle glycogen, is critical for normal oxidative metabolism. Glycogen supports a peak rate of oxidative phosphorylation that is about twofold greater than fat. Though incompletely understood, this may be based upon a requirement for glycogen-derived pyruvate to support optimal function of the tricarboxylic acid cycle. The proportion of carbohydrate relative to lipid oxidation progressively increases as the intensity of the aerobic exercise increases until carbohydrate is the exclusive fuel of maximum oxidative metabolism. Second, glycogen is able to accelerate to maximal oxidative power output rapidly compared with other fuels. Third, the molar ratio of ATP produced to O<sub>2</sub> consumed is higher for glycogen (6.17) and glucose (5.98) than for fatty acids (5.61). The importance of this point lies in the fact that peak O<sub>2</sub> utilization in healthy humans is limited by O<sub>2</sub> delivery.

The combustion of fuels in oxidative metabolism involves the generation of reducing equivalents in  $\beta$ -oxidation, glycolysis, and the tricarboxylic acid cycle that are oxidized via the respiratory chain, where the phosphorylation of ADP is coupled to the reduction of molecular oxygen to water. Normal oxidative metabolism requires a highly integrated physiologic support system to regulate the flow of oxygen from the lungs to the respiring muscle mitochondria as well as functional mitochondria that can efficiently extract the available oxygen from blood. Muscle oxygen utilization in oxidative phosphorylation may increase 50-fold or greater from rest to peak exercise. This increase is achieved by increases in the level of oxygen extraction from oxyhemoglobin in red blood cells and in the rate of delivery of oxygenated blood to working muscle by the circulation.

The primary source of energy for resting muscle is derived from FAO. At rest, glucose utilization accounts for 10% to 15% of total oxygen consumption. Both slow and fast twitch fibers have similar levels of glycogen content at rest. The choice of the bioenergetic pathway in working muscle depends on the type, intensity, and duration of exercise (Gollnick et al., 1974), but also on diet and physical conditioning. In the first 5 to 10

minutes of moderate exercise, high-energy phosphates are used to first regenerate ATP. This is followed by muscle glycogen breakdown, which is indicated by a sharp rise in lactate during the first 10 minutes. Blood lactate levels then drop as muscle triglycerides and blood-borne fuels are used. After 90 minutes, the major fuels are glucose and FFAs. During 1 to 4 hours of mild to moderate prolonged exercise, muscle uptake

of FFAs increases approximately 70%, and after 4 hours, FFAs are used twice as much as carbohydrates.

The disorders discussed here have a genetic basis. The inheritance pattern, gene, gene product, and function are summarized in the following sections for each disorder. More detailed and current molecular genetic information can be obtained from the Online Mendelian Inheritance in Man ([omim.org](http://omim.org)), Gene Table of Neuromuscular Disorders ([muscle.genetable.fr](http://muscle.genetable.fr)), Gene Cards human gene database ([genecards.org](http://genecards.org)), and [MitoMap.com](http://MitoMap.com) websites.

A fuller discussion of the history, genetic, biochemistry, and pathophysiological aspects of these disorders can be obtained from the online version of the chapter.

## MYOGLOBINURIA

Myoglobinuria is a clinical syndrome, not just a biochemical state. In the alert patient, myalgia and limb weakness are the most common presenting symptoms. Urine color is usually brownish rather than red, and the urine tests positive for both albumin and heme (a concentration of at least 4 µg/mL). There are few or no red blood cells. Myoglobin can be identified by immunochemical methods. The sarcoplasmic enzymes, including serum CK, are usually elevated to more than 100 times normal. Inconstant features include hyperphosphatemia, hyperuricemia, and hypocalcemia. If renal failure occurs, serum potassium and calcium levels may rise. If the patient is comatose or if the presenting disorder is one of acute renal failure, there may be no muscle symptoms or signs. Under these conditions, the diagnosis can be made if (1) there is renal failure and (2) the serum content of sarcoplasmic enzymes is 100 times normal. The potentially life-threatening hazards of an attack of myoglobinuria include renal or respiratory failure and cardiac arrhythmias. The etiologies of heritable myoglobinuria differ in adults compared with children. In a study of 77 adult patients aged 15 to 65 years, [Tonin et al. \(1990\)](#) identified the enzyme abnormality in 36 patients (47%) as follows: CPT deficiency in 17 patients; glycolytic defects in 15 patients (including PPL in 10, PPL b kinase in 4, and PGK in 1); myoadenylate deaminase in 3; and combined CPT and myoadenylate deaminase in 1. In contrast, in 100 cases of recurrent childhood-onset myoglobinuria, a lower percentage of children have been diagnosed biochemically (24%): 16 with CPT deficiency, 1 with SCHAD deficiency, and 7 with various glycolytic defects, including 2 PPL, 1 PGK, 3 PGAM, and 1 LDH deficiency. These children could be divided into two groups: a type I exertional group, in which exertion was the primary precipitating factor (56 cases), and a type II toxic group, in which infection and/or fever and leukocytosis were the primary precipitants (37 cases). The type II toxic childhood- and adult-onset groups by its etiologies, which were limited to FAO defects, as well as its slight female predominance, which contrasted with the marked male predominance in the latter two groups. The type II toxic group was further distinguished by the earlier age at onset of myoglobinuria, the presence of a more generalized disease (e.g., ictal bulbar signs, seizures, encephalopathy, developmental delay), and a higher mortality rate. Currently the most common etiology for recurrent myoglobinuria in both adults and children is CPT II deficiency ([Tein et al., 1992](#)).

## GLYCOGENOSES

Only glycogenoses affecting skeletal muscle, alone or in association with other tissues, are discussed in this section (Figure 149-1). Molecular genetic analysis has led to the cloning of genes encoding the enzymes involved in the glycogenoses,

**TABLE 149-2** Clinical Presentation of Muscle Glycogenoses

Type	Enzyme Defect	Affected Tissues	Clinical Presentation
II Infancy	Acid maltase	Generalized	Cardiomegaly, weakness, hypotonia, death <age 1 yr
II Childhood	Acid maltase	Generalized	Myopathy simulating Duchenne dystrophy, respiratory insufficiency
II Adult	Acid maltase	Generalized	Myopathy simulating limb girdle dystrophy or polymyositis, respiratory insufficiency
III	Debrancher	Generalized	Hepatomegaly, fasting hypoglycemia, progressive weakness
IV	Brancher	Generalized	Hepatosplenomegaly, cirrhosis of liver, hepatic failure, myopathy, cardiomyopathy, APBD
V	Muscle phosphorylase	Skeletal muscle	Intolerance to intense exercise, cramps, myoglobinuria
VII	Muscle phosphofructokinase (PFK-M)	Skeletal muscle RBC	Intolerance to intense exercise, cramps, myoglobinuria
VIII	Phosphorylase kinase	Liver	Asymptomatic hepatomegaly
VIII	Phosphorylase kinase	Liver and muscle	Hepatomegaly, growth retardation, hypotonia
VIII	Phosphorylase kinase	Skeletal muscle	Exercise intolerance, myoglobinuria
VIII	Phosphorylase kinase	Heart	Fatal infantile cardiomyopathy
IX	Phosphoglycerate kinase 1 (PGK1)	Generalized	Hemolytic anemia, seizures, mental retardation, intolerance to intense exercise, myoglobinuria
X	Muscle phosphoglycerate mutase (PGAM-M)	Skeletal muscle	Intolerance to intense exercise, myoglobinuria
XI	Muscle lactate dehydrogenase (LDH-M)	Skeletal muscle	Intolerance to intense exercise, myoglobinuria
XII	Aldolase A	Skeletal muscle RBC	Nonspherocytic hemolytic anemia, exercise intolerance, weakness
XIII	$\beta$ -Enolase	Skeletal muscle	Exercise intolerance
XIV	Phosphoglucomutase 1	Skeletal muscle	Exercise intolerance, myoglobinuria

APBD, adult polyglucosan body disease; RBC, red blood cells.

(Modified with permission of DiMauro S, Lamperti C. *Muscle glycogenoses. Muscle Nerve* 2001;24:985, John Wiley and Sons, Inc.)

as well as their chromosomal localization (Table 149-1). Inheritance is autosomal recessive, in the majority, or X-linked recessive. In the glycogenoses, fixed weakness is the primary presentation in acid maltase, debrancher, aldolase, and brancher enzyme deficiencies, whereas exercise intolerance with cramps, myalgia, and recurrent myoglobinuria are the primary presentation in phosphorylase kinase, phosphorylase, phosphofructokinase, phosphoglycerate kinase, phosphoglycerate mutase,  $\beta$ -enolase, and lactate dehydrogenase deficiencies (Table 149-2).

### Pathophysiology (see online version for details)

The pathophysiology of glycogenoses relates more to the impairment of aerobic than anaerobic glycolysis. The energy substrates used by muscle for aerobic metabolism depend on the type, intensity, and duration of exercise, as well as on physical conditioning and diet. During low-intensity exercise the primary source of energy is derived from blood glucose and FFAs. During intense exercise, energy is derived from anaerobic glycolysis and the proportion of energy derived from carbohydrate oxidation increases, with glycogen serving as an important fuel. Fatigue occurs when glycogen stores are exhausted. Individuals with defective glycolysis/glycogenolysis are most vulnerable during the initial stages of intense exercise, and they must rest soon after beginning exercise because of muscle cramps. However, if they continue to exercise at low intensity, they are able to continue for a longer time. This is known as the *second-wind phenomenon* and has been attributed

to a metabolic switch from carbohydrate to fatty acid utilization and to increased circulation with increased availability of blood glucose from hepatic glycogenolysis.

Provocative testing with the ischemic or non-ischemic forearm exercise test has been performed traditionally to measure the change in lactate and ammonia levels in blood (see online version of this chapter for details). The sensitivity and positive predictive value of this test vary among the glycogenoses. Now, with the availability of gene panels for myoglobinuria, this testing is often omitted.

### Glycolytic/Glycogenolytic Defects

The specific clinical features, laboratory tests, pathology, pathophysiology, inheritance pattern, biochemistry, molecular genetics, and treatment for each defect in this pathway with muscle involvement are presented in the online version. For a summary of the chromosomal assignment and pattern of inheritance, see Table 149-1, and for a summary of the clinical presentations, see Table 149-2.

## FATTY ACID OXIDATION DISORDERS

### Historical Background

FAO disorders are an important group of diseases because they are potentially rapidly fatal and a source of major morbidity. They present with a spectrum of clinical disorders, including recurrent myoglobinuria, progressive lipid storage myopathy, neuropathy, progressive cardiomyopathy, recurrent

hypoglycemic hypoketotic encephalopathy or Reye-like syndrome, seizures, and mental retardation. All of the currently known conditions are inherited as autosomal-recessive traits. Thus there is frequently a family history of sudden infant death syndrome (SIDS) in siblings. Early recognition and prompt institution of therapy and appropriate preventive measures, and in certain cases specific therapy, may be life-saving and may significantly decrease long-term morbidity, particularly with respect to CNS sequelae. There are now at least 25 enzymes and specific transport proteins in the pathway of  $\beta$ -oxidation, and defects in 18 of them have been recognized to cause disease in humans. With the significant advances in biomedical technology, there has been a rapid increase in the number of subsequently diagnosed cases. The incidence for MCAD deficiency was 1 in 8930 live births in a survey from the Pennsylvania newborn screening program using tandem mass spectrometry followed by confirmation through molecular analysis for several common mutations. Identification of the individual serum acylcarnitine esters has been facilitated by electrospray ionization–tandem mass spectrometry (ESI-MS/MS) and is now being used in newborn screening for early diagnosis and treatment of FAO disorders

### Fasting Adaptation

Fats constitute the most important and efficient fuel for oxidative metabolism and are the largest reserve of fuel in the body. As liver glycogen stores are depleted within a few hours of a meal and because there are no reserve stores of protein in the body, fatty acids become the predominant substrate for oxidation quite early in fasting.

Fatty acids serve three major functions. First, the partial oxidation of fatty acids by the liver produces ketones, which are an important auxiliary fuel for almost all tissues and particularly for the brain. Second, fatty acids serve as a major fuel for cardiac and skeletal muscle. Exercising muscle, during mild to moderate prolonged exercise, and resting muscle depend primarily on FAO (Gollnick et al., 1974). Third, the high rates of hepatic gluconeogenesis and ureagenesis needed for maintaining fasting homeostasis are sustained by the production of energy (ATP), reducing equivalents, and metabolic intermediates derived from FAO.

### Increased Susceptibility of the Child

Children with FAO defects are most prone to decompensation, within the context of depleted glycogen and glucose reserves, during conditions that place stress on the FAO pathway for fuel generation. These conditions include prolonged exercise (particularly after 1 hour of mild to moderate aerobic exercise), fasting, infection with vomiting, and cold-induced shivering thermogenesis. After an overnight fast, children are most likely to be found comatose in the early morning hours. During infection, there may be an added problem with vomiting and decreased oral intake with shivering thermogenesis. If not recognized and therefore untreated, children may progress to a Reye-like syndrome. There are several reasons for an increased risk of problems with fasting adaptation in infants and young children. First, given the large ratio of surface area to body mass, basal energy needs in the infant are high to maintain body temperature. Shivering thermogenesis, which maintains body temperature, is highly dependent on efficient FAO. Second, infants have a larger brain compared with body size. The developing brain is highly dependent on glucose and has a high rate of metabolism; therefore, infants and children show an even earlier activation of FAO with hyperketonemia within 12 to 24 hours of fasting. Third, there is a lower activity of several key enzymes involved in energy production in the

infant compared with the older child and adult, leading to further impairment of the infant's ability to maintain glucose homeostasis.

### Normal Pathway of Fatty Acid Oxidation

The pathway of mitochondrial FAO is outlined in Figure 149-2 and is described in detail in the online version.

### Clinical and Biochemical Features of Identified Defects

#### Common Features of Fatty Acid Oxidation Disorders

Hale and Bennett (1992) suggest that there are at least four clinical and laboratory features that should lead the clinician to suspect a genetic defect in FAO: (1) acute metabolic decompensation in association with fasting, (2) chronic involvement of tissues highly dependent on efficient FAO (e.g., heart, muscle, liver), (3) recurrent episodes of hypoketotic hypoglycemia, and (4) alterations in the quantity of total carnitine or of the percentage of esterified carnitine in plasma and tissue.

#### Involvement of Fatty Acid Oxidation–Dependent Tissues

**Hypoketotic Hypoglycemia.** Tissues such as skeletal muscle, heart, and liver have high energy demands and are therefore dependent on efficient FAO. When there is a defect in hepatic ketogenesis, glucose becomes the only available fuel and thus becomes rate limiting under conditions of FAO stress when glycogen and glucose stores have been depleted. As a result, FFAs, which are liberated during fasting and cannot be metabolized because of the block, may be stored in the cytosol as triglycerides. This produces a progressive lipid storage myopathy with weakness, a hypertrophic and/or dilatative cardiomyopathy, and a fatty liver.

The pattern of hypoketotic hypoglycemia reflects the accelerated rate of glucose utilization that occurs when fatty acids cannot be used as fuels and ketone bodies are not generated to spare glucose/glycogen stores. An increase in the ratio of serum FFAs to ketones, from the normal ratio of 1:1 to greater than 2:1, therefore would suggest a block in  $\beta$ -oxidation.

#### Alterations in Plasma and Tissue Concentrations of Carnitine.

In most cases of intramitochondrial  $\beta$ -oxidation defects, the total carnitine concentration is decreased (<50% or normal), and the acylcarnitine fraction is increased (>50% esterified; normal is 10% to 25% in the fed state and 30% to 50% in the fasted state). In the intramitochondrial  $\beta$ -oxidation disorders, the excessive acyl-CoAs that accumulate proximal to the metabolic block may be converted into acylcarnitines by chain length-specific carnitine acyltransferases.

#### Additional Laboratory Findings

During acute catabolic crises, other biochemical derangements may be noted. A modest hyperammonemia (100 to 200  $\mu$ mol/L) accompanied by threefold to fivefold elevation of liver transaminases may be documented during the Reye-like syndrome presentation. In acute myoglobinuria there are marked increases in the sarcoplasmic enzymes, including serum CK, which may rise higher than 100,000 IU/L (normal <250 IU/L). The serum concentrations of amino acids (especially taurine), creatinine, potassium, phosphate, and urate may also be increased. The hyperphosphatemia may lead to secondary hypocalcemia, which may be later followed by hypercalcemia (Tein et al., 1992). It is urgent to prevent renal failure. These changes may have deleterious renal and cardiac effects, thereby further exaggerating the damage. Lactic acidosis

**TABLE 149-3** Clinical Features Associated With Specific Genetic Defects of Fatty Acid Oxidation

Deficiency	Fasting Disorder	Tissue Involved	Hypoketotic Hypoglycemia	Altered Carnitine	Dicarboxylic Acids	Reye-Like Syndrome	SIDS
LCFAUD	+	L	+	+	NR	NR	NR

ACAD9, acyl-CoA dehydrogenase 9; B, brain; CPT, carnitine palmitoyltransferase; D, dysmorphic features; ETF, electron transfer flavoprotein; H, heart; HMG,  $\beta$ -hydroxy- $\beta$ -methylglutaryl; K, kidney; L, liver; LCAD, long-chain acyl-CoA dehydrogenase; LCFAUD, long-chain fatty acid uptake defect; M, muscle; MCAD, medium-chain acyl-CoA dehydrogenase; Mg, myoglobinuria; N, neuropathy; NR, no case yet reported.; OCTN2, plasmalemmal high-affinity carnitine transporter; P, pancreatitis; Qo, coenzyme Q oxidoreductase; R, retinopathy; SCAD, short-chain acyl-CoA dehydrogenase; SCHAD, short-chain L-3-hydroxyacyl-CoA dehydrogenase; TRANS, carnitine acylcarnitine translocase; trifunctional, long-chain enoyl-CoA hydratase + long-chain L-3-hydroxyacyl-CoA dehydrogenase + long-chain 3-ketoacyl-CoA thiolase; VLCAD, very long-chain acyl-CoA dehydrogenase.

(Modified with permission of Tein I. *Fatty acid oxidation and associated defects*. American Academy of Neurology Proceedings, Seattle, 1995. Madison, WI: Omnipress.)

may also be noted during the acute catabolic presentations. Urine organic acid screening may demonstrate unusual or excessive amounts of organic acids, which may be diagnostic of a specific block in  $\beta$ -oxidation.

### Specific Features of Individual Genetic Defects

 (see online version of this chapter for details)

The specific features of individual FAO disorders are outlined in the online version, and the clinical and laboratory characteristics are summarized, respectively, in [Table 149-3](#) and

 [Table 149-4](#).

### Differentiating Laboratory Features

Analysis of the fatty acid intermediates in the serum or urine of affected children may suggest the site of defect, depending on the chain-length specificity and the species type of the intermediates. These intermediates often require specialized biomedical technology, which may require referral to specialized metabolic laboratories. Particularly useful are the assessment of plasma total and free carnitine, serum acylcarnitines, urine acylcarnitines and urine acylglycines, and organic acids. These intermediates may be absent at times when the child is metabolically stable and receiving adequate supplies of glucose because this would reduce the stress on the FAO pathway. They are best detected in the serum and urine of children during acute catabolic crises or during times of fasting.

Serum acylcarnitine analysis from dried blood spots by electrospray ionization–tandem mass spectrometry (ESI-MS/MS) is increasingly used in newborn screening programs and

can be used to detect FAO disorders, carnitine cycle disorders, and organic acidurias. Stored dried blood spots are also a valuable source for postmortem investigations to elucidate the cause of SIDS.

## Diagnostic Approaches and Screening Methods

### History and Physical Examination

The key to investigation of these patients is a careful history and clinical examination. The presentation may be either acute and recurrent, or more chronic and slowly progressive. The more typical presentation is the acute one in which the child has a history of decreased oral intake during the preceding 24 to 36 hours followed by increasing lethargy and progressive obtundation or coma. The important initial investigations in a comatose child should include serum glucose and urine ketone measurements. Determination of urine ketones may be complicated because ill children are often dehydrated and will have concentrated urine that may demonstrate a relatively spurious elevation in ketones. If the blood glucose is above 3.3 mmol/L (60 mg/dL) and if it is accompanied by large amounts of urinary ketones, this tends to rule out an FAO disorder. However, if the blood glucose is less than 3.3 mmol/L and the urine ketones are trace or small in amount, this would suggest the possibility of an FAO disorder and would warrant further investigation. Most important, samples from the acute presentation, particularly before intravenous glucose therapy, should be saved for the determination of serum carnitine total and free, serum acylcarnitines, serum FFAs and ketones, urine organic acids, acylglycines, and acylcarnitines. With normal

FAO, the serum FFA/ketone ratio is 1:1. In the event of a block in FAO, this ratio increases to greater than 2:1 and is therefore useful as an initial screen. The serum and urine specimens during the acute episode can also be used to assess the integrity and hormonal regulation of the biochemical pathways involved in glucose homeostasis.

Once presumptive evidence for a defect in FAO has been established, the clinical picture, in combination with an analysis of serum acylcarnitines, urinary organic acid profiles, and urinary acylglycines, may suggest a specific site of defect and the chain-length specificity of the defect (e.g., short chain, medium chain, or long chain). Further investigations to identify the specific site of defect may include oxidation rates of [ $^{14}\text{C}$ ]-labeled palmitate (C16), octanoate (C8), and butyrate (C4) and deuterium-labeled oleic acid in the fibroblasts to establish the chain-length specificity of the defect. Depending on the suspected site of defect, a direct enzymatic assay may then be performed for the specific enzyme (Table 149-5). These assays can be performed in cultured skin fibroblasts or in biopsied muscle specimens. However, certain of these defects may be tissue specific, such as muscle SCHAD deficiency, in which case the defect is expressed in biopsied muscle and not in fibroblasts, and therefore may be missed unless the affected tissue is examined. For the carnitine uptake defect or OCTN2 deficiency, diagnosis is confirmed by *in vitro* studies of carnitine uptake in cultured skin fibroblasts. After identification of a specific enzyme or transporter defect, molecular genetic analysis can be performed to identify the underlying mutations.

## Treatment

The biochemical consequences of a defect in FAO can be divided into the following: (1) inadequate energy supply; (2) accumulation of toxic metabolites (e.g., misfolded proteins, membranotoxic long-chain acylcarnitines, increased ROS in ETFDH deficiency); (3) sequestration or loss of vital components (e.g., sequestration of Coenzyme A in the formation of excessive acyl-CoA intermediates); (4) altered production of enzyme product; (5) loss of protein-protein interaction (e.g., loss of inhibition of glutamate dehydrogenase by the SCHAD protein in SCHAD deficiency).

The mainstay of therapy is the avoidance of precipitating factors, particularly prolonged fasting. General treatment strategies are discussed next.

### Avoidance of Precipitating Factors

Avoidance of precipitating factors, such as prolonged fasting, prolonged aerobic exercise (>30 minutes), and cold exposure leading to shivering thermogenesis, is key. Suggested maximal fasting periods (during stable metabolic conditions) from a European consensus panel are as follows: neonates, 3 hours, also at night; <6 months, 4 hours, also at night; >6 months, 4 hours in the daytime, 6 (to 8) hours at night in well-nourished infants; >12 months to 3 years, 4 hours in the daytime, 10 (to 12) hours at night; 4 to 7 years, 4 hours during day, 10 (to 12) hours at night (Spiekerkoetter et al., 2009). These fasting periods apply under healthy, steady-state conditions, when on a normocaloric diet, glycogen stores can be built up during the day and used for glucose production during longer fasting intervals at night. In the event of progressive lethargy or obtundation or an inability to take oral feedings because of vomiting, the child should be taken immediately to the emergency room for intravenous glucose therapy. Intravenous glucose should be provided at rates sufficient to prevent fatty acid mobilization (8 to 10 mg/kg/

min). This regimen should be continued until the catabolic cascade has been reversed and the child is able to take oral feedings again. It is prudent to institute intravenous glucose therapy as soon as there is a concern regarding the status of the child and not to wait until the occurrence of severe symptoms or a drop in blood glucose <3.3 mmol/L, as a delay may lead to serious morbidity or death. It is wise to avoid prolonged exercise (i.e., >30 minutes) because during this time there is increased fat mobilization. A high-carbohydrate load before exercise is advisable, with a rest period and repeat carbohydrate loading at 15 minutes. Avoidance of cold exposure to limit shivering thermogenesis is essential.

### High-Carbohydrate, Low-Fat Diet

In general, it is advisable to institute a high-carbohydrate, low-fat diet with frequent feedings throughout the day, which would be commensurate with the nutritional needs of the child given his or her age. This goal is best achieved with the aid of a dietitian, aiming toward approximately 60% of calories from carbohydrate sources, 15% from protein, and approximately 25% to 30% from fat. Long-chain fat intake in healthy infants is 40% to 45% of total energy, and in children of school age it is 30% to 35%. Monitoring of essential fatty acid levels is important to ensure that the child is receiving adequate essential fatty acids, as these may require supplementation. See the online version for additional details.

### Uncooked Cornstarch

Routine enrichment of the diet with glucose polymers or cornstarch is not recommended, but is part of oral prophylactic and therapeutic emergency management. To delay the onset of fasting overnight, the nightly institution of uncooked cornstarch, in doses similar to those used in the treatment of glycogen storage disease (1 to 2 g/kg body weight/day as a single nighttime dose), will prolong the postabsorptive state and delay fasting. Cornstarch provides a sustained release source of glucose, thereby preventing hypoglycemia and lipolysis. Cornstarch is usually initiated at 8 months of age when pancreatic enzymes are first able to function at full capacity for appropriate absorption. The initial recommended doses are generally 1.0 g/kg/day, which can be gradually increased to 1.5 to 2.0 g/kg/day by age 2 years as needed. This may lead to undesirable weight gain.

### Other Treatments

Specific treatments for individual FAO disorders may include consideration of medium-chain triglyceride (MCT) oil for long-chain FAO disorders, riboflavin for the multiple acyl-CoA dehydrogenase deficiencies, carnitine for OCTN2 deficiency, and docosahexaenoic acid (DHA) for TFP/LCHAD deficiency, and prednisone, triheptanoin, PPAR agonists (bezafibrate), resveratrol, premature stop codon read-through drugs (gentamicin and ataluren), and gene therapy approaches for selected disorders, as discussed in more detail in the online version.

### Clinical Monitoring

On a chronic basis, clinical monitoring of individuals with FAO disorders is very important. This should include evaluation of growth, development, neurologic examination, and diet as well as reinforcement of the prevention of risk factors and management of acute crises. Yearly ophthalmologic examinations are important for long-chain FAO disorders (e.g., pigmentary retinopathy in TFP/LCHAD deficiency) and

GA II. ECG and echocardiography are important to monitor cardiac function in long-chain disorders and OCTN2 defects. Liver ultrasonography may be important in LCHAD/TFP deficiency. Biochemical follow-up should include serum carnitine total and free and serum acylcarnitines to monitor metabolic control, and CK. Essential fatty acid and DHA status should be monitored in long-chain defects. Regular follow-up and education of the child and family is important throughout life to help prevent morbidity and mortality.

### Genetics and Presymptomatic Recognition

All known FAO disorders are inherited as autosomal-recessive conditions. The inclusion of FAO disorders in newborn screening programs with comprehensive and consistent long-term follow-up is highly desirable to prevent morbidity and mortality, to implement preventative measures and treatment strategies, and to reduce the cost of care of affected patients.

### MITOCHONDRIAL ENCEPHALOMYOPATHIES (also refer to Chapter 42)

Though all of the mitochondrial encephalomyopathies that are expressed in muscle are at potential risk for the development of myopathy and exercise intolerance, the specific defects in which acute episodes of myoglobinuria have been documented to date include defects of complexes I, II, III, and IV activities as well as multiple mtDNA deletions, mtDNA depletion syndromes, and Coenzyme Q10 (CoQ10) deficiency. Mitochondrial myopathy commonly manifests with exercise intolerance and premature fatigue, which is often out of proportion to the degree of muscle weakness. The myopathy may selectively involve the extraocular muscles (progressive external ophthalmoplegia [PEO]) and/or may extend to bulbar, limb (usually proximal but may be distal), and axial muscles. Onset may occur at any age, although more severe phenotypes present earlier in life and milder phenotypes present later in life. As there is an entire chapter dedicated to the detailed discussion of the individual mitochondrial disorders (see Chapter 42), the following sections will serve to briefly summarize and highlight the key clinical, morphologic, biochemical, genetic, and physiologic features of this group of disorders.

### Morphologic Considerations

Although the finding of ragged-red fibers (RRF) or ultrastructural alterations of mitochondria in muscle biopsy specimens suggests the possibility of a mitochondrial disorder, there are important limitations. These have been articulated by DiMauro (2001) as follows:

1. Nonmitochondrial disorders, such as muscular dystrophies, polymyositis, and some glycogenoses, may demonstrate RRF or ultrastructural mitochondrial abnormalities in which they likely represent secondary changes.
2. Conversely, many primary mitochondrial diseases, such as enzyme defects in metabolic pathways other than the respiratory chain (e.g., the pyruvate dehydrogenase complex [PDHC], CPT, beta-oxidation, and fumarase deficiencies), do not have RRF.

In addition, there are defects of the respiratory chain, such as Leigh syndrome secondary to cytochrome c oxidase (COX) deficiency, that tend not to have RRF. RRF are often COX negative, although not all COX-negative fibers are RRF.

A global decrease in the activity of COX is usually suggestive of a nuclear mutation in an ancillary protein required for COX assembly such as SURF1 but can also be associated with some homoplasmic mt-tRNA defects. A mosaic appearance of COX-negative fibers generally suggests an mtDNA mutation because of the variable degrees of heteroplasmy between muscle cells. There may be increased numbers of mitochondria (pleoconial myopathy), increased size (megaconial myopathy), disoriented or rarefied cristae, or osmiophilic or paracrystalline inclusions on electron microscopy. The paracrystalline inclusions are deposits of mitochondrial CK. There may also be lipid or glycogen storage on muscle biopsy, signifying a defect of terminal oxidation. It should be noted that muscle histochemistry and/or electron microscopy may be normal even in the context of genetically proven mitochondrial syndromes, particularly early in the disease course or when the biochemical abnormality does not involve complex IV (COX).

### Clinical Considerations

Mitochondrial diseases are clinically heterogeneous. There may be variation in the age at onset, course, and distribution of weakness in pure myopathies. On average, the age of onset reflects the level of mutation and the severity of the biochemical defects; however, other factors, including nuclear genetic and/or environmental factors, can also affect the expression of disease. Additional features may include exercise intolerance and premature fatigue. Mitochondria and mtDNA are ubiquitous, which explains why every tissue in the body can be affected by mtDNA mutations. The most common presenting clinical features include short stature, sensorineural hearing loss, migraine headaches, ophthalmoparesis, myopathy, axonal neuropathy, diabetes mellitus, hypertrophic cardiomyopathy, and renal tubular acidosis. Additional features may include stroke-like episodes, seizures, myoclonus, retinitis pigmentosa, optic atrophy, ataxia, and gastrointestinal pseudoobstruction. In the case of mtDNA mutations, there may be a diverse spectrum of associated syndromes, even in a single pedigree, because of heteroplasmy and the threshold effect whereby different tissues harboring the same mtDNA mutation may be affected to different degrees or not at all. Furthermore, the same mutation can cause different syndromes (e.g., the T8993G mutation can cause either neuropathy, ataxia, retinitis pigmentosa [NARP] or maternally inherited Leigh syndrome [MILS]) and different mutations can cause the same phenotype (e.g., A3243G mutation, single deletion, and multiple deletions of the mtDNA can all cause progressive external ophthalmoplegia [PEO]). Thus the diagnosis of mtDNA-related disorders often requires a careful synthesis of the clinical history, signs, mode of inheritance, laboratory data, neuroradiological findings, exercise physiology, muscle biopsy, muscle biochemistry with measurement of respiratory chain enzyme activities in fresh or snap-frozen muscle samples, and molecular genetics.

### Biochemical Classification

Mitochondrial encephalomyopathies can be classified into five groups according to the area of mitochondrial metabolism specifically affected: (1) defects of transport, (2) defects of substrate utilization, (3) defects of the Krebs cycle, (4) defects of the respiratory chain, and (5) defects of oxidation/phosphorylation coupling (Figure 149-3) (see Chapter 42). Limitations of this classification scheme relate to the respiratory chain defects that can result from genetic defects of

mtDNA, which are usually heteroplasmic, and to deletions of mtDNA or point mutations in tRNA, which affect mtDNA translation as a whole and may lead to multiple respiratory chain defects and from genetic defects of nDNA.

### Physiologic Considerations (see online version of this chapter for details)

Standard exercise physiology tests, such as cycle ergometers or treadmills, can be used to detect alterations of oxidative metabolism. Maximal oxygen uptake is the most useful indicator of a patient's capacity for oxidative metabolism. Typical physiologic responses in patients with defects in oxidative metabolism are as follows (Taivassalo et al., 2003):

1. The increase of cardiac output during exercise is greater than normal relative to the rate of oxidative metabolism.
2. Oxygen extraction per unit of blood remains almost unchanged from rest to maximal exercise.
3. Ventilation is normal at rest but increases excessively relative to oxygen uptake.
4. Venous lactate, which is usually elevated at rest, increases excessively relative to workload and oxygen uptake.

### Genetic Classification (see Chapter 42)

Specific defects of mtDNA and nuclear DNA with myopathy as a feature are discussed in detail in the online version (Tables 149-6 and 149-7).

### Therapeutic Approaches in Mitochondrial Diseases

Overall the therapy of mitochondrial respiratory chain disorders is highly inadequate, though there are currently multiple new emerging therapeutic strategies that may hold promise for the future. The therapeutic approaches have been comprehensively reviewed.

**Palliative therapy:** Palliative therapy includes anticonvulsants, treatment of endocrinopathies (e.g., thyroxine, insulin), adequate nutrition (enteral feeding via gastrostomy is frequently needed), pancreatic enzyme replacement, electrolyte replacement in patients with severe renal tubulopathy, renal dialysis and/or transplantation, hearing aids, blood transfusions for sideroblastic anemia, psychological support for patients and families, and surgical procedures, for example, cochlear implants for hearing loss, pacemakers for cardiac conduction blocks, surgery for cataracts and for ptosis, and liver and cardiac transplantation for related organ failure. Valproic acid should be avoided because it inhibits cellular carnitine uptake and mitochondrial OXPHOS. Valproic acid should be absolutely avoided in Alper's disease. Other medications to be used cautiously or to be preferentially avoided include statin medications, where there should be careful monitoring of symptoms and serum CK and antiretroviral agents, which are known to cause reversible and dose-dependent mitochondrial toxicity.

**General anesthesia:** General anesthesia may be needed in individuals with mitochondrial disorders and requires special perioperative, intraoperative, and postoperative care. It is important to maintain normothermia, normoglycemia, and normal electrolytes. Given the impairment in lactate metabolism, lactated Ringer's solution should be avoided. It has been suggested that volatile inhalational anesthetics and depolarizing muscle relaxants should be avoided and that some individuals fail to tolerate local anesthetics. A listing of anesthetic recommendations from different investigators is provided by Rivera-Cruz (2013).

**Removal of noxious metabolites:** Other strategies include removal of noxious metabolites, including lowering the lactic acidosis. Though dichloroacetate (DCA) lowers serum lactic acid, a double-blind, placebo-controlled, randomized, crossover trial of DCA in a cohort of MELAS patients with the A3243G mutation had to be terminated because of significant peripheral nerve toxicity. Therefore DCA should not be used long-term in mitochondrial patients prone to peripheral neuropathy. Attempts to bypass respiratory chain blocks through the administration of electron acceptors have been disappointing.

**Cofactor and metabolite supplementation:** Cofactor and metabolite supplementation has been the mainstay of therapy, particularly in disorders of primary deficiencies, for example, CoQ10 deficiency and primary carnitine deficiency caused by OCTN2 deficiency. Supplementation with oral CoQ10 (10 to 30 mg/kg/day in children and 1200 to 3000 mg/day in adults) has been effective in patients with COQ2 mutations, especially for the neurologic and renal manifestations of this disorder. In contrast, poor responses to CoQ10 supplementation have been observed in patients with PDSS2 and COQ9 mutations.

Other agents used include riboflavin, thiamine, folic acid, and creatine. Antioxidants and reactive oxygen species scavengers are an area of increasing interest, particularly in complex I and III deficiencies. Agents used have included vitamin E, CoQ10, idebenone, and dihydrolipoate.

**Aerobic endurance and resistance exercise and physical therapy:** Aerobic endurance and resistance exercise and physical therapy help to prevent deconditioning and disuse muscle atrophy and have been shown to improve exercise tolerance in patients with mtDNA mutations through mitochondrial proliferation and gene shifting, respectively, as outlined in the online version.

In a recent Cochrane review of trials with vitamin, antioxidant, and nutrient supplements (CoQ10, lipoic acid, creatine, whey-based supplement, dimethylglycine), pharmacologic agents (dichloroacetate), and exercise therapy used in mitochondrial disorders, out of 1335 abstracts, only 12 studies fulfilled criteria for randomized controlled trials (including cross-over studies) (Pfeffer et al., 2012). It was concluded that, though there were some improvements in secondary outcome measures, there was no clear evidence supporting the use of any of these interventions in mitochondrial disorders. The ideal clinical trial should be adequately powered, statistically valid, and randomized, double-blinded, placebo-controlled and include a large group of homogenous patients in terms of clinical presentation, biochemical findings, and genetic defect, ideally at a similar stage of disease progression. However, this is very difficult for mitochondrial disorders because of the marked heterogeneity of diseases with different clinical manifestations and problems, the vast number of different genetic causes that may be individually rare, and the unpredictable course of the disease.

There are a number of emerging approaches that may hold future promise.

**Antioxidants:** The accumulation of reactive oxygen species (ROS) is generally accepted as a major cause of mitochondrial disease pathogenesis, leading to depletion of glutathione (GSH). Therapeutic strategies have included analogs of CoQ10. Though CoQ10 in high doses is of proven value in CoQ10 biosynthesis defects, its use in other mitochondrial disorders is less certain. Other analogs of interest include idebenone, which has reportedly better blood-brain barrier penetration. Another synthetic analog is EPI-743, which has had some potentially encouraging results in open-label studies in Leigh disease and other progressive mitochondrial disorders, but the unpredictable course of the disease makes the interpretation of results challenging. A summary of ongoing or recent

completed clinical trials in mitochondrial disease is provided by Rahman. N-acetylcysteine combined with metronidazole has been suggested as beneficial in ethylmalonic encephalopathy arising from mutations in the *ETHE1* gene.

**Stem cells:** In mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) syndrome, the loss of thymidine phosphorylase (TP) activity causes toxic accumulations of the nucleosides thymidine and deoxyuridine that are incorporated by the mitochondrial pyrimidine salvage pathway and cause deoxynucleoside triphosphate pool imbalances, which in turn cause mtDNA instability. Allogenic hematopoietic stem cell transplantation to restore TP activity and to eliminate the toxic metabolites is a promising therapy for MNGIE.

**Mitochondrial biogenesis:** Newer pharmacologic approaches have sought to upregulate mitochondrial biogenesis. Bezafibrate, a PPAR panagonist, has been used to activate mitochondrial proliferation enhancing oxidative phosphorylation capacity per muscle mass in a murine model of mitochondrial myopathy because of cytochrome c oxidase deficiency. Other pharmacologic agents that increase mitochondrial biogenesis and are under investigation include resveratrol, which activates the sirtuin SIRT1, which in turn is responsible for NAD<sup>+</sup>-dependent deacetylation of multiple proteins, including PGC1 $\alpha$  and the mitochondrial transcription factor TFAM. Additional agents include 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR), which is a pharmacologic activator of the adenosine monophosphate kinase (AMPK)-PGC1 $\alpha$  axis, and nicotinamide riboside, which is able to stimulate mitochondrial biogenesis by increasing NAD<sup>+</sup> availability, leading to NAD<sup>+</sup>-dependent activation of SIRT1.

**Dietary approaches:** Dietary approaches include the ketogenic diet as a potential treatment, particularly for the associated epilepsy, though evidence in patients remains anecdotal.

**Future pharmacologic approaches:** A comprehensive review of future pharmacologic approaches to restore mitochondrial function, including mitochondrial biogenesis, mitochondrial dynamics (fission and fusion), mitophagy, and the mitochondrial unfolded protein response, is given by Andreux et al. (2013). New and powerful phenotypic assays in cell-based models as well as multicellular organisms have been developed to explore these different aspects of mitochondrial function for the development of new drugs. Translating the emerging therapies to the bedside remains challenging because of the lack of large cohorts of clinically, biochemically, and genetically homogenous individuals; natural history data; and validated meaningful outcome measures for use in clinical trials. However, the recent development of national and international mitochondrial disease consortia and several large natural history studies will lay the groundwork for these trials.

**Gene therapy:** Gene therapy is a highly challenging area because of heteroplasmy and polyplasm, but approaches have been developed to decrease the ratio of mutant to wild-type mitochondrial genomes (gene shifting), converting mutated mtDNA genes into normal nuclear DNA genes, and importing cognate genes from other species. Emerging approaches in gene therapy, currently largely experimental, include the use of restriction endonucleases with mitochondrial targeting sequences, zinc finger nucleases to selectively degrade mtDNA mutations, transcription activator–like effector (TALE) nuclease and CRISPR/Cas9 mutant gene editing, rescue by overexpression of aminoacyl tRNA synthetases, and gene therapy for nuclear-encoded mitochondrial disorders.

**Germline therapy:** Germline therapy raises ethics issues, but may be considered in the future for prevention of maternal transmission of mtDNA mutations. Preventive therapy through genetic counseling and prenatal diagnosis is important for nuclear DNA-related disorders.

## MYOADENYLATE DEAMINASE DEFICIENCY

### Clinical Presentation

Myoadenylate deaminase (mAMPD) deficiency is detected in 1% to 3% of all muscle biopsies and may be characterized by exercise-related myalgia and cramps. However, the pathogenic significance of this defect is controversial because (1) in patients with unexplained myopathy, symptoms are generally mild, ill-defined, and often subjective, and (2) more than 50% of patients had either well-defined myopathies, such as Duchenne or Becker muscular dystrophy, McArdle's disease, spinal muscular atrophy, or amyotrophic lateral sclerosis. Therefore Fishbein divided mAMPD into the following two forms: (1) a primary (hereditary) mAMPD deficiency characterized by myopathy alone with exercise intolerance, myalgia, and cramps; very low residual activity (<1% of normal); and lack of cross-reacting material (CRM) in muscle, and (2) a secondary (acquired) mAMPD deficiency associated with well-defined myopathies or neuromuscular disorders in which there is a higher residual activity and detectable CRM. Isolated mAMPD deficiency may present with recurrent myoglobinuria.

### Laboratory Tests

The resting serum CK level is usually normal but may increase after exercise. The forearm ischemic exercise test demonstrates a normal rise in venous lactate but no rise in ammonia or inosine monophosphate. The EMG may be normal or may demonstrate nonspecific myopathic features.

### Pathology

Muscle biopsy is usually normal; however, decreased mAMPD activity can be detected by histochemical staining.

### Biochemistry and Molecular Genetics

There are three tissue-specific subunits: M (muscle), L (liver), and E (erythrocyte), which are under separate genetic control. Adult human muscle contains almost exclusively the M homotetramer. AMPD converts AMP to inosine monophosphate (IMP) and ammonia.

# 150 Inflammatory Myopathies

Anthony A. Amato and John T. Kissel

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

The inflammatory myopathies are a heterogeneous group of disorders characterized pathologically by inflammation in skeletal muscle, with resulting muscle fiber damage and subsequent clinical weakness. There are two major categories of inflammatory myopathy—idiopathic and infectious (Box 150-1). Although several types of muscular dystrophy may be associated with inflammation (e.g., facioscapulohumeral dystrophy and some of the limb-girdle dystrophies), these disorders traditionally are excluded from classification of inflammatory myopathy because they result from a fundamental genetic defect. The classic idiopathic inflammatory myopathies are usually considered to be autoimmune diseases, although a genetic predisposition may exist for many of these diseases based on inherited human leukocyte antigen haplotypes.

As a group, the inflammatory myopathies are the most common acquired myopathies of childhood (Rider et al., 2013; Shah et al., 2013). The infectious myositides are the most prevalent of these conditions worldwide, with acute viral myositis clearly the most common variety in North America and Europe. In contrast, the idiopathic varieties are relatively uncommon, with a combined incidence (including adult cases) of approximately 1 in 100,000. There are four major forms of idiopathic inflammatory myopathy—dermatomyositis, polymyositis, inclusion body myositis, and immune mediated necrotizing myopathy—with dermatomyositis by far the most common form in childhood (Amato and Griggs, 2003; Amato and Greenberg, 2013; Dalakas and Holfeld, 2013). Polymyositis is relatively uncommon in children and usually is seen as an overlap syndrome with other connective tissue disorders (CTD). Immune mediated necrotizing myopathy is a recently recognized entity usually seen in the setting of other connective tissue diseases or as a paraneoplastic syndrome. More commonly it is idiopathic in nature or associated with a CTD; it may be associated with antisignal recognition antibodies. In adults, it may be seen as a rare complication of statin medications and associated with autoantibodies directed against 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMGCoAR). Inclusion body myositis is exclusively a disease of adulthood and therefore is not discussed here.

## IDIOPATHIC INFLAMMATORY MYOPATHIES

Although clinicians often conceptualize the idiopathic inflammatory myopathies as a single entity (e.g., polymyositis is dermatomyositis without the rash), the disorders are clinically, histologically, and pathogenetically distinct. Banker and Victor first reported the unique vascular changes of juvenile dermatomyositis and highlighted the involvement of organs other than muscle and skin. Subsequent immunologic and pathologic observations confirmed distinct pathophysiologies for each of these disorders, and recent observations have solidified this view. Although there have been occasional reports of siblings or parent/child cases of both dermatomyositis and polymyositis, most cases are sporadic.

## Dermatomyositis

### Clinical Features

Juvenile dermatomyositis (JDM) can present at any age, including infancy, although most cases occur between ages 5 and 14 years. Females are affected more commonly than males. Onset of weakness is typically over weeks to a few months, although fatigue, muscle aches and stiffness, decreased activity, and fever can precede the onset of weakness by months. More acute, fulminate onset (over days) or an indolent, slowly progressive course (sometimes lasting a year) also has been described. Weakness typically affects the neck flexors along with shoulder and pelvic girdle muscles first, so that the child may have difficulty getting up from the floor, riding a bicycle, running, climbing steps, or raising the arms above the head. Distal weakness is usually present, although not as severe as in proximal muscles. Complete sparing of distal strength should always lead the clinician to suspect another diagnosis, particularly one of the dystrophies. Dysphagia occurs in approximately one-third of patients; also, individuals will rarely have chewing difficulties, dysarthria, and speech delay because of oropharyngeal involvement.

The rash frequently precedes the muscle symptoms and often provides the most important clue to diagnosis. Skin changes typically involve the fingers and periorbital regions first, although any area may be involved. A purplish discoloration of the eyelids (heliotrope rash) with periorbital edema and extension on to the cheeks and forehead is typical (Fig. 150-1). On the hands, the periungual regions become erythematous and scaly, with dilated capillary loops in the nail beds (Fig. 150-2). Papular, erythematous, scaly lesions over the knuckles (Gottron sign) are characteristic, with similar lesions occurring on the elbows, knees, and malleoli. A more macular, erythematous rash may appear on the face, neck, and anterior chest (V sign) or on the shoulders and upper back (shawl sign). Subcutaneous calcifications, which do not occur in adult cases, are present in 30% to 70% of childhood cases. The calcinosis tends to develop over pressure points (e.g., buttocks, knees, elbows) but can occur anywhere and develops more commonly when the diagnosis has been delayed or the treatment inadequate. The lesions typically appear as painful, hard nodules that erupt through the skin in severe cases. Occasional patients have the characteristic rash but never develop weakness, a condition sometimes referred to as dermatomyositis sine myositis or amyopathic dermatomyositis.

**Associated Manifestations.** Although involvement of organs other than muscle and skin has become less common with the advent of effective immunosuppressive therapies, some children will develop clinical manifestations, in addition to weakness and rash, on the basis of the underlying vasculopathy. About 50% will have electrocardiographic abnormalities, including conduction defects and dysrhythmias pericarditis, myocarditis, and congestive heart failure can occur. Pulmonary function tests may demonstrate restrictive defects and reduced

diffusion capacity, even in patients with no pulmonary symptoms. Approximately 10% of patients, particularly those with antibodies to histidyl transfer ribonucleic acid synthetase (Jo-1), develop frank interstitial lung disease or bronchiolitis obliterans and organizing pneumonia. Vasculopathic involvement of the gastrointestinal tract can result in malabsorption, mucosal ulceration, perforation, and hemorrhage. Dysphagia

and delayed gastric emptying, caused by inflammatory involvement of the alimentary skeletal and smooth muscles, are more common.

Arthralgias are common, but true arthritis occurs mainly in children with an “overlap” connective tissue disorder (see later in this chapter). Ophthalmic involvement on the basis of vascular changes in the retina and conjunctiva can occur. Renal compromise is rare and results from acute tubular necrosis in the setting of myoglobinuria after fulminant muscle necrosis. In contrast to adult dermatomyositis patients, children have demonstrated no definitive increased incidence of malignancy.

### Laboratory Features

The laboratory evaluation of patients with inflammatory myopathy should include muscle enzyme analysis, electrodiagnostic studies, and muscle biopsy. Muscle imaging studies can indicate areas of inflammation in affected muscles but are seldom useful in making a diagnosis.

**Blood Tests.** Creatine kinase (CK) is the most reliable, sensitive, and specific marker for muscle destruction. The CK level is elevated in about 70% of patients sometime during the course of the disease, with levels up to 50 times normal. However, it is important to note that the CK level can be normal throughout the course of the disease and does not correlate consistently with weakness. Rarely, serum aldolase can be elevated when the serum CK is normal; serum myoglobin, lactate dehydrogenase, aspartate aminotransferase, and alanine aminotransferase can also be elevated but provide no additional information to the CK. Erythrocyte sedimentation rate is usually normal or mildly elevated and does not correlate with severity. Antinuclear antibodies occur in 25% to 50% of patients, most commonly in those with overlap syndromes.

Myositis-specific antibodies (MSA) may be present in both children and adults with myositis and are associated with specific clinical features, including providing some information about prognosis (Casciola-Rosen and Mammen, 2012; Ghiradello et al., 2013). The frequency of these antibodies differs between children and adults. For example, anti-p155/140 (TIF1- $\gamma$ ) and anti-NXP2 autoantibodies are more common in JDM than in adult DM, but unlike adult myositis, these antibodies are not associated with increased risk of cancer in JDM. The antisynthetase autoantibodies (i.e., anti-Jo-1), which are the most common MSA in adult myositis and associated with interstitial lung disease, are seen in less than 5% of patients with JDM.

**Electromyography.** Electromyography can serve to support a myopathic origin for the patient’s weakness and to determine which muscle to biopsy in patients with mild weakness. However, in a child with classic rash, weakness, and an elevated CK level, electromyography is often not needed. Typical electromyographic features include increased spontaneous activity with fibrillation potentials, positive sharp waves, and, occasionally, pseudomyotonic and complex repetitive discharges, as well as small-duration, low-amplitude, polyphasic motor unit potentials, which recruit early but at normal frequencies. The amount of spontaneous activity generally reflects the ongoing disease activity.

**Muscle Biopsy.** Children suspected of having dermatomyositis should undergo a muscle or skin biopsy before therapy is instituted, if there is any question regarding the diagnosis. In those children with a clearly acquired disorder presenting with a classic rash, weakness, and elevated serum CK, a muscle biopsy may not be necessary.

The classic pathologic features associated with dermatomyositis include a microvasculopathy with capillary loss, perivascular and perimysial inflammation, perifascicular atrophy, and scattered areas of fibers with central areas of myofibrillar loss (Fig. 150-3). The most characteristic of these changes is perifascicular atrophy, which is present in approximately 50% of cases and is relatively specific for dermatomyositis. The inflammatory infiltrates are predominantly perimysial and perivascular, and are composed primarily of macrophages, B cells, and CD4+ cells (Fig. 150-4). One of the earliest demonstrable histologic abnormalities on light microscopy is deposition of C5b-9 complement membrane attack complex (MAC) on small blood vessels (as well as immunoglobulin M and other complement components, including C3 and C9) (Kissel et al., 1986). These immunohistochemical findings can be helpful in making a diagnosis, especially when other histologic findings are absent or equivocal. Electron microscopy typically reveals small intramuscular arterioles and capillaries with endothelial hyperplasia, microvacuoles, and cytoplasmic inclusions, but is seldom needed to make a diagnosis.

### Pathogenesis (see online chapter)

**Treatment.** Although corticosteroids are generally regarded as the most effective therapy for dermatomyositis, there is disagreement surrounding the optimal route of administration, dosing regimen, duration of therapy, and parameters to monitor during therapy. There have been no controlled trials to examine these issues, although retrospective analyses and case series have demonstrated that prednisone reduces morbidity and improves strength and function.

**Corticosteroids.** Prednisone is the usual first line of treatment for dermatomyositis. Short courses of intravenous methylprednisolone (Solu-Medrol; 20 to 30 mg/kg/day or every other day for 3 to 5 days) may be the best way to initiate therapy in severely affected individuals, especially because this therapy may prevent calcinosis. After the intravenous pulses, most patients will require daily oral therapy as described later in this chapter. A more traditional starting regimen, especially for less severe cases, involves oral therapy (0.75 to 1.0 mg/kg/day), given as a single morning dose. After 3 to 6 weeks of daily prednisone, the dosage usually can sometimes be switched directly to an alternate-day regimen at the same dose, although most of the time we use daily prednisone. The high dose is maintained, and strength is carefully monitored. Although the CK level can sometimes be useful in monitoring response, it should never be the primary determinant of therapeutic decision making.

Patients should be evaluated at least monthly during this phase of treatment. When the child's strength has returned to normal or improvement has reached a plateau (usually within 4 to 6 months), the prednisone can be tapered at a rate no faster than 5 mg every 2 to 4 weeks. If an exacerbation occurs during the tapering, the prednisone dose is increased back to its original level and again given daily. When strength has recovered, the prednisone taper can be resumed. Although occasional patients will require daily dosing, or even split daily doses to maintain adequate disease control, alternate-day dosing is preferred because it is associated with fewer side effects. Most patients (approximately 80%) improve with therapy with approximately two-thirds having a complete response.

As most patients require therapy for 1 to 2 years to achieve remission, limiting the side effects of prednisone is an important part of management. Patients should be started on a low sodium, low carbohydrate, high protein, low calorie diet to limit weight gain and reduce the risk of hypertension. Calcium supplementation (1000 to 1500 mg/day) and vitamin D

reduce the risk of osteoporosis, as does physical therapy with axial exercise, as tolerated by the patient's weakness. Baseline determination of bone density through dual-energy x-ray absorptiometry scanning is indispensable in diagnosing and tracking osteoporosis in this population. Therapy with bisphosphonates should be considered in children who develop definite osteoporosis or in those expected to be on very long-term therapy. Exercise also reduces the risk of steroid myopathy. Blood pressure, serum glucose and potassium levels, and ocular status (for cataracts and glaucoma) should be assessed periodically. Hip pain in a child on prednisone must be investigated aggressively because avascular necrosis is an uncommon but devastating development in these individuals. Growth retardation and delayed puberty can occur with prolonged therapy.

Although the rash usually responds along with the muscle response, some patients occasionally require separate treatment for their skin changes. Hydroxychloroquine, chloroquine, topical steroids, topical tacrolimus, and sunscreen have been used to treat the rash when weakness is mild or not apparent. Treatment of calcinosis is more difficult. Colchicine, probenecid, warfarin, and phosphate buffers have been used with only limited success. Surgery may be indicated, but the lesions may recur or worsen despite surgery.

**Other Agents.** Patients who respond poorly to steroids, relapse repeatedly as prednisone is tapered, or develop intolerable side effects are candidates for alternative therapy (Table 150-1). Methotrexate is probably the drug of choice in children. In retrospective series, the majority of children refractory to prednisone improved with methotrexate therapy. In a series of 49 children with juvenile dermatomyositis initially treated aggressively with both pulsed corticosteroids and methotrexate, a prolonged, medication-free remission was attained in 28 of 49 within a median of 38 months from the time of diagnosis. Methotrexate must be used with caution because of side effects, including alopecia, stomatitis, oncogenicity, infection, interstitial lung disease, and bone marrow, renal, and liver toxicity. Pulmonary function tests, blood counts, and liver function tests must be monitored. Azathioprine, mycophenolate mofetil, cyclophosphamide, and cyclosporine have also been used in refractory patients (Table 150-1).

On the basis of a single double-blind, placebo-controlled study suggesting benefits in 15 adult dermatomyositis patients, intravenous immunoglobulin has become an important component of the treatment of dermatomyositis. Although originally used only for refractory cases, it is finding increasing use as both a steroid-sparing agent and a primary agent because of its effectiveness and low incidence of long-term side effects. Treatment is usually initiated at a dose of 2 g/kg given slowly over 2 to 5 days, with repeat infusions at 1 gm/kg at variable intervals (usually every 3 to 6 weeks) for at least 3 months. Flulike symptoms (i.e., headaches, myalgias, fever, chills, and nausea) may occur in as many as 50% of patients during the infusions but are usually mild. Rash, aseptic meningitis, transient leukopenia, renal failure, and stroke have been described rarely. A controlled trial of plasmapheresis and leukopheresis demonstrated no improvement with either modality in dermatomyositis.

Rituximab is a monoclonal antibody directed against CD20 and thus depletes B cells. A number of case reports and small series have suggested that rituximab maybe an effective therapy, but a large multicenter, double-blind, placebo-controlled trial in both adult and juvenile dermatomyositis and polymyositis failed to demonstrate efficacy (Oddis et al., 2013). However, there were flaws in the study design of this trial (e.g., crossover too early, lumping of adult and childhood polymyositis and dermatomyositis, and use of nonvalidated

**TABLE 150-1** Steroid-Sparing Immunosuppressive Therapy for Inflammatory Myopathies

Agent	Route	Dose	Side Effects	Monitor
Methotrexate	PO	10–20 mg/m <sup>2</sup> /wk	Hepatotoxicity, leukopenia, alopecia, stomatitis, neoplasia	LFTs, CBC BUN, Cr
	IV	1–3 mg	Same	Same
Cyclophosphamide	PO	1–2 mg/kg/day	Leukopenia, cystitis, alopecia, infections, neoplasia	CBC, UA
	IV	50–75 mg/m <sup>2</sup>	Same, nausea and vomiting	Same
Cyclosporine	PO	0.5–7.5 mg/kg/day	Renal toxicity, hypertension, hirsutism, hepatotoxicity, infection, gum hyperplasia	BP, BUN, Cr, LFTs, drug levels
IVIg	IV	2 g/kg; may need to be repeated at dose of 1–2 g/kg/month for maintenance therapy	Fevers, chills, diaphoresis, aseptic meningitis, headache, hypotension, leukopenia	BP, BUN, Cr
Rituximab	IV	A course is typically 750 mg-meter squared (up to 1 gm) and repeated in 2 wks Courses are then repeated usually every 6–18 months	Infusion reactions (as per IVIg), infection, progressive multifocal leukoencephalopathy	Some check B-cell count before subsequent courses (but this may not be warranted)

BP, blood pressure; BUN, blood urea nitrogen; CBC, complete blood count; Cr, creatinine; IV, intravenous; IVIg, intravenous immunoglobulin; LFTs, liver function tests; PO, orally; UA, urinalysis.

outcome measures), and most experienced clinicians feel that rituximab is effective in at least some patients. Currently, this therapy probably should be reserved for only the most refractory cases. The dose is 750 mg/m<sup>2</sup> (up to 1 g), given once and then repeated in 2 weeks. The course of rituximab then is to be repeated every 6 to 18 months.

## Polymyositis

Polymyositis, although common in adults, is relatively rare in children as an isolated entity. In one epidemiologic study, juvenile dermatomyositis was 10 to 20 times more common than polymyositis. When polymyositis does occur in children, it is usually in the setting of an “overlap” condition with features of another connective tissue disorder. Due to the absence of the rash, the diagnosis is often delayed compared with dermatomyositis.

## Clinical Features

As with dermatomyositis, patients typically present after weeks to months of neck flexor as well as symmetric, proximal greater than distal, arm and leg weakness. Muscle pain and tenderness are common but not always present. Dysphagia occurs in approximately one-third of patients secondary to oropharyngeal and esophageal involvement. Mild facial weakness occasionally may be demonstrated. Sensation and tendon reflexes are usually preserved. As in adults, other organs, most notably the heart and lungs, can be involved, although the incidence appears to be lower in children than in adults. Congestive heart failure or conduction abnormalities and interstitial lung disease are found in rare patients, the latter more commonly in patients with serum anti-Jo-1 antibodies. Polyarthritides has been reported in as many as 45% of polymyositis patients at the time of diagnosis.

**Overlap Syndromes.** In children, polymyositis occurs as part of an overlap syndrome, in which the myositis is associated with another connective tissue disorder, more frequently than as an isolated entity. The common overlap syndromes that are associated with polymyositis (and often dermatomyositis) include scleroderma, mixed connective tissue disease, Sjögren syndrome, systemic lupus erythematosus, polyarteritis nodosa, and rheumatoid arthritis. Involvement of the skin, joints,

kidneys, eyes, and salivary glands is identical to that seen for each disorder in isolation (Fig. 150-5), and the serologic abnormalities are also similar. Weakness in these patients is not always due to myositis because disuse and type 2 fiber atrophy caused by chronic steroid treatment of the underlying condition can also result in muscle weakness. In these individuals, it is crucial to document the nature of the muscle involvement with serologic and electromyographic studies and often muscle biopsy. The prognosis is often related to the underlying disorder, and treatment may have to be modified based on the associated condition.

## Laboratory Features

Laboratory evaluation in polymyositis is similar to that in dermatomyositis. Unlike dermatomyositis, the serum CK is essentially always elevated in polymyositis. The serum CK level can be helpful in monitoring response to therapy but only in conjunction with the physical examination. Positive antinuclear antibodies are present in approximately 30%. Muscle-specific antibodies have been reported in polymyositis as in dermatomyositis, as discussed previously. Close analysis of these reports, however, indicates that the muscle histopathology in many of the antibody-positive cases does not demonstrate invasion of nonnecrotic muscle fibers by CD8+ T lymphocytes, which some consider necessary to diagnosis polymyositis. Electromyography is similar to that in dermatomyositis, with a myopathic picture of increased spontaneous activity, small polyphasic motor units, and early recruitment.

**Muscle Biopsy.** The pathologic findings of polymyositis are distinct from dermatomyositis and reflect basic differences in the underlying pathophysiology. Biopsies are characterized by variability in fiber size, with scattered necrotic and regenerating fibers, and endomysial inflammation, with invasion of nonnecrotic muscle fibers by CD8+ cytotoxic/suppressor T cells and macrophages (Fig. 150-6). The invaded (and sometimes noninvaded) fibers express major histocompatibility complex class I antigen, which is not present on normal fibers. The vascular changes of dermatomyositis are not seen. Although B lymphocytes are not common, oligoclonal plasma cells have been identified in the endomysium in polymyositis. Unlike in dermatomyositis, in which there are many plasmacytoid dendritic cells that produce interferons, polymyositis

muscle biopsies have many endomysial myeloid dendritic cells that probably function as antigen-presenting cells.

### Pathogenesis (see online chapter)

**Treatment.** The treatment of children with polymyositis does not differ in any substantive way from that of dermatomyositis. Corticosteroids are the mainstay of treatment, with secondary agents used as indicated by the response. The role of intravenous immunoglobulin in polymyositis is less clear than in dermatomyositis and should probably be reserved for refractory cases. Treatment of patients with an overlap syndrome is occasionally dictated more by the degree of joint, kidney, or skin involvement than by the muscle disease. Although the majority of patients with polymyositis respond to therapy, the response is often less robust and less sustained than in dermatomyositis. Fewer patients (approximately 20%) attain a complete remission, so that more long-term therapy, along with its associated side effects from medications, is frequently required. Unfortunately, no prospective studies have examined in detail the long-term prognosis of these patients.

### Congenital Inflammatory Myopathy

Over the past three decades, there have been scattered reports of infants with “congenital inflammatory myopathy” or “infantile myositis.” The disorder is characterized by perinatal hypotonia and generalized weakness with elevated serum CK levels, myopathic electromyography, and striking inflammation on muscle biopsy. In one case of well-documented congenital myositis, the child was later diagnosed as having Prader-Willi syndrome. Most of the other patients did not improve with corticosteroid therapy, and it is likely that many of these cases had a form of muscular dystrophy with secondary inflammation. Inflammation on biopsy is not specific for a primary inflammatory myopathy and can be demonstrated in Duchenne, facioscapulohumeral, in some limb-girdle muscular dystrophies and Fukuyama-type muscular dystrophies, in Walker-Warburg syndrome, and in the Occidental type of congenital dystrophy with hypomyelination and laminin alpha-2 deficiency.

### Other Idiopathic Inflammatory Myopathies

Several other extremely rare inflammatory myositides have been described in children. Eosinophilic myositis has been described in several children with peripheral eosinophilia and focal eosinophilic infiltration in isolated muscles. However, several reports suggest that many of these cases may actually be calpainopathy (i.e., limb-girdle muscular dystrophy type 2B). Thus diagnoses of polymyositis or eosinophilic myositis should be made with extreme caution in children and then only after the various dystrophies have been carefully considered.

Focal nodular myositis, as the name implies, is also a focal disorder associated with mononuclear infiltration in individual muscles, causing the subacute onset of focal pain, swelling, and weakness. Some patients go on to develop generalized polymyositis. Improvement has been reported after surgical excision of the mass but can also occur spontaneously. A myositis with noncaseating granulomas can occur in sarcoid myopathy, a condition that may respond partially to prednisone.

### INFLAMMATORY MYOPATHY ASSOCIATED WITH INFECTIONS

Although myositis can occur after a wide variety of bacterial, parasitic, fungal, or viral infections, the viral myositides

(especially those caused by influenza), toxoplasmosis, and trichinosis are the disorders most likely to be encountered by the clinician.

### Influenza Myositis

Influenza A, B, and, rarely, C are common upper respiratory tract pathogens. Acute infection usually is associated with myalgias when fever and other constitutional symptoms are present. The myalgias presumably are caused by the systemic release of cytokines, although a true myositis can develop.

#### Clinical Features

As respiratory symptoms subside, pain, swelling, and muscle tenderness herald the onset of myositis. The pain can be so severe as to interfere with the child's ability to walk or perform routine activities, and muscle swelling and induration may be present. Weakness can be profound and myoglobinuria has been reported. Lasting less than 1 week, the symptoms are self-limited, although rare patients have recurrent symptoms associated with different influenza types.

#### Laboratory Features

The CK level is usually elevated, often markedly so, whereas it is typically normal in uncomplicated influenza infection. Electromyography reveals features of an active necrotizing myopathy. Muscle biopsy is rarely indicated but indicates scattered necrotic and regenerating fibers, with occasional interstitial inflammatory cells. Influenza virus has been isolated only occasionally on culture of the muscle specimen.

#### Pathogenesis (see online chapter)

**Treatment.** The disorder is usually self-limited, and treatment is supportive, with bed rest, hydration, and acetaminophen or nonsteroidal antiinflammatory drugs.

### Other Viral Myositides

Acute viral myositis is not specific for influenza infection, and similar syndromes can complicate infections with coxsackievirus, parainfluenza, mumps, measles, adenovirus, herpes simplex, cytomegalovirus, hepatitis B, Epstein-Barr virus, respiratory syncytial virus, echovirus, and, possibly, arboviruses. Similar to influenza, the myositis associated with these viruses is usually self-limited and requires only supportive therapy. Acute and convalescent viral titers (3 or 4 weeks after infection), as well as blood, stool, urine, and throat cultures, can be useful in identifying the responsible virus but seldom add to the management of the muscle symptoms.

An inflammatory myopathy has also been described with infection by human immunodeficiency virus (HIV). This disorder usually develops in patients with acquired immune deficiency syndrome but also can occur in early HIV infection. It has been reported exclusively in adults, although HIV-infected children also are at risk. The presentation is similar to that of polymyositis, with subacute progressive, symmetric proximal weakness, an elevated CK level, and myopathic electromyography. The disorder must be distinguished from zidovudine (AZT) myotoxicity, HIV wasting syndrome, and other disorders that can complicate HIV infection.

### Trichinosis

Trichinosis, the most common parasitic disease of skeletal muscle, is caused by the nematode *Trichinella spiralis*, which is ingested in inadequately cooked meat (usually pork). Most infected patients are asymptomatic.

## Clinical Features

Between 2 and 12 days after ingestion, the larval form of the nematode disseminates through the bloodstream and invades the muscles. Patients develop fever, headache, abdominal pain, diarrhea, generalized myalgias, and weakness during the acute systemic reaction. Periorbital edema, ptosis, subconjunctival hemorrhage, and an erythematous urticarial or petechial rash also are often present. Myalgias and weakness peak in the third week of the infection but can last for months. Severe disease can be complicated by myocarditis, pneumonitis, and central nervous system infection.

## Laboratory Features

Most patients have a marked eosinophilic leukocytosis and elevated serum creatine kinase level. Serum antibodies against *T. spiralis* can be demonstrated 3 to 4 weeks after infection. Electromyography demonstrates the typical features of an inflammatory myopathy. In the early stage of infection, muscle biopsy reveals infiltration of the muscle by eosinophils and polymorphonuclear leukocytes. With more chronic infection, mononuclear inflammatory cells are more common. Larvae, cysts with focal calcification, fibrosis, and granulomas may be observed months after the initial infection (Fig. 150-7).

## Treatment

Thiabendazole (25 mg/kg twice daily to a maximum dose of 3 g/day) is the drug of choice for killing the larvae and adult nematode, with 7 days usually an adequate course of therapy. Thiabendazole is not effective against the encysted larvae, and mebendazole may be a better agent in this regard. As a Herxheimer-like reaction can develop after degeneration of the larvae, concurrent prednisone administration is beneficial (2 mg/kg/day for several weeks). The majority of patients respond quickly to treatment.

## Toxoplasmosis

Toxoplasmosis is caused by the protozoan *Toxoplasma gondii*. The common mode of infection is through the ingestion of food, usually undercooked meat, contaminated with oocysts or cysts containing bradyzoites of the organism. The cysts mature and enter the bloodstream and lymphatics to invade other organs. Exposure to the organism is common worldwide, although symptomatic infection usually occurs in immunocompromised patients. Skeletal muscle involvement can occur in isolation or as part of more generalized infection.

## Clinical and Laboratory Features

In most patients, symptoms are mild and nonspecific; they include fever, malaise, fatigue, and myalgias. Patients with more severe disease have lymphadenopathy, hepatosplenomegaly, uveitis, pneumonia, myocarditis, rash, or meningoencephalopathy. Weakness develops in those with significant muscle involvement. The serum creatine kinase level is elevated, and the typical myopathic picture is evident on electromyography. Muscle biopsy may reveal cysts containing the organism, along with inflammation and giant cells. The diagnosis is confirmed through serologic studies indicating immunoglobulin M reactivity to the organism.

## Treatment

A combination of pyrimethamine and sulfadiazine or trimethoprim is the treatment of choice for the primary infection, although, once the organisms have become encysted in muscle, no medication is effective. Clindamycin also is an

effective agent and can be used in place of sulfadiazine. The duration of therapy is variable and depends on the severity of the illness.

## Cysticercosis

Cysticercosis is caused by the tapeworm *Taenia solium*, another organism usually transmitted through eating undercooked meat. Although central nervous system infection usually dominates the clinical picture, with focal neurologic deficits, seizures, and encephalopathy, skeletal muscles also can be involved. Weakness, myalgias, muscle tenderness, and muscle pseudohypertrophy are accompanied by an elevated creatine kinase level and eosinophilia. The biopsy is characterized by fibrosis, inflammation with eosinophils, giant cells, and encysted organisms. Praziquantel (50 mg/kg/day in three divided doses for 2 weeks) is effective against central nervous system infection, but its efficacy in muscle is less clear. Albendazole (15 mg/kg/day in divided doses for 8 days) also has been used. Niclosamide and paromomycin are useful for treating the adult worms, and corticosteroids suppress the inflammatory reaction against degenerating parasites.

## Bacterial Infections

Pyomyositis refers to the multifocal abscesses associated with bacterial infection of the muscle. Although bacterial infections are more common in developing countries, they are being seen with increasing frequency in developed countries as a result of HIV infection and intravenous drug abuse.

Muscle pain, tenderness, and fever are the initial symptoms, most commonly affecting the quadriceps, glutei, and deltoids. Most patients have a neutrophilic pleocytosis, elevated erythrocyte sedimentation rate, and normal or elevated serum creatine kinase level. Blood cultures are usually negative early in the infection until the patient becomes septic. Ultrasound, computed tomography, and magnetic resonance imaging of muscle can be useful in localizing abscesses for diagnostic needle aspiration. The most common organisms are *Staphylococcus aureus*, streptococci, *Escherichia coli*, *Yersinia* organisms, and *Legionella* organisms. Pyomyositis usually arises as an extension of infection from adjacent tissues or via hematologic spread of the organisms. Early in the illness, the infection may respond to appropriate antibiotics, although more severe infections require incision and drainage.

## Fungal Myositis

Fungal infection of the muscles is very uncommon and usually occurs in an immunosuppressed adult patient. Candidiasis is the most common fungal myositis and almost always is associated with disseminated disease. Diffuse muscle pain, tenderness, weakness, fever, and a papular erythematous rash are evident but may be obscured by other systemic involvement. Muscle biopsy demonstrates infiltration of the muscle by hyphal and yeast forms of the organism, inflammation, and hemorrhagic necrosis. Myositis also has been reported as complicating cryptococcal infection, sporotrichosis, actinomycosis, and histoplasmosis.

## Channelopathies: Myotonic Disorders and Periodic Paralysis

Richard T. Moxley III and Chad Heatwole

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

The term *channelopathies* extends to include disorders affecting all organ systems. This chapter focuses on channelopathies of skeletal muscle. It includes a number of diseases associated with mutations in the genes for specific skeletal muscle channels for chloride, sodium, calcium, and potassium ions. (Jurkat-Rott et al., 2015; Statland and Barohn, 2013; Suetterlin, Mannikko, and Hanna, 2014; Heatwole, Statland, and Logigian, 2013; Matthews et al., 2010; Cannon, 2002)

### THE MYOTONIC DYSTROPHIES

#### Mode of Inheritance of Myotonic Dystrophy Types 1 and 2

Myotonic dystrophy types 1 and 2 (DM1 and DM2) are autosomal dominant. Anticipation (earlier onset of more severe symptoms in successive generations) occurs primarily in DM1 (see Figure 151-1) (Kamsteeg et al., 2012; Moxley, Ciafaloni, and Guntrum, 2015). Congenital myotonic dystrophy (CDM) occurs almost exclusively through maternal transmission (see Figure 151-1). DM2 occurs neither in infancy nor childhood, although teenage onset of myotonic symptoms can occur in some DM2 patients carrying concomitant mutations in the gene for the skeletal muscle chloride channel.

#### Myotonic Dystrophy Type 1

##### Clinical Features

DM1 is a multisystem, highly variable muscle disease with an incidence of 1 in 8000 individuals (see Table 151-1) (Udd and Krahe, 2012; Moxley et al., 2015). In childhood DM1 presents as a severe early congenital form or as a milder form with symptoms occurring after infancy throughout childhood years. The congenital form presents at birth with respiratory failure, poor feeding, generalized hypotonia, clubfoot deformity, and an increased risk of intracerebral hemorrhage and eventration of the diaphragm (Moxley et al., 2015). During gestation there are often reduced fetal movements and a history of polyhydramnios. There is an increased frequency of placenta previa and miscarriage, and not uncommonly a failed labor may require urgent cesarean section. During the perinatal period, infants with congenital myotonic dystrophy may require continuous ventilator support, and those remaining ventilator dependent beyond 4 weeks of age have a poor prognosis for survival, although recent advances in neonatal intensive care have allowed many affected infants to survive with subsequent slow improvement in function throughout childhood and the teen years (Moxley et al., 2015) (see Figure 151-1). During the first 2 years of life, children with congenital myotonic dystrophy are at increased risk for aspiration pneumonia and difficulties with feeding. Mental retardation and learning disabilities are common in congenital myotonic dystrophy. Determining the degree of cognitive deficit requires

careful evaluation because these patients have marked facial weakness and are unable to speak and communicate well until middle to late childhood. There is also an increased incidence of hearing loss. These problems often complicate neuropsychologic testing. The bottom panel of Figure 151-1 shows a mother with two daughters, both of whom have congenital myotonic dystrophy. Both children had delayed ability to speak and cognitive impairment. Their mother has mild ptosis, minimal grip myotonia, and minimal distal weakness. The figure legend provides follow-up information on the clinical course of all three over the subsequent 15 years (Moxley et al., 2015). The top left panel of Figure 151-1 shows another mother with classical DM1 and her infant with congenital DM1 who is not longer ventilator dependent. Figure 151-1 emphasizes the phenomenon of anticipation and the fact that almost all DM1 patients with the severe newborn onset of congenital DM1 are born to females with DM1.

The later childhood-onset form of DM1 usually is evident from nonmuscular manifestations of the disease, such as intellectual deficiency, difficulty with speech or hearing, clumsiness, or, rarely, with a cardiac dysrhythmia or postoperative apnea. DM1 patients may have an increased sensitivity to sedative medications, especially barbiturates and opiates, and occasionally experience increased muscle stiffness, myotonia during general anesthesia (Moxley et al., 2015). Cardiac arrhythmias are more common complications for the adult-onset forms of DM1. However, other nonmuscular manifestations, such as gastrointestinal hypomotility with chronic constipation, and intermittent urinary tract symptoms, such as urgency or frequent urination, are common in childhood myotonic dystrophy (Moxley et al., 2015).

#### Myotonic Dystrophy Type 2 (Formerly Proximal Myotonic Myopathy)

##### Clinical Features

DM2, proximal myotonic myopathy (PROMM) typically appears in adult life and has variable manifestations, such as early-onset cataracts (younger than 50 years), varying grip myotonia, thigh muscle stiffness, muscle pain, and weakness (hip flexors, hip extensors, abdominal muscles, or long flexors of the fingers) (Udd and Krahe, 2012). Symptoms often appear between 20 and 70 years of age, and patients and their care providers ascribe them to overuse of muscles, "pinched nerves," "sciatica," arthritis, fibromyalgia, or statin use. Younger patients may complain of stiffness or weakness when running up steps. In general, DM2 muscle pain has no consistent relationship to exercise or to the severity of myotonia found on clinical examination. The pain, which tends to come and go without obvious cause, usually fluctuates in intensity and distribution over the limbs. It can last for days to weeks. This pain seems qualitatively different from the muscle and musculoskeletal pain that occurs in patients with DM1.

**TABLE 151-1** Myotonias Attributable to Unstable Nucleotide Repeat Expansion

Clinical Features	Myotonic Dystrophy of Steinert (Myotonic Dystrophy Type 1; DM1)	Myotonic Dystrophy Type 2 (Proximal Myotonic Dystrophy; DM2)
Inheritance	Dominant	Dominant
Gene defect	Chromosome 19q33, 3' untranslated region; CTG expansion affecting a protein kinase (DMPK); repeat size ranges from 50 to > 2000; normal 5–37 repeats	Chromosome 3q21.3, intron 1; CCTG expansion affecting the CNP (previously zinc finger 9 protein) gene; repeat sizes vary from 75 > 11,000; normal < 75 repeats
Age of onset	Broad range of ages (infancy to adulthood), with infant onset in most severe cases; approximately 10% begin in childhood	Broad range of ages (late childhood to late adulthood)
Myopathy	Face, eyes, forearm, hands, and legs, with generalized weakness and hypotonia in affected infants	Mild; thighs, hips, neck flexors, abdominal muscles; occasional calf muscle hypertrophy
Myotonia	Primarily affects hand and forearm muscles and tongue; often absent on clinical testing in infants and young children; occasionally affects respiratory muscles and smooth muscle, such as intestine or uterus; myotonia improves with heat and exercise; myotonia results from a decrease in chloride channel protein	Mainly in hands and thighs; varies; frequently hard paraspinal muscles detect; pain occurs sometimes with and without myotonia; myotonia improves with repeated contractions; myotonia results from a decrease in chloride protein
Provocative stimuli	Myotonia worsened by rest and cold; myotonia is relatively constant in severity and muscles affected once it develops	Myotonia worsened by rest but varies in severity, occasionally being absent on clinical examination; hand grip and thigh stiffness are usual sites
Therapy for symptoms	Bracing; cataract removal; monitoring dysrhythmias and respiratory insufficiency; pacemaker; antimyotonia therapy (mexiletine); avoid depolarizing muscle relaxants, opiates, and barbiturates with surgery	Cataract removal; occasional need for pacemaker; antimyotonia therapy often not necessary (mexiletine); monitor carefully during and after surgery for muscle rigidity and rhabdomyolysis

Early in the presentation of DM2 there is only mild weakness of hip extension, thigh flexion, and finger flexion. Myotonia of grip and thigh muscle stiffness vary from minimal to moderate severity over days to weeks. Direct percussion of forearm extensor and thenar muscles is the most sensitive clinical test for myotonia in DM2 but may be absent. Myotonia of grip is sometimes prominent and often has a jerky quality that seems to differ from that in DM1 and the nondystrophic myotonias. Myotonia is often less apparent in DM2 compared with patients with DM1. In cases of late-onset DM2, myotonia may only appear on electromyographic testing after examination of several muscles. Facial weakness is mild in DM2, as is muscle wasting in the face and limbs. Weakness of neck flexors is frequent. Trouble arising from a squat is common, especially as the disease progresses. Calf muscle hypertrophy occasionally is prominent. Other manifestations, such as excessive sweating, hypogonadism, glucose intolerance, dysphagia, cardiac conduction disturbances, and cognitive/neuropsychologic alterations may also occur and worsen over time. A higher rate of premature labor and preterm deliveries has also been reported. In contrast to DM1, respiratory insufficiency or failure and cardiac conduction disturbances are less common in DM2. Difficulty swallowing, gastrointestinal dysfunction, and cognitive disturbances do occur in DM2, but they appear to be less frequent.

At present there is no clear evidence of a congenital form of DM2 (Moxley et al., 2015). When symptoms occur in childhood, they typically are transient and relate to grip myotonia in the hands and thighs (Moxley et al., 2015). Proximal weakness, muscle pain, cataracts, and occasional cardiac dysrhythmias usually do not develop until mid or late adult life.

### DM1 and DM2: Genotype–Phenotype Correlations

In general, the greater the length of the abnormal CTG expansion in circulating leukocytes, the more severe are the disease manifestations and the earlier is the onset (Moxley et al., 2015). There are important exceptions to this generalization. In DM2 there is no clear relationship between disease onset

and severity and the length of the abnormal CCTG repeat in circulating leukocytes (Udd and Krahe, 2012). See the online chapter for a more detailed and helpful explanation of genotype–phenotype correlations.

### DIAGNOSTIC APPROACH

The major problem in making the diagnosis of DM1 and DM2 is the tendency of clinicians to ignore these entities in their practice. DM1 can present as a floppy infant or as child with delayed motor and cognitive development (Figures 151-3 and 151-4 show the workup of an infant with congenital DM1 and the workup of a child suspected to have childhood DM1, respectively). There are long lists indicating more common causes for these presentations in infants and in childhood than DM1. If there is a low diagnostic suspicion of DM1, the clinician may not probe the family history sufficiently and may not examine the parents of the patient using a focused approach to search for characteristic features of DM1 (Tables 151-1 and 151-2). The failure to consider DM1 is the principal contributor to the diagnostic odyssey and delays DNA testing, family counseling, and appropriate management and treatment (Moxley et al., 2015).

DM1 and DM2 present primarily in adult life. The core clinical features and the multisystem manifestations can occur in isolation or combination and usually develop gradually (Moxley et al., 2015). Muscle stiffness, muscle pain, intermittent trouble with clear speech and swallowing, dropping of items, gait instability, and trouble seeing are frequent initial symptoms (Udd and Krahe, 2012). Early-onset cataracts (typically, iridescent posterior capsular cataracts) and cardiac arrhythmias are examples of multisystem manifestations that can occur early in DM1 and DM2. In contrast, patients with other hereditary myotonic disorders, such as chloride or sodium channel myotonias, do not have cardiac arrhythmias or posterior capsular cataracts. DM1 patients occasionally present with prolonged apnea or delayed-onset apnea following general anesthesia. These complications can occur in individuals with only mild clinical signs of DM1. The risk of

complications after general anesthesia in DM2 patients appears to be low, but until more long-term data are available, it is prudent to monitor both DM2 and DM1 patients closely during and 24 hours or more following general anesthesia (Moxley et al., 2015).

The current gold standard to establish the diagnosis is DNA testing to identify the abnormally expanded CTG repeat in the *DMPK* gene for DM1 and the abnormally expanded CCTG repeat in the *CNBP* gene for DM2 (Kamsteeg et al., 2012; Udd and Krahe, 2012). If a patient suspected of having DM1 or DM2 has negative DNA testing, performance of a muscle biopsy may help establish the diagnosis of another myotonic disorder. However, if the muscle biopsy findings are typical for DM1 (increased central nuclei, atrophy of type-1 fibers, ringed fibers, subsarcolemmal masses) or DM2 (very small fibers, type-2 nuclear clumps, type-2 fiber atrophy), further genetic analysis, including bidirectional triplet-primed polymerase chain reaction (TP-PCR), may provide evidence of a mutation variant (Kamsteeg et al., 2012).

The diagnosis of congenital or childhood DM1 usually involves DNA testing for abnormal CTG repeat enlargement in the *DMPK* gene and usually prompts additional DNA testing of family members. Immediate counseling of the family is necessary to provide an understanding of current management of DM1 at its different stages. Parents need to know that preventive therapy and in vitro fertilization are available, along with the important supportive and symptomatic treatments (Table 151-2).

## LABORATORY TESTING FOR DM1 AND DM2

### DM1 Testing

Identifying the abnormally expanded CTG repeat in the *DMPK* gene isolated from circulating leukocytes establishes the diagnosis of DM1. Electromyography to detect myotonia is helpful in older children, but myotonia may be absent in infancy and early childhood. Slit-lamp examination is helpful in older children to identify the typical iridescent spokelike posterior capsular cataracts that develop early in the disease. Muscle biopsy is not necessary to diagnose DM1. Careful examination of the mothers of patients with congenital DM1 may reveal clinical signs of the disease. Creatine kinase levels are often normal or only mildly elevated in children and adults with DM1, whereas gamma glutamyltransferase levels are often high normal to significantly elevated, two- or threefold over the upper limit of normal.

### DM2 Testing

Leukocyte DNA testing is also available for DM2 (Kamsteeg et al., 2012). Slit-lamp examination to detect early cataract formation and electromyography, especially of the first dorsal interosseous, anterior tibialis, and anterior thigh muscles, are useful. Grip myotonia varies in severity and may be absent. Some patients have an elevation (twofold to eightfold) in creatine kinase and gamma glutamyltransferase levels. Muscle biopsy in DM1 and DM2 is rarely necessary for diagnosis.

## TREATMENT OF DM1 AND DM2

### DM1 Treatment

Table 151-2 summarizes treatment of the typical multisystem problems that occur in congenital and childhood-onset DM1. Treating patients with congenital myotonic dystrophy involves ventilatory support, use of a feeding tube, bracing for clubfoot deformities when present, and occasional corrective surgery

for foot deformities (Moxley et al., 2015). Speech problems and abdominal pain may improve with antimyotonia treatment. Mexiletine is sometimes helpful in alleviating some of the symptoms, especially in later childhood or adolescence when patients may have recurrent dislocation of the mandible and pain and muscle spasm in the masseter muscles. Electrocardiographic monitoring is necessary on a regular basis, particularly during treatment with mexiletine, to search for covert dysrhythmias. Treatment should be coordinated with the child's school to ensure that cognitive deficiencies and hearing deficits are monitored. The increased risk for cardiac dysrhythmia and apnea after administration of general anesthesia for surgery requires overnight hospitalization with monitoring. Apnea can develop several hours after a patient has been extubated. No specific limitation on physical activity is necessary during childhood provided the child has gained sufficient strength and coordination to carry out activities requested in the school environment.

### DM2 Treatment

In general, the management of DM2 is similar to that of DM1, but there is less need for supportive care, such as bracing, scooters, or wheelchairs (Moxley et al., 2015). Cataracts require monitoring, and serial monitoring with an electrocardiogram (ECG) is necessary to check for covert dysrhythmia. Disturbances in cardiac rhythm are less frequent in DM2, but abnormalities do occur. Hypogonadism and insulin resistance need monitoring as in DM1. Myotonia tends to be less marked and less troublesome in DM2, but in specific circumstances antimyotonia therapy is helpful, especially if muscle stiffness is frequent and persistent or if pain is prominent. Cognitive difficulties also occur in DM2 as in DM1, but the changes are less severe than in DM1. Management of these brain symptoms is similar to that for DM1.

A frequent and difficult problem in DM2 is the peculiar muscle pain described earlier. Carbamazepine or mexiletine along with nonsteroidal antiinflammatory medications or Tylenol ameliorate this pain in some patients.

## AUTOSOMAL-DOMINANT AND AUTOSOMAL-RECESSIVE MYOTONIA CONGENITA

Thomsen's disease (autosomal-dominant myotonia congenita) and Becker's disease (autosomal-recessive myotonia congenita) represent two forms of chloride channelopathies (Heatwole et al., 2013; Statland and Barohn, 2013; Suetterlin et al., 2014; Jurkat-Rott et al., 2015) (Table 151-3). The chloride channelopathies that produce myotonia as their primary symptom resemble the sodium channel disorders without periodic paralysis and may resemble mild forms of DM1 and DM2. Other causes of muscle stiffness or poor coordination, including central nervous system diseases affecting the frontal lobes, brainstem, and cerebellum, require initial consideration but are rarely confused with these channelopathies.

### Clinical Features

Generalized myotonia is the major clinical symptom in dominant and recessive forms of chloride channel myotonia congenita. Recent studies indicate pain occurs in almost 30% of patients with chloride channel myotonia, and as many as 75% have mild generalized muscle weakness that is slightly greater proximally. Symptoms develop in the first or second decade of life. Myotonic stiffness occurs with sudden physical exertion after a period of rest. Repeated muscle contractions ameliorate the stiffness. This response is the "warm-up phenomenon,"

**TABLE 151-3** Chloride Channel Myotonias

Clinical Features	Autosomal-Dominant Myotonia Congenita of Thomsen	Autosomal-Recessive Generalized Myotonia of Becker
Inheritance	Dominant	Recessive
Gene defect	Chromosome 7; mutation in skeletal muscle chloride channel	Chromosome 7; mutation in skeletal muscle chloride channel
Age of onset	Infancy to early childhood	Late childhood, occasionally starts earlier or begins in teens
Myopathy	Muscle hypertrophy frequent; no myopathy, although variants uncommonly develop weakness	Occasional muscle wasting and weakness can occur late; hypertrophy of muscles frequently occurs in legs
Myotonia	Generalized stiffness, especially after rest; improves with exercise; prominent myotonia of eye closure, but not paradoxical myotonia	Generalized stiffness, especially after rest; transient weakness is prominent after complete relaxation for several minutes; myotonia occurs in eyes; no paradoxical myotonia
Provocative stimuli	Prolonged rest or maintenance of the posture	Prolonged rest or maintenance of the same posture
Therapy for symptoms	Exercise; antimyotonia therapy (e.g., mexiletine); Achilles' tendon stretching helps prevent need for heel cord-lengthening surgery	Exercise; especially avoiding prolonged rest; antimyotonia therapy (e.g., mexiletine); transient weakness does not improve after mexiletine

which helps distinguish chloride channel myotonia congenita from certain forms of sodium channel myotonia that display increasing muscle stiffness with repeated contractions, a paramyotonic response. DM1 and DM2, like chloride channel myotonia, demonstrate the typical warm-up response.

In contrast to Thomsen's disease, patients with autosomal-recessive myotonia congenita (Becker's disease) have transient proximal muscle weakness. The transient weakness appears for a few seconds during the initial attempt at a specific movement after a period of inactivity. Muscle strength improves to normal after several strong contractions.

Patients have prominent muscle hypertrophy, especially in the legs, in both the autosomal-dominant and autosomal-recessive forms of myotonia congenita. Tendon reflexes, cerebellar function, sensation, and strength are normal. Myotonia can be noted with hand contraction or after eye closure. If patients lie supine for 5 to 10 minutes and suddenly arise, generalized myotonic stiffness in the proximal and paraspinous muscles becomes apparent. The estimated prevalence of autosomal-dominant myotonia congenita is 0.14/100,000, and the prevalence for autosomal-recessive myotonia congenita is 0.12/100,000.

## Genetics

Point mutations in the gene for the skeletal muscle chloride channel cause both autosomal-dominant and autosomal-recessive forms of myotonia congenita (Jurkat-Rott et al., 2015). Over 100 mutations of the *CLCN1* gene have been associated with myotonia congenita.

## Pathophysiology

 See the online chapter for commentary on pathophysiology.

## Clinical Laboratory Tests

Evaluation of patients with suspected myotonia congenita should include consideration of other myotonic disorders, such as DM1, DM2, paramyotonia congenita, sodium channel myotonias of other types, and chondrodystrophic myotonia (Schwartz-Jampel syndrome). Distinguishing patients with chloride channel myotonia, either the autosomal-dominant or autosomal-recessive form, from those with sodium channel myotonic disorders is often difficult. Both cause myotonic

stiffness and muscle hypertrophy, especially in the legs. One distinguishing feature of sodium channel myotonia is the paradoxical myotonia of the eyelids that develops with repeated forceful eye closure. In contrast, patients with autosomal-dominant and autosomal-recessive forms of chloride channel myotonia exhibit warm-up after repeated contractions. Patients with chloride channel myotonia do not have a worsening of myotonic stiffness or paralysis after prolonged exposure of muscle to cold. To search for cold-induced paralysis, it is necessary to soak the hand or forearm muscles in cold water (15° C) for 15 to 20 minutes. If there is weakness with exercise after this cold exposure, this observation strongly favors sodium channel myotonia rather than chloride channel disease (Heatwole and Moxley, 2007). Electrodiagnostic studies should be considered in every patient suspected of having a myotonic disorder or channelopathy. Short and long exercise tests can identify differentiating patterns associated with specific channelopathies or myotonic conditions.

## Treatment

Antimyotonia treatment with mexiletine is often helpful (Heatwole and Moxley, 2007). Before initiating treatment with mexiletine, a baseline ECG is necessary to identify patients with unsuspected cardiac conduction abnormalities. Side effects of mexiletine, which are usually mild and dose related, include dysgeusia, light-headedness, and diarrhea. Carbamazepine is an alternative antimyotonia medication to consider for myotonia congenita. Children with moderately severe myotonia develop heel cord shortening and contractures at their elbows. If these contractures do not respond to stretching and other physical therapy exercises, it is appropriate to initiate antimyotonia treatment even when patients do not complain of stiffness.

## ACETAZOLAMIDE-RESPONSIVE SODIUM CHANNEL MYOTONIA AND MYOTONIA FLUCTUANS

Two disorders that mimic myotonia congenita and are forms of sodium channel myotonia without periodic paralysis are acetazolamide-responsive sodium channel myotonia and myotonia fluctuans (Heatwole and Moxley, 2007) (Table 151-4).

**TABLE 151-4** Sodium Channel Myotonias Without Periodic Paralysis

Clinical Features	Acetazolamide-Responsive Sodium Channel Myotonia	Myotonia Fluctuans
Inheritance	Dominant	Dominant
Gene defect	Chromosome 17; mutation in skeletal muscle sodium channel	Chromosome 17; mutation in skeletal muscle sodium channel
Age of onset	First decade	First or second decade
Myopathy	Rare	Rare, muscle hypertrophy common
Myotonia	Face, paraspinal muscles, paradoxical myotonia of eyelids, grip limbs; varies in severity and often there is pain with myotonia	Face, limbs, eyelids; frequently fluctuates in severity; especially after exercise
Provocative stimuli	Fasting, cold, oral potassium, infection	Exercise–rest–exercise, oral potassium
Therapy for symptoms	Acetazolamide, mexiletine; avoid high-potassium diet; monitor during and after surgery for rigidity and rhabdomyolysis	Mexiletine; avoid high-potassium diet; monitor during and after surgery for rigidity and rhabdomyolysis

## Clinical Features

Acetazolamide-responsive sodium channel myotonia often initially presents to the pediatrician rather than the neurologist with common complaints, such as clumsiness causing frequent falls, a lazy eye, growing pains, back muscle spasm, or stridor. Parents may observe that after prolonged crying, an infant or young child will have “their eyes stuck.” This symptom is a manifestation of paradoxical eyelid myotonia that develops with repeated bouts of forceful closure of the eyes during crying. Myotonia is most apparent in the face, eyes, and larynx in very young patients. Stiffness in the hands, proximal limb muscles, and paraspinal muscles is more apparent in middle childhood. Muscle hypertrophy, especially in the legs, is frequent. Cerebellar function, sensory testing, tendon reflexes, and muscle strength are normal. Grip and percussion myotonia, and lid lag, are present. The severity of these complaints varies both in affected individuals within the same kindred and between kindreds. Episodes of painful muscle spasm occur in some patients, usually during or immediately after exercise. Pain is relatively infrequent in recessive and dominant chloride channel myotonias. In contrast, pain is common and can be severe in acetazolamide-responsive sodium channel myotonia and in DM2.

The clinical findings in myotonia fluctuans are similar to those described previously for acetazolamide-responsive sodium channel myotonia, with one important additional finding. The severity of the muscle stiffness fluctuates to a greater degree in this illness. On “good days” the myotonia can vanish. The fluctuating myotonia also has an interesting relationship with prolonged exercise. A phenomenon termed *exercise-induced delayed-onset myotonia* occurs. Patients report that after a period of rest following vigorous exercise, if they resume exercise “at the wrong time,” severe muscle stiffness may develop. The time interval between the period of rest and the resumption of exercise is critical. If it is only a few minutes or an hour or more, stiffness does not occur. During the intermediate time interval, the fluctuation and provocation of severe myotonia happen.

The myotonic symptoms in both acetazolamide-responsive sodium channel myotonia and myotonia fluctuans tend to persist throughout a patient’s lifetime. Some individuals note a lessening in severity in middle to late adulthood. This finding may represent only an adjustment to the illness and a decrease in physical activity.

## Genetics

See Table 151-4 and the Genetics section in the online chapter for more information.

## Pathophysiology

See the online chapter for commentary on pathophysiology.

## Clinical Laboratory Tests

Laboratories may screen for known mutations in the gene for the sodium channel in selected patients (Jurkat-Rott et al., 2015; Statland and Barohn, 2013; Suetterlin et al., 2014). The remainder of the laboratory evaluation is as described previously for chloride channel myotonia.

## Treatment

Acetazolamide often controls myotonic stiffness and pain in acetazolamide-responsive sodium channel myotonia (Heatwole and Moxley, 2007). This treatment usually ameliorates the muscle pain. Annual ultrasound of the abdomen is useful to detect early formation of kidney stones, which are a common complication of acetazolamide. Dysesthesia and dysgeusia typically occur. For attacks of severe muscle spasm and pain, cyclobenzaprine can be tried. Patients undergoing surgery require monitoring during and after the procedure for signs of worsening muscle stiffness. Maintaining plasma potassium levels between 3.8 and 4.2 mEq/L helps to decrease perioperative muscle stiffness. Stress, muscle tissue damage, and bleeding all elevate plasma potassium levels and worsen myotonia. Postoperatively, intravenous diazepam or lorazepam may be necessary to decrease myotonic stiffness, especially if patients are unable to take medications by mouth. Mexiletine is an effective alternative to acetazolamide, and, if necessary, these drugs can be used in combination (Heatwole and Moxley, 2007).

The management of myotonia fluctuans is similar to that of acetazolamide-responsive sodium channel myotonia. Careful attention to the pattern and timing of exercise helps to decrease episodes of severe muscle stiffness. Intraoperative and postoperative monitoring is important, as noted previously.

## THE PERIODIC PARALYSES

This section focuses on those disorders listed in Tables 151-5 and 151-6, which are associated with periodic paralyses, including channelopathies affecting the sodium, potassium, and calcium channels in skeletal muscle. See the online chapter for commentary on general classification and features of the periodic paralyses.

**TABLE 151-5** Sodium Channel Myotonias With Periodic Paralysis

Clinical Features	Paramyotonia Congenita	Paramyotonia Congenita With Hyperkalemic Periodic Paralysis	Hyperkalemic Periodic Paralysis With Myotonia
Inheritance	Dominant	Dominant	Dominant
Gene defect	Chromosome 17; mutation in skeletal muscle sodium channel	Chromosome 17; mutation in skeletal muscle sodium channel	Chromosome 17; mutation in skeletal muscle sodium channel
Age of onset	First decade	First decade	First decade
Myopathy	Very rare	Rare	Infrequent
Myotonia	Especially paradoxical myotonia of the eyelids, and grip	Especially paradoxical myotonia of the eyelids, and grip	Especially paradoxical myotonia of the eyelids
Provocative stimuli	Cold exposure followed by exercise leads to focal paralysis; occasionally exercise provokes stiffness	Oral potassium load, rest after exercise mainly in morning (hyperkalemic weakness), cold exposure followed by exercise (focal paralysis)	Rest after exercise, cold, oral potassium
Therapy for symptoms	Mexiletine, mild exercise, keep patient warm	Mild exercise, thiazides, mexiletine	Thiazides, acetazolamide, sodium restriction

**TABLE 151-6** Channelopathies With Hypokalemic Periodic Paralysis

Clinical Features	Andersen's Syndrome: Periodic Paralysis With Cardiac Dysrhythmia	Calcium Channel Periodic Paralysis	Sodium Channel Periodic Paralysis	Potassium Channel Periodic Paralysis	Periodic Paralysis With Thyroid Disease
Inheritance	Dominant	Dominant	Dominant	Dominant	Sporadic-occasionally dominant
Age of onset	First or second decade	First to third decade	First to third decade	Not yet determined	Third decade (males 20:1)
Myopathy	Typical; also short stature; dysmorphic features; prolonged QT interval on electrocardiogram; ventricular dysrhythmias	Moderately common late; vacuoles frequently seen on biopsy	Not yet determined	Not yet determined	Infrequent
Myotonia	No	No	No	No	No
Provocative stimuli	Rest after exercise, oral glucose	High-carbohydrate meals, rest after exercise, cold, emotional stress/excitement	High-carbohydrate meals, rest after exercise, cold, emotional stress/excitement	Usually by strenuous exercise followed by rest; less consistent provocation after high carbohydrate intake	High-carbohydrate meals, rest after exercise, acetazolamide
Therapy for symptoms	Mild exercise, glucose, high sodium intake, acetazolamide, dichlorphenamide	Acetazolamide, dichlorphenamide, potassium, spiro lactone	Acetazolamide, dichlorphenamide, spiro lactone	Acetazolamide	Propranolol, restoration of euthyroid state, oral potassium, spironolactone

## Hyperkalemic Periodic Paralysis

### Clinical Features

Table 151-5 outlines the major clinical and diagnostic features of hyperkalemic periodic paralysis and important issues in management. All three forms are autosomal dominant with high penetrance in both sexes (Cannon, 2002). Attacks begin in childhood and are usually brief, being shorter and more frequent than attacks in hypokalemic periodic paralysis. The attacks can occur with or without myotonia; in certain families, hyperkalemic paralysis occurs in combination with coexisting paramyotonia congenita (Jurkat-Rott et al., 2015; Statland and Barohn, 2013; Cannon, 2002; Heatwole and Moxley, 2007). At the onset of an attack, myalgia may develop. Patients with hyperkalemic periodic paralysis plus myotonia frequently develop muscle stiffness and prominent paradoxical myotonia of the eyelids during attacks. Similar symptoms occur in patients with hyperkalemic periodic paralysis in association with paramyotonia congenita (Jurkat-Rott et al.,

2015; Statland and Barohn, 2013). Most patients with hyperkalemic attacks manifest signs of myotonia and notice increasing muscle tension, especially in the paraspinal muscles. The estimated prevalence of hyperkalemic periodic paralysis is 0.13/100,000.

### Genetics

See Table 151-5 and the Genetics section in the online chapter for more information.

### Pathophysiology

See the online chapter for commentary on pathophysiology.

### Clinical Laboratory Tests

The primary laboratory evaluation involves monitoring of serum electrolytes during attacks to identify hyperkalemia or hypokalemia and monitoring the ECG to search for any evidence of dysrhythmia or other conduction disturbance, such

as the ECG changes that occur in Andersen–Tawil syndrome. A dominant family history helps to limit additional laboratory testing to search for secondary forms of hyperkalemia, which might lead to muscle weakness. Laboratory evaluation for secondary hyperkalemic weakness should include a search for hormonal disturbances, such as insulin deficiency or adrenal insufficiency, or toxic effects of medications, such as beta-adrenergic antagonists, alpha-adrenergic agonists, digitalis intoxication, or the use of succinylcholine. Full gene screening can be performed for mutations in the skeletal muscle sodium, chloride, calcium, and potassium channel genes to search for a mutation to account for one of the forms of nondystrophic myotonia or one of the forms of periodic paralysis (Jurkat-Rott et al., 2015; Statland and Barohn, 2013; Suetterlin et al., 2014). In patients not observed during a spontaneous attack of weakness or posing a continuing problem in definite classification of the form of periodic paralysis, it may be necessary to perform provocative testing with oral potassium loading or exercise followed by potassium challenge. Electrodiagnostic testing including short and long exercise tests may also provide diagnostic utility (Statland and Barohn, 2013).

### Treatment

Attacks of weakness in hyperkalemic periodic paralysis are seldom severe enough to require emergency room evaluation. Oral glucose hastens recovery. Severe attacks usually respond to oral glucose and crystalline insulin subcutaneously. Occasionally, severe attacks may fail to respond to these treatments. Calcium gluconate is sometimes effective. Inhalation of beta-adrenergic agents, such as metaproterenol, every 15 minutes for three doses has also been utilized.

Preventive treatment includes avoidance of fasting, exposure to cold, and overexertion. A prudent consumption of frequent meals high in carbohydrate content is helpful. Diuretics that promote kaluresis, such as hydrochlorothiazide and carbonic anhydrase inhibitors, are good primary therapies (Heatwole and Moxley, 2007).

## Paramyotonia Congenita

### Clinical Features

Symptoms develop usually during the first decade of life and have a predilection for facial, lingual, neck, and hand muscles (see Table 151-5) (Jurkat-Rott et al., 2015; Heatwole and Moxley, 2007). Attacks of increased muscle stiffness followed by paralysis occur on exposure to cold followed by exercise. The hallmark clinical sign is paradoxical myotonia or paramyotonia, that is, stiffness that worsens with repeated muscle contraction. This sign is most prominent in the muscles of eye closure. Clinical myotonia may be restricted to the eye muscles and not be apparent in grip or after percussion. Some patients experience lid lag and diplopia. See the online chapter for commentary on rare severe variants. The estimated prevalence of this paramyotonia congenita is 0.17/100,000.

### Genetics

Mutations in the gene for the skeletal muscle sodium channel in several locations cause paramyotonia congenita (Jurkat-Rott et al., 2015; Matthews et al., 2010). See the online chapter for more details.

### Clinical Laboratory Tests

Standardized testing using immersion of the hand and forearm in cold water for 15 minutes followed by exercise is effective in provoking paramyotonic stiffness and paralysis in most patients. Most cooperative children can tolerate this testing. If

no clear evidence of cold-induced muscle stiffness and weakness is apparent, further laboratory testing as indicated previously under hyperkalemic periodic paralysis and as noted under laboratory tests for chloride channel myotonia may be necessary. Repetitive nerve stimulation of the ulnar nerve at the wrist as a short exercise test before and after cold exposure helps to identify certain forms of sodium channel myotonia, including paramyotonia congenita, but it is uncomfortable and has been standardized only in adults. DNA analysis to search for known mutations in the gene for the sodium channel is available (Jurkat-Rott et al., 2015; Statland and Barohn, 2013; Matthews et al., 2010).

### Pathophysiology

See the online chapter for commentary on pathophysiology. 

### Treatment

Mexiletine is usually effective in preventing attacks of cold-induced weakness (Heatwole and Moxley, 2007). Patients having the combination of paramyotonia congenita plus hyperkalemic periodic paralysis require additional treatment with either a thiazide diuretic or acetazolamide.

## Hypokalemic Periodic Paralysis

Hypokalemic periodic paralysis is an autosomal-dominant disorder caused most commonly by mutations in the alpha subunit of the skeletal muscle calcium channel gene Cav1.1 (Jurkat-Rott et al., 2015; Statland and Barohn, 2013). A clinically identical form of hypokalemic periodic paralysis can also result from specific mutations of the alpha subunit of the Nav1.4 skeletal muscle sodium channel associated with hyperkalemic periodic paralysis (Jurkat-Rott et al., 2015; Statland and Barohn, 2013). Approximately 60% of cases are caused by missense mutations of the calcium channel gene, Cav1.1, and 15% to 20% of cases are caused by mutations in the sodium channel gene, Nav1.4. The estimated prevalence is 0.17/100,000.

### Clinical Features

Attacks of hypokalemic periodic paralysis usually have their onset in the first or second decade, and about 60% of patients are affected before the age of 16 years (Jurkat-Rott et al., 2015; Statland and Barohn, 2013). Rarely, attacks occur in infancy. Initially, attacks tend to be infrequent but eventually may recur daily. Diurnal fluctuations in strength may develop so that patients demonstrate greatest weakness during the night or early morning hours and gradually gain strength as the day passes. During major attacks, the serum potassium level decreases but not always to below normal. There is urinary retention of sodium, potassium, chloride, and water. Oliguria or anuria develops during such attacks, and patients tend to be constipated. Sinus bradycardia and ECG signs of hypokalemia appear when the serum potassium falls below normal. Usually during the fourth and fifth decades of life, attacks become less frequent and may cease. However, repeated attacks may leave the patient with permanent residual weakness (Jurkat-Rott et al., 2015). Treatment with acetazolamide can aggravate hypokalemic periodic paralysis caused by sodium channel mutations in some but not all kindreds.

### Genetics

In most kindreds familial hypokalemic periodic paralysis results from missense mutations at charged residues of the S4 voltage-sensing segments in either the L-type voltage-gated calcium channel Cav1.1 encoded by the *CACNA1S* gene or in the voltage-gated sodium channel Nav1.4.

## Pathophysiology

See the online chapter for commentary on pathophysiology.

## Clinical Laboratory Tests

Evaluation of serum electrolytes and ECG during attacks of weakness is essential to diagnosis and treatment. Muscle biopsy is usually not necessary but may reveal vacuoles, especially in patients with fixed weakness. In patients not observed during attacks of weakness, it may be necessary to undertake careful provocative testing if DNA analysis does not identify the responsible mutation. This testing requires hospitalization and continuous monitoring of the ECG, as indicated in previously published protocols. Occasionally, hypokalemic paralysis develops from acquired, secondary causes. Causes for secondary hypokalemic weakness include the following: hypokalemia in association with hyperthyroidism, beta-adrenergic stimulation, excessive insulin, alkalemia, barium poisoning, poor potassium intake (e.g., alcoholics, anorexia nervosa), excessive potassium excretion (e.g., diarrhea, laxative abuse, profuse sweating during athletic training), and renal loss of potassium (e.g., renal tubular acidosis, osmotic diuresis, and medication use, such as large doses of penicillin antibiotics).

## Treatment

Acute attacks may respond to oral potassium chloride. Monitoring of ECGs, serum potassium levels, and muscle strength helps determine the frequency of these doses. Milder attacks resolve spontaneously, and mild exercise of the weakened muscles speeds recovery. If a patient has a severe attack and is unable to swallow or is vomiting, very cautious intravenous infusion of potassium may be necessary. Treating physicians should keep in mind that a patient's serum potassium levels do not represent a total body deficit of potassium but rather a temporary intracellular shift. Therefore potassium replacement formulas tend to overestimate the replacement needs and result in potentially dangerous hyperkalemia. Preventive therapy for attacks of hypokalemic weakness is usually needed. A low-sodium (2–3 g/day) and low-carbohydrate (60–80 g/day) diet, avoidance of exposure to cold and overexertion, and supplemental doses of potassium chloride taken two to four times daily are preventive measures that may help. However, no convincing data are available to indicate that oral potassium chloride prevents attacks.

Acetazolamide in divided doses usually abolishes attacks of weakness in most patients when taken daily. Dichlorophenamide is another carbonic anhydrase inhibitor that is useful as preventive treatment if acetazolamide proves ineffective. Carbonic anhydrase inhibitors produce a metabolic acidosis, and despite their kaluretic action and their tendency to lower serum potassium levels, they appear to act on skeletal muscle to stabilize potassium flux, especially during insulin stimulation. There are rare familial cases of hypokalemic periodic paralysis in which acetazolamide exacerbates attacks of weakness. This weakness appears to be a consistent but not universal feature of hypokalemic periodic paralysis families carrying sodium channel mutations. In these families, triamterene or spironolactone may control the attacks.

## Periodic Paralysis With Cardiac Arrhythmia: Andersen–Tawil Syndrome

### Clinical Features

Andersen syndrome (Jurkat-Rott et al., 2015; Statland and Barohn, 2013) or, as recently recognized, Andersen–Tawil

syndrome, is a rare inherited disorder with an estimated prevalence of 0.08/100,000 that is characterized by periodic paralysis, long QT syndrome, ventricular dysrhythmias, and skeletal developmental abnormalities. Skeletal abnormalities include low-set ears, widely spaced eyes, scoliosis, short stature, small mandibles, and fifth-digit clinodactyly (Statland and Barohn, 2013). The early reports of this disorder raised the possibility of hyperkalemia during attacks of weakness, but as more specific identification of kindreds with Andersen–Tawil syndrome has occurred, it is apparent that the disorder occurs with both hyper- and hypokalemia. One form is a variant of hypokalemic periodic paralysis. Patients with this type of hypokalemic weakness have short stature, clinodactyly, and microcephaly, and ventricular dysrhythmias (Figure 151-7). Attacks of weakness develop during the first or second decade. The attacks of limb weakness can vary from mild, resembling those in the sodium channel form of hyperkalemic periodic paralysis, to severe, resembling the typical calcium channel form of hypokalemic periodic paralysis. The major difference is that occasionally the episodes of weakness are associated with syncopal attacks and rarely sudden death. The cardiac arrhythmias and extrasystoles improve with an elevation in extracellular potassium, whereas hypokalemia tends to aggravate the cardiac dysrhythmias. Cardiac symptoms can be provoked by digitalis; are refractory to disopyramide phosphate, propranolol, and phenytoin; and may respond to imipramine. Weakness and cardiac symptoms in some patients occur following corticosteroid treatment. Patients with Andersen–Tawil syndrome have a neurocognitive phenotype, with individuals having deficits in executive function and abstract reasoning compared with their siblings. Isolated reports have also identified patients with afebrile seizures, dilated cardiomyopathies, and renal tubular defects (Statland and Barohn, 2013).

## Genetics

One of the responsible mutations involves the KCNJ2 gene encoding the inward-rectifying potassium channel Kir2.1. Autosomal-dominant inheritance occurs with variable severity within families. See the online version of chapter for more information.

## Pathophysiology

See the online chapter for commentary on pathophysiology.

## Clinical Laboratory Tests

Periodic monitoring of the ECG (or Holter monitoring) is important to identify covert dysrhythmias. ECG can reveal premature ventricular contractions, QT interval prolongation, large U-waves, and bidirectional ventricular tachycardia. DNA testing is helpful in confirming the diagnosis. Secondary forms of periodic paralysis must be ruled out with assessments of thyroid, renal, and adrenal functions. Muscle biopsy may help to distinguish patients with Andersen–Tawil syndrome from those with other myopathic disorders, especially various congenital myopathies. Electrophysiologic cold studies are helpful in confirming the presence of skeletal muscle membrane and excitability using the exercise nerve conduction study, which can in many patients distinguish those with known sodium, chloride, and calcium channel mutations from individuals with Andersen–Tawil syndrome.

## Treatment

Acetazolamide in doses used to treat sodium channel forms of hyperkalemic periodic paralysis is sometimes effective in preventing attacks of weakness. Dichlorophenamide or

flecainide may provide an effective alternative if acetazolamide fails. Oral potassium repletion with ECG monitoring can be used during episodic weakness if a patient's serum potassium concentration is low (Statland and Barohn, 2013). If serum levels of potassium are high, exercise or carbohydrates may shorten an attack. Cardiac dysrhythmias are less frequent if serum potassium is permitted to range from 4 to 4.4 mEq/L. However, this elevation in potassium may be difficult to achieve because it is typically not feasible with the use of carbonic anhydrase inhibitors. In general, agents that create drug-induced hypokalemia or prolong QT intervals should be avoided. Management of the cardiac dysrhythmia is best handled by a cardiologist. Cardiac dysrhythmia in this condition is typically difficult to control and can result in sudden cardiac death.

## Thyrotoxic Periodic Paralysis

### Clinical Features

Attacks of thyrotoxic periodic paralysis tend to develop in the late teens and during the 20s. Thyrotoxic periodic paralysis is much more frequent in Asians and males; 95% of cases are sporadic. Precipitating factors include sleep, hot weather, and excessive physical activity. Recurrent attacks of weakness may occur in over 60% of patients who have not returned to the euthyroid state. Cardiac problems, including sinus tachycardia, atrial fibrillation, supraventricular tachycardia, and ventricular fibrillation, can occur.

### Pathophysiology

 See the online chapter for commentary on pathophysiology.

### Genetics

 The gene defect responsible for thyrotoxic hypokalemic periodic paralysis remains unclear. See the online chapter for more information.

### Clinical Laboratory Tests

Measurement of thyroid function tests and the ECG are essential in establishing the diagnosis and in directing treatment. Other aspects of clinical laboratory evaluation are as described for familial hypokalemic periodic paralysis.

### Treatment

Treatment consists of antithyroid therapy until the patient achieves the euthyroid state. Preventive measures should be undertaken after treatment of the acute attack as described for primary familial hypokalemic periodic paralysis. Propranolol is often effective in preventing attacks in thyrotoxic periodic paralysis. Recent studies emphasize the importance of propranolol as an initial treatment and suggest caution about the use of potassium replacement. Acetazolamide is ineffective and may worsen or precipitate symptoms in thyrotoxic hypokalemic periodic paralysis and should be avoided. In general, beta-blocking drugs are helpful to use throughout the early stages of management until the patient becomes euthyroid.

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

The management of pediatric neuromuscular disorders is complex and challenging. Developing an effective management plan requires an understanding of the underlying pathophysiology, genetics, and natural history, as well as the interactions of normal maturation, treatment modalities, and the environment. Optimum management requires a multidisciplinary approach that focuses on anticipatory and preventive measures as well as active interventions to address the primary and secondary aspects of the disorder (Bushby et al., 2009). Implementing comprehensive management strategies can favorably alter the natural history of the disorder and improve function, quality of life, and longevity (Fig. 152-1). This chapter will discuss general recommendations for management of pediatric neuromuscular disorders along with specific recommendation for individual diseases.

Appropriate management of patients with neuromuscular disorders requires an accurate diagnosis, including the relevant patient and family history, and focused general, musculoskeletal, neurologic, and functional physical examinations. All diagnostic information should be interpreted, not in isolation, but within the context of relevant historical information, family history, examination findings, laboratory data, molecular diagnostic studies, electrophysiologic findings, and pathologic information, if obtained (McDonald, 2010).

Therapeutic treatment includes early intervention, age-appropriate functional training, therapy programs, play, therapeutic exercise, adjustment to disability support and transition planning. Engaging in play activities and working on developing activities of daily living are the primary mechanisms by which children with neuromuscular disorders can maintain muscle strength. The available evidence suggests that in patients with neuromuscular diseases, both strength training and aerobic exercise programs appear to be safe, without any notable deleterious effects. Gentle, low impact aerobic exercise (swimming, stationary bicycling) improves cardiovascular performance, increases muscle efficiency, and lessens fatigue (Narayanawami et al., 2014).

Muscles can be strengthened by prescribing progressive resistance exercises, stretching and aerobic exercise. A minimum of once-a-day muscle contraction at 30% to 50% of maximal strength for 3 to 5 minutes, 3 times per week, for a single muscle group has been shown to be effective. High resistance strengthening has not demonstrated additional benefit. Patients who are participating in an exercise program need to be aware of the warning signs of overwork weakness, which includes feeling weaker rather than stronger within 30 minutes post exercise or excessive muscle soreness 24 to 48 hours after exercise, severe muscle cramping, heaviness in the extremities, and prolonged shortness of breath. Significant muscle pain or myoglobinuria in the 24-hour period after specific activity is a sign of overexertion and indicates that activity should be modified.

The management of limb contractures in patients with progressive neuromuscular disease and the role of stretching, orthotics, and surgery have been comprehensively reviewed.

Principle therapies include: 1) regularly prescribed periods of daily standing and walking if the patient is functionally capable of being upright; 2) passive stretching of muscles and joints with a daily home program; 3) positioning of the legs to promote extension and oppose joint flexion when the patient is nonweight-bearing; and 4) splinting, which can be useful measure for the prevention or delay of ankle contracture (Bushby et al., 2009).

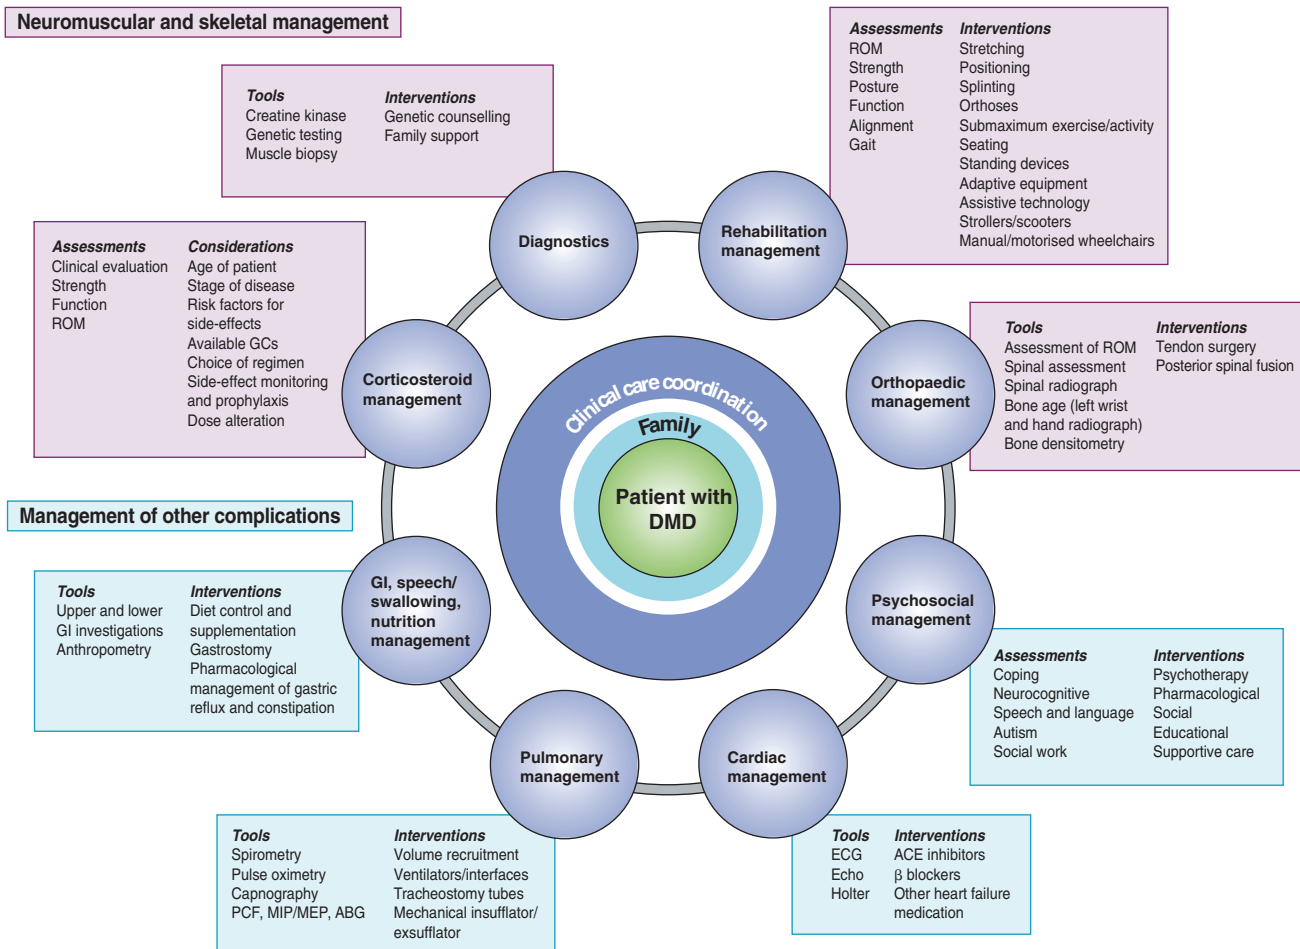

Stretching to maintain optimal muscle resting length as well as viscoelastic properties is important for maintaining muscle function. Muscles that cross two joints, such as the gastrocnemius, hamstrings, hip flexors, biceps, and the long back extensors, are particularly prone to develop contractures. Once a contracture has developed, the treatment is active and passive range of motion exercises combined with a sustained terminal stretch on a daily basis. The intensity of stretch should be of a mild degree without discomfort. Static stretches are held 15 to 60 seconds. Sustained stretching can be obtained by splinting orthotics. Resting ankle foot orthoses (AFOs) can help to prevent or minimize progressive equinus contractures. Knee-ankle-foot orthoses (KAFOs) can be of value in late ambulatory and early nonambulatory stages to allow standing and limited ambulation for therapeutic purposes (see Fig. 152-2). A passive standing device can be used with either no or mild hip, knee, or ankle contractures.

Dynamic splinting provides tension in the desired direction with the use of springs or elastic bands. This type of splinting is often used in the hand and arm because it allows a measure of function while providing stretching. To achieve optimal joint position, it is sometimes necessary to surgically lengthen the contracted tendon.

In the upper extremity, elbow flexion contractures in dystrophic myopathies may occur soon after wheelchair transition secondary to static positioning of the arms and elbow flexion on the armrests of the wheelchair. Other associated deformities include forearm pronator tightness and wrist flexion-ulnar deviation in the later stages of the disease. Mild elbow flexion contractures of 15° or less are of no functional consequence. Severe elbow flexion contractures of greater than 60° are associated with decreased distal upper extremity function and produce difficulty when dressing. Nighttime resting splints, which promote wrist extension, metacarpophalangeal extension, and proximal interphalangeal flexion, are recommended. Daytime positioning should emphasize wrist and finger extension, but splinting should not compromise sensation or function.

Weakness is the major cause of loss of ambulation in Duchenne muscular dystrophy (DMD), not contracture formation. The primary indication for orthopedic surgical tenotomies is the provision of optimal alignment. Little evidence supports the efficacy of early prophylactic lower extremity surgery in DMD for prolonging ambulation.

The release of contractures at both the heel cord and iliotibial band may be necessary to obtain optimal alignment. Hip and knee flexion contractures generally are not severe enough

**Figure 152-1.** Interdisciplinary management of DMD. (With permission from Bushby, K., Finkel, R., Birnkrant, D.J., et al., 2010. *Diagnosis and management of Duchenne muscular dystrophy, part 1: diagnosis, and pharmacological and psychosocial management*. *Lancet Neurol* 9(1), 77–79.)

to require surgery. The ankle deformity may be corrected by either a tendo-Achilles lengthening (TAL) or a TAL combined with a surgical transfer of the posterior tibialis muscle tendon to the dorsum of the foot.

Those still ambulating independently without orthotics use their ankle equinus posturing from the gastrocnemius-soleus group to create a knee extension moment at foot contact, thus stabilizing the knee when the quadriceps muscle is weak. Several authors have cautioned against isolated heel cord tenotomies. Overcorrection of the heel cord contracture may result in immediate loss of the ability to walk without bracing unless the quadriceps are grade 4 strength or better.

Adaptive devices are frequently used to maintain function. During the early ambulatory phase, a lightweight wheelchair can be used for distances. As the weakness progresses in the late ambulatory phase, use of manual wheelchair, scooter, or power chair can be considered. As functional community ambulation declines, a power wheelchair is advocated. Generally, children can be taught to safely operate a power wheelchair at the developmental age of approximately 2 years. The initial power wheelchair prescription needs to consider the natural history of the neuromuscular disease disorder over the following 5 years, as some children will develop the need for a power recline system. In more severely disabled, the power wheelchair electronics should be sufficiently sophisticated to incorporate alternative drive control systems, environmental control adaptations, and possibly augmentative communication

systems in patients who are unable to vocalize. The power wheelchair should include: a solid custom seat and back, lateral trunk supports, hip guides, headrest, power tilt/recline, elevating or swing away leg rests, and a pressure-relieving cushion.

Upper extremity weakness can be augmented with a lap tray, extended straws, balance forearm orthoses, and environmental controls. Bathing equipment, hospital bed, and transfer devices are frequently used in nonambulatory patients.

Severe spinal deformity in progressive neuromuscular disorders leads to multiple problems, including poor sitting balance, difficulty with upright seating and positioning, pain, difficulty in parental or attendant care, and potential exacerbation of underlying restrictive respiratory compromise. Fixed pelvic obliquity (pelvic tilt) may increase the risk of developing pressure ulcers due to imbalanced seating. Increased spinal deformity may require the patient to utilize the upper extremities to support an upright position, thereby leaving the hands unable to be used for other activities.

Populations at risk for scoliosis include DMD, autosomal recessive LGMD, congenital muscular dystrophy, FSH muscular dystrophy, congenital myotonic muscular dystrophy, spinal muscular atrophy II and III, and Friedreich ataxia (Wang et al., 2007).

Close clinical monitoring is essential for children at risk for scoliosis. Baseline spinal radiography is indicated near time of wheelchair dependency and then annually for curves less than

20 degrees. Curves may progress rapidly during the adolescent growth spurt, and children will then need to be monitored every 6 months with clinical assessments and spine radiographs. Patients who are likely to require surgical arthrodesis at some point should be monitored with pulmonary function tests every 6 months.

Scoliosis progression in the thoracic spine can lead to the development of restrictive lung disease and increased need for noninvasive positive pressure ventilation, especially during sleep. Patients with DMD are expected to lose 4% of their forced vital capacity per year with an additional 4% decline for each 10 degree increase of their scoliosis. Similar reductions in pulmonary function with an increase in scoliosis have also been demonstrated in children with spinal muscular atrophy (SMA).

The management of spinal deformity with orthotics is relatively ineffective in DMD. Spinal orthoses are often reported to be uncomfortable and poorly tolerated in this population. Furthermore, vital capacity potentially can be lowered with constrictive orthoses. On the other hand, in neuromuscular diseases with spinal deformity beginning in the first decade of life such as SMA, congenital muscular dystrophy, congenital myotonic muscular dystrophy, some congenital myopathies, and congenital myasthenic syndromes, spinal orthoses are generally used to improve sitting balance.

Recent data have demonstrated markedly decreased incidence of scoliosis and progression to surgery for scoliosis in children with DMD treated with glucocorticoids. In a nonrandomized comparative cohort of 54 children, 6 of 30 (20%) of children in the glucocorticoid group developed scoliosis and had surgery, compared with 22 of 24 (92%) in the group not treated with glucocorticoids.

Surgical correction of scoliosis should be considered based upon the patient's curve progression, pulmonary function, and bone maturity. Evidence suggests that earlier surgery results in better outcomes. The beneficial effects on pulmonary function remains controversial, but the rate of decline may be slowed.

The extent of the fusion depends on the degree of spinal curvature, pelvic obliquity, and mobility. Generally, posterior spinal fusion is appropriate for curves greater than 30 degrees. If there is pelvic obliquity greater than 15 degrees, it is necessary to perform correction and stabilization from the upper thoracic region to the sacrum (Fig. 152-4).

Multidisciplinary preoperative evaluation is recommended before considering treatment for scoliosis in DMD and SMA. These evaluations are useful to prepare the patient and optimize the treatment plan to minimize surgical complications. These assessments also can prove critical for families who are trying to decide whether or not to pursue surgery. In some cases, patients are so severely compromised medically that surgery no longer is a practical option due to unacceptably high risks of postoperative complications.

At minimum, the preoperative evaluation should include pulmonary, anesthesia, cardiology, and nutritional assessments. Sleep studies are often recommended to assess for hypoxia and obstructive sleep apnea. Pulmonary evaluation helps prepare the patient and surgeon for the potential need for postoperative respiratory support that can range from supplemental oxygen to mechanical ventilation with tracheostomy.

A plan should also be in place for changes in seating equipment that will be needed after the major alteration in body contour after scoliosis surgery. Most children will no longer comfortably fit in their old custom seating systems after scoliosis correction. Resuming upright posture as soon as possible after surgery is important to help with expansion of the lungs and prevention of atelectasis and pneumonia.

Figure 152-4. Posterior spinal fusion.

Figure 152-5. VEPTR (vertical expandable prosthetic titanium rib) implants.

For children who develop severe scoliosis at a young age (younger than 10 years), however, spinal fusion has been discouraged due to the concern that it will lead to restrictive lung disease as the child grows. Various "growth friendly" surgical options have been studied in neuromuscular patients. Growing rod treatment involves short fusions of the spine at the upper and lower ends with connecting rods that are periodically distracted (every 6 months) to maintain growth. VEPTR (vertical expandable prosthetic titanium rib) implants function in a similar manner, with fixation proximally on the ribs instead of the spine (see Fig. 152-5). Although these advances can be beneficial for some patients, they have high complication rates. A rod that can be expanded via a magnet

external to the patient has recently been approved for use in the United States and may prove beneficial for young patients with neuromuscular scoliosis.

Complications occur at a high rate in neuromuscular scoliosis surgery. Surgical site infection has been reported in 5% to 15% of patients. Infection typically requires return to the operating room for debridement and prolonged antibiotic treatment. Pulmonary and gastrointestinal complications in neuromuscular scoliosis are also frequent, and seen in up to 50% of patients. Postoperative respiratory support is frequently needed as is enteral or parenteral nutritional support.

Complications are also frequent in growing rod and VEPTR surgery for neuromuscular scoliosis. These include failure of rib/spine anchors and infection. Together, these complications affect about 1 in 3 patients undergoing growing rod or VEPTR treatment. Complications appear to be less frequent in patients with SMA compared with idiopathic diagnoses, perhaps due to decreased functional demand on the nonfusion constructs.

Quality of life data after surgery for neuromuscular scoliosis is sparse. Scoliosis surgery in patients with SMA and DMD is generally thought to provide good functional results with improvements in sitting balance, caregiver burden, and patient/parent perception of self-image after surgery.

Respiratory involvement in neuromuscular disorders is variable depending on the diagnosis. It may be progressive or static. In some disorders such as Duchenne muscular dystrophy, the progression of respiratory involvement is predictable. The pathophysiology depends on the pattern of muscle weakness. Weakness of the diaphragm, accessory respiratory muscles, and pharynx can lead to impaired cough strength, recurrent pneumonia, aspiration, persistent atelectasis, restrictive lung disease, hypoventilation, obstructive sleep apnea, and chronic respiratory failure. Scoliosis can further complicate respiratory function by contributing to chest wall restriction by impairing normal chest and diaphragm mechanics.

Neonatal respiratory distress or failure is seen in many of the congenital myopathies, spinal muscular atrophy type I, and myotonic dystrophy type I. These infants often require assisted ventilation, provided either invasively or noninvasively. They may also require airway clearance with chest physiotherapy or mechanical insufflation-exsufflation (commonly referred to as cough assist). Examination findings include feeding difficulty, tachypnea, nasal flaring, accessory muscle use, thoracoabdominal asynchrony ("see-saw breathing"), weak cough, decreased air entry, crackles, and dullness to percussion.

In toddlers and children, respiratory muscle dysfunction may or may not be commensurate with other skeletal muscle function (e.g., age-appropriate developmental milestones such as sitting, crawling, and walking). Therefore a high index of suspicion for respiratory disease is needed. In toddlers or patients in whom voluntary pulmonary function testing is not possible due to cognitive or other barriers, detailed history is needed. Questions should focus on daily respiratory symptoms of cough, dyspnea, exercise tolerance (if applicable), swallowing difficulty, history of pneumonia, and difficulty with anesthesia. As diaphragm function is often more affected in the supine position and during sleep, detailed inquiries searching for sleep-disordered breathing are vital. These findings may be subtle and questions should include the presence or absence of snoring, overt apnea or gasping, abnormal respiratory patterns, restless sleep, nocturnal diaphoresis, frequent awakenings, enuresis, morning headaches, mood on awakening, and need for daytime sleep. Children whose sleep is disrupted may also experience attention deficits and hyperactivity rather than daytime somnolence. Should any concerns for impaired sleep-disordered breathing arise, referral for a

formal polysomnogram (not overnight home pulse oximetry) is recommended.

In children who can complete voluntary pulmonary function tests, findings include decreased vital capacity (restrictive defect), decreased inspiratory and/or expiratory pressures, and decreased peak cough flows. Vital capacity may be further reduced in the supine position. A 20% decrease in vital capacity from prone to supine position is consistent with diaphragm dysfunction and increases the risk for sleep-disordered breathing.

Every patient with a neuromuscular disorder and known or suspected respiratory manifestations should be referred to a pulmonologist with expertise in neuromuscular disease. Frequency and nature of monitoring is determined by the underlying diagnosis, interval history, pulmonary function, and polysomnography where relevant.

Published guidelines are available for Duchenne muscular dystrophy, spinal muscular atrophy, congenital myopathies as a whole, and congenital muscular dystrophies as a whole (Finder et al., 2004; Manzur et al., 2003; Wang et al., 2012). All infants and children should receive standard immunizations. Influenza immunization should only be given using inactivated virus vaccine given by intramuscular injection and not with a live attenuated vaccine given by nasal inhalation. Infection with respiratory syncytial virus (RSV) leads to more severe RSV-related disease in infants and children with neuromuscular impairment than in those without neuromuscular impairment. Therefore passive RSV immunization with palivizumab has been recommended by some providers. Immunization with pneumococcal polysaccharide vaccine (PPSV) is recommended for those patients with respiratory disease over the age of 5 years.

Treatment of respiratory weakness is supportive and focuses on improving cough clearance, optimizing sleep-disordered breathing, and maximizing oxygenation and ventilation, all while improving quality of life. Supplemental oxygen may correct hypoxemia but may lead to worsened hypercapnia by eliminating the hypoxemic drive to breathe. Mechanical airway clearance, similar to mechanical insufflation-exsufflation, is used when peak cough flow is impaired. Daily mechanical insufflation may also play a role in maintaining chest compliance. Breath stacking, glossopharyngeal breathing, and abdominal thrusts (also called "quad cough") have been used to varying degrees of success. Other modalities of airway clearance such as inhaled bronchodilators, inhaled or oral mucolytics, and mechanical vibration (e.g., pneumatic vest or intrapulmonary percussive ventilation) have not been well-studied in neuromuscular disorders. These are often used as adjunctive therapies, especially in the setting of acute respiratory illness.

Continuous positive airway pressure (CPAP) is not recommended as it does not provide inspiratory support for normal tidal breathing. Bilevel positive airway pressure provides continuous airway pressure to maintain functional residual capacity as well as inspiratory tidal support. Settings for nocturnal use are best determined in the sleep laboratory during sleep. Progression to daytime hypercapnia and chronic respiratory failure occurs in many neuromuscular disorders. This can be managed noninvasively (with nasal or oronasal interfaces or mouthpiece ventilators) or invasively with tracheostomy. Clinical monitoring with pulse oximetry and noninvasive measurements of CO<sub>2</sub> can also direct mechanical ventilation strategies. Many patients are not able to tolerate noninvasive ventilation initially and may benefit from sleep psychology services for desensitization therapy.

Discussions about goals of care, end-of-life decisions, and code status should be conducted well in advance of any surgery or the development of chronic respiratory disease. This

should be undertaken on a recurrent basis with providers with whom the patient and family are familiar. Enlisting the assistance of palliative care services is a vital but often neglected part of the patient's care.

Cardiac involvement is not uniform in neuromuscular diseases. Yet in some disorders such as Duchenne muscular dystrophy (DMD), Becker muscular dystrophy (BMD), some of the limb-girdle muscular dystrophies, and myotonic dystrophy, cardiac disease is a major cause of morbidity and mortality. Early diagnosis and detection of cardiac involvement provides opportunity for early therapy and intervention, which will hopefully affect positive outcomes.

In DMD, cardiac manifestations include cardiomyopathy and cardiac arrhythmia. Dystrophin is present both in the myocardium as well as in the cardiac Purkinje cells that affect conduction. Cardiomyopathy is progressive and a major source of morbidity and mortality in DMD and BMD. Myocardial disease is present before symptoms becoming apparent. By age 10, cardiomyopathy is clinically evident and virtually all boys by age 18 are affected. ECG abnormalities are present in almost all boys with DMD age 13 years and over. Most boys will have a resting tachycardia. This is possibly due to autonomic disturbance or direct involvement of the sinus node. As cardiomyopathy progresses, decreased stroke volumes can also result in tachycardia. Fibrosis localized to the posterior wall of the left ventricle has been noted in DMD but not in other muscular dystrophies.

Close cardiac monitoring is essential. Current care guidelines recommend that patients have a baseline cardiac assessment at the time of diagnosis or at least by 6 years old. Baseline assessments include electrocardiogram and a noninvasive cardiac imaging study such as echocardiogram. Subsequently, patients should have a cardiac evaluation every 2 years until the age of 10, then annually thereafter. If symptoms occur earlier than age 10, they should be evaluated more urgently. Increased frequency of evaluations should occur if ventricular dysfunction is diagnosed.

Early pharmacologic therapy is indicated. Angiotensin-converting-enzyme inhibitors such as lisinopril or enalapril to reduce afterload are typically used as first-line therapy. Alternatively, angiotensin II receptor blockers such as losartan may be used. Diuretics and beta-blockers are also appropriate as recommended by published heart failure guidelines. Patients with DMD commonly have a sinus tachycardia but should be assessed including use of event monitoring if necessary. There are a variety of opinions on routine use of cardiac MRI devices, steroid use, and appropriateness of transplant in these patients.

Although in general the BMD phenotype is milder and weakness develops more slowly, cardiac failure may progress rapidly, independent of progression of skeletal myopathy. In fact, some patients may present with cardiomyopathy and no discernable skeletal involvement. Seventy-five percent or more of BMD patients have ECG abnormalities, but resting sinus tachycardia is not typical as it is in DMD. Cardiac transplant should be considered in cases of BMD when rapid cardiac failure is diagnosed in the face of slowly progressive functional impairment.

Selected types of limb-girdle muscular dystrophy have associated cardiomyopathy and warrant referral to a cardiologist and close follow-up. Laminopathies (LMNA mutations) carry a high risk of cardiac disease including primary dilated cardiomyopathy conduction defects and both supraventricular and ventricular arrhythmias. Cardiac involvement is early, and sudden death has been reported.

Patients with dystroglycanopathies frequently have myocardial dysfunction. Patients with the fukutin-related protein (FKRP) gene develop an early dilated cardiomyopathy whereas those with the Fukuyama-type present in the second decade.

Thirty to fifty percent of patients with FKRP have cardiomyopathy. Arrhythmias have not been reported. No increased risk of cardiac involvement is seen in COL6 or SEPNI diseases. LAMA 2 (merosin deficiency) patients develop severe heart failure, noted in about one-third of patients whether or not they are symptomatic.

Care guideline recommendations suggest that all patients undergo cardiac evaluation at the time of diagnosis. If diagnosed with dystroglycanopathy or laminopathy, annual cardiac examinations are recommended. If symptomatic, examinations every 6 months are suggested. Standard evaluations consist of ECG and echocardiogram in most patients, but because of the risk of arrhythmias and paroxysmal conductive defects in LMNA, 24-hour Holter monitoring is useful.

Tachyarrhythmia and conduction abnormalities are commonly observed in myotonic dystrophy type 1. Cardiomyopathy is not typical. Cardiac complications as a cause of death include sudden unexpected death possibly due to arrhythmias, ischemic heart disease, and progressive left ventricular dysfunction. The mean age of death is 53 years, with a third due to cardiovascular disease or sudden death. Prolonged PR and or QRS interval, second- or third-degree heart block, nonsinus rhythm noted on ECG, or an atrial tachyarrhythmia predicted sudden death in one study. Conduction defects progress and severe bradycardia or asystole may occur secondary to atrioventricular heart block.

Patients with myotonic dystrophy should be monitored with yearly ECGs and referred to cardiology if prolongation of PR or QRS complex is noted or if the patient has any cardiac symptoms. Early placement of a pacemaker or defibrillator should be considered.

Primary cardiomyopathies are rare in congenital myopathies. Some cases of nemaline myopathy have had transient cardiac failure and ECG abnormalities. Guidelines suggest that screening evaluations occur every 2 years in asymptomatic congenital myopathy patients if their genetic diagnosis is uncertain.

Kearns-Sayre syndrome is a mitochondrial myopathy featuring a triad of progressive external ophthalmoplegia, pigmentary retinopathy, and heart block. Patients may have ptosis, proximal weakness, short stature, hearing loss, and endocrine disorders. Cardiac pacemakers may be placed in patients with conduction blocks.

For any patient with neuromuscular weakness, decreased mobility, or weak abdominal muscles, constipation and reflux are chronic medical concerns. Standard treatments for constipation include dietary management, hydration, use of stool softeners, laxatives, and agents to stimulate GI motility (Ducolax, Sennakot). For acute constipation, in addition to the agents mentioned, enemas may be needed. A routine bowel management program should be introduced soon after diagnosis. Chronic constipation may require daily use of agents such as lactulose or polyethylene glycol in addition to increased fluid intake and diet modification.

H2 receptor antagonists (ranitidine, cimetidine), proton-pump inhibitors (omeprazole, lansoprazole), or antacids (magnesium or calcium carbonate) are typically used for medical management of gastroesophageal reflux. Sucralfate may be used in addition. Prokinetic agents such as metoclopramide or erythromycin may be considered if delayed gastric emptying or decreased gastric motility is diagnosed. For children on chronic corticosteroids for DMD, myasthenia gravis, or inflammatory myopathies, antacids, ranitidine or proton-pump inhibitors should be considered for GI prophylaxis.

Patients with myotonic dystrophy commonly have gastrointestinal issues. Bowel dysmotility may result in constipation and diarrhea. They have esophageal issues and are at higher risk for cholelithiasis. Liver function studies may be

mildly elevated but typically not progressive Triglycerides and cholesterol may be elevated as well. DMD patients are at risk for intestinal pseudoobstruction, gastric dilatation, and dysphagia. Delayed gastric emptying in disorders such as SMA may lead to decreased oral intake.

Many neuromuscular disorders have dysphagia as another prominent feature. Palatal and pharyngeal muscles are affected in myasthenia gravis, congenital myasthenic syndromes, SMA, and congenital myopathies such as myotubular myopathy. Choking, aspiration, pocketing food, or pooling of secretions may all result from pharyngeal muscle dysfunction. Fatiguing during meals and prolonged meal times (longer than 30 min) may occur. Patients with myotonic dystrophy or facioscapulo-humeral dystrophy may have severe facial weakness leading to difficulty chewing effectively. Swallowing problems may present with coughing, aspiration pneumonia, and unintentional or unexplained weight loss.

When swallowing concerns are raised, patients should be evaluated promptly. Speech therapists, nutritionists, dentists, and gastroenterologists are all members of the multidisciplinary team who can address these issues. A swallowing study is typically indicated when there are concerns about swallow safety. As weakness progresses, recurrent pneumonias or continued weight loss may necessitate discussion regarding placement of a gastrostomy tube for feeding.

Patients with severe SMA have bulbar dysfunction. With less severe involvement, the degree of dysfunction is variable. Patients may have difficulty getting food to their mouths, limited mouth opening, fatigue with chewing, poor oral manipulation of food, and poor coordination of swallow. As patients lose head control, they are unable to use compensatory postures for swallowing. Reflux can be a life-limiting event in patients with SMA, which necessitates consideration for a Nissen procedure in addition to G-tube placement.

Careful monitoring of weight and nutritional status for neuromuscular patients is an integral part of medical management. With decreased movement and decreased calorie expenditure, patients are at risk for gaining excess weight. On the contrary, decreased oral intake due to fatigue and dysphagia can lead to weight loss. Nutrition and dietician consults are helpful in management of these issues.

Common to all neuromuscular diseases is concern for bone health. Muscle strength has a significant effect on bone density. Nonambulatory neuromuscular patients and children with chronic steroid exposure (DMD, myasthenia gravis, inflammatory myopathies) are at heightened risk for osteoporosis or osteopenia. As a result of these conditions, patients develop fractures, compression fractures, and kidney stones. According to the International Society for Clinical Densitometry guidelines (2014), if a child with risk factors for osteoporosis in the absence of trauma develops a vertebral fracture, the diagnosis of osteoporosis is confirmed. The society suggests monitoring of the spine with a lateral spine radiograph. Although there is no true consensus in terms of monitoring or prevention of osteoporosis, treatment with calcium and vitamin D is recommended. Prophylactic use of bisphosphonates has been tried without evidence that fracture rates are diminished (Quinlivan et al., 2010).

Boys with Duchenne or Becker muscular dystrophy are even at increased risk for osteopenia/osteoporosis and fractures secondary to decreased mobility and muscle weakness. The addition of steroids compounds the combined risk, resulting in significant scoliosis, osteopenia, osteoporosis, and fractures (Henricson et al., 2013).

Growth is also affected by chronic steroid use, although there are some regimens (high-dose weekend) that reportedly do not induce short stature. It is important to monitor side effects of chronic steroid use such as weight gain, Cushingoid

features, hirsutism, acne, delayed growth, delayed puberty, hypertension, glucose intolerance, gastroesophageal reflux and ulcers, cataracts, disordered sleep, and behavioral changes. Vitamin D levels should also be monitored and supplemented if low.

Patients with myotonic dystrophy have multiple endocrine abnormalities, including hypothyroidism and insulin resistant diabetes. Men have hypogonadism, erectile dysfunction, decreased sperm counts, and decreased fertility. An increase in miscarriages and menstrual irregularities are common in women. Insulin-like growth factor 1 levels may be decreased as well as decreased growth hormone release. Monitoring with thyroid stimulating hormone, fasting glucose, or hemoglobin A1C should be a part of routine healthcare in these patients.

As a part of comprehensive care for neuromuscular disorders of any kind, monitoring emotional and psychosocial well-being is of utmost importance. Patients and their families face many kinds of stress—financial, social, and emotional, as well as physical. These issues should be acknowledged from very early on in the relationship so that trust and good communication are established from the outset. If the resources are available, a social worker or other qualified professional who is knowledgeable about neuromuscular disease should be introduced at the first appointment. Assessment of family and patient stressors and resources, coping skills, and emotional adjustment to the diagnosis is an ongoing, dynamic process that will continue to change over time. Continuity of care is a priority. A clinic coordinator can be very helpful to serve as a point person for a patient or family. The coordinator can provide education to the patient and family as well as the school or daycare, communicate with the medical team, offer a wide variety of resources, and ongoing support. Depending on the diagnosis and clinical presentation, palliative care may be another excellent resource to be involved early in the clinical course. Help with family and sibling support, partnering in difficult decision making, offering spiritual guidance, and dealing with loss and bereavement are a few of the palliative care services that may improve quality of life for a patient and their family.

Many neuromuscular patients will need an IEP (individual education plan) developed in conjunction with their school. An IEP is formulated to guide therapies, insure accessibility and safety, modify physical activity (if indicated), and address learning issues that may accompany such diagnoses as DMD or myotonic dystrophy.

Boys with DMD are likely to have intellectual disabilities, specifically learning disorders, and behavioral problems such as attention deficit disorder, obsessive compulsive disorder, and autism spectrum diagnoses. Depression and anxiety may be evident both in the boys as well as their families.

Congenital myotonic dystrophy patients have significant cognitive impairment, and in the noncongenital form, intelligence is generally lower (86 to 92 full-scale IQ), although IQ values vary and seem to correlate with size of the CTG repeat expansion at the DM1 gene. Other behavioral issues such as apathy, executive dysfunction, memory difficulty, and avoidant behavior are common.

Children with complex medical and genetic conditions are living longer than was predicted in the past due to better treatments and overall care. Often, the success of excellent pediatric medicine results in young adults who require ongoing, sometimes intensive, medical supervision throughout their lives. Children with DMD are living longer into adulthood due to a variety of improvements in healthcare interventions. These include multidisciplinary care, regular cardiac and respiratory monitoring, corticosteroid initiation, and assisted ventilation. Patients with neuromuscular disease present many complex transition issues and medical problems. Transitioning from a

nurturing pediatric care system to a more self-directed adult care model can be very difficult for patients and their families. Adult healthcare providers may lack expertise and interest in childhood-onset disabling conditions and services can be fragmented. Preserving wellness, function, independence, activity, participation in society, and quality of life needs to be the ultimate focus, not necessarily episodic or acute care management.

A consensus policy statement, issued by the American Academy of Pediatrics, the American Academy of Family Physicians, and the American College of Physicians American Society of Internal Medicine, states that the transition of care should “maximize lifelong functioning and potential through the provision of high-quality, developmentally appropriate healthcare services that continues uninterrupted as the individual moves from adolescence to adulthood” (AAFP et al., 2002). An effective transition includes having a primary care provider with responsibility for transition planning, incorporating the necessary knowledge and skills to provide developmentally appropriate healthcare transition services, maintaining an up-to-date portable medical summary, creating a written healthcare transition plan by age 14, implementing recommended preventive service guidelines, and ensuring continuous health insurance coverage (AAFP et al., 2002). According to the 2005–2006 National Survey of Children With Special Healthcare Needs, only 41.2% of youth aged 12 to 17 years have ever talked with healthcare providers about their changing health-related needs, decreasing dependence on parents for health management, or their eventual transition to adult care.

Healthcare professionals should be aware of both positive feelings (sense of achievement) and negative feelings (anxiety about the future) about transition. It is important to provide support to address negative feelings and the progressive effects of neuromuscular disorders such as DMD. There are many barriers that challenge families, patients, and physicians alike, which greatly complicate the process. For example, the age of typical transition can be a time when cardiac and/or pulmonary status is most vulnerable in boys with DMD, thus emphasizing the importance of transition to an adult multidisciplinary clinic or providers well versed in DMD.

As young adults with disabilities transition to more independence, physicians need to educate patients and their families about potential age-related changes and medical issues. Prevention strategies require anticipation of potential secondary conditions, recognition of changes that alter function and require intervention, and an understanding of interventions that have an influence on function. This requires that adults with childhood-onset disabling chronic diseases have access to knowledgeable healthcare providers and the medical systems necessary to implement a medical home approach to management of chronic illness and disease. Environmental, communication, attitudinal, and systems barriers must be overcome.

Pain is a significant problem for most patients with neuromuscular disease, although it is not typically a direct consequence of the disease. Most commonly, the pain is caused by immobility. A significant correlation has been shown between increased pain and lower levels of general health, vitality, social function, and physical role. Pain assessment needs to be a standard aspect of care. In a study of adults with DMD, symptoms of fatigue (40.5%), pain (73.4%), anxiety (24%), and depression (19%) were reported, and individuals often had multiple conditions.

End-of-life directives are a critical part of anticipatory care. The role of palliative care to maximize quality of life in

patients with progressive neuromuscular disease cannot be overlooked. Respiratory failure can occur suddenly or in association with a prolonged process. Many families are hesitant to discuss end-of-life issues during periods of medical stability, but it is important that education about ventilatory and palliative options be discussed before ventilatory failure. There is evidence that healthcare professionals underestimate the quality of life of ventilator-dependent patients with DMD. Those choosing to forgo long-term ventilation must receive palliative care and guidance.

# 153 Endocrine Disorders of the Hypothalamus and Pituitary in Childhood and Adolescence

Roger K. Long and Stephen M. Rosenthal

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Through integrated neural and hormonal signaling, the hypothalamus and pituitary regulate a broad range of physiologic processes, including statural growth, sexual maturation, lactation, metabolic actions ascribed to adrenal (glucocorticoid) and thyroid hormones, appetite, and water balance. Each of these physiologic processes involves hypothalamic/pituitary regulation of a variety of target tissues, which, in turn, regulate hypothalamic/pituitary function through feedback loops. A comprehensive endocrine approach to abnormalities of any of these physiologic loops or axes requires consideration of disorders intrinsic to the hypothalamus/pituitary or to the target tissues. This chapter will focus on those endocrine disorders specifically caused by abnormalities of the hypothalamus and pituitary.

## ANATOMIC AND PHYSIOLOGIC ASPECTS

The hypothalamus is an evolutionarily conserved region of the mammalian brain. The hypothalamus is separated by the third ventricle and functions as the primary control center for a variety of physiologic processes, integrating neural and hormonal signaling. Hypothalamic nuclei are not well-demarcated regions; however, these cell groups in the walls of the third ventricle possess specific physiologic functions. The supraoptic and paraventricular nuclei produce arginine vasopressin (AVP, also known as antidiuretic hormone [ADH]) and oxytocin. Paraventricular nuclei and arcuate nuclei release thyrotropin-releasing hormone (TRH), corticotropin-releasing hormone (CRH), somatostatin (SST), growth-hormone-releasing hormone (GHRH), gonadotropin-releasing hormone (GnRH), and dopamine into the hypophysial portal circulation to regulate the synthesis and release of anterior pituitary hormones. In addition, hypothalamic neurons that regulate appetite and energy balance are also located in the paraventricular and arcuate nuclei of the hypothalamus, such as proopiomelanocortin (POMC), neuropeptide Y (NPY), and agouti-related protein (AgRP)-expressing neurons.

The pituitary (hypophysis) is housed in the sella turcica and is attached to the hypothalamus by the hypophysial stalk, which serves as an anatomic and functional link between the hypothalamus and the pituitary. The optic chiasm is situated directly anterior to the pituitary stalk (Fig. 153-1). The pituitary is small, weighing about half a gram, and is divided into the anterior lobe (adenohypophysis), which is embryonically derived from oral ectoderm (Rathke's pouch); the posterior lobe (neurohypophysis), which is a downward extension of the diencephalon; and a vestigial intermediate lobe. Six hormones,

growth hormone (GH), thyroid-stimulating hormone (TSH), adrenocorticotropic hormone (ACTH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), and prolactin (PRL), are synthesized, stored, and secreted from well-differentiated distinct cell types (somatotrophs, thyrotrophs, corticotrophs, gonadotrophs, and lactotrophs) within the adenohypophysis. The neurohypophysis synthesizes, stores, and secretes AVP and oxytocin.

The blood supply in the hypothalamic-pituitary-portal system allows bidirectional hypothalamic-pituitary hormonal interaction. The superior hypophysial arteries from the internal carotid arteries form a primary plexus that travel down to the anterior pituitary as the major blood supply. The hypothalamic-pituitary-portal circulation carries the hypothalamic releasing and inhibiting hormones to the adenohypophysis. Retrograde blood flow within the internal capillary plexus (gomitoli), derived from the stalk branches of the superior hypophysial arteries, provides local hormonal feedback to the hypothalamus.

Normal development of the hypothalamus and the pituitary relies on expression of multiple homeodomain transcription factors, morphogenic proteins, and growth factors. Differentiation of anterior pituitary cell types requires a spatiotemporally regulated cascade of homeodomain transcription factors. Several pituitary-specific transcription factors, such as Lhx3/Lhx4 (LIM-homeobox-3 and 4), Rpx (Rathke's pouch homeobox, also known as Hesx1), Pitx (pituitary homeobox), Prop-1, Pit-1, POU1F1, Sox2, and Sox3, are important determinants of pituitary cell lineages. Mutations in these and other transcription factors can lead to either isolated or combined pituitary hormone deficiencies, with or without detectable anatomic abnormalities (Dauber et al., 2014).

## HYPOTHALAMIC/PITUITARY DISORDERS OF PUBERTAL DEVELOPMENT

### Normal Physiology of Puberty and Adrenarche

Puberty is the transitional period between the juvenile state and adulthood, characterized by attainment of secondary sex characteristics and reproductive capability. The control center of puberty is comprised of hypothalamic GnRH neurosecretory neurons (pulse generator). The GnRH pulse generator becomes pulsatile by midgestation, and remains active until about 6 months of age in boys and 12 to 24 months in girls. Between late infancy and the onset of puberty, the GnRH pulse generator becomes relatively quiescent as a consequence of a poorly defined central nervous system (CNS) inhibitory mechanism. After a quiescent period of approximately 10 years, the

GnRH pulse generator is disinhibited, leading to increased amplitude and frequency of LH and FSH secretion, and resulting in increased sex steroid production (estradiol and testosterone) and attainment of physical puberty. Kisspeptin and the kisspeptin receptor, also known as GPR54, have emerged as key regulators of the hypothalamic–pituitary–gonadal (HPG) axis, triggering and guiding the tempo of sexual maturation at puberty (Oakley et al., 2009). In addition, the tachykinin neuropeptide B and its receptor NK3R also serve as central regulators for normal gonadotropin secretion and pubertal development, and *MKRN3* appears to have an inhibitory function in pubertal regulation (Abreu et al., 2013; Bulcao et al., 2014).

The normal age of onset of secondary sexual characteristics is 8 to 13 years in girls and 9 to 14 years in boys. The appearance of secondary sexual characteristics, acceleration of growth, and the capacity of reproduction are hallmarks of puberty. In females, secondary sexual characteristics include breast development, the appearance of pubic and axillary hair, maturation of the labia, and estrogenization of the vaginal mucosa. The development of pubic and axillary hair is influenced by androgens produced in both the adrenal cortex and the ovary. Menarche usually occurs 2 to 3 years after initiation of breast development. The pubertal growth spurt, which normally occurs in the early stages of puberty for girls, can result in a gain in height of 25 cm or more. In males, puberty begins with testicular enlargement ( $\geq 2.5$  cm in the longest dimension) followed by the appearance of sexual hair and phallic enlargement. The growth spurt occurs during midpuberty, which results in an average 28-cm gain in height. Abnormalities of puberty include sexual precocity and delayed or arrested puberty, each with a broad differential diagnosis.

## Sexual Precocity

Sexual precocity is usually defined as the development of secondary sexual characteristics before 6 to 7 years of age in girls, and before 9 years of age in boys. Precocious puberty is defined as early puberty specifically resulting from premature reactivation of the GnRH pulse generator. Precocious puberty most commonly is idiopathic, but can result from a broad range of abnormalities, including CNS tumors, hamartoma of the tuber cinereum, congenital malformations, subarachnoid cysts, CNS infection, irradiation, and trauma. The incidence of precocious puberty is significantly higher in females. In studies of girls with precocious puberty, idiopathic precocious puberty ranges from 63% to 74%. In contrast, only 6% of boys with precocious puberty are idiopathic. Idiopathic precocious puberty is a diagnosis of exclusion and it is, thus, essential to search for underlying neurologic causes. Tumors involving the posterior hypothalamus, such as glioma, germinoma, and teratoma, can cause precocious puberty. Most of these tumors are thought to trigger early puberty by interfering with mechanisms that normally inhibit the GnRH pulse generator. Few LH/FSH-secreting adenomas have been reported. Hamartoma of the tuber cinereum, a congenital malformation, can cause central precocious puberty. Hamartomas are small lesions (4 to 25 mm), may be sessile or pedunculated, and usually do not enlarge with time (Fig. 153-2). Histologically, they appear to be composed of normal brain tissue and contain GnRH secretory neurons, which may serve as an “ectopic pulse generator.”

Human chorionic gonadotropin (hCG)-secreting tumors can cause sexual precocity in boys. Such patients do not have central precocious puberty, in that they do not have premature reactivation of the hypothalamic GnRH pulse generator. Rather, the ectopic hCG interacts with the LH/hCG receptor on testicular Leydig cells, resulting in increased testosterone secretion and virilization. In girls, ovarian estrogen secretion

requires both LH and FSH. Thus ectopic secretion of hCG alone causes sexual precocity only in boys.

The accurate diagnosis of precocious puberty and its cause requires a detailed history, physical examination, hormonal testing, and imaging studies of the CNS. Precocious puberty may be familial, rare gain-of-function mutations in *KISS1* and *GPR54* (*KISS1R*) have been found, and loss-of-function mutations in *MKRN3* represent the most frequent known cause of familial central precocious puberty. The occurrence of early breast and pubic hair development is often seen in girls with precocious puberty, whereas testicular enlargement and other signs of virilization are seen in boys. Hormonal analysis demonstrates increased amplitude and frequency of LH and FSH pulsatile secretion, resulting from increased pulsatile secretion of GnRH. This finding can be demonstrated either by serial sampling of LH and FSH or by single LH/FSH measurements using highly sensitive assays. Dynamic testing using GnRH or a GnRH agonist is also used routinely to diagnose precocious puberty. Magnetic resonance imaging (MRI), with particular attention to the hypothalamic–pituitary area, should be carried out in any child diagnosed with precocious puberty.

## Management

If a CNS lesion that causes precocious puberty is identified, an appropriate treatment plan for that lesion should be developed. Surgical treatment of hamartomas of the tuber cinereum carries a significant risk of morbidity and mortality, whereas medical management with GnRH agonist demonstrates excellent long-term response. Rarely, the rapid progression of pubertal development is reversed or arrested after treatment of CNS disorders causing precocious puberty. More commonly, once puberty has been initiated, it will continue, despite treatment of the primary CNS disorder. Such patients require hormonal treatment with a GnRH agonist, which desensitizes pituitary GnRH receptors, leading to suppression of the HPG axis. This treatment is commonly given by regular depot intramuscular injection or implant placement. Long-term studies demonstrate resumption of normal puberty after discontinuation of a GnRH agonist.

## Delayed or Arrested Puberty

Delayed puberty may be defined, in boys, by the absence of testicular enlargement by 14 years of age, and in girls, by the absence of breast development by 13 years of age. The differential diagnosis of delayed puberty can be divided into three major categories: constitutional delay in growth, hypogonadotropic hypogonadism, and hypergonadotropic hypogonadism. Constitutional delay in growth, the most common cause of delayed puberty, is a normal variant, and is thought to result from a prolonged quiescent period of the GnRH pulse generator. Such patients often have a family history of delayed puberty and have delayed skeletal maturation without evidence of endocrinopathy or other organic diseases. Hypergonadotropic hypogonadism indicates a defect at the level of the gonads. Hypogonadotropic hypogonadism indicates a defect at the level of the hypothalamus or pituitary, and can be congenital or acquired, can occur alone or in association with multiple hypothalamic and pituitary hormone deficiencies, and may be organic or functional in etiology.

### Isolated Congenital Hypogonadotropic Hypogonadism

Isolated hypogonadotropic hypogonadism (IHH) caused by congenital GnRH deficiency may or may not be associated with olfactory abnormalities. IHH associated with anosmia or

hyposmia is referred to as Kallmann syndrome, and is thought to be a consequence of defective embryonic migration of GnRH neurons from the olfactory placode to the hypothalamus. Kallmann syndrome is the most common form of IHH. Considerable genetic heterogeneity exists for hypogonadotropic hypogonadism with or without anosmia; it is transmitted in an X-linked, autosomal-dominant, autosomal-recessive, or oligogenic fashion with variable penetrance. Mutations in the *KAL1* gene account for half of males with X-linked hypogonadotropic hypogonadism and only 5% of sporadic IHH cases. The clinical phenotype of *KAL1* mutation includes microphallus, cryptorchidism, and anosmia. Some patients may also have unilateral renal agenesis, synkinesia (mirror movements), high-arched palate, cerebellar ataxia, and pes cavus. IHH without olfactory abnormalities (normosmic IHH) and Kallman syndrome are associated with autosomal loss-of-function mutations of the fibroblast growth factor receptor 1 (*FGFR1*) (also known as *KAL2*), and with mutations in a variety of other genes, including *FGF8* (ligand for *FGFR1*), prokineticin-2 (*PROK2*), and prokineticin receptor-2 (*PROKR2*). Individuals with CHARGE syndrome often manifest hypogonadotropic hypogonadism and olfactory bulb aplasia, features of Kallmann syndrome. Mutations of *CHD7* (CHARGE syndrome gene) have been identified in patients with Kallmann syndrome, suggesting that IHH caused by *CHD7* mutations is a mild variant of CHARGE syndrome. Lack of correlation between genotype and phenotype has been described in Kallmann syndrome.

Normosmic IHH is associated with mutations in a variety of genes, including the GnRH receptor, the *GNRH1* gene, *GPR54*, *TAC3*, and *TACR3*. Another form of X-linked hypogonadotropic hypogonadism is associated with adrenal hypoplasia congenita caused by defects of *DAX1*. *DAX1* encodes a transcription factor that appears to play key developmental roles in the hypothalamus, pituitary, gonad, and adrenal cortex. In addition, mutations in the beta subunits of FSH and LH have been reported in association with primary amenorrhea and hypogonadism.

### Hypogonadotropic Hypogonadism Associated with Multiple Hypothalamic/Pituitary Hormone Deficiencies

Hypogonadotropic hypogonadism can also present in combination with other hypothalamic/pituitary hormone deficiencies. Mutations of pituitary transcription factors known to cause delayed puberty include *Prop-1* and *Lhx3*. Combined pituitary hormone deficiencies caused by mutations in *Prop-1* occur with an incidence of about 1 in 8000 births. Patients with mutations in *Prop-1* have combined pituitary hormone deficiencies, which may include deficiencies of GH, PRL, TSH, and gonadotropins. Such patients have hypogonadotropic hypogonadism in association with short stature and hypothyroidism. Mutations in *Lhx3* have been associated with anterior pituitary hypoplasia and complete deficits of GH, PRL, TSH, and gonadotropins. *Lhx3* mutations are also associated with decreased range of motion in the cervical spine.

Other genetic factors that lead to delayed puberty include mutations of prohormone convertase (PC1), leptin, and leptin receptor genes. A defect in PC1 has been shown to disrupt GnRH processing, and results in hypogonadotropic hypogonadism and obesity associated with impaired processing of insulin and POMC. Mutations in leptin and the leptin receptor are associated with a similar clinical picture of hypogonadotropic hypogonadism, hyperinsulinemia, and obesity. Congenital midline defects of the CNS, such as septo-optic dysplasia (SOD), empty sella syndrome, and Rathke's cyst, are often associated with hypothalamic/pituitary dysfunction, which may include hypogonadotropic hypogonadism.

Numerous CNS lesions can lead to hypogonadotropic hypogonadism, including CNS tumors, CNS infection, invasive diseases, cranial irradiation, and trauma. These CNS disorders often present with combined anterior and posterior pituitary hormone deficiencies. CNS tumors of the sella and parasellar region associated with multiple hypothalamic/pituitary hormone deficiencies include craniopharyngioma, pituitary adenomas, optic and hypothalamic gliomas, and germ-cell tumors. Delayed or arrested puberty is the second most common presenting symptom of CNS tumors after headache. Craniopharyngiomas, the most common tumor of the sella and parasellar region in children, are slow-growing, space-occupying tumors (Fig. 153-3). Most patients present before their teenage years with headache, visual loss, and multiple hypothalamic/pituitary hormone deficits. Pituitary adenomas in children with pituitary hormone hypersecretion usually present as microadenomas (<1 cm in diameter). Prolactinoma, prolactin-secreting pituitary adenoma, is the most common pituitary adenoma in the pediatric population and frequently is associated with delayed or arrested puberty. Nonsecreting microadenomas found incidentally by MRI are common in children, about 28% of children. Nonsecreting macroadenomas (>1 cm in diameter) are rare, but can also cause delayed puberty, at least in part, through elevation of prolactin as a consequence of stalk compression.

### Functional Hypogonadotropic Hypogonadism

Reproductive capability is intimately linked to nutritional and metabolic homeostasis. Chronic systemic disease, malnutrition, hypothyroidism, hypercortisolism, poorly controlled diabetes mellitus, and anorexia nervosa are known to cause delayed or arrested pubertal development as a consequence of hypogonadotropic hypogonadism. Functional gonadotropin deficiency may be associated with marijuana use and may occur in some female athletes and ballet dancers. In general, weight loss to less than 80% of ideal weight may result in functional gonadotropin deficiency.

### Evaluation of Delayed or Arrested Puberty

As part of an initial evaluation, basal gonadotropin levels (LH, FSH) should be measured. Elevated gonadotropins indicate primary ovarian or testicular failure, whereas low or normal gonadotropins indicate either constitutional delay or hypogonadotropic hypogonadism. A GnRH stimulation test is often useful in distinguishing patients with constitutional delay from those with hypogonadotropic hypogonadism. If hypogonadotropic hypogonadism is strongly suspected, further evaluation to identify a specific etiology should be undertaken. An important aspect of the physical examination is evaluation of the sense of smell. Any patient with proven hypogonadotropic hypogonadism should have a thorough evaluation of all hypothalamic/pituitary hormones and should undergo an MRI with particular focus on the third ventricular area.

### Management

Once the etiology of delayed or arrested puberty has been established, an appropriate treatment plan can be designed. For constitutionally delayed pubertal development, short-term (3 to 6 months) low-dose sex steroid replacement may be useful to induce maturation of the GnRH pulse generator. Permanent hypogonadotropic hypogonadism requires long-term sex hormone replacement. Testosterone for boys can be administered either by intramuscular or subcutaneous injection or topically. Long-term hormonal therapy for girls

includes the use of oral, intramuscular, or transdermal estrogen and progestin cycling.

## DISORDERS OF PROLACTIN SECRETION

### Normal Biochemistry and Physiology of Prolactin

Regulation of prolactin secretion is distinct from that of other anterior pituitary hormones. PRL is the only pituitary hormone that is regulated predominantly by the hypothalamus through an inhibitory mechanism mediated by dopamine via the hypothalamic–pituitary–portal circulation. The principal physiologic functions of PRL are enhanced mammary gland development during pregnancy and lactation. PRL may be increased through physiologic and pathologic mechanisms. Physiologic stimuli include pregnancy, lactation, stress, sleep, and exercise. Pathologic causes of hyperprolactinemia include prolactinomas; injury to the hypothalamic–pituitary stalk; a variety of systemic disorders, including chronic renal failure and cirrhosis; and a variety of drugs.

### Clinical Features and Management of Hyperprolactinemia

In postpubertal females the principal clinical feature of hyperprolactinemia, regardless of the cause, is galactorrhea, which may be unilateral or bilateral. Other clinical features may include delayed or arrested puberty and hypogonadism; menstrual irregularities, including amenorrhea in females; and gynecomastia in males secondary to hypogonadism. Prolactinoma is the most common tumor of the pituitary, comprising about 50% of anterior pituitary adenomas. Most prolactinomas are microprolactinomas, and normally do not cause significant mass effects. Macroprolactinomas are predominately found in males because of poor appreciation of hypogonadal symptoms and inability to manifest menstrual irregularities or galactorrhea, early indicators of hyperprolactinemia.

If a prolactinoma is diagnosed, therapeutic options include medical management with dopamine agonists, surgery, and adjunctive radiotherapy. Medical management is considered the principal intervention; however, microprolactinomas can be removed surgically, though with variable recurrence rates. Macroprolactinomas are less likely to be cured surgically and often require chronic dopamine agonist treatment. Dopamine agonists are effective and safe pharmacologic interventions for both micro- and macroprolactinoma. Withdrawal of medication after long-term therapy has been safe, although careful monitoring of tumor progression is necessary. Adjunctive radiotherapy has been considered beneficial in some patients with macroprolactinoma. The skill and experience of the surgeon clearly play a role in determining the optimal treatment and outcome.

## HYPOTHALAMIC/PITUITARY DISORDERS OF GLUCOCORTICOID PRODUCTION

ACTH is produced in response to stimulation, principally by hypothalamic CRH, and increases adrenal production of cortisol, the principal glucocorticoid. Cortisol, in turn, regulates the production of both CRH and ACTH through negative-feedback loops. An intact hypothalamic–pituitary–adrenal (HPA) axis is essential for general homeostasis, including regulation of blood pressure and glucose, and for response to stress. Increased levels of circulating glucocorticoids lead to Cushing’s syndrome, whereas hypersecretion of pituitary ACTH leads to Cushing’s disease. Inadequate

production of CRH/ACTH will cause adrenal glucocorticoid insufficiency.

### Adrenocorticotrophic Excess

Excessive production of ACTH from the pituitary arises either from CRH overproduction or from a primary ACTH-producing adenoma. The first sign of Cushing’s disease in a growing child is often impaired linear growth. Other classic signs and symptoms of Cushing’s disease include central obesity, buffalo hump, plethora, “moon facies,” acne, striae, hypertension, hirsutism, fatigue, pubertal delay or arrest, bruising, and headache. Usually, at the time of diagnosis, ACTH-producing adenomas are significantly smaller than other pituitary adenomas (Fig. 153-4).

Determination of the cause of Cushing’s syndrome can pose significant challenges. Patients with hypercortisolism will demonstrate elevated urinary cortisol excretion and loss of normal diurnal variation in plasma cortisol and ACTH. Endogenous hypercortisolism is either ACTH dependent or ACTH independent. Of the ACTH-dependent causes, Cushing’s disease is most common. A rare ACTH-dependent cause is ectopic ACTH production associated with a variety of extrapituitary neoplasms. In general, patients with Cushing’s disease show suppression of cortisol and ACTH only with high-dose dexamethasone administration. An MRI of the hypothalamic/pituitary area should be obtained if Cushing’s disease is suspected, though small adenomas may not be visualized. Bilateral inferior petrosal sinus sampling before and after ovine CRH stimulation may be utilized to determine a pituitary source of ACTH production.

Transsphenoidal resection of pituitary adenomas has emerged as the treatment of choice for Cushing’s disease (Lonser et al., 2013). Because of small size, some of these tumors are difficult to identify intraoperatively. The recurrence rate after surgery is about approximately 8%, even in the hands of skilled neurosurgeons (Lonser et al., 2013). Radiotherapy has been shown to be effective for unsuccessful transsphenoidal surgery. Other therapeutic options for recurrent Cushing’s disease include repeated pituitary exploration, bilateral adrenalectomy, and the use of pharmacologic agents that directly impair cortisol synthesis and secretion.

### Adrenocorticotrophic Hormone Deficiency

Secondary adrenal insufficiency is defined as hypocortisolism as a consequence of ACTH deficiency. Secondary adrenal insufficiency can be isolated or occur as part of multiple hypothalamic/pituitary deficiencies. Chronic suppression of CRH and ACTH by long-term glucocorticoid therapy also can result in secondary adrenal insufficiency.

Isolated ACTH deficiency is a rare cause of secondary adrenal insufficiency, caused by either CRH deficiency or a primary decrease in ACTH production by corticotrophs. Clinical presentation is highly variable. Neonatal onset of isolated ACTH deficiency usually presents with sudden, severe episodes of hypoglycemia, sometimes with seizure and coma. Neonates may also present with prolonged cholestatic jaundice. Death may occur if treatment is not initiated promptly. Over 70% of these patients have a loss-of-function mutation in the *TPIT* gene, which encodes a transcription factor that is expressed specifically in corticotrophs and is required for expression of POMC, the precursor of ACTH. ACTH deficiency can be associated with multiple hypothalamic/pituitary hormone deficiencies as described previously.

Secondary adrenal insufficiency is characterized by an inappropriately low serum cortisol level and a nonelevated ACTH

level suggestive of inadequacy of the HPA axis. Assessment of the HPA axis adequacy is challenging. A peak cortisol level after an injection of synthetic ACTH may be used to assess adrenal gland responsiveness to ACTH. However, a false normal response will occur in the setting of acute pituitary dysfunction. HPA axis integrity can be confirmed by dynamic testing protocols that measure the adrenal glucocorticoid production response to acute hypoglycemia induced by insulin injection or an overnight cortisol insufficiency caused by metyrapone treatment, an inhibitor of the last enzymatic step in cortisol production.

Cortisol (hydrocortisone) replacement is based on studies of the cortisol secretory rate in the pediatric population, which is 7 to 9 mg/m<sup>2</sup>/day. During periods of significant stress, such as febrile illness and surgery, such patients are managed routinely with a temporary increase in glucocorticoids (given orally or parenterally) at doses up to 50 mg/m<sup>2</sup>/day of hydrocortisone.

## HYPOTHALAMIC/PITUITARY DISORDERS OF STATORAL GROWTH

Statural growth is a complex process influenced by multiple factors. Endocrine regulation of postnatal growth stems from hormones produced in the hypothalamus and the pituitary, including GHRH, SST, GH, TRH, TSH, CRH, and ACTH. Abnormal statural growth related to either GH deficiency or GH excess is discussed in this section.

Pulsatile GH secretion is regulated principally by two hypothalamic regulatory peptides, GHRH and SST. Acute glucocorticoid administration stimulates GH secretion, whereas chronically elevated glucocorticoids inhibit GH, as seen in Cushing's disease and during chronic administration of glucocorticoids. Sex steroids (estradiol and testosterone) stimulate GH secretion, contributing to a pubertal rise in GH. In addition, GH levels are decreased in hypothyroidism. The growth-promoting effects of GH are mediated principally through endocrine, autocrine, and paracrine production of insulin-like growth factors (IGFs).

### Growth Hormone Deficiency

Children with congenital GH deficiency are of normal size at birth. However, after approximately 6 months of life, growth failure becomes apparent when linear growth becomes GH dependent. Usually, children with GH deficiency are short and cherubic, with a doll-like appearance. Approximately 10% to 20% of GH-deficient patients present with severe hypoglycemia in addition to short stature. In the neonatal period, hypoglycemia and microphallus strongly suggest GH deficiency.

Although abnormalities can occur at any level of the GHRH-GH-IGF-I axis, the majority of these abnormalities occur at the hypothalamic/pituitary level. In fact, most patients with GH deficiency (80% to 90%) are GHRH deficient. As with gonadotropins or ACTH, a deficiency of GH may be isolated or associated with other hypothalamic/pituitary hormone abnormalities. Isolated GH deficiency has been reported to be familial in 3% to 30% of cases. Mutations have been found in only a minority of such patients, primarily involving the *GH1* and *GHRHR* genes. Mutations in the gene *Rpx/Hesx1* are associated with septo-optic dysplasia, a common midline malformation characterized by the classical triad of optic nerve hypoplasia, midline malformations (such as agenesis of the corpus callosum and absence of the septum pellucidum), and pituitary hypoplasia with consequent panhypopituitarism. The phenotypes of mutations in the *Rpx/*

*Hesx1* gene are highly variable, ranging from isolated GH deficiency without any midline defects, to the complete spectrum of the disease with panhypopituitarism.

Evaluation of a child with suspected GH deficiency includes a thorough history, physical examination, and careful review of growth charts and laboratory studies. Severe neonatal hypoglycemia is suggestive of GH deficiency. Most children with GH deficiency will have not only short stature, but also a subnormal height velocity with relative preservation of weight and head circumference. The diagnosis of GH deficiency is often difficult to make with a single blood test, in light of the pulsatile nature of GH secretion. GH-dependent IGF-I and IGF binding protein 3 (IGF-BP3) levels, and provocative tests of GH secretion have been used widely to evaluate GH status. If a diagnosis of GH deficiency is made, it is essential to evaluate all pituitary hormones, and to obtain an MRI with particular attention to the third ventricular area.

The principal treatment of children with GH deficiency is recombinant GH administered as a daily subcutaneous injection. Some children with GH deficiency on the basis of GHRH deficiency have been treated successfully with GHRH. Adequacy of treatment is determined by assessment of growth velocity and serum IGF-I and IGF-BP3 levels. Recent studies demonstrate beneficial effects of continued GH treatment (at lower doses) after final height is reached in adolescents with permanent GH deficiency. GH treatment occasionally is associated with side effects, such as increased intracranial pressure, hyperglycemia, and slipped capital femoral epiphysis.

### Growth Hormone Excess

Gigantism is a rare condition caused by GH excess in children who have open epiphyses, primarily caused by increased GH production from the pituitary. GH-producing adenomas constitute up to 10% of pituitary adenomas. Ectopic GHRH overproduction is a rare cause of GH excess. In addition, McCune-Albright syndrome (MAS) can present with gigantism because of constitutively active G proteins in somatotrophs that result in increased GH secretion.

Accelerated longitudinal growth and acromegalic features (enlarged head, large hands and feet, big tongue, and broad nose) are the most prominent signs of GH excess. In girls, menstrual irregularity is common. Mass effect of the tumor can cause impaired vision and headache caused by increased intracranial pressure. Some patients also may have hyperprolactinemia as a result of cosecretion. A diagnosis of pituitary gigantism is made by demonstrating nonsuppressible GH in response to glucose loading, in association with elevated IGF-I and IGF-BP3 levels. Usually, sellar MRI will reveal a pituitary mass.

The goal of treatment in GH-secreting adenomas is normalization of GH and IGF-I levels. Transsphenoidal surgery has resulted in a greater than 80% cure rate, and thus remains the first choice of treatment. If surgery is unsuccessful, somatostatin analogs, GH receptor antagonists, and dopamine agonists can be used. Somatostatin analogs may be used as first-line treatment should the patient prefer medication over surgery (Colao et al., 2009). Radiotherapy may be beneficial to treat an adenoma that increases in size despite medical therapy.

## HYPOTHALAMIC/PITUITARY DISORDERS OF THYROID FUNCTION

### Normal Thyroid Physiology

Under regulation by the hypothalamus and pituitary, the thyroid gland produces thyroid hormones, which have broad effects on metabolism, growth, and CNS development. TSH is

a heterodimeric glycoprotein consisting of alpha and beta subunits. The alpha subunit is common to TSH, LH, FSH, and hCG, whereas the beta subunit confers specificity. TSH acts on the thyroid gland to stimulate thyroid hormone synthesis and secretion. TSH is negatively regulated by thyroid hormones and positively regulated by TRH.

## Central Hypothyroidism

Central (hypothalamic/pituitary) hypothyroidism is rare in comparison to primary hypothyroidism, and may be congenital or acquired. Signs and symptoms associated with hypothyroidism may arise insidiously and are often nonspecific. In the neonatal period, newborns may have lethargy, hypotonia, hypothermia, or prolonged jaundice. Untreated hypothyroidism during infancy and early childhood can result in developmental delay, mental retardation, and poor statural growth. Presenting symptoms in older children include weight gain, subnormal height velocity, constipation, cold intolerance, hoarse voice, dry skin, and lethargy.

Congenital TSH deficiency occurs in 1:50,000 to 150,000 newborns. Underlying etiologies include isolated TSH deficiency, developmental defects of the hypothalamus and pituitary, and familial panhypopituitarism. Isolated TSH deficiency is caused by usually autosomal-recessive mutations in the TSH beta subunit. TSH deficiency, in combination with other pituitary hormone deficiencies, is seen frequently in patients with *HESX1*, *PIT-1*, and *PROP-1* mutations or CNS insults. In addition, isolated central hypothyroidism can result from a loss-of-function mutation in the TRH receptor. Patients with congenital TSH deficiency are usually not detected by neonatal screening for hypothyroidism, as most programs are designed to screen for the hyperthyrotropinemia that accompanies primary hypothyroidism.

With respect to laboratory assessment of thyroid function, it is critical to recognize that normal ranges vary significantly with age. In particular, TSH and free T4 are relatively high in newborns in comparison to older infants, children, and adolescents. The principal goals of treating central hypothyroidism are normalization of thyroxine levels and prevention of mental retardation and growth impairment. Thus thyroxine replacement should be instituted promptly after diagnosis of hypothyroidism, regardless of etiology.

## Central Hyperthyroidism

Most cases of hyperthyroidism in the pediatric population are autoimmune and TSH-independent. Central hyperthyroidism as a consequence of a pituitary TSH-secreting adenoma is exceedingly rare. Such patients may have a prominent local mass effect of the tumor. Signs and symptoms of hyperthyroidism, such as agitation, tall stature, goiter, tremor, and palpitation, are manifested in central hyperthyroidism. Biochemically, patients with central hyperthyroidism have elevated concentrations of TSH in the context of elevated T4 and T3. If a pituitary adenoma is not identifiable on imaging studies, rare selective pituitary T3 resistance attributable to inactivating mutation of thyroid hormone receptor beta should be considered. Surgical removal of the tumor is the treatment of choice for TSH-secreting pituitary adenoma. The treatment of selective pituitary T3 resistance remains a therapeutic challenge.

## HYPOTHALAMIC DISORDERS OF APPETITE REGULATION AND ENERGY BALANCE

Appetite and energy balance are regulated by a complex network, in which the hypothalamus serves as the central

**Figure 153-5. Hormonal regulation of food intake and energy balance in the hypothalamus.** The dashed lines indicate inhibitory effects and the solid lines with arrows indicate stimulatory effects. Long-term signals affecting body fat mass include leptin and insulin, whereas short-term signals determining meal initiation and termination include peptide YY<sub>3-36</sub> and ghrelin. AgRP, agouti-related protein;  $\alpha$ -MSH,  $\alpha$ -melanocyte-stimulating protein; MC4R, melanocortin 4 receptor; POMC, proopiomelanocortin; PYY, peptide YY<sub>3-36</sub>; Y1R, Y1 subtype of neuropeptide Y (NPY) receptor.

processing unit for hormonal, nutritional, and neuronal input from both peripheral tissue and higher brain centers. In humans, it is well known that hypothalamic damage can lead to excessive weight gain, hypothalamic obesity. These patients present with excessive weight gain without response to caloric restriction or exercise. Traditionally, the ventromedial hypothalamus has been viewed as the “satiety” center, because damage to the ventromedial hypothalamus can cause hyperphagic obesity. In contrast, the lateral hypothalamus has been viewed as the “feeding” center, because its disruption leads to hypophagia and weight loss.

Insights into mechanisms of hypothalamic obesity derive from advances in our understanding of hypothalamic control of appetite regulation and energy balance (Fig. 153-5). Energy storage and appetite are regulated at the hypothalamus through signaling by leptin and insulin. Both leptin and insulin affect anorexigenic and orexigenic pathways in the hypothalamus. The effects of leptin are quantitatively much greater than that of insulin, and there are complex responses of various neuron subsets within hypothalamic nuclei (Sohn et al., 2013; Morton et al., 2014). In the anorexigenic pathway, leptin maintains expression of POMC in the arcuate nuclei, and POMC-derived  $\alpha$ -melanocyte-stimulating hormone ( $\alpha$ -MSH) activates the melanocortin-4 receptor (MC4R) in the paraventricular nuclei and the lateral hypothalamic area. This melanocortin signal is appetite suppressing. In addition, leptin and insulin inhibit NPY and AgRP within the arcuate nuclei, both of which are appetite-stimulating peptides. NPY decreases POMC expression through the neuropeptide Y1 receptor (Y1R). AgRP is an antagonist for MC4R, competing with  $\alpha$ -MSH for binding to the MC4R and leading to increased food intake.

Hypothalamic obesity frequently is seen in children with hypothalamic insults, such as brain tumor, surgery, irradiation, or trauma. Approximately 50% of children with craniopharyngioma develop hypothalamic obesity. Other tumors, such as germinoma, optic glioma, prolactinoma, and hypothalamic astrocytoma, also are associated with hypothalamic obesity. These patients usually have unrelenting weight gain

after tumor removal or radiotherapy, without documented excessive food intake. Reduced physical activity, rather than increased energy intake, was shown to be primarily responsible for obesity in patients with craniopharyngioma. Decreased resting energy expenditure also may be present in children after brain tumor therapy, including hypothalamic irradiation (greater than 51 Gy).

Numerous examples of monogenic obesity have been described at many levels of hypothalamic control of energy balance, including leptin, leptin receptor, POMC, prohormone convertase 1/3 (PC1/3), and MC4R (Ranadive and Vaisse, 2008). Mutations in leptin and leptin receptor are extremely rare monogenic forms of morbid obesity. The children reported with leptin deficiency had normal birth weight, but became hyperphagic in infancy and developed severe obesity with undetectable levels of leptin. Exogenous administration of leptin induced sustained weight loss because of loss of fat mass. Similar results were observed in adults with congenital leptin deficiency. Mutations of the leptin receptor also are associated with severe childhood obesity associated with absent pubertal development, reduced levels of both TSH and GH, and impaired immune function. Loss-of-function mutations in *POMC* result in severe hyperphagia and obesity as a consequence of lack of MC4R activation by  $\alpha$ -MSH, and adrenal insufficiency as a consequence of defective synthesis of ACTH. Patients may also have red hair from lack of MC1R activation by  $\alpha$ -MSH in melanocytes. Mutations in *PC1/3*, thought to result in defective processing of POMC to  $\alpha$ -MSH, as well as defective ACTH synthesis, lead to hyperphagia, early onset obesity, and partial ACTH deficiency. *MC4R* mutations have been found in 2.5% of obese children, representing the most common genetic defects in human obesity.

## HYPOTHALAMIC/PITUITARY DISORDERS OF WATER BALANCE

Under normal circumstances, plasma osmolality is maintained within a relatively narrow range by adequate water intake, regulated by thirst, and appropriate free water excretion by the kidneys, mediated by appropriate secretion of vasopressin (AVP). AVP is produced in the magnocellular neurons, which originate in the paraventricular and supraoptic nuclei of the hypothalamus and terminate in the posterior pituitary gland. AVP exerts its antidiuretic action by binding to the X chromosome–encoded V2 vasopressin receptor (V2R) on the basolateral membrane of renal collecting duct epithelial cells. After V2R activation, the water channel aquaporin 2 (AQP-2) is shuttled to the apical membrane of collecting duct epithelial cells, resulting in increased water permeability and antidiuresis.

AVP secretion is regulated principally by changes in plasma osmolality and in effective circulating volume. AVP levels are normally low and do not increase until plasma osmolality exceeds 280 mOsm/kg, but responds to as little as 1% increases in plasma osmolality. AVP secretion also is regulated by changes in blood volume. Baroreceptors in the venous and arterial circulation become activated when stretched by increases in intravascular volume, leading to inhibition of AVP secretion. In addition, a variety of other factors affect AVP secretion. It is stimulated by pain, stress, and a variety of drugs, and is inhibited by surgery, trauma, and infiltrative processes of the hypothalamus.

Clinical disorders of water balance are common, and abnormalities in many steps involving AVP secretion and responsiveness have been described (Ranadive and Rosenthal, 2009). The focus of this section is on the principal hypothalamic/pituitary disorders of water balance, diabetes

insipidus (DI), and the syndrome of inappropriate antidiuretic hormone secretion (SIADH).

## Diabetes Insipidus

DI may result from a deficiency of AVP or from nephrogenic causes that manifest resistance to AVP. Central DI is rarely congenital and more frequently acquired. Congenital central DI may be associated with congenital conditions, including congenital hypopituitarism, Wolfram syndrome, and SOD, and through both autosomal-dominant and autosomal-recessive mutations in the *AVP/NP11* gene. Of the latter, the autosomal-dominant causes are more common, and are thought to be a consequence of heterozygous mutations in the *AVP/NP11* gene that lead to misfolding of the precursor AVP/NP11 protein. The dominant negative effect is thought to occur as a consequence of the misfolded precursor protein, which accumulates in the endoplasmic reticulum of vasopressinergic neurons, ultimately resulting in death of these neurons. In such patients, clinical DI usually develops several months to years after birth. A rare autosomal-recessive form of central DI has been reported, resulting in a biologically inactive AVP.

Acquired forms of DI occur in association with a variety of disorders in which there is destruction or degeneration of vasopressinergic neurons. Etiologies include primary tumors (e.g., craniopharyngioma, germinoma) or metastases, infection (meningitis, encephalitis), histiocytosis, granuloma, vascular disorders, and autoimmune disorders (lymphocytic infundibuloneurohypophysitis). Acquired DI may occur in association with trauma and surgery. Idiopathic DI is a diagnosis of exclusion, and one that is made with decreasing frequency concurrent with improved sensitivity of CNS MRI and of cerebrospinal fluid and serum tumor markers.

The principal presenting sign of DI is polyuria, which, in addition to deficiency or impaired responsiveness to AVP, may result from an osmotic agent (e.g., hyperglycemia in diabetes mellitus) or from excessive water intake (primary polydipsia). Hypernatremia usually does not occur if patients have an intact thirst mechanism, adequate access to fluids, and no additional ongoing fluid losses (e.g., diarrhea). Infants with DI, in addition to polyuria and polydipsia, may be irritable and have fever of unknown origin, growth failure secondary to inadequate caloric intake, and hydronephrosis. Older children may have nocturia and enuresis. DI may not be apparent in patients with coexisting untreated anterior pituitary-mediated adrenal glucocorticoid insufficiency, as cortisol is required to generate a normal free water loss.

A diagnosis of DI can be made if screening laboratory studies reveal serum hyperosmolality concurrent with inappropriately dilute urine. However, as most patients with DI do not have hyperosmolality and hypernatremia, a standardized water deprivation test is useful to distinguish DI. If DI is indicated during the water deprivation test, then an AVP level should be obtained and AVP or a synthetic analog (desmopressin) should then be administered to distinguish AVP deficiency from AVP unresponsiveness.

Once a diagnosis of central DI is made, a brain MRI of the third ventricular area should be obtained. An absent posterior pituitary “bright spot” is seen in virtually all patients with central DI. Under normal circumstances, a posterior pituitary bright spot is seen on T1-weighted images because of stored AVP in neurosecretory granules (see Fig. 153-1). In central DI patients with an absent posterior pituitary bright spot, an otherwise-normal MRI warrants close follow up with cerebrospinal fluid tumor markers and cytology, serum tumor markers, and serial contrast-enhanced brain MRIs for early detection of an evolving occult hypothalamic-stalk lesion.

In addition to treatment of a primary disease causing central DI, the drug of choice for most patients with AVP deficiency is desmopressin. This AVP analog has markedly reduced vasopressor activity in comparison to native AVP, has a prolonged half-life, and can be administered orally, intranasally, or by subcutaneous injection.

## Syndrome of Inappropriate Antidiuretic Hormone Secretion

SIADH is characterized by the inability to excrete a free water load, with inappropriately concentrated urine, and resultant hyponatremia, hypo-osmolality, and natriuresis in the absence of renal dysfunction, hypothyroidism, and adrenal insufficiency. Although most patients with SIADH have inappropriately measurable or elevated levels of plasma AVP relative to plasma osmolality, 10% to 20% of patients with SIADH do not have measurable AVP levels. This may reflect issues of assay sensitivity or may indicate a syndrome resembling SIADH, nephrogenic syndrome of inappropriate antidiuresis (NSIAD), which is associated with an activating mutation in the X-linked V2R and unmeasurable circulating levels of AVP.

Euvolemia in chronic SIADH is an important distinguishing factor in the evaluation of a patient with serum hypo-osmolality and has a bearing on treatment issues. Euvolemia in chronic SIADH is thought to represent an adaptation to water overload. Natriuresis, thought to be mediated in part through secretion of atrial natriuretic peptide, also contributes to volume regulation in chronic SIADH. Cerebral salt wasting, associated with some intracranial diseases (e.g., subarachnoid hemorrhage), is often considered in the differential diagnosis of SIADH. However, the hypo-osmolality, hyponatremia, and natriuresis in cerebral salt wasting are associated with volume contraction, which distinguishes this disorder from the euvolemic condition of SIADH.

A large number of disorders and conditions are associated with SIADH. These include disorders of the CNS (e.g., infection, trauma, cerebrovascular accident, tumors), surgery, ectopic AVP production from non-CNS tumors, medications, and pulmonary disorders. Therapy for SIADH includes treatment of the underlying disorder (or discontinuation of an offending drug) and fluid restriction. Replacement of lost body sodium also may be necessary but usually can be achieved through normal dietary salt intake. Severe hyponatremia may be associated with CNS abnormalities, including seizures, and may require treatment with hypertonic intravenous sodium chloride solution. Concurrent use of a diuretic, such as furosemide, may be indicated. Urea has been used as an osmotic diuretic in pediatric SIADH and NSIAD. A variety of nonpeptide V2R antagonists have been approved by the Food and Drug Administration for use in adults.

If SIADH and hyponatremia are acute (<48 hours), it is thought that hyponatremia can be corrected quickly. However, if SIADH and hyponatremia are chronic (>48 hours), overzealous treatment can result in CNS damage, including central

pontine myelinolysis. Generally, it is recommended that plasma sodium be corrected to a "safe" level of approximately 120 to 125 mEq/L, at a rate of no greater than 0.5 mEq/L per hour, with an overall correction that does not exceed 12 mEq/L in the initial 24 hours and 18 mEq/L in the initial 48 hours of treatment.

## INTRODUCTION

Dysfunction of the autonomic nervous system (ANS) is an increasingly recognized health problem in the pediatric population. Patients with ANS dysfunction may present with a number of seemingly unrelated symptoms, including lightheadedness on standing, syncope, labile blood pressure, problems with sweating or thermoregulation, gastrointestinal dysmotility, bladder urgency or incontinence, and sleep abnormalities.

The vast majority of complaints in children referred to an autonomic disorders clinic correspond to physiologic responses to emotional states. Neuronal pathways connect the limbic system to the autonomic system, and as a consequence, emotions have a profound effect on autonomic outflow to the organs. In these cases, rather than a primary autonomic disorder, the symptoms result from activation of the classic “flight-or-fight” autonomic response to a perceived (but not always obvious) threat.

Autonomic dysfunction in children can be secondary to metabolic disorders, including obesity, anorexia, and diabetes. Severe, sometimes life-threatening derangements of autonomic function occur in a number of rare genetic and autoimmune disorders. Autonomic dysreflexia as a result of spinal cord lesions and afferent baroreflex failure as a result of neck tumors or as sequelae of surgery or radiotherapy can occur in children and adolescents and presents with dramatic blood pressure volatility.

## ANATOMY AND PHYSIOLOGY OF THE AUTONOMIC NERVOUS SYSTEM

### Anatomy of the Autonomic Nervous System

The ANS innervates most of the organs in the body and controls involuntary functions to maintain homeostasis. In 1898, physiologist John Langley divided the ANS into three branches: sympathetic, parasympathetic, and enteric. The sympathetic and the parasympathetic nervous system have opposing actions.

### Efferent Autonomic Pathways

The autonomic outflow from the central nervous system (CNS) to the effector organs consists of a two-neuron pathway with one synapse in the peripheral autonomic ganglia (Fig. 154-1).

**Sympathetic Efferent Pathways.** The cell bodies of preganglionic *sympathetic neurons* are in the intermediolateral cell column (IML) of the thoracic and lumbar spinal cord (levels T1 through L3). Preganglionic sympathetic axons leave the spinal cord as small myelinated fibers to synapse with (post)ganglionic neurons in sympathetic ganglia close to the spinal cord. Unmyelinated axons from postganglionic neurons

emerge from sympathetic ganglia to synapse with target organs. Preganglionic sympathetic neurons in the IML cell column receive direct descending excitatory inputs from hypothalamic nuclei and from the ventromedial and rostral ventrolateral medulla (RVLM). Preganglionic sympathetic axons exit the spinal cord through the ventral roots toward paravertebral or prevertebral ganglia.

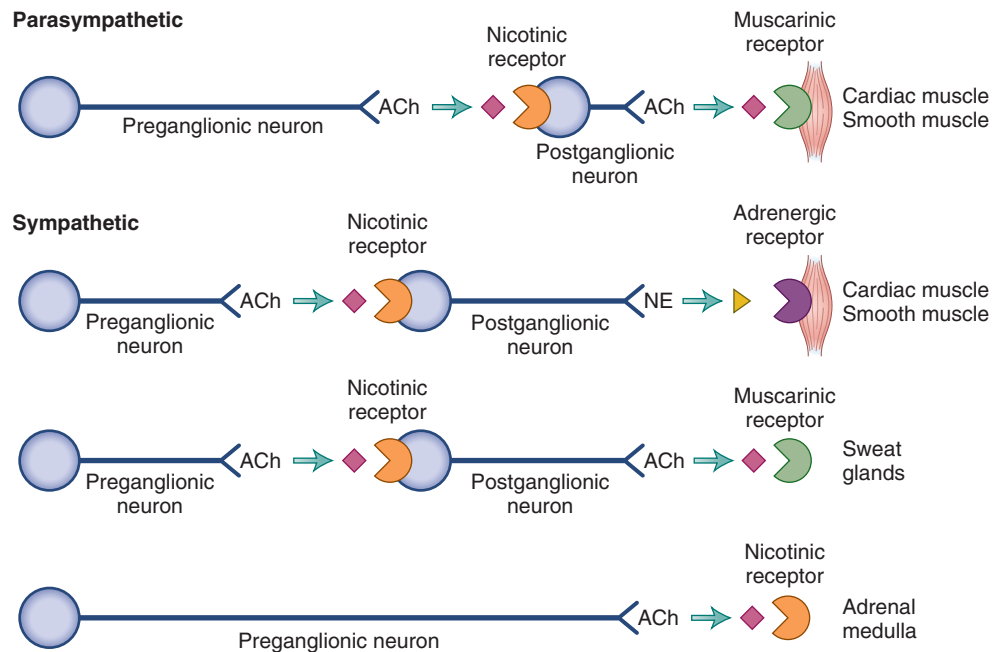

**Parasympathetic Efferent Pathways.** The cell bodies of preganglionic *parasympathetic neurons* are located in the brainstem and at the sacral (S2-S4) level of the spinal cord. Axons of preganglionic parasympathetic neurons are myelinated and leave the brainstem or spinal cord to synapse with cell bodies of postganglionic parasympathetic neurons in autonomic ganglia close to (or within) the effector organs. Short unmyelinated postganglionic parasympathetic fibers synapse with target tissues.

**Efferent Neurotransmission.** Acetylcholine is the neurotransmitter of preganglionic neurons, both sympathetic and parasympathetic. Acetylcholine, via activation of nicotinic receptors, produces excitation of postganglionic neurons. The main neurotransmitter of postganglionic sympathetic neurons is norepinephrine, which activates alpha- and beta-adrenergic receptors. The sympathetic neurons innervating sweat glands release acetylcholine, which activates muscarinic receptors. The main neurotransmitter of postganglionic parasympathetic neurons is also acetylcholine, which acts on different types of muscarinic receptors (Fig. 154-1).

### Afferent Autonomic Pathways

The classic descriptions of the ANS were of a purely efferent motor system. The ANS, however, has afferent pathways that run parallel to the efferent pathways and can also be divided into sympathetic and parasympathetic. *Parasympathetic* afferents are small-diameter fibers that transmit information to the CNS via the vagus (X) and glossopharyngeal (IX) nerves and have their cell bodies in the nodose and petrosal ganglia, respectively. Vagal afferents relay information from aortic, cardiac, pulmonary, and gastrointestinal receptors. Glossopharyngeal afferents carry signals from baroreceptors and chemoreceptors in the carotid sinus. Parasympathetic afferents synapse with neurons in the NTS in the brainstem.

*Sympathetic* afferents relay information about an array of physiologic variables, including the mechanical, thermal, chemical, metabolic, and hormonal status of the skin, muscle, joints, teeth, and viscera. They are responsible for muscular and visceral sensations, vasomotor activity, hunger, thirst, and “air hunger.” These neurons synapse with neurons in lamina I of the dorsal horn of the spinal cord. Lamina I neurons in turn project densely to the IML cell column synapsing with preganglionic sympathetic neurons, forming a spino-spinal loop for autonomic reflexes.

**Figure 154-1.** Elements of the parasympathetic and sympathetic nervous systems. Most organs receive both sympathetic and parasympathetic innervation, except for the blood vessels (only sympathetic adrenergic), the sweat glands (only sympathetic cholinergic), and the adrenal medulla (receives direct sympathetic innervation from the intermediolateral cell column in the spinal cord).

## Central Nervous System Integration

Spinal, brainstem, and rostral cortical areas modulate signals from the afferent pathways, resulting in precise reflex activation or inhibition of autonomic efferent nerves. A well-studied example of an autonomic reflex pathway is the arterial baroreflex (Fig. 154-2). As with other polysynaptic autonomic reflexes, baroreflex information is integrated with other sensory information and with input from more rostral cortical areas.

## CLINICAL APPROACH TO THE DIAGNOSIS OF PEDIATRIC AUTONOMIC DISORDERS

### Clinical History Taking

Children with autonomic dysfunction can present with a variety of symptoms involving different organs. Detailed history taking is of paramount importance to establish a diagnosis. A structured clinical interview can provide valuable diagnostic clues. Careful review of current medications can rule out drug-induced causes. A thorough family history is key to the diagnosis of genetic disorders.

### Orthostatic Intolerance

Because the sympathetic nervous system plays a crucial role maintaining blood pressure and cerebral blood flow when standing, orthostatic intolerance with symptoms of tissue hypoperfusion is the most characteristic presentation of sympathetic failure (see following discussion). The clinical interview should be framed with the goal of carefully reconstructing the events, signs, symptoms, and outcome of the syncopal/presyncopal episode.

**Syncope.** Most children are referred to an autonomic clinic after experiencing brief episodes of transient loss of consciousness. Although seizures are frequently suspected, syncope is much more frequent. Syncope is defined as a transient loss

of consciousness and postural tone resulting from global cerebral hypoperfusion; it is short-lived, with spontaneous recovery and no neurologic sequelae. Urinary incontinence and myoclonic jerks can occur in children with both reflex syncope and seizures, but a clear-cut aura and postictal confusion are signs of a seizure. Tongue biting is rare in syncope but common in seizures. Syncope most commonly occurs when standing, whereas seizures have no postural predilection.

Questions should aim to differentiate reflex (vasovagal) syncope—a reversible physiologic condition with a benign prognosis—from cardiac syncope or chronic impairment of sympathetic outflow. Although the latter is very infrequent in children, it does occur in genetic and immune-mediated autonomic disorders.

### Orthostatic Intolerance with Orthostatic Tachycardia.

The second most commonly encountered problem in an autonomic clinic is the so-called postural tachycardia syndrome (PoTS), a heterogeneous syndrome common in young females. It is associated with a myriad of symptoms, including lightheadedness, palpitations, tremulousness, weakness, fatigue, exercise intolerance, hyperventilation, paresthesiae, shortness of breath, anxiety, chest pain, nausea, acral coldness or pain, and difficulty concentrating. Syncope is not common in PoTS. The overlap with anxiety/panic disorders is often readily apparent.

**Abnormal Gastrointestinal Motility.** Constipation and diarrhea are common in children with functional autonomic disorders and are also a side effect of some medications or diets. Reduced salivation and dry mouth (xerostomia) can occur in autoimmune autonomic disorders and may result in dysphagia when eating. Autonomic diseases affecting the esophagus (e.g., achalasia) may cause dysphagia and heartburn. Abdominal distension, nausea, vomiting, and early satiety as a consequence of gastroparesis can be seen in metabolic disorders (e.g., diabetes, anorexia nervosa).

**Figure 154-2.** The arterial baroreflex. The arterial baroreceptors are mechanoreceptors located in the carotid sinus (innervated by the glossopharyngeal nerve, IX) and aortic arch (innervated by the vagus nerve, X) that respond to stretch elicited by increase in arterial pressure. Baroreceptor afferents provide monosynaptic excitatory inputs to the nucleus of the solitary tract (NTS) in the brainstem. Barosensitive NTS neurons initiate a sympathoinhibitory pathway that involves projections from the NTS to the caudal ventrolateral medulla (CVL) that send inhibitory projections to sympathoexcitatory neurons in the rostral ventrolateral medulla (RVLN). There is also direct input from the NTS to the vagal preganglionic neurons of the nucleus ambiguus (NAmb). These neurons project to the cardiac ganglion neurons that promote bradycardia. The baroreflex, via the NTS, also inhibits secretion of vasopressin by neurons of the supraoptic (SON) and paraventricular (PVN) nuclei of the hypothalamus, by inhibiting cells of the A1 noradrenergic group.

Neonatal severe constipation is a feature of Hirschsprung disease. Nausea and vomiting in response to emotional or physical stimuli occur in the rare genetic condition familial dysautonomia, although such occurrences are more frequently a result of functional disorders (e.g., cyclic vomiting syndrome).

**Genitourinary Symptoms.** Urinary symptoms are frequent in children, and in most cases they are not indicative of an underlying autonomic disorder. Interpretation in young children should take into account that 10% of those younger than 8 years old suffer from daytime or nocturnal enuresis. In rare cases, daytime enuresis is attributable to detrusor overactivity. Urinary retention can be seen in autoimmune autonomic disorders and in spinal cord injury (Neveus and Sillen, 2013). In adolescents and young men, erectile dysfunction and failure to ejaculate can be a consequence of autonomic dysfunction. Milky-colored urine may represent retrograde ejaculation.

**Thermoregulatory Abnormalities.** Anhidrosis and hypohidrosis are manifestations of sympathetic cholinergic failure, and lesions causing these abnormalities can occur anywhere from the level of the cerebral cortex to the eccrine sweat glands. Anhidrosis can lead to hyperthermia, heat stroke, and death. In spinal cord injury there often is a band of hyperhidrosis above the lesion with anhidrosis below. Hypothermia may occur in hypothalamic disorders and spinal cord injury.

Hyperhidrosis (excessive sweating beyond that required for thermal homeostasis) can be generalized or focal. It should be distinguished from normal night sweats, which can occur in up to 12% of healthy children. In the vast majority of cases, hyperhidrosis is linked to anxiety. Hyperhidrosis may accompany episodes of paroxysmal sympathetic activation in familial dysautonomia or pheochromocytoma.

**Ocular Symptoms.** Blurry vision and photophobia can be symptoms of abnormal autonomic innervation of the pupil. Impaired lacrimation may be a sign of autonomic impairment of the lacrimal glands.

**Respiratory Symptoms.** Hyperventilation is common and can be found in up to 15% of children and adolescents. Hyperventilation is frequently a feature in patients with functional autonomic symptoms, including PoTS and reflex syncope. Daytime symptoms of hypoventilation and central sleep apnea in children include decreased attention span, poor performance in school, and behavioral changes.

## PEDIATRIC AUTONOMIC DISORDERS

Pediatric autonomic disorders can be classified in several ways. Table 154-1 depicts proposed schemes based on the pathophysiological features of autonomic dysfunction in children. In clinical practice, the main goal is to distinguish functional disorders, which are very common, from the more severe, but rare disorders.

**TABLE 154-1** Classifications of Pediatric Autonomic Disorders

Etiology	Topography	Frequency	Neurotransmission
<b>Functional</b> Reflex (vasovagal) syncope Postural tachycardia syndrome Orthostatic intolerance without tachycardia	<b>Generalized</b> Reflex (vasovagal) syncope Postural tachycardia syndrome Orthostatic intolerance without tachycardia Hereditary sensory autonomic neuropathies Other rare genetic disorders Reflex (vasovagal) syncope Postural tachycardia syndrome Orthostatic intolerance without tachycardia Immune-mediated	<b>Common</b> Reflex (vasovagal) syncope Postural tachycardia syndrome Orthostatic intolerance without tachycardia Obesity Diabetes Anorexia nervosa Other metabolic disorders	<b>Pandysautonomia (adrenergic and cholinergic failure)</b> Autoimmune autonomic ganglionopathy Acute autonomic and sensory neuropathy Guillain-Barré syndrome Paraneoplastic neuropathies Porphyria
<b>Inherited</b> Hereditary sensory autonomic neuropathies Other rare genetic disorders	<b>Pupil</b> Argyll Robertson pupil Adie pupil Horner syndrome Pourfour du Petit syndrome	<b>Rare</b> Immune-mediated Traumatic Hereditary sensory autonomic neuropathies Other rare genetic disorders	<b>Pure adrenergic failure</b> Dopamine-beta hydroxylase deficiency Pure adrenergic neuropathy
<b>Metabolic</b> Obesity Diabetes Anorexia Other metabolic disorders	<b>Face</b> Cluster headache Harlequin syndrome Gustatory sweating		<b>Pure cholinergic failure</b> Botulism Lambert-Eaton syndrome Adie pupil Chagas disease Acute cholinergic neuropathy
<b>Immune-mediated</b> Autoimmune autonomic ganglionopathy Guillain-Barre syndrome Anti-NMDA receptor encephalitis Paraneoplastic autonomic neuropathy Sjögren disease	<b>Limbs</b> Raynaud phenomenon Acrocyanosis Primary idiopathic hyperhidrosis		
<b>Infectious</b> Chagas disease HIV Tetanus			
<b>Neoplasia</b> Catecholamine-secreting tumors Brainstem and posterior fossa tumors			
<b>Trauma and malformations</b> Spinal cord injury Traumatic brain injury Syringomyelia Arnold-Chiari			
Drugs			
<b>Postsurgical or postradiotherapy</b> Acquired baroreflex failure			

## Functional Disorders of Unknown Origin

### Reflex (Vasovagal) Syncope

Reflex syncope (i.e., the common faint, also known as vasovagal, neurally mediated, or neurocardiogenic syncope) refers to a sudden fall in blood pressure and slowing of the heart rate causing impaired cerebral perfusion that leads to a brief episode of loss of consciousness and muscle tone. Patients with reflex syncope usually describe classical prodromal signs and symptoms (pallor, diaphoresis, nausea, abdominal discomfort, yawning, sighing), and many children begin to hyperventilate in the time leading up to the faint. If blood pressure continues to fall, cerebral and retinal hypoperfusion (visual disturbances, concentration difficulties, and lightheadedness) develop just before the loss of consciousness. Scenarios likely to provoke reflex syncope are motionless standing,

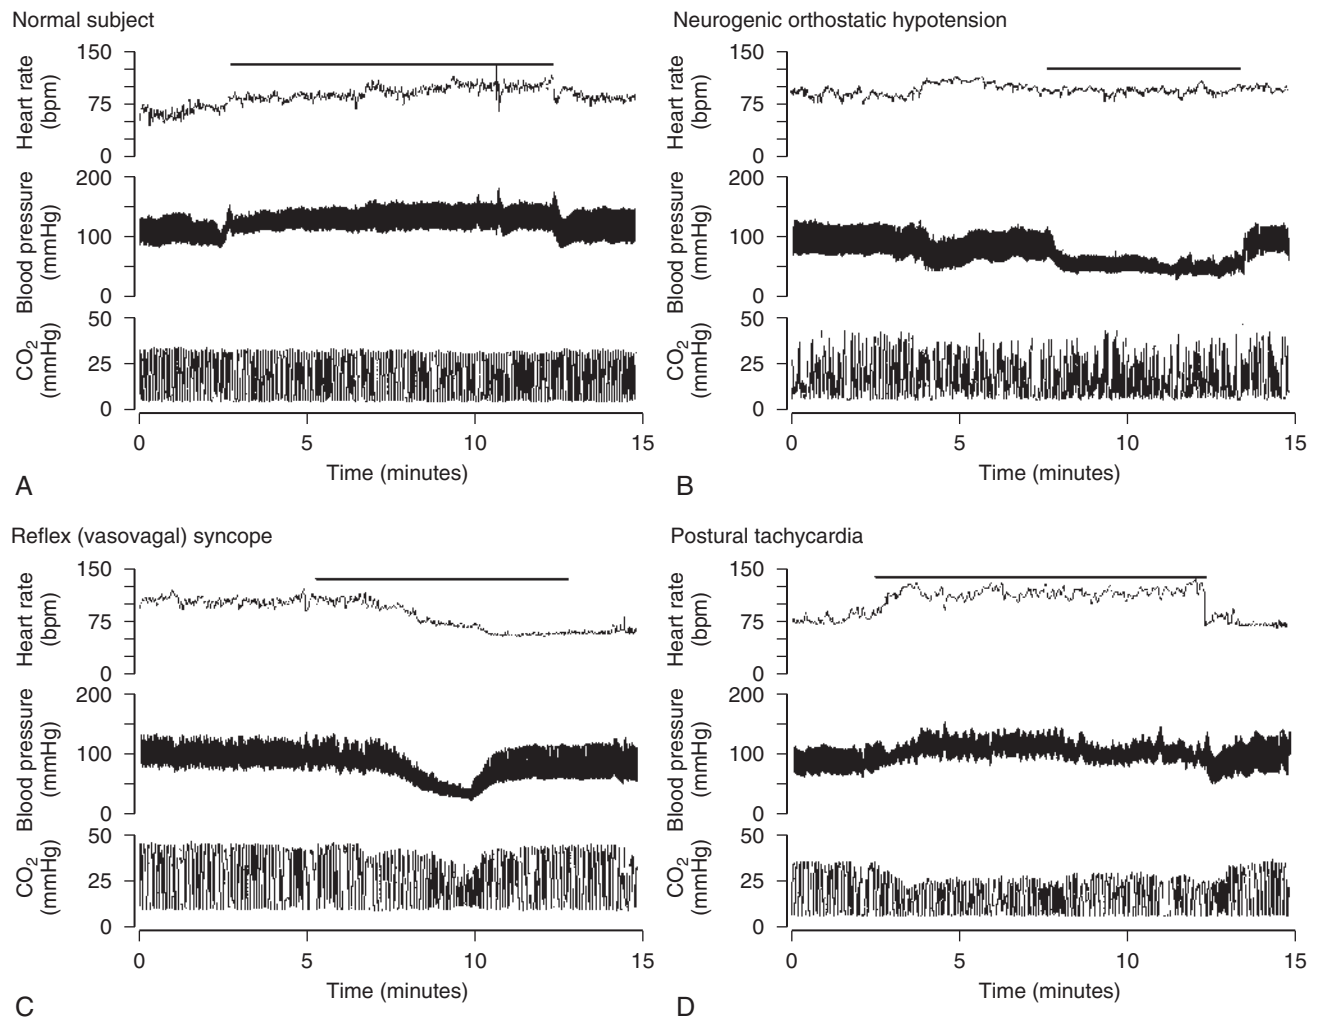

elevated ambient temperatures, and dehydration. Known emotional triggers are fear, anger, blood sampling, pain, and TV programs about medical matters (Wieling et al., 2009).

The prevalence of reflex syncope in the pediatric population is high. A survey of young adults averaging 20 years of age showed that about 20% of males and 50% of females reported having experienced at least one syncopal episode in their lifetime. The median age at the first episode of reflex syncope is approximately 15 years.

In most cases, reflex syncope can be diagnosed by eyewitness accounts and careful reconstruction of the event. In cases when the diagnosis is not straightforward, prolonged tilt testing can be helpful by replicating symptoms while recording the typical acute drop in blood pressure and slowing of the heart rate (Fig. 154-4).

Key aspects of the management of young patients with reflex syncope include reassurance, advice, and patient

**Figure 154-4.** Changes in heart rate (HR), blood pressure (BP), and ventilation pattern during head-up tilt test. **A**, In a normal subject, no major changes are observed in BP, HR, or end-tidal CO<sub>2</sub> during the tilt test. **B**, Neurogenic orthostatic hypotension features a dramatic decrease in blood pressure and absence of compensatory increase in heart rate. Hyperventilation does not occur. **C**, Reflex (vasovagal) syncope. During the episode, a dramatic decrease in blood pressure occurred, accompanied by a decrease in HR; CO<sub>2</sub> levels also decreased right before and during the syncope. **D**, In postural tachycardia syndrome (PoTS), heart rate increases during tilt and CO<sub>2</sub> levels decrease, with no significant changes in BP. The bar above the graphs denotes the period during the 60-degree-angle head-up tilt.

education. Time should be taken to identify triggers that exaggerate venous pooling and provoke syncope. Children should be taught nonpharmacologic measures that can prevent or abort the episode, including slow breathing and muscle-tensing maneuvers to increase venous return. Increasing salt and water intake and sleeping with the head of the bed raised are helpful nonpharmacologic means to expand intravascular volume. In cases of refractory reflex syncope, the short-acting pressor agent midodrine can be used “on demand” to improve orthostatic intolerance before situations known to trigger syncope. Pacemakers are ineffective (Kaufmann and Hainsworth, 2001).

### Postural Tachycardia Syndrome

Postural tachycardia syndrome (PoTS) is a complex disorder that is not well understood. It is characterized by chronic symptoms of orthostatic intolerance accompanied by a heart-rate increment within 10 minutes of standing or head-up tilt with no orthostatic hypotension. Current consensus criteria of PoTS require, at least, a heart rate increment of 40 beats/min in children aged 12 to 19 years (Fig. 154-4).

Symptoms may develop gradually or acutely, range from mild to severe, and resolve spontaneously or continue intermittently for years. Syncope is not a typical feature of PoTS. Many children with PoTS also report symptoms not attributable to orthostatic intolerance, including those of functional gastrointestinal or bladder disorders, chronic headache, fibromyalgia, and sleep disturbances.

The pathophysiology of PoTS is unclear but likely involves a combination of factors, including cardiovascular deconditioning, hyperventilation, and volume depletion. Emotional comorbidities, including somatic hypervigilance, anxiety, and depression, are common and contribute to symptom chronicity. The severity of the symptoms is often linked to the degree of hyperventilation-induced hypocapnia, which exacerbates venous pooling and tachycardia. Many patients with PoTS go on to develop additional symptoms, including constipation, bloating, bladder sensitivity disorders, and chronic headache, and despite comprehensive workup, usually no structural cause can be identified.

Management of PoTS should begin by removing any medications that produce tachycardia, including norepinephrine reuptake inhibitors and stimulants. Surreptitious use of

diuretics should be ruled out in any adolescent or young adult with elevated renin levels. Exercise training and cognitive behavioral therapy are the most appropriate interventions. Correcting the standing heart rate with beta blockers or cholinesterase inhibitors may not be effective to improve symptoms (Benarroch, 2012).

## Metabolic Disorders

### Obesity

The prevalence of pediatric obesity (defined as a body mass index [BMI]  $\geq$  95th percentile for age and sex) has more than tripled during the past decades in the United States, and around 20% of children and adolescents are now overweight. Epidemiologic studies have evaluated the effect of obesity in cardiac autonomic modulation in children. Most studies show an increase in sympathetic and a decrease in parasympathetic function with abnormal cardiac circadian patterns. The pathophysiology of autonomic abnormalities in obesity is not well understood but is likely mediated by comorbidities such as sleep apnea, metabolic abnormalities, and arterial hypertension. Children with obesity as a result of genetic disorders, such as Prader-Willi syndrome, appear to have diminished parasympathetic nervous system activity.

### Eating Disorders

Anorexia nervosa is a potentially life-threatening eating disorder characterized by an intense fear of gaining weight, distorted body image, and amenorrhea. It affects 0.5% to 4% of adolescent girls in the United States, and its incidence has increased over the past few decades. Children with anorexia are predisposed to arrhythmias and sudden cardiac death. Bradycardia, hypotension, and cardiac atrophy are all features of the disease. Patients have significantly lower heart rates at night and increased heart rate variability. These abnormalities are reversible after weight recovery. Bulimia nervosa affects 1% to 2% of adolescent girls in the United States and has similar cardiovascular autonomic findings.

### Diabetes Mellitus

Although diabetes mellitus is one of the most common causes of autonomic dysfunction in adults, signs and symptoms of autonomic dysfunction are infrequent in pediatric patients. However, autonomic neuropathy should be considered in adolescents and young adults with long duration of type 1 diabetes mellitus, who may have early evidence of cardiovascular autonomic dysfunction.

### Other Metabolic Disorders

Hypothyroidism (with symptoms of fatigue, dry skin, sleep disturbances, and constipation) and hyperthyroidism (with symptoms of fever, tachycardia, hypertension, and gastrointestinal abnormalities) can present with symptoms of autonomic dysfunction. Symptoms of Addison disease include hypotension, hyperpigmentation, and adrenal crises.

## Autonomic Dysfunction Secondary to Focal Disease

Areas distributed throughout the neuraxis, including the anterior insula, anterior cingulate cortex, amygdala, hypothalamus, periaqueductal gray matter, parabrachial nucleus, and several regions of the medulla, are involved in autonomic control, particularly in cardiovascular regulation. Therefore lesions of various etiologies (e.g., trauma, hydrocephalus,

demyelination, stroke, malformations, tumors) can potentially cause autonomic dysfunction.

Spinal cord injury in the pediatric population is relatively rare. More than half of pediatric spinal cord injuries occur in the cervical area. Signs and symptoms depend on the level of the lesion and whether the section is complete or incomplete. Destruction of the descending cardiovascular autonomic pathways results in (a) blunted release of norepinephrine when upright, leading to neurogenic orthostatic hypotension, and (b) loss of inhibitory and excitatory supraspinal input to the sympathetic preganglionic neurons, leading to unrestrained sympathetic activity of fibers arising below the level of the lesion (referred to as "autonomic dysreflexia"), particularly in subjects with an injury at the T6 level or above.

## ACQUIRED AFFERENT BAROREFLEX FAILURE

Bilateral destruction of baroreceptor afferent neurons in the glossopharyngeal and vagus nerves that relay information to the NTS can result in afferent baroreflex failure. Patients with baroreflex failure have extremely labile blood pressure and heart rates. Many alternate between orthostatic hypotension and paroxysmal hypertension. Hyperadrenergic signs and symptoms usually dominate the clinical picture and can resemble those of a pheochromocytoma.

Causes of afferent baroreflex failure include nerve injury secondary to neck surgery or delayed effect of radiotherapy to the neck for cancer, or trauma; brainstem strokes that damage the nucleus of the solitary tract and other areas of the brainstem; and rare hereditary conditions that affect the development of afferent baroreceptor pathways, including familial dysautonomia and Moebius syndrome. Treatment involves techniques to manage stress and medications to control blood pressure. Preliminary data suggest that carbidopa, a DOPA decarboxylase inhibitor that does not cross the blood-brain barrier, may reduce norepinephrine surges and lessen blood pressure peaks.

## Catecholamine-Secreting Tumors

Paragangliomas are rare neuroendocrine tumors derived from neural crest cells that arise in the peripheral ANS. Pheochromocytomas are paragangliomas that arise from chromaffin cells of the adrenal medulla. These are characterized by unpredictable paroxysmal episodes of excessive catecholamine secretion, resulting in hypertension, tachycardia, and headaches. Approximately 50% are malignant. Treatment requires surgery.

## Autoimmune Autonomic Disorders

### Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) is less common in children than in adults, with an incidence of 0.4 to 1.3 cases per 100,000 per year in children in the United States; it is rarely seen in children younger than 2 years old. GBS (also known as acute inflammatory demyelinating polyneuropathy) is responsible for most cases of acute and subacute flaccid paralysis in infants and children. Approximately two thirds of patients diagnosed with GBS had a respiratory or gastrointestinal infection prior to the start of the symptoms. Autonomic instability with episodes of hypertension and hypotension and cardiac arrhythmia can occur. This can be life threatening, so close monitoring is required. Other autonomic symptoms such as gastrointestinal and bladder dysfunction can also be present. Treatment includes intravenous immunoglobulin (IVIG) or plasma exchange.

## Autoimmune Autonomic Ganglionopathy

Autoimmune autonomic ganglionopathy is characterized by an acute-onset widespread sympathetic and parasympathetic failure. Cholinergic deficits are pronounced and include severe impairment of gastrointestinal motility, with gastroparesis and constipation, bladder retention, dry eyes, and dry mouth. Abnormal pupillary responses are common. Orthostatic hypotension can be severe. There is no motor or sensory impairment. In 30% to 50% of patients, high titers of antibodies against the neuronal ganglionic nicotinic acetylcholine receptor (AChR) are identified. In the remaining cases, other autoantibodies not yet identified are the likely cause. Patients may respond to IVIG, plasma exchange, or rituximab. Some cases in children and adolescents have been reported, although its incidence in children is unknown.

## Acute Autonomic and Sensory Neuropathy

Acute autonomic and sensory neuropathy is a rare disorder in which patients develop acute-onset fine-touch and proprioceptive sensory deficits leading to severe ataxia. Autonomic involvement includes neurogenic orthostatic hypotension, lack of sweating, and urinary and fecal incontinence. Plasma norepinephrine levels are low or undetectable. In most cases a gastrointestinal or respiratory infection precedes the neuropathy, suggesting an immune-mediated process, in some cases associated with antigalactocerebroside or antisulfatide antibodies. IVIg and plasma exchange have been used, with varied success (Koike et al., 2010).

## Anti-NMDA Receptor Encephalitis

Anti-NMDA receptor encephalitis results from antibodies against the NR1 and NR2 subunits of the NMDA receptor. Symptoms in children include behavioral and personality changes. As the disease progresses, patients develop sleep disorders, seizures, movement disorders, and autonomic instability (tachycardia, hypertension, hypoventilation, urinary incontinence, and hypothermia or hyperthermia). It has been linked to ovarian neoplasms, although it has been described in patients without cancer (Florance et al., 2009).

## Lambert-Eaton Myasthenic Syndrome

In addition to weakness and reduced or absent deep tendon reflexes, autonomic dysfunction is a recognized feature of Lambert-Eaton myasthenic syndrome (LES). Dry mouth is the most frequent autonomic symptom, followed by sweating abnormalities and impaired cardiac parasympathetic reflexes. The majority of patients have antibodies against P/Q-type voltage-gated calcium channels (VGCC), and approximately 30% of patients have N-type VGCC autoantibodies. This syndrome is frequently found in association with small-cell carcinoma of the lung, but it has also been found in patients without neoplasms. Lambert-Eaton syndrome is very rare in children.

## Dipeptidyl-Peptidase-Like Protein-6 (DPPX) Potassium Channel Antibody Encephalitis

Dipeptidyl-peptidase-like protein-6 (DPPX) potassium channel antibody encephalitis, a recently described autoimmune encephalitis, affects adults and young teenagers and is characterized by the presence of antibodies against DPPX, a subunit of Kv4.2 potassium channels. Main features are insidious and subacute cognitive impairment, abnormal eye movements, dysphagia, insomnia, and autonomic abnormalities, most prominently gastrointestinal symptoms (diarrhea, gastroparesis, constipation), followed by urinary symptoms,

fluctuating hyperthermia/hypothermia, and asymptomatic ventricular tachycardia.

## Genetic Autonomic Disorders

There are a number of rare, early-onset genetic disorders that affect the ANS. Although the extent of autonomic involvement varies, certain genetic conditions are associated with widespread autonomic dysfunction.

### Hereditary Sensory and Autonomic Neuropathies

Hereditary sensory and autonomic neuropathies (HSANs) are a group of rare disorders caused by different mutations that affect different aspects of the development, function, or survival of sensory and autonomic neurons. Classification is evolving as a result of the discovery of increasing numbers of mutations and the availability of whole-exome sequencing (Table 154-2). For each HSAN type, penetrance is complete, but phenotypic expression varies markedly. Impaired pain and temperature perception are common traits.

**HSAN Type 1.** HSAN type 1 is the most common HSAN, but it is an adult-onset disorder. Patients have varying degrees of sensorineural hearing loss, distal anhidrosis, and episodes of lancinating pain in the limbs. There are several subtypes (Table 154-2).

**HSAN Type 2.** HSAN type 2 is an autosomal-recessive disorder characterized by impaired temperature, pain, and fine-touch sensation. Onset varies from birth up until the beginning of the teens. There are at least four causative gene mutations, resulting in subsequent subtype designations (A through D). Autonomic involvement varies markedly (Table 154-2).

**HSAN Type 3 (Familial Dysautonomia).** HSAN type 3 (familial dysautonomia, Online Mendelian Inheritance in Man database (OMIM) #223900) is an autosomal-recessive disease almost exclusively affecting children with Eastern European Jewish ancestry. Over 99% of affected patients are homozygous for the founder point mutation (6T>C change) in the gene encoding for the elongator-1 protein (ELP-1), known also as I-k B kinase-associated protein (IKAP). IKAP (ELP-1) is expressed in most cells throughout the body. The deficiency of IKAP (ELP-1) during embryogenesis affects the development of primary sensory (i.e., afferent) neurons that carry information to the CNS with cell bodies in the dorsal root and cranial nerve ganglia. Efferent (motor) neurons are mostly spared.

In contrast to other HSANs, in HSAN type 3, autonomic dysfunction dominates the clinical picture. The main autonomic defect in patients with HSAN type 3 is in the afferent (sensory) neurons that convey incoming information from the arterial baroreceptors, resulting in the unusual combination of orthostatic hypotension and paroxysmal hypertension. Although reduced in number, the efferent sympathetic nerves are functionally active. Supine plasma norepinephrine levels are normal. Stimuli that activate efferent sympathetic neurons, independently of baroreceptor afferent pathways, such as cognitive tasks and emotional arousal, dramatically increase blood pressure, heart rate, and circulating norepinephrine levels (Norcliffe-Kaufmann, Axelrod, and Kaufmann, 2010).

Episodic retching and vomiting attacks accompanied by skin blotching, diaphoresis, hypertension, and tachycardia ("dysautonomic crises") are common. These are the result of sudden increases in circulating catecholamines that are unrestrained by baroreceptor feedback. End-organ target damage (e.g., chronic kidney disease) occurs as a long-term consequence of hypertension and excessive blood pressure variability.

**TABLE 154-2** Hereditary Sensory and Autonomic Neuropathies

Type	Gene	Inheritance	Onset	Autonomic Features	Sensory Features	Other Features
HSAN 1A	SPTLC1	AD	Adult	Varying degrees of distal anhidrosis	Progressive loss of pain, temperature, and fine-touch sensation; Varying degrees of sensorineural hearing loss	One case with congenital presentation reported with severe growth and mental retardation, microcephaly, hypotonia, and respiratory insufficiency
HSAN 1B	3p24-p22 locus				Episodes of lancinating limb pain	Cough and gastroesophageal reflux
HSAN 1C	SPTLC2					Varying degrees of distal muscle weakness
HSAN 1D	ALT1			None		—
HSAN 1E	DMNT1			None		Early-onset dementia
HSAN 1F	ATL3			None		—
HSAN 2A	WNK1	AR	Childhood or adolescence	None	Varying degrees of progressive loss of pain, temperature, and fine-touch sensation	—
HSAN 2B	FAM134B			Varying degrees of hyperhidrosis, urinary incontinence, and pupillary abnormalities		
HSAN 2C	KIF1A			None		—
HSAN 2D	SCN9A			Urinary and fecal incontinence, reduced sweating		Lack of fungiform lingual papillae, hyposmia, hearing loss, hypogeusia, and bone dysplasia
HSAN 3	IKAP (ELP-1)	AR	Newborn	Impaired lacrimation Orthostatic hypotension Paroxysmal hypertension and vomiting episodes with skin blotching Normal or increased sweating	Impaired pain and temperature sensation with preserved fine-touch sensation	Described in Ashkenazi Jewish ancestry; Neonatal hypotonia; Respiratory and feeding difficulties; Neuropathic joints Optic neuropathy Chronic lung disease Scoliosis; Rhabdomyolysis Renal failure Varying degrees of cognitive and behavioral problems
HSAN 4	NTRK (TRKA)	AR	Newborn	Anhidrosis; Episodic hyperthermia Undetectable plasma norepinephrine	Loss of pain and temperature sensation Preserved fine-touch and vibration sensation	Frequent fractures Neuropathic joints Slow-healing wounds Varying degrees of cognitive and behavioral problems
HSAN 5	NGFβ	AR	Newborn	Variable degree of anhidrosis	Loss of pain and temperature sensation. Preserved fine touch and vibration sensation	Frequent fractures Neuropathic joints Tooth loss from gingival disease
HSAN 6	DST	AR	Newborn	Impaired lacrimation Labile blood pressure and heart rate Hyperthermia and skin-blotching episodes	Loss of pain and temperature sensation	Described in Ashkenazi Jewish ancestry; Neonatal hypotonia Respiratory and feeding difficulties, delayed psychomotor development, neuropathic joints All described patients died before age 3
HSAN 7	SCN11A	AD (only a heterozygous de novo mutation described)	Newborn	Hyperhidrosis and gastrointestinal dysfunction	Loss of pain and temperature sensation	Frequent fractures Neuropathic joints Slow-healing wounds

Superficial pain perception is severely decreased, but patients complain of abdominal discomfort and/or bone pain following fractures or surgical procedures, suggesting that some visceral pain perception is preserved. Corneal analgesia often results in abrasions and ulcerations complicated by alacrima. Patients with HSAN type 3 have been shown to have a specific type of optic neuropathy that resembles mitochondrial neuropathies.

Gait ataxia and incoordination, resulting from a lack of muscle spindle afferents, affect patients from birth and progressively worsen over time. Other features include feeding problems as a result of neurogenic dysphagia, failure to thrive, and increased frequency of rhabdomyolysis. Cognitive and behavioral issues, such as anxiety, reduced IQ, emotional overreaction, and emotional rigidity, prevent many patients from living independently. Abnormal spinal curvature, corrective spinal surgery, depressed ventilatory drive, sleep-disordered breathing, and frequent aspirations compromise respiratory function. The incidence of sudden death, particularly during sleep, is increased.

Therapeutic focus in HSAN type 3 is on reducing the catecholamine surges caused by blunted baroreceptor feedback (i.e., afferent baroreflex failure). Carbidopa is frequently used to block dopamine production outside the CNS and prevent dopamine-induced vomiting. Additional therapeutic measures include management of neurogenic dysphagia, early treatment of aspiration pneumonias, and noninvasive ventilation during sleep. Clinical trials of compounds that increase levels of IKAP (ELP-1) are under way (Palma et al., 2014).

**HSAN Type 4 (Congenital Insensitivity to Pain with Anhidrosis).** HSAN type 4 (OMIM #256800) is an autosomal-recessive disorder first described in children with mental retardation, insensitivity to pain, self-mutilating behavior, and unexplained fevers. A cardinal feature of the disease is complete anhidrosis in response to thermal, emotional, or direct stimulation of the skin. Self-mutilation is extremely common. Pinprick sensation is also diminished. Skin wounds and bone injuries heal poorly. Joints are susceptible to repeated trauma, resulting in neuropathic joints and osteomyelitis. Avoidance of harmful stimuli is crucial to prevent recurrent injuries but is frequently difficult to accomplish because patients usually have intellectual disability with impulsivity and reckless behaviors.

HSAN type 4 is associated with missense, nonsense, and frame-shift mutations in the gene that encodes for the neurotrophic tyrosine kinase-1 receptor (NTRK, previously known as TRK or TRKA). Skin biopsies of patients with HSAN type 4 reveal that sweat glands are preserved, but they lack sympathetic cholinergic innervation, thus the anhidrosis, which can lead to hyperthermia and death.

Patients with HSAN type 4 have very low or undetectable levels of circulating norepinephrine but normal epinephrine levels, suggesting that lack of NTRK-NGF signaling affects the development of sympathetic adrenergic neurons but spares chromaffin cells in the adrenal medulla. Interestingly, despite the very low norepinephrine levels indicating impaired or absent sympathetic activity, patients with HSAN type 4 have normal cardiovascular responses to orthostatic stress (Norcliffe-Kaufmann et al., 2015).

**HSAN Type 5.** Patients with HSAN type 5 (OMIM # 608654) have a selective loss of temperature and pain sensation, leading to painless fractures, bone necrosis, and neuropathic joints. They have variable degrees of sweating impairment. The disorder is caused by homozygous mutations in the nerve growth factor  $\beta$  (NGFB) gene. Heterozygous carriers can present in adulthood with a mild phenotype.

**HSAN Type 6.** Reported in a large consanguineous Ashkenazi Jewish family, HSAN type 6 is a severe autosomal-recessive disorder resulting from homozygous truncating mutations in the dystonin gene (OMIM #614653). The disorder is characterized by neonatal hypotonia, areflexia, respiratory and feeding difficulties, delayed psychomotor development, neuropathic joints, labile blood pressure and heart rate, and lack of corneal reflexes. All patients died before age 3.

**HSAN Type 7.** Reported in two unrelated patients (OMIM # 615548), HSAN type 7 includes the clinical features of congenital insensitivity to pain resulting in self-mutilations, slow-healing wounds, painless fractures, hyperhidrosis, and gastrointestinal dysfunction requiring parenteral nutrition. The disorder results from de novo heterozygous missense mutations in the SCN11A gene.

**Other Syndromes with Sensory and Autonomic Involvement.** *Navajo familial neurogenic arthropathy* was initially described in Native American (Navajo) children. It is characterized by diminished or absent sweating with variable sensory deficits, ranging from insensitivity to pain (leading to fractures, corneal injuries, and neuropathic joints) to normal sensation.

*Stuve-Wiedemann syndrome* (OMIM #601559), also known as neonatal Schwartz-Jampel syndrome type 2 (SJS2), is an autosomal-recessive disorder caused by mutations in the LIFR gene. It is characterized by bowing of the lower limbs, wide metaphyses with abnormal trabecular pattern, and camptodactyly (one or more fingers permanently bent as a result of fixed-flexion deformity of the proximal interphalangeal joints). Additional features include feeding and swallowing difficulties, respiratory distress, and episodes of hyperthermia, which can be fatal in the first months of life. Sensory abnormalities, including decreased sensitivity to pain and temperature, lead to corneal injury and absent deep tendon reflexes. Cognition and behavior appear to be normal. Hypertrichosis is common.

## Inborn Errors of Metabolism

**Dopamine Beta-Hydroxylase Deficiency.** Dopamine beta-hydroxylase deficiency, a rare disorder, is caused by mutations in the gene encoding the enzyme dopamine beta-hydroxylase (DBH), which converts dopamine to norepinephrine (OMIM # 223360). Affected patients have undetectable levels of plasma norepinephrine and epinephrine, with increased dopamine levels. Newborns can show a delay in eye opening and palpebral ptosis. Hypotension, hypoglycemia, and hypothermia may occur early in life. The absence of norepinephrine leads to deficient vasoconstriction, resulting in hypotension, syncope, and reduced exercise capacity. Symptoms generally worsen in late adolescence and early adulthood. Treatment with droxidopa (Northera®), a synthetic norepinephrine precursor, replenishes norepinephrine, increases blood pressure, and improves symptoms of hypotension (Biaggioni and Robertson, 1987).

**Aromatic L-Amino Acid Decarboxylase Deficiency.** Aromatic L-amino acid decarboxylase deficiency, an extremely rare autosomal recessive disorder, is caused by mutations in the *DDC* gene. The enzyme aromatic L-amino acid decarboxylase (AADC) converts L-dopa and 5-hydroxytryptophan to dopamine and serotonin, respectively (OMIM #608643). Neonatal symptoms include poor feeding, lethargy, ptosis, hypothermia, hypotension, intermittent eye movement abnormalities (oculogyric crises), hypotonia, and motor symptoms such as rigidity and difficulty with movements. Diagnosis is based on measurement of AADC activity in plasma and *DDC*

gene sequencing. Increased levels of urinary vanillic acid (VLA) are diagnostic. Treatment is aimed at correcting the neurotransmitter abnormalities with different medications (e.g., dopamine agonists, monoaminoxidase inhibitors, selective serotonin reuptake inhibitors, pyridoxine, droxidopa, 5-hydroxytryptophan).

**Menkes Disease.** Also known as kinky-hair disease, Menkes disease is an X-linked neurodegenerative disease of impaired copper transport. It is caused by mutations in the *ATP7A* gene (OMIM #309400). Children usually present at 2 to 3 months of age with loss of developmental milestones, failure to thrive, truncal hypotonia, and epileptic and myoclonic seizures. Autonomic abnormalities are not well characterized, although orthostatic hypotension and chronic diarrhea have been reported. Decreased serum copper and serum ceruloplasmin levels can be useful in the differential diagnosis. Decreased norepinephrine levels have been found. An elevated hydroxyphenylalanine (DOPA) and dihydroxyphenylglycol (DHPG) ratio resulting from decreased activity of DBH may be observed, with higher values reflecting more severe disease. Treatment with droxidopa might be useful.

**Fabry Disease.** Fabry disease, an X-linked inborn error of glycosphingolipid catabolism, is caused by mutations in the *GLA* gene, resulting in deficient or absent activity of the lysosomal enzyme alpha-galactosidase A (OMIM # 301500). This leads to systemic accumulation of globotriaosylceramide (Gb3) and related glycosphingolipids in plasma and organ cells throughout the body, including autonomic and dorsal root ganglia. Clinical manifestations begin in childhood or adolescence and include severe neuropathic or limb pain, telangiectasias and angiokeratomas, and renal manifestations. Symptoms of autonomic dysfunction include sweating abnormalities (hypohidrosis or hyperhidrosis), decreased lacrimation, decreased salivation, and gastrointestinal dysmotility. The degree of cardiovascular autonomic involvement is unclear.

**Porphyrias.** Porphyrias are inherited defects in the biosynthesis of heme. Acute intermittent porphyria (OMIM #176000) is the most common form of porphyria and is inherited in an autosomal-dominant manner. It is characterized by acute, recurrent episodes of abdominal pain, gastrointestinal dysfunction, and neurologic impairment. Patients are asymptomatic in between episodes. Autonomic abnormalities include tachycardia, hypotension, urinary retention, and gastrointestinal symptoms (nausea, vomiting, diarrhea, or constipation). Acute attacks rarely occur before puberty and can be precipitated by medications, alcohol, infection, starvation, and hormonal changes. Increased urinary excretion of delta-aminolevulinic acid (ALA) and porphobilinogen (PBG) during the attacks supports the diagnosis.

Porphyria variegata (OMIM #176200) is also an autosomal-dominant disorder and is caused by heterozygous mutations in the gene encoding for protoporphyrinogen oxidase (PPOX). The clinical features are similar to those of acute intermittent porphyria, but with an increased frequency of skin photosensitivity and hypertrichosis.

### Hirschsprung Disease

Also known as aganglionic megacolon, Hirschsprung disease is characterized by congenital absence of ganglionic cells in the myenteric and submucosal plexuses of the gastrointestinal tract. Affected patients have severe gastroparesis, leading to partial or complete bowel obstruction and dilatation of the colon. Cardiovascular autonomic dysfunction has been described. Mutations in the *RET* gene and several other identified loci increase susceptibility to the disorder.

Heterozygous mutations in the *ECE1* gene (OMIM #613870) cause Hirschsprung disease with cardiac defects and autonomic dysfunction (episodes of severe agitation in association with tachycardia, hypertension, and hyperthermia).

### Congenital Central Hypoventilation Syndrome and Related Ventilatory Disorders

Congenital central hypoventilation syndrome (CCHS; OMIM #209880) is an autosomal-dominant disorder most commonly caused by mutations in the *PHOX2B*, *RET*, *GDNF*, *EDN3*, *ASCL1*, and *BDNF* genes. These patients typically present in the first hours of life with cyanosis and increased hypercapnia during sleep. They have an impairment of ventilatory and arousal responses to both hypercapnia and hypoxemia. Children with CCHS often have additional autonomic symptoms, including severe constipation, dysphagia, pupillary abnormalities, and decreased body temperature. Sympathetic activity can be exaggerated.

Pitt-Hopkins syndrome (OMIM # 610954), caused by heterozygous (sometimes de novo) mutations of the *TCF4* gene, is characterized by abnormal psychomotor development, distinctive facial features, microcephalia, clubbing, and intermittent hyperventilation followed by apnea during both wakefulness and sleep.

### Allgrove Syndrome and Related Disorders

Also known as achalasia-addisonianism-alacrima syndrome, and triple-A syndrome, Allgrove syndrome is caused by mutations in the gene encoding the protein aladin (AAAS; OMIM #231550). It is inherited in a recessive fashion. Children present with classic symptoms of primary adrenal insufficiency, including hypoglycemic seizures and shock. Less frequently, they present with recurrent vomiting, dysphagia, and failure to thrive, or ocular symptoms associated with alacrima. At presentation, review of systems may also be positive for hyperpigmentation, developmental delay, seizures, hypernasal speech, and symptoms related to orthostatic hypotension.

Alacrima, achalasia, and mental retardation (AAMR) syndrome is an autosomal-recessive disorder caused by homozygous mutations in the *GMPPA* gene and characterized by onset of features at birth or in early infancy. Patients with AAMR do not have adrenal insufficiency.

### Other Genetic Disorders with Autonomic Dysfunction

**Rett Syndrome.** Rett syndrome is a neurodevelopmental disorder that occurs almost exclusively in females. Autonomic dysfunction results in abnormal, irregular breathing during wakefulness and sleep, including hyperventilation, hypoventilation, and apnea; abnormal heart-rate variability; and labile blood pressure with episodic hypertension and tachycardia. Almost a third of all deaths from Rett syndrome are sudden and unexpected, which has been linked to autonomic dysregulation.

**Alexander Disease.** Alexander disease, an autosomal-dominant disease, is caused by mutations (usually de novo) in the gene encoding glial fibrillary acidic protein (*GFAP*; OMIM # 203450). The disorder is subclassified as infantile, juvenile, or adult onset. Patients present with seizures, megalencephaly, developmental delay, and spasticity. They have early signs of autonomic dysfunction, including constipation, episodic hypothermia, and sleep-disordered breathing. Brain MRI typically shows cerebral white-matter abnormalities affecting the frontal region; brainstem and cerebellar atrophy also can be present.

**Hyperbradykininism.** Hyperbradykininism is an autosomal-dominant disorder characterized by orthostatic hypotension (leading to lightheadedness upon standing and syncope), facial erythema, and purple discoloration of the legs after standing. Plasma bradykinin is elevated.

**Panayiotopoulos Syndrome.** Panayiotopoulos syndrome is a form of idiopathic benign childhood focal epilepsy in which the seizures are associated with signs of increased autonomic activity. Recent reports document hypertension, tachycardia, and release of vasopressin during the seizures, suggestive of activation of the central autonomic network. In rare cases, respiratory and cardiac arrest have been reported. Mutations in the *SCN1A* gene increase susceptibility for this disorder.

**Congenital Alacrima.** Children with congenital alacrima have markedly deficient lacrimation from infancy, leading to corneal epithelial lesions, presumably as a result of hypoplasia of the lacrimal glands. Genetic mutations have not yet been identified.

**Cold-Induced Sweating Syndrome.** Cold-induced sweating syndrome, an autosomal recessive disorder, presents in the neonatal period with orofacial weakness and feeding difficulties related to impaired sucking and swallowing. During the first year, most infants have episodes of unexplained fever. From childhood onward, the most disabling symptoms stem from impaired thermoregulation. Patients have hyperhidrosis, mainly of the upper body, in response to cold temperatures, and sweat very little with heat. The disorder is caused by homozygous or compound heterozygous mutations in the *CRLF1* gene or in the *CLCF1* gene (OMIM #272430 and # 610313).

#### E-BOOK FIGURES AND TABLES

The following figures and tables are available in the e-book at [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

- Fig. 154-3 Diagnostic evaluation of pediatric patients with orthostatic intolerance and transient loss of consciousness.
- Fig. 154-5 Tracing of Valsalva maneuver in a healthy subject showing muscle sympathetic nerve activity (MSNA) recording from the peroneal nerve electrocardiogram (ECG) and beat-to-beat blood pressure measured with plethysmography in the finger (BP) showing the four characteristic phases of the maneuver.
- Fig. 154-6 Histogram showing the incidence of reflex (vasovagal) syncope in a population of young individuals up to the age of 24.
- Fig. 154-7 Catecholamine pathways. Droxidopa (L-DOPS) converts to norepinephrine as a result of the action of the enzyme dopa-decarboxylase (L-amino acid aromatic decarboxylase).

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Our understanding of bowel and bladder control has changed dramatically in the last 20 years with the introduction of fMRI and PET scanning of the brain. In this period of time, it has become more apparent that micturition and defecation involve and interplay with numerous sites in the spinal cord, brainstem, midbrain and cortex. In this chapter, we will examine the control of storing and emptying of urine and stool from what will be a new perspective, integrating the frontal lobes into the process and moving beyond the pons on which most of the literature had focused in the past.

## DISORDERS OF MICTURITION

Attainment of bowel and bladder control is an important milestone in the lives of children and their parents. When this occurs varies from geographic region to geographic region and from ethnic group to ethnic group, but the maturational order is the same regardless, with bowel control preceding bladder control, and the sequence being:

1. Nocturnal bowel control
2. Daytime bowel control
3. Daytime bladder control
4. Nocturnal bladder control

What is certain is that girls tend to achieve continence quicker than boys, irrespective of the society in which they live. Daytime control is achieved between 3 to 4 years and nighttime control between 3.5 and 4 years of age. It may be obvious that we have refrained from using the term “diurnal incontinence” and are using the term “daytime incontinence.” Throughout this chapter, we will use the terminology recommended by the International Children’s Continence Society to allow for the proper communication in future clinical studies and to thereby enhance reproducibility of studies and outcomes (Austin et al., 2014). We will only deal with daytime urinary incontinence in this chapter. Nocturnal enuresis is a completely different entity that is best seen as an arousal disorder in the majority of patients. In fact, some patients have an appropriate diurnal variation in antidiuretic hormone production. Many children with nocturnal enuresis have “nonmonosymptomatic nocturnal enuresis,” nocturnal enuresis with daytime lower urinary tract symptoms. These entities are well discussed in consensus papers put out by the International Children’s Continence Society (Neveus et al., 2010).

Voiding in the infant is a reflexive action which lacks adequate volitional control, because the frontal lobes are not yet able to properly inhibit micturition. This concept is verified in previous studies in which frontal lobe arousal was recognized even in newborns, and some even awaken before urination. The human neonate initially voids hourly, and there is evidence that there is an interrupted voiding pattern that is the result of dyssynergia between the bladder and the sphincter. By 1 to 2 years of age, children can hold their urine, but it is difficult for them to willfully relax the external

sphincter. There is a gradual expansion in bladder capacity, and by 2 to 3 years of age, the bladder capacity has reached appropriate size to withhold urination for extended periods of time.

## EPIDEMIOLOGY

The prevalence of daytime incontinence varies widely from study to study. For the most part nocturnal enuresis tends to be more prevalent than daytime incontinence. A meta-analysis of 3 studies was performed giving an overall prevalence of 6.4%. The English ALSPAC longitudinal study (Heron et al., 2008) found the following trajectories for daytime incontinence over the age range 4.5 to 9.5 years:

1. Normative (86.2%); dry by 4.5 years
2. Delayed (6.9%); steadily decreasing probability of daytime incontinence from 80% at 4.5 years of age to less than 10% at 9.5 years of age
3. Persistent (3.7%); probability of daytime incontinence greater than 80% until 7.5 years of age with steady reduction to 60% at 9.5 years of age
4. Relapsing (3.2%); probability of daytime incontinence less than 10% at 5.5 years of age, increasing to 60% at 6.5 years with slow decline thereafter

There was no gender difference in the delayed group, but girls outnumbered boys in the persistent and relapsing groups. In one study that looked at children with persistent urinary incontinence who had urodynamics and imaging of their spines revealed that, if extrapolated out to 18 years of age, up to 33% of the children that were wetting at 10 years of age were likely to persist with some form of urinary symptoms. From a pediatric urologist’s perspective, the child who has OAB has a very good chance of becoming an adult who continues to have problems with OAB. This correlation has been seen in two published reports in adult females.

## NEUROPSYCHIATRIC COMORBIDITY

Children with elimination disorders have an increased rate of comorbid behavioral or psychological disorders. About 20% to 40% of children with daytime urinary incontinence are affected by comorbid behavioral disorder. In a large epidemiologic study of a cohort of 8213 children aged 7.5 to 9 years, children with daytime wetting had significantly increased rates of psychological problems, especially separation anxiety (11.4%), attention deficit (24.8%), oppositional behavior (10.9%), and conduct problems (11.8%). In the same cohort, 10,000 children aged 4 to 9 years were analyzed. Delayed development, difficult temperament, and maternal depression/anxiety were associated with daytime wetting and soiling. In another population-based study that included 2856 children, the incidence of incontinence was 16.9% within the previous 6 months. In a retrospective study of patients with ADHD, 20.9% wetted at night and 6.5% wetted during the day. The odds ratios were 2.7 and 4.5 times higher, respectively, which

means that there is unspecific association of ADHD and both nighttime and daytime wetting. The association of urinary incontinence and lower psychological well-being in adults also has been noted in other studies. Further discussion of neuropsychiatric disorders and urinary incontinence can be found in the online version of this chapter (von Gontard and Neveus, 2006).

## ANATOMY OF THE LOWER URINARY TRACT (LUT)

The three main components of the bladder are the detrusor smooth muscle, connective tissue, and urothelium. The detrusor constitutes the bulk of the bladder, and is arranged into inner longitudinal, middle circular, and outer longitudinal layers. Elastin and collagen make up the connective tissue, which determines passive bladder compliance. The detrusor maintains a baseline tension, which is modulated by hormones, local neurotransmitters, and the autonomic nervous system.

Although the urothelium was previously thought to be an inert barrier, we now know that urothelial cells participate in afferent signaling. Bladder nerves terminate close to as well as on urothelial cells. Urothelial cells have pain receptors and mechanoreceptors, which can be modulated by ATP to activate or inhibit sensory neurons. Abnormal activation of these channels by inflammation can lead to pain responses to normally nonnoxious stimuli. Urothelial cells release factors such as acetylcholine, ATP, prostaglandins, and nitric oxide that affect sensory nerves (Fig. 155-2).

The internal and external urethral sphincters (EUS) are vital for urinary continence. The internal urethral sphincter functions as a unit with the bladder base and trigone to store urine. The smooth muscle of the female EUS has less sympathetic innervation than the male, and the male EUS is larger in size. The skeletal muscle of the EUS has both slow and fast twitch fibers, of which the slow twitch fibers are more important in maintaining tonic force in the urethra.

The lower urinary tract is innervated by both the autonomic and somatic nervous systems. Sympathetic nervous system control of the lower urinary tract travels via the hypogastric nerve (T10–L2) (Fig. 155-1, sympathetic preganglionic nucleus in thoracolumbar spinal cord), whereas parasympathetic control travels via the pelvic nerve (S2–S4) (Fig. 155-1, Gert's nucleus in sacral spinal cord). The somatic motor neurons control the skeletal muscle of the EUS via the pudendal nerve (S2–S4). Its motor neurons are found in Onuf's nucleus (Fig. 155-1, sacral spinal cord). The sympathetic and somatic nervous systems promote storage of urine and stool and facilitates ejaculation (Sympathetic: Storage and Shoot), whereas the parasympathetic system promotes bladder and bowel emptying and erections (Parasympathetic: Pee, Poop, and Point).

## AFFERENT MECHANISMS

The sensation of bladder fullness is carried by two types of afferent fibers via the pelvic, hypogastric, and pudendal nerves. Normal bladder sensations are carried by A $\delta$  fibers, whereas C fibers become more important in diseased bladders. In humans, C fibers transmit pain sensations and are found in the urothelial and suburothelial layers, whereas A $\delta$  fibers are found in the smooth muscle (Fig. 155-2).

These fibers terminate in the dorsal horn of the lumbar and sacral cord. Spinal connections in this area mediate segmental reflexes. Some of the spinal interneurons send ascending projections to two nuclei in the brainstem. The gracile

**Figure 155-1. Afferent pathways for the control of micturition.** (With permission from Birder, L., de Groat, W., Mills, I., et al., 2010. *Neural control of the lower urinary tract: peripheral and spinal mechanisms. NeuroUrol Urodyn* 29, 128–139.)

nucleus relays nociception to the thalamus and cortex. The parabrachial nucleus is a major relay center for visceral afferent information going to the amygdala and the insular cortex integrating nociceptive and autonomic inputs. A significant degree of convergence of inputs from pelvic viscera is seen at the level of the medullary reticular formation.

During bladder storage, afferent signals from the hypogastric nerve and pelvic nerve travel to the thoracolumbar and sacral spinal cord, respectively (Fig. 155-1). The hypogastric nerve sends signals via the sympathetic nervous system to block bladder contraction and contact the internal urethral sphincter. Onuf's nucleus maintains contraction of the EUS, which is coordinated with bladder storage by the pontine micturition center (PMC) in the medial pons (Fig. 155-1).

Once the bladder pressure threshold is exceeded, afferent signals travel via the pelvic nerve to synapse on interneurons in Gert's nucleus in the S1–S2 spinal cord (Fig 155-3). These interneurons send projections up to the periaqueductal gray (PAG) in the midbrain to initiate voiding, which occurs if the cerebral cortex determines that it is appropriate to void. The medial anterior frontal lobes connect to the pudendal neurons via the corticospinal tracts (pyramidal tracts). They send connections to the PAG that sends caudal projections to the PMC, which is the final efferent center of the lower urinary tract. The

**Figure 155-3. Efferent pathways for the control of micturition.** (With permission from Birder, L., de Groat, W., Mills, I., et al., 2010. *Neural control of the lower urinary tract: peripheral and spinal mechanisms. NeuroUrol Urodyn* 29, 128–139.)

PMC sends projections caudally via the corticospinal tracts in the cord to the sacral parasympathetic nucleus, activating the neurons which cause bladder contraction and EUS relaxation (Fig. 155-3). Bilateral pathologic involvement of the pyramidal tract, usually in the spinal cord, results in impaired volitional control of the urethral sphincter; therefore the urethral sphincter may undergo inappropriate relaxation, or increased sphincter activity may occur during detrusor contraction. This imbalance is termed detrusor-urethral sphincter dyssynergia (Birder et al. 2010).

Disorders that affect the spinal cord and have effects on the micturition and sensation are described in the online version of this chapter.

### Periaqueductal Gray (PAG) and Pontine Micturition Center (PMC)

The PAG is involved in neurobiological functions that include the control and expression of pain, analgesia, fear, anxiety, vocalization, lordosis, cardiovascular function, and

reproductive behavior. Conceptually the structure may be involved in balancing or segueing information related to survival.

Forebrain projections to the PAG arise mainly from the prefrontal cortex, the insular cortex, and the amygdala. Further, the PAG receives highly organized projections from the central nucleus of the amygdala and, in turn, has reciprocal connections with the central nucleus. The PAG also projects to the thalamus, hypothalamus, brainstem, and deep layers of the spinal cord with some somatotopic organization, but projections to cortical regions have not been identified.

The central role of the PAG is evident, as it both receives sacral afferents and transmits efferent signals (via the PMC) to the sacral spinal cord. During storage, it is chronically suppressed by a net inhibition from the many other regions shown in Figure 155-4A. These include prefrontal cortex and hypothalamus, as well as insula and anterior cingulate cortex. The posterior hypothalamic region, which is involved in fight or flight (defense) responses, has direct connections to the PAG and may account for the urination reported in conscious animals during a defense response (Linnman et al., 2012).

The PMC, however, is the ultimate arbiter of lower urinary tract function, acting as a switch between the storage and voiding phases. It is believed that, for voiding to occur, the PMC requires both an excitatory signal from the PAG and a “safe” signal from the hypothalamus as suggested by Figure 155-4B.

Micturition problems with inability to empty well and urinary retention have been associated with posterior fossa tumors, discrete pontine lesions, brainstem gliomas, or vascular lesions that support the role of the dorsolateral pons (pontine reticular nucleus and the reticular formation, adjacent to the medial parabrachial nucleus, and locus coeruleus). Functional imaging shows activations near the postulated location of the PMC during voiding. PMC activity during bladder filling has also been seen, though this might be inhibitory rather than excitatory.

The area thought responsible for off-switching at the end of urination is the pontine continence center (PCC) also known as the L region described by Bradley. This area is located in the dorsolateral tegmentum. Projections from the PCC appear limited to Onuf's nucleus. Activation of this site can cause the detrusor to relax and the pelvic floor musculature and urethral sphincter to contract. A few functional imaging studies appear to localize this area ventral, lateral, or caudal to the PMC.

## Insula

The cardinal feature of enterceptive system is that the afferent input is from small diameter fibers (A $\delta$  and C). These afferents project via the spinothalamic tracts to subcortical homeostatic centers, including the hypothalamus and PAG. In humans they relay in the thalamus and converge on the nondominant anterior insula. The insula has come to be regarded as the homeostatic afferent cortex and has been shown to be activated by a range of modalities associated with visceral sensation. Insula activation has been extensively studied in the fMRI experiments carried out by other investigators and have shown a correlation between the degree of bladder filling and insula activation in healthy controls (Figure 155-5A and B). The conscious desire to void or urgency is lost in extensive frontal lobe lesions involving the insula (Griffiths and Tadic, 2008).

## Anterior Cingulate Cortex (ACC)

The anterior cingulate cortex (ACC) is the cortical region associated with motivation. Motivation plays a critical role in human homeostasis. Therefore if the insula is regarded as the limbic sensory cortex, the ACC can be considered as the limbic

motor cortex, the two being frequently seen to be coactivated in functional brain imaging studies. A wide range of cerebral functions has been attributed to the ACC over the years as its activation is seen with many different executive tasks but the demonstration that output was correlated with sympathetic activation led to the hypothesis that the ACC “mediates context-driven modulation of bodily arousal states.”

The ACC also is the site in which pain is processed. The proximity of the nociceptive, motor, and attentional regions of ACC suggests possible local interconnections that might allow the output of the ACC pain area to command immediate behavioral reactions. Similarly, the ACC pain area might participate in the substantial interconnections between the ACC and the “fight or flight” regions of the midbrain and the periaqueductal gray matter. The anatomic connections between ACC, IC (rostral insula), SI, and SII (primary and secondary somatosensory cortices) suggest that these regions do not function independently in encoding different aspects of pain but are highly interactive.

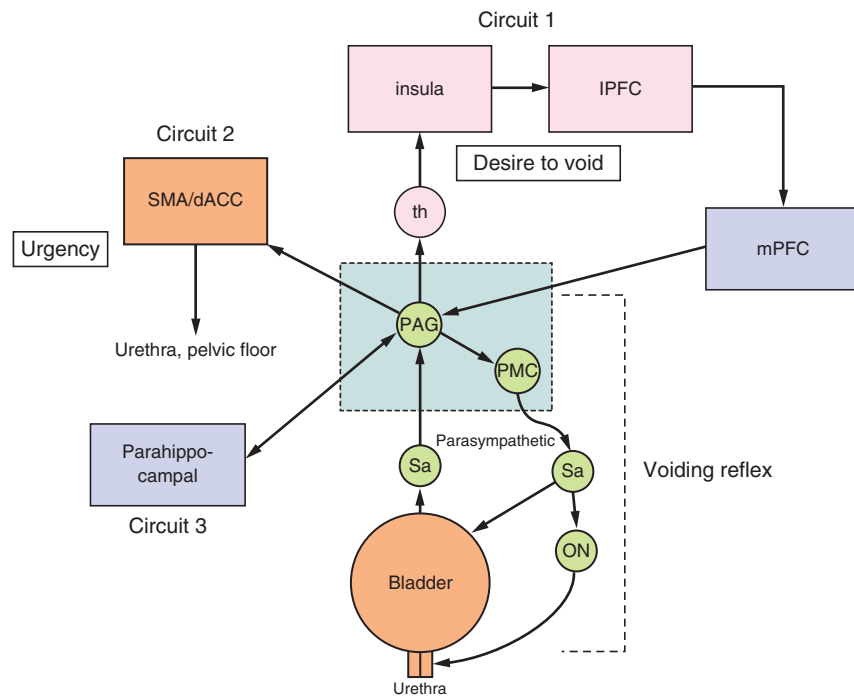

Another key feature of the ACC is the role it plays in autonomic control. Previous fMRI studies and neuropsychological and physiologic observations have shown that a direct link exists between ACC activity and modulation of cardiac function via sympathetic output. These observations argue for control of the ACC in the production and control of behaviorally integrated patterns of autonomic activity (Critchley et al., 2003).

## Prefrontal Cortex

The ventral region of prefrontal cortex (PFC) is involved in aspects of cognition, and the inferior lateral parts are involved in emotions. The orbitofrontal or prefrontal lateral cortex (PFLC) has extensive interconnections with the limbic system—the hypothalamus, amygdala, insula, and ACC. The importance of the prefrontal cortex in bladder control was established from clinical studies both by previous studies that found that acts of micturition and defecation occur in a normal manner; however, what is disturbed by this frontal lesion is the higher control of these acts. The lesion causes frequency and extreme urgency of micturition when the patient is awake and incontinence when asleep. The sensation of gradual awareness of increasing fullness of the bladder and the sensation that micturition is imminent are impaired. In the most complete form of the syndrome, the patient cannot inhibit the detrusor contraction of the micturition reflex and is forced to empty the bladder as soon as the reflex occurs. When the syndrome is less pronounced, the patient can make a conscious effort to stop the act of micturition and may or may not succeed. The lowering of the micturition reflex threshold may account for the fact that the patient does not feel the normal gradual filling of the bladder that underlies the desire to micturate; however, it cannot account for the unawareness of the sensations arising from the activity of pelvic and perineal muscles or of the sensation that urine is passing. A further discussion on the effects of strokes is in the online chapter.

Cortical areas such as the prefrontal cortex have the ability to inhibit limbic system activation and have been implicated in the therapeutic effects of distraction techniques such as hypnosis therapy and the use of placebo.

In the PFC, cortisol modulates dopaminergic projections with a remarkable degree of lateralization. Dopaminergic projections to the right hemisphere display an enhanced sensitivity to stressors that are perceived as severe and uncontrollable such as those that arise from social conflict. Thus chronic psychological stress can disinhibit reflexive circuits through a cortisol-induced right PFC dysfunction that is caused by a prolonged activation of the hypothalamic-pituitary-adrenal axis. This reduction in activity in the PFC can

**Figure 155-6. Proposed interconnections between the different areas of the cortex, midbrain, and brainstem structures that are involved in the control of micturition.** Arrows show probable directions of connectivity but do not preclude movement in the opposite direction. Three circuits are described that are critical to the control of micturition. The green area is the critical transit point that includes the periaqueductal gray area (PAG) and pontine micturition center (PMC). They control contraction and relaxation of the bladder via the sacral parasympathetic regions (Sa) and Onuf's nucleus (ON). These reflexes are controlled by three cerebral neural pathways. Circuit 1 involves the thalamus (th), insula, and lateral prefrontal cortex (LPFC) that maps for desire to void, although the mPFC (medial prefrontal cortex) makes the executive decision when and where to void. Circuit 2 involves the supplemental motor area (SMA) and the dorsal anterior cingulate cortex (dACC). Here, urgency is processed as an emotion, and lesions in this area lead to urge incontinence; pain is processed here as well. Circuit 3 goes the parahippocampal area. Areas in blue are typically deactivated with filling; orange and red areas are activated with bladder filling. (From Griffiths, D., Clarkson, B., Tadic, S.D., Resnick, N.M., 2015. Brain mechanisms underlying urge incontinence and its response to pelvic floor muscle training. *J Urol* 194, 708–715.)

lead to the inability to inhibit the urge to urinate and it may lead to urge incontinence as well as fecal incontinence. The information in Figure 155-6 has been proposed as a summary illustration of the current thinking about brain control of the bladder during filling and emptying (Griffiths et al., 2015).

## DIAGNOSIS

### History and Physical Examination

The evaluation of the child with bowel and bladder dysfunction should start with a good history and physical examination. Generally, it is best to try to get the history from the child if he or she is cooperative, but in other cases there may be no choice but to obtain it from the parents. Crossing the legs, running to the bathroom, grabbing the penis, rubbing the clitoris, squatting, and sitting on the heels are all signs of urgency. These maneuvers trigger reflexive suppression of the voiding reflex. Urinary frequency is also another manifestation of an overactive bladder and quantifying the number of times that the patient goes to the bathroom and the amount is useful in determining whether there is true frequency. Urinary urge incontinence is another classic hallmark of overactive bladder. The physician should also ask about a history of dysuria. Dysuria without evidence of infection is usually due to

dyssynergic voiding. One should ascertain the type of stream and the strength. Whether the patient strains to void or uses the Credé maneuver is critical to know. In infants, grunting with urination may be a sign of dyssynergic voiding.

On entering the room, the physician should take close note of the interaction between the child and parent as well as the child and the physician. Excessive anxiety or inappropriate fear is something that should be noted. The parents should be questioned as to whether this type of behavior is commonly present at home or during other stressful situations. A careful history should be taken with regards to a family history of anxiety, phobias, ADD/ADHD, or depression within the first-line family members.

A thorough history of the bowel habits of the patient should be obtained from the patient directly. Documentation of the size and nature of the bowel movements should be obtained. Use of a diagram is quite beneficial, and it facilitates communication with the child. Chronic constipation can be a clue of a cord lesion, especially if it is refractory.

The presence of bladder fullness or urgency and frequency would indicate that the sensory pathways are intact. Urgency in a neurologically impaired patient is a sign of a partial suprasegmental injury whereas a complete lesion is usually associated with incontinence associated with no warning or sensation. On the other hand, the patient that does not void unless prompted may have inappropriate sensation. Those that void with Valsalva or Credé maneuver can have a myogenic failure of the detrusor or failure of the efferent pathways. Obstruction would need to be excluded as well.

Autonomic dysreflexia may occur and is discussed in the online chapter.

Peripheral motor lesions involving the conus medullaris, which anatomically is located between T12 and L1, or the cauda equina will lead the majority of patients to complain of an “obstructive” symptom and will need to strain or use the Credé maneuver to urinate. Further discussion of cauda equina, conus, and epiconus lesions are in the online chapter.

## Physical Examination

Examination of the abdomen is critical in determining whether there is stool present in the colon. Examination of the back will typically reveal a normal-appearing back and anocutaneous folds. In rare instances, one will notice flattening of the buttocks or abnormal creasing at the SI joint indicative of some type of sacral anomaly. Low-lying sacral dimples are typically not of concern. Dimples that are associated with tufts of hair or if located higher up on the back are of concern and should be evaluated with an MRI of the lumbosacral spine.

Examination of the genitalia should be performed on all children with bowel and bladder dysfunction. First and foremost, one should look at the underwear when it is pulled down to help gauge the gravity of the problem. Visual inspection of the anus is a very useful tool, which allows one to assess whether the patient has skin tags, fissures, and hemorrhoids that are indicators of chronic problems with constipation or large bowel movements. Laxity of the anal sphincter is another good sign that the child is passing massive bowel movements or has a neurologic problem. Evidence of an anal wink is a sign of an intact sacral reflex arch (S2–S4) and is commonly seen as soon as the buttocks are separated to inspect the anus. Pinprick testing for sensation of the perineum and anus is critical as well. A bulbocavernosus reflex test should be performed and should be present in 98% of all males and 81% of females. Absence indicates a complete lower motor neuron lesion of the sacral cord that correlates well with perineal floor denervation. Digital rectal examination is rarely necessary in these children. If it is going to be done, then the bulbocavernosus reflex should be tested at the same time. Rectal examination neither confirms nor denies the presence of constipation.

Examination of the patient's smile is another critical part of the examination in children that have evidence of a severely trabeculated bladder or evidence of severe voiding dysfunction without sacral dysraphism. Children who have Ochoa urofacial syndrome (OMIM 236730) when asked to smile will have an unusual inversion of facial expression when smiling is attempted. The face becomes contorted into a grimace that makes it appear as if the subject is sobbing and crying, thus, making it possible to recognize afflicted patients early in life (Fig. 155-8). Please see the online chapter for a more thorough discussion of this topic.

## Clinical Testing

In children suspected of having a disorder of micturition or storage, the first study should be a urinalysis and urine culture to rule out infection that can lead to such symptoms. The next study should be a postvoid residual ultrasound measurement. This determines whether the patient is adequately emptying the bladder and thereby frequently helps to differentiate disorders of emptying from storage disorders, even though some children, especially those with functional voiding problems, can simultaneously have both disorders. If at all possible, uroflowmetry utilizing EMG of the perineal muscles should be done initially. Perineal EMG allows for the identification of external sphincter dyssynergia and internal sphincter

dyssynergia that can be identified utilizing the lag time, which is the delay before the initiation in urination. Internal sphincter dyssynergia has been associated with dizziness and autonomic dysfunction (hypotension on standing without concomitant increase in heart rate) with specificity rates in the high 90s for both males and females when patients are asked if they get dizzy on standing. Renal and bladder ultrasounds are next in order if there is evidence of large bladder capacities or urinary retention or an abnormal uroflowmetry. Patients that exhibit markedly abnormal uroflowmetry or ultrasonography should then have a voiding cystourethrogram if indicated or a KUB radiograph with an AP and lateral of the spine at a minimum. Blood tests evaluating renal function are indicated if the ultrasound or VCUG are abnormal. In refractory patients, it is necessary to obtain a VCUG to further delineate voiding dynamics and to make sure that anatomic problems are not missed.

Urodynamics are not necessary in patients who have functional voiding problems in the vast majority of cases. In one study, urodynamics did not offer any information that was not noted on the MRI if it was positive. If there is suspicion of a spinal problem, it is best to initially obtain a spinal MRI, and later, if a spinal abnormality is identified, then urodynamics are indicated to define the problem and to provide a baseline for future reevaluations to assess whether there is progression of the disease or before when surgery is to be done. There are noninvasive means of testing the bulbocavernosus reflex latency, but these are not done routinely in children.

## Disorders of Defecation

### Normal Defecation Patterns

Defecation patterns in childhood differ with age and are determined by the change from breastfeeding to solid foods. In breastfed infants, defecation occurs from six to seven times a day to once every seventh day, and, on average, three times daily. At 6 to 12 months, the average defecation rate is just lower than two times per day; at 1 to 3 years, the average defecation rate is one and a half times per day. At 3 to 12 years, the defecation rate settles at once daily. There is no difference in gender until puberty. During puberty and adulthood, the defecation rate among females is less than among males. To appreciate colorectal motility of defecation, the neurophysiology, and the various pathologic changes related hereto, it is important to understand the functional anatomy and neurophysiology of colon, rectum, and anus.

## FUNCTIONAL ANATOMY OF COLON, RECTUM, AND ANUS

The main functions of the large intestine are intraluminal bacterial fermentation of nutrients resistant to digestive enzymes (e.g., short-chain fatty acids), reabsorption of water and electrolytes, and transport and storage of feces until it can be discharged from the body.

Histologically, the wall of the large intestine is made up of mucosa, submucosa, tunica muscularis, and serosa. The mucosa consists of an inner layer epithelium, underlying the lamina propria, and the muscularis mucosa. Distributed within the columnar epithelium are absorptive cells, goblet cells, and enteroendocrine cells. The lamina propria is a connective tissue rich in cells. It includes immunocompetent cells, nerve fibers, fibroblasts, lymphatic vessels, and capillaries. The muscularis mucosa is a thin layer of intestinal smooth muscle. The submucosa consists of loose connective tissue and substantial fatty tissue; here lies the submucosal plexus (Meissner's

plexus), one of the plexuses of the enteric nerve system (ENS), together with larger nerves, blood, and lymph vessels. The tunica muscularis consists of the inner complete circular layer that, during contraction, divides the colon into segments—the characteristic haustra and an outer incomplete longitudinal layer, which is made up by three flat longitudinal bands, taenia coli. In the rectum, the taenia disappears, and the longitudinal muscle layer becomes complete. The feces is transported as a result of contractions in the muscle layer containing the myenteric plexus (Auerbach's plexus), the other plexus of the ENS located between the circular and the longitudinal layers. The serosa consists of a mesothelial lining resembling the visceral peritoneal surface. The rectum initially runs distally and posteriorly, then directly downward, and finally anteriorly and ends as the anus in the perineum. The rectum is closely related to the bladder. The rectum is divided into two segments: the rectal ampulla and the anal canal. As a reservoir for storage of feces, the function of the rectum is to maintain fecal continence and allow defecation at an appropriate time and place. The upper and the lower part of the anal canal are separated by a mucocutaneous zone. The lower squamous epithelium is rich in somatosensory fibers and is highly sensitive to temperature, touch, movement, and pain. The anal canal in children is estimated to be between 2.5 and 3 cm long. At the anorectal junction, the puborectalis muscle creates an angle of approximately 80 degrees, which is considered to contribute to anal continence. The continuation of the circular smooth muscle layer constitutes the internal anal sphincter (IAS), whereas the external sphincter (EAS) consists of striated muscle and hence is partly under voluntary control. With the support from the pelvic floor, the levator ani muscle and the internal and external anal sphincters maintain a higher pressure in the anal canal than in the rectal ampulla (Fig. 155-10A and B).

### Colorectal Motility and Defecation

There are at least three regulatory mechanisms in the gastrointestinal tract; endocrine, paracrine, and the enteric nervous system (ENS). The scope of this paragraph is the ENS, its modulators and colorectal motility. Overall, neural control of colorectal motility is provided by the ENS, the intrinsic nervous system, modulated through the extrinsic nervous system; the lumbar sympathetic nerves; sacral parasympathetic nerves; and extrinsic sensory innervations.

### THE INTRINSIC NERVOUS SYSTEM

The majority of the neural control of colorectal motility is mediated by the ENS. Auerbach's plexus mainly controls the motility, and Meissner's plexus mainly controls the secretion and blood flow. Generally, the ENS consists of sensory neurons, interneurons, and both excitatory and inhibitory motor neurons. Different neurotransmitters, neuropeptides, and other molecules either inhibit (e.g., noradrenalin, dopamine, somatostatin) or increase (e.g., acetylcholine, serotonin, histamine) motility.

### THE EXTRINSIC NERVOUS SYSTEM

Indirectly, by modulating the ENS via the interneurons, the sacral parasympathetic nerves increase digestion and motility whereas the lumbar sympathetic nerves decrease digestion and motility. This is caused by an increase/decrease of vasodilation, secretion, and peristaltic activity and relaxation/constriction of the sphincters. The colorectal extrinsic sensory innervation is provided by spinal afferent neurons and a subpopulation of these, mechanosensitive afferents that are

highly sensitive to intestinal distension by feces, can consequently be an important factor of conscious awareness of rectal filling, of continence, and in initiating defecation. The somatic innervation of the extrinsic anal sphincter is via a perineal branch of the S4 nerve and the pudendal nerve.

## MUSCLE CONTRACTIONS AND COLORECTAL MOTILITY

Control of muscle contractions are discussed in the online version of this chapter.

Defecation, to void feces from the distal colon and rectum, is a complex process involving the previously described ENS, autonomic nervous system, and smooth and striated muscles. It is initiated when a colonic mass movement continues to rectum generating a slow distension of the rectal wall. As the distension proceeds, the filling of the rectum stimulates the rectoanal inhibitory reflex (RAIR), mediated by the ENS, and causes relaxation of the IAS. Additionally, the rectum now serves as a conduit, and the RAIR stimulates the filling of the upper anal canal. The upper anal canal's sensory innervations make it possible to detect consistency and thereby distinguish between air, solid or liquid. The filling creates the urge to defecate. Defecation will proceed with the voluntary relaxation of the puborectal muscle, straightening of the anorectal angle, and relaxation of the EAS. Defecation is normally improved by the Valsalva maneuver. As wall tension relaxes, the defecation reflex subsides and rectal compliance increases, which leads to a resting pressure of the anal canal higher than in rectum and thereby reaching continence.

## CNS AND THE GUT

More than 90% of the body's serotonin (5-HT) is found in the enterochromaffin cells in the gastrointestinal canal, and plasma 5-HT has been found increased in diarrheal diseases and decreased in constipation. The 5-HT<sub>4</sub> agonist, prucalopride, is used to treat chronic constipation if laxatives prove insufficient. It has shown promising results, but research among children is lacking (Brookes et al., 2009).

Higher brain centers that influence and control defecation are the ACC, PFC, insula, the amygdala, the stria terminalis, and the hypothalamus. In humans, response to external stressors is mediated through the coordinated action of the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic branch of the autonomic nervous system. With this in mind, research in treatment with 5-HT<sub>3</sub>-antagonist in irritable bowel syndrome among adults found a decrease in brain activity in the emotional motor systems with correlates to a decrease in gastrointestinal symptoms. One model for irritable bowel syndrome proposes that altered central stress circuits have been introduced. It is hypothesized that triggering of these circuits by external stressors results in the development of gut and extraintestinal symptoms in predisposed individuals. Central control of defecation and gastrointestinal function are in the same sites as that for urination (Mayer et al., 2006).

Further discussion of this topic is in the online version of the chapter.

## PATIENT EVALUATION

### History

Fecal incontinence, constipation and abdominal pain are the most common complaints in children seeking help. In some patients, fecal incontinence and abdominal pain may be due

to constipation. But in other individuals, these symptoms may be isolated problems. Questioning should precede the same as for disorders of micturition.

As with disorders of micturition, the same questioning process should be used except that specific questions assessing alterations in bowel habits, stool mass, stool color, and stool consistency should be done. The age at onset, frequency, related circumstances (e.g., time of day, association with sleep, behavioral aspects), and alterations in bowel habits, stool mass, stool color, and stool consistency should be established. It should be determined whether the child feels stool in the rectum, has the urge to defecate, whether soiling occurs without notice, or whether the child has some sensation when he/she has an accident. It is helpful to ascertain whether the child can differentiate between passage of flatus and feces. Similarly, efferent function can be evaluated by asking questions related to volitional inhibition of defecation. Fecal incontinence is unlikely to be due to spinal cord disease in the absence of urinary symptoms or neurologic abnormalities involving the lower limbs.

## Neurologic Examination

As the neural pathways are similar, neurologic evaluation of bowel incontinence parallels that described for disorders of micturition. Further insight to the examination is discussed in the online version of the chapter.

## Clinical Studies

A simple flat plate of the abdomen is necessary to evaluate for constipation. An AP and lateral film should be done to look at the sacrum. In children with a history of imperforate anus, a sacral ratio less than 0.52 correlates well with spinal cord anomalies and with unfavorable prognosis in children with anorectal malformations. We also know that children with high imperforate anus have a 70% to 80% rate of neurogenic bladder dysfunction.

Current promising pediatric anorectal investigations are manometry, measuring contractility in the anus and rectum, and impedance planimetry, studies of rectal compliance. Proctoscopy and fiber optic studies of the lower bowel are efficient methods of excluding the presence of structural abnormalities. Barium enema studies sometimes are necessary, as are defecography studies, which monitor the functional events visually during defecation.

## Differential Diagnosis

The most common cause of fecal incontinence is encopresis, which is not associated with neurologic dysfunction. Encopresis is fecal incontinence without organic cause for more than a month in children 4 years of age or older. Males outnumber females by 3.5 to 1. Children with fecal incontinence (or encopresis) have the highest rates of coexistent behavioral disorders: 30% to 50% of all children have clinically relevant behavioral disturbances. Many will exhibit withholding of stools that will lead to stool smearing of the underwear and, at times, outright full defecation. In some, the urge to control defecation may not be processed appropriately in executive areas, leading to inability to suppress the reflexive event. Neurogenic and other organic conditions causing bowel dysfunction must be excluded. Other causes of functional bowel problems such as irritable bowel syndrome and abdominal migraines may have their origins in the frontal lobes as well.

Lumbosacral defects may be associated with reduced or absent external sphincter function, which is demonstrated by sphincter electromyography. Denervation potentials or reduced large-amplitude potentials may be observed. In Hirschsprung disease, manometric studies demonstrate an absence of the rectoanal inhibitory reflex; that is, the internal sphincter fails to relax in response to a transient rectal distention. The relaxation wave is absent.

## Management

Assessment of contributing factors, including psychosocial milieu, anorectal examination, and appropriate neurologic evaluation, is necessary for adequate management. Therapeutic approaches include dietary, behavioral, pharmacologic, and surgical methods. For fecal incontinence, the management of the concomitant constipation is paramount and a thorough bowel cleansing is in order. Education is important in achieving good outcome.

Further discussion of management techniques is included in the online version.

# 156 Poisoning and Drug-Induced Neurologic Diseases

Kristyn Tekulve, Laura M. Tormoehlen, and Laurence Walsh

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Many substances are potential nervous system toxins. Manufactured and naturally occurring agents may be ingested, inhaled, injected, or absorbed, with subsequent deleterious effects on a child's central or peripheral nervous system. Most childhood ingestions are accidental. Effects may be acute, subacute, or chronic, and may occur at any age. Neurologic dysfunction may be isolated or part of a systemic derangement. Neurotoxins are among the most commonly encountered toxins, although less common in children younger than 6 years (Mowry et al., 2014). Poisonings and drug-induced neurologic disease may mimic infection, trauma, neoplasm, psychiatric illness, or metabolic disorders.

A more detailed description of the following toxins and information about additional toxins can be found in the online version.

## Emergency Evaluation

Management of the poisoned child requires immediate stabilization of the patient and appropriate corrective and supportive therapy. Physicians must review the history and examine the child carefully and have a high index of suspicion. Three-quarters of poisonings are by ingestion. Medications account for most deaths. Physical examination can establish the cause and guide therapy. Neurologic findings may result from the toxin itself or its systemic effects. Systemic effects include CNS hypoxia, cardiac dysrhythmias, gastrointestinal disturbances, and metabolic acidosis.

## Management

Gastric lavage has been a mainstay of treatment; however, experts now recommend against it as it does not improve outcomes and can have severe complications, including aspiration pneumonia, laryngospasm, arrhythmias, esophageal or stomach perforation, fluid and electrolyte imbalances, and small conjunctival hemorrhages. Local poison control should be consulted if gastric lavage is considered.

Ipecac syrup works as an emetic, but there is insufficient data to recommend its use. The most common adverse effects are diarrhea, lethargy, prolonged vomiting, irritability, fever, and diaphoresis. If the vomiting is severe, Mallory-Weiss tears, pneumomediastinum, and aspiration pneumonia may result. Some experts argue that ipecac syrup may be used in rare circumstances, such as when medical care cannot be achieved within 1 hour, the toxin ingested was dangerous, there is no alteration in mental status, and the ipecac syrup would not affect further medical care. Many other experts disagree and recommend never using ipecac syrup.

Whole-bowel irrigation with large volumes of polyethylene glycol-electrolyte solutions to prevent toxin absorption has been used. There has also not been evidence to show that this improves patient outcomes. Complications of the treatment include vomiting, diarrhea, electrolyte abnormalities, aspiration, and rarely angioedema/anaphylactic reactions. It may be

considered when a sustained-release or enteric-coated preparation has been ingested, if the toxin cannot be removed by activated charcoal, or if illicit drugs are carried in the body.

Appropriate general management steps are outlined in [Box 156-1](#); details may be found in several references (Leikin and Paloucek, 1995). Therapy for specific toxidromes is discussed with the individual agents.

## Testing

The value of routine toxicologic testing in cases of possible intoxications is debated. The low sensitivity of specific tests and the inability to test for all possible agents, medicolegal concerns, cost-effectiveness, and limited use specifically for children suggest that routine testing should be limited. Ideally, history and physical examination narrow the list of possible exposures and direct specific toxicologic testing.

## Other Ancillary Testing

Ancillary testing is directed by specific clinical findings. Electroencephalography (EEG) is important to exclude subtle or subclinical seizures if altered mental status is present. Neuroimaging is used if there is a suspicion of concomitant trauma or hemorrhage. It also may be helpful to detect specific radiologic patterns associated with toxins and to assess for any cerebral injury.

## Neurologic Examination

Examination of a poisoned child includes initial and serial assessment of neurologic status. This assessment guides clinical management, predicts prognosis, and often identifies the offending agent. Please see the online version for specific examination findings associated with toxins (see [Box 156-3](#)).

## COMMON TOXIDROMES

The neurologic examination may indicate poisonings and drug intoxications that fit clinically into one of several toxidromes (Leikin and Paloucek, 1995). The major toxidromes include the following: anticholinergic, cholinergic, sympathomimetic, serotonergic, antihistaminic, opioid, and sedative-hypnotic syndromes.

The anticholinergic syndrome has peripheral and central muscarinic signs. Peripheral muscarinic signs include tachycardia, dry skin and mucous membranes, dilated pupils, decreased gastrointestinal motility, urinary retention, and hyperthermia. Central anticholinergic signs include confusion, disorientation, agitation, hallucinations, incoordination, ataxia, and frank psychosis ("mad, hot, dry, and blind"). The anticholinergic toxidrome is caused by atropine, belladonna alkaloids, plants (jimson weed), antihistamines, low-potency phenothiazines, and antidepressants, especially tricyclic antidepressants.

Cholinergic toxidromes, which include both muscarinic and nicotinic effects, are produced by organophosphate

**BOX 156-1** Suggested General Management of Suspected Intoxications and Poisoning

1. Establish patent airway, adequate respirations, pulse, and systemic perfusion; monitor level of consciousness and urine output.
2. Establish intravenous access.
3. Administer oxygen, glucose, and naloxone as necessary, especially in patients with acute alteration of mental status.
4. Obtain pertinent history and perform careful physical examination, specifically looking for entry sites for envenomation, needle tracks, or other evidence of agent entry (e.g., nasal mucosa, mouth, genital orifices); examine for systemic signs of intoxication, including fever, abnormal vital signs, excessive tearing or salivation, odor, skin and nailbed color, hyperhydrosis or anhydrosis, trauma, or hemorrhages.
5. Perform age-appropriate neurologic examination, including mental status examination and cranial nerve, speech, motor, cerebellar, muscle stretch reflex, and sensory evaluations. Observe patient for posture and gait.
6. Obtain laboratory studies, such as a chemistry profile, including serum glucose and electrolyte levels, blood pH, complete blood count, urine and serum toxicologic studies (for specific agents when indicated), and drug levels, if suggested by history or physical examination.
7. Prevent further absorption or maximize elimination of the toxic agent using gastric lavage or activated charcoal only when indicated. Recent reviews suggest that both methods carry some risk and that they should be used only when there is a reasonable chance that they will reduce the load of toxin present. Furthermore, intact airway protection or intubation is required for their use.
8. Administer specific antidote when indicated.
9. Obtain electrocardiogram and, when indicated, neuroimaging studies (e.g., computed tomography, magnetic resonance imaging), electroencephalogram, and cerebrospinal fluid for examination.
10. Monitor closely; reassess the child frequently.

insecticides, carbamate insecticides, nicotine, physostigmine, and their congeners. Consciousness may be severely depressed with respiratory depression; pinpoint pupils; widespread fasciculations; salivation; lacrimation, urination, defecation, gastrointestinal distress, and emesis (SLUDGE syndrome); bronchoconstriction and bronchorrhea; pulmonary edema; hypotension or hypertension; and bradycardia. Seizures may occur. Young children may not display typical peripheral cholinergic signs and symptoms.

Serotonin syndrome is traditionally described as neuromuscular abnormalities, autonomic hyperactivity, and mental status changes. The Hunter serotonin toxicity criteria are used to increase the accuracy of diagnosis. The most significant finding is clonus. Other findings associated with the syndrome include diaphoresis, agitation, hyperreflexia, and tremor (Dunkley et al., 2003). Hyperthermia is seen in severe cases (Dunkley et al., 2003). Symptoms usually occur rapidly and can be the result of a single initial medication dosage, a change in the dose, or in an overdose. Serotonin syndrome can occur after ingestion of many classes of medications. Treatment is removal of the drug source and supportive care. Benzodiazepines should be used early to control agitation. Cyproheptadine and chlorpromazine have some efficacy. Hyperthermia should be treated with sedation, intubation, and neuromuscular paralysis.

Antihistaminic agents are divided into histamine-1 and histamine-2 receptor antagonists. Both may cause significant CNS side effects at therapeutic doses, but the degree is agent-specific. Older histamine-1 blockers cause sedation, delirium, and subtle cognitive defects. Delirium is especially prominent in children. They may also have significant toxicity, including movement disorders and autonomic dysfunction. With overdose, ataxia and seizures may supervene. Toxicity may be delayed by several days. Histamine-2 blockers tend not to have significant antihistaminic side effects (except cimetidine) in children at therapeutic doses. At high doses, mental status changes predominate, especially with cimetidine.

The opioid-induced toxidrome is diagnosed and treated with naloxone. It includes CNS depression with coma, pinpoint pupils, muscle flaccidity, respiratory depression, and bradycardia. All opioid-derived agents may cause this syndrome.

Sedative-barbiturate toxidromes are manifested by lethargy/profound sedation, respiratory depression, miotic pupils, and generalized hypotonia with areflexia and ataxia. Signs and symptoms may be progressive, especially in intoxication with longer-acting agents, such as phenobarbital.

## POISONS AND ENVIRONMENTAL TOXINS

### Biologic Toxins

Biologic toxins include snake, arthropods (tick), insect, and fish toxins; botanic toxins; and bacterial toxins (e.g., diphtheria, tetanus, botulism) (Table 156-1, Box 156-2, and Boxes 156-4 to 156-9) (Stommel, 2008).

### Snake Venom

There are two major families of poisonous snakes, Crotalids and Elapids. Crotalid venom is primarily hemotoxic, whereas Elapid venom is neurotoxic. Symptoms include fever, nausea, vomiting, diarrhea, tachycardia, altered blood coagulation, and local effects of envenomation. Neurotoxins affect the neuromuscular junction and occasionally altered states of consciousness and convulsions. Initial treatment is immobilization of the bite area and transport to the hospital. Incisions, suction, tourniquets, and ice are not recommended. Venom extraction within 5 minutes can be beneficial. Treatment should include wound cleaning, tetanus prevention, and antivenin. Exercise hastens absorption of venom. Intravenous administration of specific antivenoms is recommended.

**Tick Bites.** Neurotoxins from various ticks can cause acute paralysis or ataxia through impaired acetylcholine release at the neuromuscular junction. This causes restlessness and irritability followed by progressive ataxia or symmetric ascending flaccid paralysis with loss of deep tendon reflexes. Removal of the tick early leads to reversal of the clinical manifestations within 24 hours. Insect repellents may be used as a preventive measure.

**Botulism.** Botulinum toxin also irreversibly blocks acetylcholine presynaptic release at the neuromuscular junction. It causes three different clinical syndromes: childhood or adult food-borne, infantile, and wound botulism (Stommel, 2008). Inhalation botulism has been rarely reported. Food-borne botulism causes gastrointestinal symptoms of diarrhea and vomiting, followed by rapidly developing progressive paralytic disease associated with visual blurring and diplopia, dysphagia, dysarthria, and subsequent weakness of extremities and intercostal muscles. Onset is within 2 days. Botulinum antitoxin has been effective in shortening the length of ventilation, feeding dysfunction, and hospitalization. It must be administered within 7 days of hospital admission. Treatment

**TABLE 156-1** Selected Agents Causing Cranial Nerve Deficits

Cranial Nerve Deficit	Medications	Industrial Toxins	Biologic Toxins
General	Methotrexate, vincristine	Organic mercury, ethylene glycol	Cobra venom
Olfactory	Levodopa	–	–
Optic nerve and retina	Antibiotics, phenothiazines, antineoplastics, cyclosporine, disulfiram (retrobulbar neuritis), isoniazid, minoxidil, quinines, valproic acid, vigabatrin	Cyanide, methanol, lead, thallium, organic mercury, hexachlorophene	Lathyrus
Extraocular muscles	Botulinum A toxin, bretylium, interferon	–	<i>Clostridium botulinum</i> toxin
Mydriasis	Antihistamines, anticholinergics, nortriptyline, barium, bromides, carbamazepine, cocaine, cyclobenzaprine, glutethimide, sertraline, sympathomimetics	Ethylene glycol, benzene, cyanide	Black nightshade ( <i>Solanum nigrum</i> ), box thorn ( <i>Lycium halmifolium</i> ), lupine, morning glory, potato (leaves, stems, immature tubers), tetrodotoxin (puffer fish, others), water hemlock ( <i>Cicuta</i> spp.), mescaline, peyote
Miosis	Buspirone, cholinergics, narcotics	–	–
Dysgeusia	Dipyridamole, disulfiram, selegiline, ethambutol, lithium, nedocromil, tocainide, topiramate	Dimethyl sulfoxide	Ciguatera toxin (red snapper, farm-raised salmon)
Auditory	Antibiotics, especially aminoglycosides, antifungals, antineoplastics, lithium (acute), nonsteroidal antiinflammatory drugs and salicylates, quinine antiarrhythmics, angiotensin-converting enzyme inhibitors, danazol, dantrolene, dapsone, antidepressants, digoxin, dimenhydrinate, diuretics, vitamin A	Carbon monoxide, cyanide, methanol, solvents, mercury (organic)	Tobacco (acute), lathyrus

otherwise is supportive and neuromuscular effects may linger, even after recovery.

Infantile botulism can be a severe paralytic disease affecting the limbs, trunk, bulbar musculature, and cranial nerves. It is preceded by a history of severe constipation without other gastrointestinal symptoms. It has been associated with ingestion of honey. Human-derived botulinum immune globulin (BIG) has also been effective in reducing hospitalization, ventilation, and enteral/parental feeding in infants, but it has not been shown to reduce adverse outcomes.

**Tetanus.** Pediatric tetanus is extremely rare in the vaccination era. Neonatal tetanus is reported, resulting from infection of the umbilical stump. Presentation is generalized rigidity and mortality is high, especially in neonates less than 10 days of age (Stommel, 2008).

## Insecticides

**Organophosphate and Carbamate Insecticides.** Account for most childhood insecticide exposures. Poisoning is rare. Toxins can be absorbed through the skin and gastrointestinal tract, but most childhood poisonings are the result of ingestion. Toxicity produces a cholinergic syndrome within 12 to 24 hours. Salivation, lacrimation, bronchoconstriction, wheezing, and increased pulmonary secretions are all muscarinic manifestations. Peripheral nicotinic signs include muscle weakness, decreased respiratory effort, and muscle fasciculations. CNS signs are anxiety, restlessness, confusion, headache, slurred speech, ataxia, and generalized seizures. With low-dose organophosphate exposure, muscarinic signs predominate, but in more severe acute intoxication, the nicotinic and CNS signs appear. Long-term effects may include memory difficulties, attention problems, and brisk reflexes. With longer-acting agents, recovery is protracted and possibly incomplete. Rarely, a myopathy may occur.

Treatment includes decontamination, general supportive therapy, and administration of specific antidotes, including atropine and oximes. Single-dose activated charcoal is most effective if given within 1 hour after ingestion. Oximes, such as pralidoxime or obidoxime, are cholinesterase reactivators. They are beneficial if given soon after the ingestion, but can be harmful if treatment is delayed.

**Insect Repellents.** The most effective general insect repellent currently in use is diethyltoluamide (DEET). Preparations containing more than 20% diethyltoluamide are likely to cause neurotoxicity. Seizures (8 to 48 hours after exposure), ataxia, and tremor are the most common neurotoxic effects.

## Metals

**Lead.** Acute lead poisoning is rare. Acute lead encephalopathy consists of listlessness, drowsiness, and irritability, followed by seizures and signs of increased intracranial pressure. Severe resultant cerebral edema often results in significant neurologic sequelae. Blood levels in acute pediatric lead encephalopathy exceed 90 mcg/dL (Kumar, 2008). Acute lead encephalopathy at any blood lead level constitutes a life-threatening emergency and should be managed accordingly (Kumar, 2008). The most important treatment is to remove the patient from the lead exposure.

Chronic lead exposure as a result of ingestion of lead paint, inhalation of automobile exhaust fumes from leaded gasoline, or inhalation of industrial pollutants may result in high levels of blood lead and is the more common form of intoxication today. Effects can include antisocial behaviors, attention-deficit/hyperactivity disorder, learning disabilities, and reduced intelligence scores. Oral succimer, intravenous ethylenediaminetetraacetic acid (EDTA), or oral meso-2,3-dimercaptosuccinic acid can be considered for children who

have elevated lead levels; however, there is no improvement in later cognitive, neuropsychiatric, or behavioral measures or blood levels.

**Mercury.** Mercury poisoning can result from elemental, inorganic, and organic mercury exposure. Elemental mercury exposure can occur from a laboratory exposure, broken thermometer, light bulbs, or interior paint. The majority of children are asymptomatic. Headache, abdominal pain, and nausea are the most common symptoms. Rarely visual deficits and peripheral neuropathy can persist. Inorganic mercury exposure can occur acutely after accidental ingestion of an antiseptic solution containing mercury. Chronic poisoning may follow prolonged use of mercury-containing teething powders, repeated applications of ammoniated mercury ointment to the skin, or application of mercury-containing antiseptics to the oral mucosa. Acute inorganic mercury poisoning results primarily in severe gastrointestinal problems, whereas chronic or subacute mercury toxicity causes coarse tremor, irritability, and peripheral neuropathy. Symptoms and signs of acrodynia (“pink disease”) include irritability and profound peripheral neuropathy.

Organic mercury poisoning has occurred as a result of ingestion of contaminated fish, grain, or pork and in occupational exposures. Symptoms include ataxia, peripheral neuropathy, choreoathetosis, visual loss, confusion, and coma.

Dimercaprol (BAL), meso-2,3-dimercaptosuccinic acid (DMSA), and 2,3-dimercapto-propanesulphonate (DMPS)

- Stonefish (Scorpaenidae)

effectively chelate and remove mercury from the tissues; however, this has not been shown to reduce morbidity or mortality.

**Thallium.** The primary sources of thallium ingestions are rodenticides and insecticides. Thallium poisoning presents with abdominal pain, alopecia, and mixed peripheral neuropathy. Abdominal pain is usually secondary to peripheral neuropathy. Other neurologic effects of thallium include cranial neuropathies, coma, dementia, delirium, and seizures. CNS levels of thallium may continue to rise for at least a few days after the initial exposure. Cardiovascular involvement includes hypertension and myocardial damage, with shock and death occurring in massive doses. Painful distal glossitis, Mees’s lines, and black thallium deposits at the base of abnormally tapered hairs may also be present. Cerebrospinal fluid protein may be elevated. Treatment is to lower thallium blood levels through hemodialysis, hemoperfusion, and/or continuous veno-venous hemofiltration. Prussian blue can help prevent absorption from the gastrointestinal tract.

**Arsenic.** Most arsenic toxicity occurs by contamination of the water supply. Inhalation of smoke from coal and industrial

- Strychnine (*Strychnos nux vomica*, “slang nut”)
- Tetanus toxin

wastes may also cause poisoning. Acute poisoning manifests with nausea and vomiting, abdominal pain, diarrhea, cutaneous, and neurologic findings. Severe inorganic arsenic poisoning also results in encephalopathy in older children. A Guillain-Barré-like neuropathy may follow. Other acute cutaneous findings may include facial edema, transient flushing, conjunctival hemorrhage, and maculopapular rash in intertriginous areas. Mees’s lines may be found several months after exposure. Unlike thallium, arsenic typically does not cause alopecia. Treatment includes removal of the exposure. Chelation is the mainstay of acute exposure treatment. It has limited efficacy in chronic exposures.

Heavy-metal exposure, including cadmium, lead, arsenic, mercury, and thallium, may occur from intake of medicinals. Ernst and Coon provide a review of such metal toxicity in traditional Chinese medicines.

**DRUGS OF ABUSE****Cocaine**

Cocaine inhibits reuptake of norepinephrine, dopamine, and serotonin. Acute toxicity includes behavioral effects, hyperthermia, tremors, diaphoresis, tachycardia, cardiac dysrhythmias, myocardial infarctions, vasoconstriction, and hypertension. These effects are followed by anxiety, agitation, depression, exhaustion, and sometimes paranoid psychosis. Addiction follows continued use. Stroke, intracranial hemorrhage, vasculitis, and death have been reported. Seizures have also been reported; however, validity of the association is debated. First-line treatment for all symptoms is benzodiazepines. Alpha-antagonist treatment may follow.

**Opiates**

There are limited data available regarding opiate use in childhood. Symptoms of intoxication include CNS depression, miotic pupils, respiratory depression/arrest, circulatory collapse, and convulsions. Morphine sulfate can rarely cause

a leukoencephalopathy. Heroin can cause a spongiform leukoencephalopathy. Treatment of opiate intoxication includes administration of naloxone and supportive care.

**Cannabis**

Cannabis (tetrahydrocannabinol) is usually inhaled or ingested. Tetrahydrocannabinol intoxication produces psychomotor slowing, short-term memory loss, analgesia, pupillary dilatation, conjunctival hyperemia, tachycardia, and appetite stimulation. Coma has been reported. Long-term sequelae include mild cognitive impairment, psychiatric conditions, chronic bronchitis, bone loss, cardiovascular effects, and teratogenicity. Dependency may occur.

**Gamma-Hydroxybutyrate**

Gamma-hydroxybutyrate is most often a “date-rape” drug. It can lead to a profound flaccid, areflexic coma. This may mimic brain death. Treatment is supportive.

**Hydrocarbons**

“Hydrocarbons” are a broad range of substances that are organic in nature with hydrogen and carbon as their main

elements. Common examples are glue, kerosene, leaded gasoline, and Freon<sup>®</sup>. Toxicity most often occurs through inhalation. The exact mechanism of hydrocarbon toxicity is unknown. Toxicity is substance- and dose-dependent. Acute effects include euphoria, disinhibition, impulsivity, headache, dizziness, and nausea. Blurred vision, tinnitus, arrhythmias, peripheral numbness, muscle weakness, and dysesthesia of the tongue have also been described. Long-term abuse may result in neuropsychiatric alterations, cerebellar dysfunction, encephalopathy, tremor, spasticity, and dementia. White matter abnormalities on MRI have been described. Treatment is symptomatic and includes removal of exposure source.

**Hallucinogens**

Phencyclidine (PCP) is commonly inhaled or ingested. It causes euphoria, violent behavior, extreme muscular rigidity, and exaggerated muscle strength. Vertical and horizontal nystagmus with marked pupillary dilatation is common. A syndrome of catatonic rigidity, opisthotonus, dystonic posturing, stupor or profound fluctuations in the level of consciousness, seizures, and myoclonus can occur. Extreme elevations of blood pressure are common. Intracranial hemorrhage can occur. Treatment includes sedation, hyperthermia treatment, and hypertensive management.

LSD is a hallucinogen. Intoxication results in acute personality changes, hallucinations, panic reactions, and feelings of depersonalization. Ataxia, tremors, diaphoresis, convulsions, coma, and respiratory arrest may occur. Treatment is supportive care with sedation.

**Amphetamines**

Amphetamines cause a sense of well-being and decreased fatigue. With toxic doses, acute paranoid psychosis may develop, with mania, hyperactivity, and severe sympathomimetic effects. The most common adverse effects in children are agitation and tachycardia. Less commonly hypertension,

hyperthermia, and convulsions occur. Cerebral vasculitis, cerebral infarction, subarachnoid hemorrhage, and intracranial hemorrhage have been reported. Severe agitation or seizures may be treated with intravenous benzodiazepines; hallucinations and agitation may also be treated with haloperidol or olanzapine. Hyperthermia and hypertension should be treated aggressively.

**“Ecstasy”**

3,4-Methylenedioxyamphetamine (ecstasy) both stimulates and blocks reuptake of serotonin (5-HT). It also has a lesser effect on other monoaminergic neurotransmitters. It typically causes euphoria. Acutely, it commonly causes serotonergic symptoms of confusion, hyperkinesia, and increased body temperature. Rarely, these symptoms can develop into a serotonergic syndrome. Once the acute effects wear off, depressive symptoms occur. Treatment is supportive.

**Emerging Drugs of Abuse**

Synthetic cathinones (bath salts) can be snorted, ingested, or injected. They cause increased release and decreased reuptake of norepinephrine, serotonin, and dopamine. Sympathomimetic toxicity can result, causing symptoms of agitation, hyperthermia, tachycardia, anxiety, confusion, seizures, chest pain, nausea, palpitations, fever, diaphoresis, hypertension, dizziness, and peripheral vasoconstriction. Symptoms have a significant overlap with both serotonin and sympathomimetic syndromes. Treatment is with benzodiazepines, antipsychotic agents, and supportive care.

Synthetic cannabinoids (i.e., K2 and spice) exert their effects through the CB1 and CB2 cannabinoid receptors. Their effects include mood alteration, hallucinations, conjunctival injection, tachycardia, and dry mouth. They may also provoke anxiety and psychotic reactions. Seizures have been reported. Treatment is primary supportive.

Salvia is a hallucinogen that acts as an agonist at the kappa opioid receptor. Adverse effects include agitation, tachycardia, hypertension, seizures, leukocytosis, hyperglycemia, and elevated creatine kinase.

**Barbiturates**

Barbiturate intoxication produces confusion and varying degrees of sedation and coma; lesser amounts may result in ataxia. Respiratory depression, flaccid areflexia, miotic pupils, and absent brainstem reflexes occur with more severe poisoning. Activated charcoal, given repeatedly, is the most efficacious treatment along with supportive care. Hemodialysis is of unproved value but may benefit severely intoxicated patients. Renal function monitoring is recommended.

**Benzodiazepines**

Benzodiazepine intoxication produces ataxia and sedation at low doses, and confusion, somnolence, and coma at higher doses. Respiratory depression and hypotension may occur. The combination of benzodiazepines and other CNS depressants is potentially fatal. Treatment is supportive care and administration of flumazenil. Flumazenil-induced convulsions may occur in individuals with chronic benzodiazepine use.

**Baclofen**

Baclofen is a GABA B receptor agonist that is most often used to treat spasticity. Mild toxicity typically results in sedation or agitation. More severe toxicity may manifest as hypothermia, hypotonia, respiratory depression, cardiac conduction abnormalities, hyporeflexia, and/or coma. Seizures or myoclonic jerks are common. A burst suppression pattern on EEG may occur and may persist for days after ingestion (Leikin and Paloucek, 1995). The clinical picture may mimic brain death. Treatment is supportive.

**Antipsychotic Agents (Neuroleptics)**

Older neuroleptics include phenothiazines and butyrophenones. These can cause sedation, acute dystonic reactions, akathisia, pseudoparkinsonism, withdrawal, emergent dyskinesia, tardive dyskinesia, and neuroleptic malignant syndrome. Acute intoxication in a young child usually results in a confusional state or depressed level of consciousness. Acute dystonic reactions may manifest as an oculogyric crisis or sudden dystonic posturing of the head and neck, including opisthotonus, retrocollis, torticollis, facial grimacing, and tongue thrusting. These acute reactions are not necessarily dose related, and are usually readily reversed with the intravenous administration of diphenhydramine. Miosis, coma, hypothermia or hyperthermia, and hypotension may occur after ingestion of a large dose of either phenothiazines or butyrophenones.

Akathisia is a dose-related neurologic complication of neuroleptic treatment and is rare in children. It usually responds to treatment with benzodiazepines, beta-adrenergic blockers, or dose reduction. Tardive dyskinesia is extremely rare in children.

Neuroleptic malignant syndrome is a rare complication of neuroleptic drug therapy and is characterized by fever, muscular rigidity, autonomic dysfunction, and altered sensorium, with waxing and waning of consciousness. The patient may be in a catatonic-like stupor and may be mute. Myoglobinuria and acute renal failure may occur. Treatment consists of intensive supportive care, aggressive fluid management, and, in selected cases, dantrolene or bromocriptine administration. This syndrome can occur with both first- and second-generation antipsychotics (Belvederi et al., 2015).

The second-generation antipsychotics, such as clozapine, risperidone, olanzapine, quetiapine, ziprasidone, and sertindole, have clinically significant pharmacologic activity at multiple receptors, and fewer typical antidopaminergic side effects. They can cause acute extrapyramidal effects (clozapine and risperidone), confusion, lethargy, ataxia, seizures (clozapine), and myoclonus.

**Antidepressants**

Tricyclic antidepressants (i.e., amitriptyline, imipramine, and desipramine) are associated with acute toxicity and significant morbidity and mortality (Qin et al., 2014). Dry mouth, palpitations, and tachycardia are typical anticholinergic effects.

An acute encephalopathy with ataxia, hallucinations, and nystagmus can occur followed by somnolence and tremor or myoclonus. Death may occur as a result of progressive coma, seizures, and cardiac conduction defects resulting in hypotension. In acute poisoning, activated charcoal with a cathartic may be helpful. Seizures are treated with benzodiazepines. Tachyarrhythmias from prolongation of the QRS interval can be treated with sodium bicarbonate and potassium. Prolonged QTc intervals should be treated with magnesium supplementation and potassium repletion.

Selective serotonin reuptake inhibitors' neurotoxicity is generally limited to accidental ingestions or intentional overdoses. This can lead to a serotonergic syndrome, including coma and convulsions. Sedation and vomiting are the most common side effects. Paradoxical behavioral reactions and SSRI-induced hyperkinetic movement disorders are the most likely adverse neurologic effects (Qin et al., 2014). Citalopram intoxication can be associated with severe encephalopathy and seizures requiring intensive care admission. Extrapyramidal symptoms can occur from duloxetine, escitalopram, and citalopram. A neonatal withdrawal syndrome has been reported. Bupropion has the highest risk for seizures.

## Lithium

Lithium carbonate is often used for the treatment of bipolar disorder. Most cases of lithium intoxication occur during the course of prolonged therapy. An acute encephalopathy can occur, but most chronic toxicity manifests as an irreversible cerebellar syndrome. This can be displayed as apathy, drowsiness, nystagmus, tinnitus, dysarthria, ataxia, coarse muscle tremors, vomiting, and diarrhea. Choreiform movements, dystonic posturing, and cogwheel rigidity may occur. Severity of symptoms does not appear to correlate well to serum concentrations, but instead to chronic exposure. Seizures and coma indicate severe toxicity. Treatment is supportive care and drug discontinuation.

## Salicylates

Salicylates are present in a myriad of medicinal preparations, ranging from aspirin tablets to oil of wintergreen and long-used Chinese medicinal oils. The classic triad of acute intoxication is hyperventilation, tinnitus, and gastrointestinal irritation. Symptom onset in acute intoxications is within a few hours. Salicylates directly affect the CNS and cause central hyperventilation with respiratory alkalosis. Mortality is related to brain salicylate concentration; respiratory decompensation and subsequent worsening acidosis facilitate salicylic acid passage into the CNS.

Chronic toxicity occurs after several days of use. CNS disturbances include lethargy, coma, and convulsions; however, the predominant toxicity is pulmonary edema.

Isotonic alkaline solution, activated charcoal, management of hypoglycemia, early hemodialysis, and supportive therapy are the best treatments.

## Stimulants

Stimulant medications are used to treat attention-deficit/hyperactivity disorder. They may produce increased activity and varying dyskinesias, including motor tics and chorea. Stimulants overall do not worsen tic severity or exacerbate epileptic seizures.

Atomoxetine is a nonstimulant agent approved for the treatment of attention-deficit/hyperactivity disorder. Side effects are mild and can include headache, decreased appetite,

gastrointestinal disturbances, and somnolence. Atomoxetine overdoses have been associated with dyskinesias and seizure activity.

## Diphenhydramine

The antihistamine and anticholinergic diphenhydramine is contained commonly in over-the-counter cold/allergy remedies and in topical preparations. Neurologic side effects are sedation or paradoxical hyperactivity. Hallucinations, seizures, and death have been reported in a dose-dependent manner.

## Drugs Used in Organ Transplantation

### Cyclosporine

Cyclosporine is an immunosuppressant that likely has the most neurotoxicity among transplant medications (de Groen et al., 1987). It also causes nephrotoxicity and hypertension. The most common nervous system effects are headache, confusion, and seizures. Cortical blindness, hemiparesis, ataxia, and tremor are also reported. Posterior reversible encephalopathy syndrome can occur. These complications are reversible and usually dose dependent. Other factors that exacerbate cyclosporine toxicity include hypertension, fever, hypomagnesemia, hypocholesterolemia, aluminum overload, and concurrent methylprednisolone treatment (de Groen et al., 1987).

### Muromonab-CD3 (OKT3)

Muromonab-CD3 (OKT3) is a murine monoclonal antibody used in acute cellular allograft rejection or graft-versus-host disease. Aseptic meningitis with fever, photophobia, cephalgia, and cerebrospinal fluid pleocytosis has been described. Other complications include cerebral edema, akinetic mutism, seizures, cerebritis, and tremor.

### Tacrolimus (FK-506)

Tacrolimus (FK-506) inhibits interleukin-2 and is thought to act by inhibiting T-cell activation. Serum levels of tacrolimus are altered significantly by multiple drugs. Toxicity may be related to dosing. Symptoms include delirium, catatonia, dysphasia, seizures, peripheral neuropathy, and tremor. Posterior reversible encephalopathy syndrome can occur.

## Antibiotics

### Chloramphenicol

Chloramphenicol has been associated with the development of a reversible optic neuritis with long-term treatment.

### Nitrofurantoin

A rare, reversible polyneuropathy can develop with prolonged nitrofurantoin treatment, particularly in the presence of impaired renal function.

### Aminoglycosides

Aminoglycosides are potentially ototoxic. Symptoms may arise from oral, parenteral, or wound irrigation administration of the drug. A myasthenic-like syndrome accompanied by generalized muscle weakness may also result. This reaction usually occurs after the simultaneous administration of a neuromuscular blocking agent. It may be partially antagonized by neostigmine. These antibiotics may also cause a transient clinical deterioration in patients with myasthenia gravis.

## Beta-Lactam Antibiotics

Penicillins, cephalosporins, and carbapenems may cause seizures as the result of inhibition of gamma-aminobutyric acid (GABA) receptors and are most likely to occur with renal impairment. Cefepime may provoke seizures independent of renal function, especially in those with an underlying epileptic risk. Supratherapeutic levels can lead to an acute encephalopathy and movement disorders. Effects may be magnified in a child with an altered blood-brain barrier.

## Antineoplastic Drugs

### Vinca Alkaloids

Neurotoxicity from vincristine and vinblastine is related to impaired nutrition, drug dosage, frequency of dosing, and duration of therapy. An axonal sensorimotor neuropathy is most common. It may worsen for weeks after treatment completion and can take months to recover ([Armstrong and Gilbert, 2004](#)). Muscle cramps, muscle weakness, cranial nerve palsies, ophthalmoparesis, ptosis, and olivocochlear bundle dysfunction can also occur ([Armstrong and Gilbert, 2004](#)). Autonomic dysfunction can present with colicky abdominal pain, paralytic ileus, constipation, and bladder atony. Generalized seizures and inappropriate secretion of antidiuretic hormone are rare complications. Temporary cortical blindness, ataxia, parkinsonism, and athetosis have been reported.

### Methotrexate

Myelopathy, headache, cognitive deficits, vomiting, nuchal rigidity with aseptic meningitis, truncal ataxia, tremor, paraplegia, delirium, and somnolence have been described as complications of both intrathecal and systemic therapy with methotrexate. Methotrexate toxicity may have a genetic component. Toxicity may be improved with leucovorin rescue. A dose-dependent leukoencephalopathy is the most common CNS complication. High-dose intravenous, prolonged low-dose oral, or intrathecal therapy can provoke a typically one-time reversible acute stroke-like syndrome ([Armstrong and Gilbert, 2004](#)). MRI can show hyperintense foci on FLAIR and DWI. Meningoencephalopathy can occur as late as several months after completion of methotrexate therapy. The most devastating effect of methotrexate therapy is a subacute and usually progressive leukoencephalopathy. Clinical manifestations include mental deterioration with dementia, seizures, and focal neurologic deficits. This complication may occur between 3 and 9 months, but can occur years, after high-dose methotrexate therapy.

### L-Asparaginase

L-Asparaginase therapy may produce changes in mentation, somnolence, and EEG slowing. It produces a coagulation disorder unresponsive to corrective factors. Intracranial thrombosis or hemorrhage and peripheral arterial thrombosis with headache, obtundation, hemiparesis, and seizures are also complications.

### Platinum Agents

Ototoxicity is a common complication of cisplatin therapy. Dose-dependent peripheral axonal sensory neuropathy may also occur. Retinal toxicity and autonomic neuropathy are rare. Oxaliplatin typically causes an acute and chronic sensory neuropathy. Chronic oxaliplatin exposure has similar effects to

cisplatin. Carboplatin appears somewhat less toxic to the nervous system and a neuropathy is rare. Calcium and magnesium may have some protective effects.

### Cytosine Arabinoside

Cytosine arabinoside is most commonly associated with cerebellar ataxia, developing within hours of treatment. This is typically self-resolving. It may also cause a change in sensorium (at high doses), and, rarely, peripheral neuropathy, myelopathy, brachial plexopathy, or transient paraplegia.

### Cyclophosphamide and Ifosfamide

Cyclophosphamide and ifosfamide both may cause CNS toxicity. This toxicity is manifest as an encephalopathy with mental status changes, seizures, and ataxia. Cranial neuropathies also are possible. Improvement has been reported with methylene blue administration.

## Neuroteratology

Drugs administered during pregnancy may affect the fetus. The effects of these drugs depend on the timing of administration; the dose, distribution, and metabolism in maternal tissues; placental transfer; and subsequent concentration and distribution of the drug in fetal tissues. Brain development from morphogenesis to terminal myelination represents a long period of developmental vulnerability.

Initial recognition of structural defects associated with neuroteratogens has matured into appreciation for more subtle deleterious effects of these agents. Many neuroteratogens are best thought of as neurobehavioral teratogens that cause clinically significant cognitive and behavioral alterations but minimal structural brain changes, at least on the neuroimaging level.

Despite newer clinical and imaging technologies, teratogenic risk is frequently imprecise. This discussion is limited to agents in which a neuroteratogenic effect seems likely based on human data, or in which animal data reflect a likely human scenario (e.g., some antineoplastic agents) ([Table 156-2](#)).

Fetal ethanol exposure is the most common preventable chemical cause of mental retardation in the United States. There is an estimated 6% risk that an alcoholic mother will have a child with fetal alcohol syndrome (FAS); the risk is 70% for subsequent offspring. The current CDC prevalence estimate for fetal alcohol syndrome (FASD) in infants is 0.2 to 1.9 per 1000 infants in the general population, although two recent studies report FAS prevalence in 6- to 7-year-olds of 6 to 9 per 1000 and FASD prevalence of 2% to 5% in the same group. Although most studies suggest that significant risk to the fetus occurs with maternal ethanol consumption of about two drinks per day or a few "weekend binges" during pregnancy, the neurobehavioral teratogenicity of "light" alcohol consumption (defined as 1 to 2 drinks per week or per occasion) is not clear. Regardless, a safe threshold value for alcohol consumption value has not been defined. Cardinal features of FAS are

1. prenatal and postnatal growth deficiency,
2. CNS anomalies, usually involving microcephaly and mental retardation, with irritability and restlessness in infants, and
3. craniofacial anomalies that include short palpebral fissures, frontonasal alterations, midface hypoplasia with flat midface, thin upper lip, hypoplastic maxilla, and sometimes hypoplastic mandible.

**TABLE 156-2** Selected Human Neuroteratogens

Drug/Toxin	Effect on Nervous System
Aminoglycoside antibiotics	Cranial nerve VIII damage (10–15%)
Antiepileptic drugs: oxazolinediones (trimethadione), phenytoin, valproic acid, carbamazepine)	CNS malformations, mental retardation, developmental delay, microcephaly, neural tube defect; spina bifida (1–2%)
Cisplatin	Cranial nerve III
Chloroquine, hydroxychloroquine, quinine	Hydrocephalus, optic nerve hypoplasia, cranial nerve VIII damage (10–15%)
Cocaine	CNS hemorrhage, infarction
Coumarin anticoagulants	Mental retardation, microcephaly, optic nerve hypoplasia, midline CNS malformations
Ethanol (dose-related)	Mental retardation, developmental and behavioral disabilities, dyscoordination, microcephaly, CNS midline malformations and migrational errors
Folic acid antagonists (aminopterin, methotrexate)	Cranial malformations, mental retardation
Hyperthermia	Neural tube defect, migrational errors, Möbius' syndrome
Ionizing radiation (>200 Gy)	CNS malformation, microcephaly
Lead	Learning disabilities
Maternal diabetes mellitus	Caudal regression, holoprosencephaly arhinencephalia
Organic mercury	CNS malformation, microcephaly
Solvents: gasoline, xylene, toluene (as substances of abuse)	Caudal regression malformation, CNS malformations, mental retardation
Retinoids, vitamin A	Holoprosencephaly, neural tube defect, microcephaly, posterior fossa cysts, cranial nerve palsies (II, III, VII)
Thiouracil, propylthiouracil (PTU), iodine-131	Mental retardation (congenital hypothyroidism)
Undertreated maternal phenylketonuria	Mental retardation (>90% in untreated mothers)

Partial morphologic expression of alcohol effect is referred to as partial FAS, and behavioral effects in a child without morphologic changes suggest alcohol-related neurobehavioral deficits. Fetal alcohol spectrum disorder encompasses all of these disorders. Long-term follow-up suggests that patients with FAS continue to have growth retardation, craniofacial anomalies, and cognitive and behavioral problems in school. Children with FAS had lower weight, shorter length, and smaller head circumference at 3 years of age. Decrease in intelligence quotient at 4 and 7 years of age has been reported. FAS carries worse neurodevelopmental prognosis than do the milder related phenotypes. A broad pattern of postnatal effects may occur in children with FASD, including decreased cognitive abilities, executive dysfunction, anxiety and depressive disorders, and changes in social relationships.

Several antiepileptic medications are also teratogens. Phenytoin syndrome consists of facial and digital anomalies, growth deficiency, and mental deficiency. Neurodevelopmental abnormalities may occur in up to 10% of prenatally exposed children. Carbamazepine, trimethadione, and valproic acid are also teratogenic. Neural tube defects occur in about 1% to 2% of valproate- or carbamazepine-exposed fetuses. Maternal folic acid supplementation may reduce the risk for antiepileptic drug-associated neural tube defects. The 2013 NEAD study found that children with prenatal exposure to valproic acid scored 7 to 10 points lower on IQ testing and had other cognitive deficits. To date, no reports concerning other anticonvulsants marketed in the United States provide convincing evidence for injury to the prenatal central nervous system.

Isotretinoin (Accutane) produces a characteristic pattern of malformation involving craniofacial, cardiac, thymic, and

CNS structures. The CNS malformations include hydrocephalus, posterior fossa defects, and focal cortical abnormalities. The syndrome is thought to relate to isotretinoin's ability to interfere with neural crest cell development. The current recommendation is to stop oral isotretinoin at least 4 weeks before conception. There is no evidence for increased frequency of birth defects in pregnancies with topical retinoid exposures, but its use cannot be recommended. Although the evidence is strongest for the agents listed in [Table 156-2](#), suggestive animal or human data support the teratogenicity of other substances, including antineoplastic medications ([Smith et al., 2013](#)).

Severe intrauterine methylmercury exposure may result in mental retardation, visual and hearing deficits, and a cerebral palsy-like picture. Stable low-level maternal exposure to mercury also appears to have neuropsychologic consequences at least into early school age. The U.S. National Research Council has concluded that 0.1 g/kg body weight per day probably is a safe level of methylmercury exposure for maternal-fetal pairs.

Finally, the effects of prenatal exposure to currently popular drugs of abuse, including cocaine, marijuana, and methamphetamine, are less defined. Despite this, at least regarding cocaine and marijuana, evidence supports some degree of neurobehavioral teratogenicity.

Prenatal exposure to cocaine may have both short- and long-term CNS sequelae. Infants and children may be exposed to cocaine through transplacental transfer, breast-milk ingestion, and passive inhalation. Although a consistent dysmorphic "syndrome" in cocaine-exposed neonates is not described, congenital urogenital malformations are linked more firmly to prenatal cocaine exposure. Infants exposed to cocaine

prenatally have intrauterine growth retardation and reduced head circumference. Sharp waves and spikes may be seen in the neonatal EEG, and there is maturational delay in the brain-stem auditory-evoked response in neonates as well. Maternal cocaine use is associated with intracranial hemorrhage and antenatal or perinatal cerebral infarction. Infants frequently are irritable and tremulous, with a high-pitched cry and sometimes hypertonia and hyperreflexia. Poor feeding, abnormal sleep patterns, inappropriate response to stimulation, and difficulties with state regulation also may be present. Long-term, there is a suggestion that prenatally exposed children are highly distractible, with poorly developed verbal, language, and motor skills, despite average test scores. Microcephaly, and increased behavioral and affective symptoms, have more recently been demonstrated in a longitudinal study of children now at age 10 years. Unfortunately, some of these studies were poorly controlled for birth weight, which also may be a predictor of cocaine neurodevelopmental effects. The role of other confounding factors is also unclear.

Chronic marijuana use is associated with persistent cognitive dysfunction and other sequelae. To date, neurobehavioral sequelae of prenatal marijuana exposure are not agreed upon, although deleterious effects have been reported in behavior, attention, and overall IQ scores into adolescence. Neonates born to women using marijuana in the immediate prenatal period may be jittery and have an abnormal cry, symptoms that may persist for the first month of life.

Patterns of prenatal exposure are becoming better understood, and more sensitive techniques with which to test the effects of those exposures on the developing nervous system are emerging. As increasingly subtle postnatal neurobehavioral consequences are reported, the discussion will move from “if” to “how” these agents affect neurodevelopment throughout the lifespan.

## CONCLUDING REMARKS AND ADDITIONAL SOURCES

The American Association of Poison Control Centers (AAPCC) compiles Toxic Exposure Surveillance System data from regional centers in the United States. This effort, combined with educational efforts by the American Academy of Pediatrics, the National Association of Medical Examiners' Pediatric Toxicology (PedTox) Registry, and local poison control center public and professional education, has significantly reduced pediatric poison-related deaths in this country. Other nations have similar programs and results.

New information concerning poisoning and drug effects on the nervous system appears rapidly. The following section lists several other sources of current toxicology information, and the phone number for AAPCC is 1-800-222-1222. Internet URLs are current as of 2015. The sites have links to other sites involving specific subtopics.

## LIST OF ABBREVIATIONS

Heart Diagnosis	Abbreviation/Acronym
Transposition of the Great Arteries	TGA
Hypoplastic Left Heart Syndrome	HLHS
Patent Ductus Arteriosus	PDA
Tetralogy of Fallot	TOF
Ventricular Septal Defect	VSD
Atrial Septal Defect	ASD
Intact Ventricular Septum	IVS
Common AV Canal	CAVC
Double Outlet Right Ventricle	DORV
Interrupted Aortic Arch	IAA
Pulmonary Atresia	PA

## INTRODUCTION

Congenital heart defects (CHDs) are among the most common birth defects with a national prevalence estimated at about 18 per 10,000 live births. The most serious heart defects (i.e., those requiring surgery in the first week of life) occur at a national prevalence of about 8 per 10,000, with transposition of the great arteries (TGA) occurring in about 4.7 and hypoplastic left heart (HLHS) in about 2.4 per 10,000 live births. Furthermore, previously healthy children can suffer from acquired cardiac disorders including endocarditis and myocarditis. Others, including those with underlying neuromuscular disorders such as Becker muscular dystrophy and Pompe disease, may have an intrinsic abnormality of myocardial function, referred to as a cardiomyopathy.

Children with cardiac disease often have neurologic complications. Acute neurologic emergencies include seizures, hypoxic-ischemic injury, arterial ischemic stroke, cerebral sinovenous thrombosis, and intracerebral hemorrhage. Evaluation and management of these neurologic conditions may be complicated due to the specific cardiac considerations and physiologic requirements.

Because the risk for the various types of brain injury are closely related to the type of heart lesion, the stage of the patient's brain development and to the perioperative management, the first part of the chapter will be organized accordingly. The second part of the chapter will cover the perioperative neurologic symptoms and will discuss the spectrum, severity, and evolution of the short-term and long-term neurodevelopmental consequences of altered fetal brain development and perioperative brain injury.

## ANATOMIC CONSIDERATIONS

Severe CHDs may be categorized as either single ventricle lesions, biventricular lesions with or without aortic arch obstructions caused by atresia, stenosis, or coarctation (Table 157-1). These lesions can be complicated by intracardiac and extracardiac shunts such as septal defects (atrial and ventricular) or a patent ductus arteriosus (DA) respectively. Mixing of venous and arterial blood and altered flow patterns from malformed heart valves or obstructed outflow tracts (aortic or pulmonary arteries) lead to diminished oxygen delivery (the product of cerebral blood flow and oxygen content of the blood) to the brain and are the major contributors of altered brain growth and development. In addition, they increase the risk for acute brain injury in the form of hypoxic-ischemic injury to the cerebral white matter, stroke, and hemorrhage. Venous to arterial shunts (also known as "right to left shunts") through septal defects or shunts are sources for paradoxical embolization to the brain. Furthermore, genetic syndromes that are associated with heart defects including Trisomy 21, Alagille syndrome, Noonan syndrome, and several other conditions; carry the risk for other cerebrovascular anomalies such as Moyamoya vasculopathy (Pierpont et al. 2015) (Table 157-2).

The two most common diagnoses for high risk severe CHD are TGA and HLHS (Fig. 157-1). In TGA (Fig. 157-1C), the pathology results from the aortic trunk, which arises from the right ventricle shunting systemic venous blood (deoxygenated) to the ascending aorta and on to the neck vessels and coronary arteries (coronaries always arise from the aorta). The pulmonary artery arises from the left ventricle and shunts arterialized (oxygenated) blood to the lungs. In HLHS (Fig. 157-1B), the pathology results from obstruction of antegrade blood flow from the left atrium, either by developmental atresia of the mitral or aortic valve. The lack of antegrade flow from the left atrium results in profound growth failure of the left ventricle and ascending aorta. Thus all cardiac output, both pulmonary and systemic, is from the right ventricle via the pulmonary trunk. Blood flow to the neck vessels and coronary arteries is retrograde from the DA, which is just distal to the left subclavian artery. These flow patterns result in an ascending aorta that has an internal diameter of 1 to 2 mm and a large pulmonary trunk that is receiving twice the normal blood volume (pulmonary and systemic blood). Regulation of vascular resistance determines how much blood is directed to the systemic circulation and how much will flow to the pulmonary bed.

## FETAL CIRCULATION

At birth, infants with severe CHD have evidence of fetal growth restriction. It has been noted that head circumferences are one-half to one standard deviation lower than the mean for normal populations, and their birth weight is likewise decreased. In keeping with the smaller head sizes, a study

using preoperative brain magnetic resonance imaging (MRI) with diffusion tensor imaging and magnetic resonance spectroscopy on infants with and without CHD, found evidence of brain immaturity that was both structural and biochemical. Using an observational scale called the Total Maturation Scale (TMS), another study demonstrated that not only was maturation delayed, but the average maturation score for infants with CHD was equivalent to infants at 35 weeks gestation (Fig. 157-2). Work from multiple centers has demonstrated that brain immaturity, as measured by the TMS, is a leading risk factor for white matter injury (WMI) and predicts functional outcomes, as measured by the Bailey Scales of Infant Development (BSID), at 2 years of age.

To understand why full-term infants with CHD have delayed brain maturation, the cardiac anatomy and the effects

of altered anatomy on fetal circulation must be considered. Oxygen delivery to the brain can be compromised by decreases in either cerebral blood flow (CBF) or a reduction in oxygen content of the blood (anemia or low oxygen saturations or both) or a combination of the two. Furthermore, placental circulation is dependent on fetal cardiac output, if cardiac output is abnormal, placental function may be compromised.

In TGA and HLHS, alterations in fetal blood flow likely lead to decreased brain oxygen delivery defined previously. In TGA, the aorta arises from the right ventricle and receives relatively desaturated blood from the vena cavae (Fig. 157-3B). The higher saturated stream from the left hepatic veins is directed normally across the foramen ovale to the left ventricle. The left ventricle, however, is connected to the pulmonary trunk and thus this higher saturated blood (approximately 65%) is delivered to the lungs and lower body by way of the DA (Fig. 157-3B). In HLHS, the fetal circulation is characterized by increased left atrial pressure (no outlet), resulting in reversal of flow across the foramen ovale (Fig. 157-3C). Left ventricular filling is impaired or nonexistent and consequently left ventricle outflow is diminished (aortic stenosis) or absent (aortic atresia). Pulmonary venous return and blood from the placenta mix at the atrial level and are ejected into the right ventricle and into the pulmonary trunk and DA (Fig. 157-3C). Although the resulting blood saturations are not as low as with TGA, a number of factors may restrict flow to the cerebral circulation. In many cases, flow to the head and neck vessels only occurs by retrograde flow into the transverse aorta and is in competition with systemic and pulmonary vascular resistance (Fig. 157-3C). Consequences of these altered flow patterns have been demonstrated on postnatal brain MRI with the TMS evaluation but more remarkably with fetal MRI (Fig. 157-4). In the fetal MRI, Limperopoulos and colleagues performed a

**TABLE 157-1** CHD Grading System

Standard CHD Grading System	Diagnoses/Examples
Grade I— Two ventricle, no aortic arch obstruction	TGA/IVS, TGA/VSD, TOF, VSD, ASD, truncus arteriosus, CAVC
Grade II— Two ventricle with aortic arch obstruction	Coarctation of the aorta, VSD with coarctation, IAA
Grade III— Single ventricle with no arch obstruction	PA/IVS,
Grade IV— Single ventricle with arch obstruction	HLHS, DORV, unbalanced CAVC

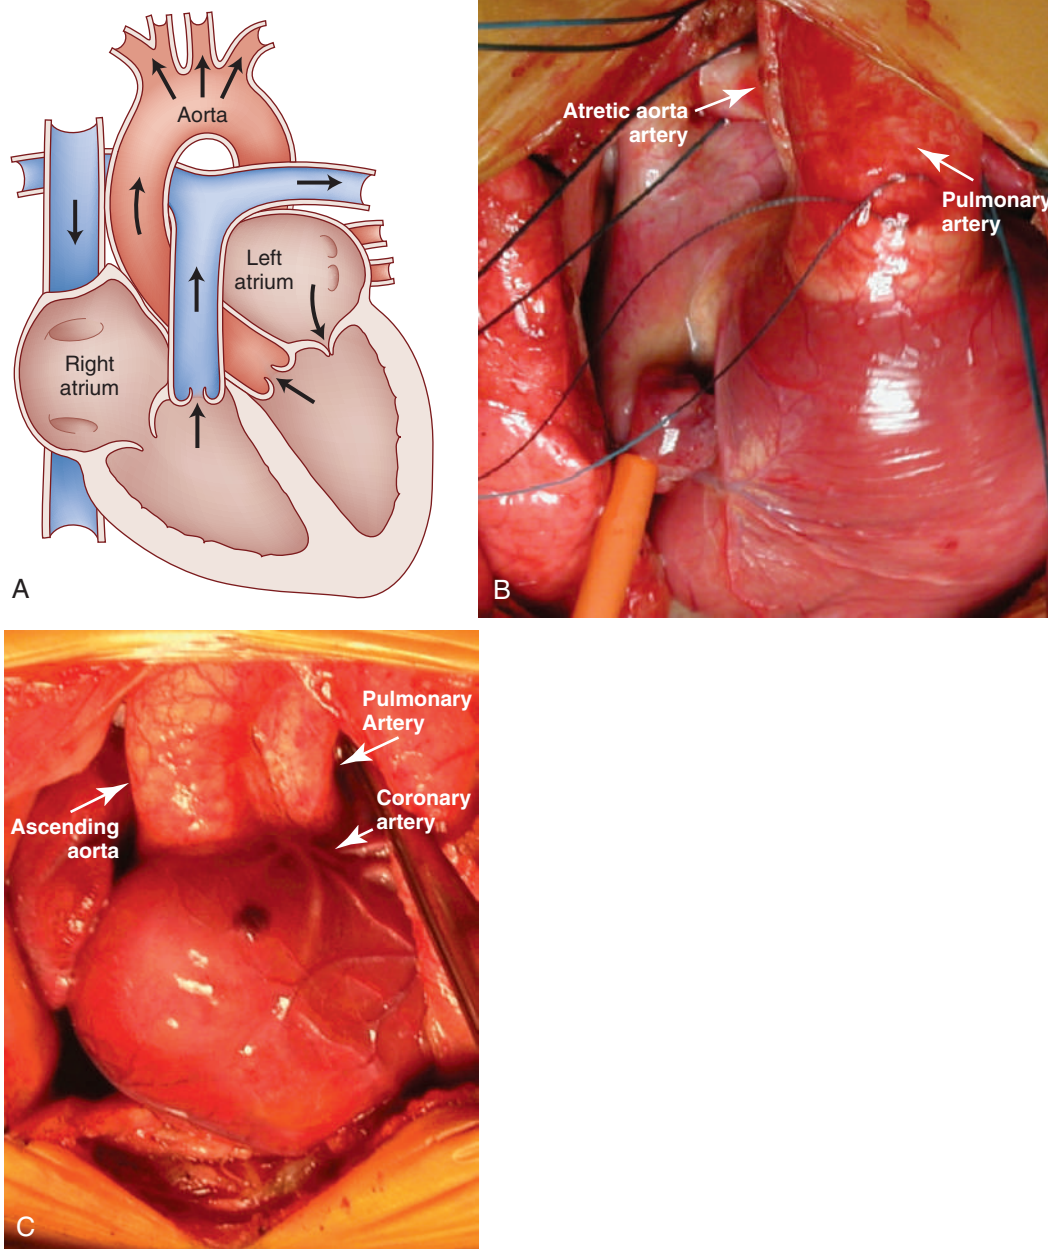

**TABLE 157-2** Common Genetic Syndromes With Cardiac and Nervous System Involvement (Listed According to Prevalence)

Name	Omim #	Prevalence	Percent With CHD	Involved Genes	Cardiac Diagnoses	Nervous System Involvement
Trisomy 21 (Down syndrome)	#190685	1:650–1:1000	40–50	Chromosome 21, particularly 21q22.3	AVSD, VSD, ASD	Muscular hypotonia, mental retardation, expressive language disorder, impaired hearing, Alzheimer disease
Noonan syndrome	#163950	1:1000–2500	80–90	12q24.13	PS, AVSD, hypertrophic cardiomyopathy	Mental retardation, speech and articulation difficulties
22q11.2 deletion syndrome (DiGeorge, VCF syndrome *)	#611867	1:6000	75	22q11.2	Interrupted aortic arch, truncus arteriosus, TOF, aortic arch anomalies	Feeding disorder, nonverbal learning disability, behavioral and psychiatric disorders (adulthood)
Williams-Beuren syndrome	#194050	1:8000	50–85	7q11.23	Supravalvular and valvular aortic stenosis, PS	Mental retardation/cognitive delay, sociable personality
CHARGE syndrome	#214800	1:10,000	75–80	8q12.2 (7q21.11)	TOF (33%), PDA, DORV, ASD, VSD,	CHARGE acronym: <b>C</b> oloboma, <b>H</b> eat defect, <b>A</b> tresia choanae, <b>R</b> etarded growth and development, <b>G</b> enital hypoplasia, <b>E</b> ar anomalies/deafness)
Alagille syndrome 1	#118450 (#610205)	1:70,000	85–95	20p12.2 (1p12 in Alagille syndrome 2)	Peripheral PA, TOF, PS	In some mental retardation or mild, learning disability

\*Patients with a clinical diagnosis of DiGeorge, VCF syndrome (velocardiofacial), or Shprintzen syndrome most often have a 22q11 deletion (Pierpont et al., 2007).

Abbreviations: ASD—atrioventricular septal defect; AVSD—atrioventricular septal defect; DORV—double outlet right ventricle; PA—pulmonary atresia; PDA—patent ductus arteriosus; PS—pulmonary stenosis; TOF—tetralogy of Fallot; VSD—ventricular septal defect.

For a full list of genetic syndromes associated with CHD see Pierpont et al., 2007. Trisomy 13 and 18 are not listed as children usually die within the first year of life, both defects have various forms of CHD and manifest with severe mental retardation.

**Figure 157-1.** Anatomy and orientation of the great arteries. **A**, Normal orientation with the pulmonary artery crossing in front of the aorta. **B**, HLHS, a very large pulmonary artery crossing in front of an atretic aorta. **C**, TGA, aorta in front of the pulmonary artery, both normal size. (Courtesy of Dr. Gil Wernovsky)

cross-sectional analysis of three-dimensional brain volumes from fetal brain MRIs performed prospectively on mothers carrying fetuses with and without CHD. Starting early in the third trimester, it is clear that, in fetuses with CHD, there is a divergence from normal of total brain volume and intracranial volume growth, resulting in the postnatal phenotype of lower brain volume (Fig. 157-4).

## POSTNATAL CIRCULATION

### Heart Surgeries

It is convenient to think of cardiac surgery as being the sole risk for brain injury. However recent research suggests that the primary/major risks for injury are the abnormal

anatomy and circulatory patterns in the fetus and newborn. Most surgical repairs and palliative procedures require cardiopulmonary bypass (CPB), whereby the chambers of the heart are isolated from the circulation by inflow (i.e., right atrium) and outflow (i.e., aortic trunk) surgical clamps, and the systemic circulation is diverted to a roller pump equipped with a membrane oxygenator via large, centrally placed cannulae.

For the more delicate surgeries involving repair of the aortic arch or the pulmonary veins, a different strategy is required. Here the suturing of the vascular structures must be accomplished in a bloodless, unencumbered field. The patient is cooled to 18°C (64.4°F) to reduce systemic and cerebral oxygen metabolism to zero (Fig. 157-5). The bypass pump is stopped and blood is drained from the body into a reservoir

**Figure 157-3.** Comparative fetal circulations. **A.** Normal fetal circulation with oxygenated blood (red color) from the placenta streaming across the foramen ovale into the left-sided heart structures and out to the ascending aorta. Venous deoxygenated blood (blue) returns to the right-side of the heart. **B.** TGA anatomy with oxygenated blood circulating to the transposed pulmonary artery and on to the ductus arteriosus. Venous blood circulates to the right side of the heart and to the ascending aorta. **C.** HLCS anatomy with complete blood mixing at the level of the common atrium. All cardiac output is through the pulmonary artery to the ductus with retrograde flow to the transverse arch, neck vessels and the ascending aorta. **D.** Normal distribution of blood flow measured by phase contrast fetal MRI. (With permission from Prsa, M., Sun, L., van Amerom, J., et al., 2014. Reference ranges of blood flow in the major vessels of the normal human fetal circulation at term by phase-contrast magnetic resonance imaging, *Circ Cardiovasc Imaging* 7(4), 663–670.)

on the circuit. The cannulae are then removed from the field. Developed in the 1950s, this strategy is called Deep Hypothermic Circulatory Arrest (DHCA) was rapidly adopted in the 1970s. The use of DHCA continues today and is particularly useful for complex adult and pediatric cases involving aortic repairs.

The effect of the use of DHCA on cognitive outcomes has been hotly debated, and surgical strategies therefore altered with the stated goal of improving outcomes. There are several surgical strategies that allow for continuous cerebral blood flow throughout the case, and these have been adopted in many centers. These new surgical strategies still require cooling to 18°C, but there is continuation of antegrade cerebral circulation. The trade-off for these modifications is longer surgical and

bypass times. Both piglet and human studies have examined DHCA and continuous flow strategies and suggest that there does not seem to be a demonstrable difference between the two strategies. A randomized controlled trial of DHCA versus continuous antegrade cerebral perfusion was performed in Europe and also failed to show significant differences. A recent retrospective collaborative study examined how BSID scores changed as a result of surgical modifications over the past decades (Gaynor et al., 2015). BSID data collected from 1770 subjects from 1996 to 2009 at 22 international institutions found that, although scores have increased over time, the clinical significance of this change was dubious (0.39 points/year or less than one-third of a standard deviation over a decade).

## Perioperative Considerations

A detailed discussion of the risks associated with each surgical intervention is beyond the scope of this chapter. Typical surgical risks involving anesthetics, mechanical ventilation, bleeding, and infection are always present. Some of the perisurgical neurologic morbidity is specific to the type of heart defect or postoperative management, and not simply the conduct of the surgery itself. The following discussion is focused on specific risks related to the care of infants and children with critical CHD regardless of diagnosis. The management of other complications such as arterial ischemic stroke, intracranial hemorrhage, and venous thrombosis are discussed in other chapters (Chapters 108–113).

## White Matter Injury

Neonatal heart surgery refers to surgical procedures performed on infants less than 30 days old. Survival beyond the neonatal period for these infants depends on surgical correction or palliation of their heart defect. For such patients, the mortality from these early surgeries has decreased dramatically since the late 1980s. In the more experienced centers with the highest surgical volumes, survival approaches 90% for the most complex and technically challenging surgeries. With this increase in survival, the focus of care has shifted to long-term neurologic morbidity.

Infants with severe CHD are prone to hypoxic-ischemic white matter injury (Fig. 157-6) that is not distinguishable from WMI, an injury seen primarily in premature infants. In infants with multiple forms of CHD, this injury is seen in 17% to 40% before surgery and in as high as 80% after surgery (Licht, 2015; Morton et al., 2015). Research has now demonstrated that the primary vulnerability for this injury is the brain-specific IUGR that arises as a consequence of the alterations in fetal hemodynamics created by the CHD, reviewed previously. Recent research supports the notion that not only is the surgery not the cause of WMI, but that delaying the correction/palliation of the native anatomy may increase the risk for postoperative WMI (Lynch et al., 2014).

Brain MRI is required to diagnose WMI as the lesions may be missed on CT or cranial ultrasonography. The typical white matter lesion occurs in the white matter watershed zone, is hyperintense on T1 imaging (Fig. 157-6) and may have susceptibility signal on T2\* sequences, reflecting hemorrhage or mineralization. If imaging is acquired acutely, the lesions may demonstrate restricted water diffusion. MRI slice thickness is an important consideration when assessing this injury as thick slices or large interslice gaps may obscure lesions. There exist some controversy in nomenclature of these white matter lesions; some researchers view lesions with restricted water mobility on diffusion-weighted imaging as arterial ischemic stroke whereas others consider these lesions part of the spectrum of WMI. An international consortium of neurologists,

**Figure 157-6.** Three dimensional segmentation. **(A)** The T1-weighted image before manual PVL segmentation, **(B)** the manual segmentation, and **(C)** the volumetric reconstruction colored by quadrant, are shown in the transverse (left), sagittal (middle), and coronal (right) plane. PVL, periventricular leukomalacia. (With permission from McCarthy, A.L., et al., 2015. Scoring system for periventricular leukomalacia in infants with congenital heart disease. *Pediatr Res* 78(3), 304–309.)

cardiologists, and radiologists is in the process of establishing a universal nomenclature and standardized imaging protocol for this population.

The prevalence of preoperative and postoperative injury is different for individual cardiac diagnoses. Across centers, there appears to be a higher preoperative prevalence seen in TGA and higher rates of postoperative injury seen in HLHS. For patients with TGA, systemic oxygen saturations are lowest before surgery and rapidly normalize after corrective surgery. Proceeding to surgical correction at the earliest time possible should be protective against WMI. Conversely, for patients with HLHS or other single ventricle heart lesions, systemic oxygen saturations are typically in the mid 80% range before surgery and are not significantly higher after initial surgical palliation. In infants with ductal dependent physiology, cerebral oxygen saturations decrease on a daily basis from birth to surgery. This decrease, coupled with increasing oxygen extraction and failure of a compensatory increase in CBF, results in an increasing risk for WMI after surgery.

### Arterial Ischemic Stroke

Classically, arterial ischemic stroke (AIS) is defined by a focal neurologic deficit that is related to a known arterial territory of the brain (Chapter 109). In children this definition has been expanded to include confirmatory neuroimaging (usually MRI). As infants with AIS are likely to be asymptomatic, the diagnosis is dependent on neuroimaging. The risk for AIS in CHD is not limited to the neonate requiring heart surgery. In fact, the risk for AIS in patients with single-ventricle heart defects increases with time and is reported to be greatest after the final stage of surgical palliation (the Fontan circulation, total cavopulmonary connection).

There is sparse literature on subsequent stroke occurrence in infants with severe CHD requiring newborn heart surgery. In a retrospective study, symptomatic stroke was identified in 12 of 122 infants (10%). Seizures were mostly identified after a clinical change or the occurrences of clinically observable seizures. Of these 12 infants, 6 had arterial ischemic stroke and 6 had watershed stroke. This low prevalence rate is congruent with the rate of stroke seen in another study and with the authors' experience of 2% to 4% preoperatively and 8.6% postoperatively, in mixed populations of infants with severe CHD. With such small numbers, investigation of risk factors is unlikely to be fruitful. Centrally placed catheters, such as umbilical catheters, right atrial catheters, and femoral artery catheters, are potential thrombus sources. Intracardiac and extracardiac shunts allow for paradoxical embolization and stroke. Poor heart function is another important source for intracardiac thrombus formation (discussed later).

Older children with single-ventricle heart lesions are highly predisposed to arterial ischemic stroke due to their unique anatomy. Lower extremity vascular access should be avoided if possible in patients with bidirectional Glenn physiology (superior cavopulmonary connection, Stage 2 palliation) as the inferior vena cava remains in direct communication with the systemic circulation. Fenestrations placed surgically at the time of Fontan completion act as a pressure pop-off valve but are obligate right-to-left (venous to arterial) shunts that may also allow for paradoxical emboli. Simple monitoring of systemic oxygen saturations will inform the clinician of the size of the right-to-left shunt. Long-term structural changes in the common atrium, higher central venous pressures resulting in sluggish venous blood flow, and failing ventricle function lead to increased risk for right atrial thrombi (and stroke), chylous effusions, protein losing enteropathies, congested liver, and plastic bronchitis. At the Children's Hospital of Philadelphia, it is the clinical practice to manage the single-ventricle patients

with prior unprovoked thrombotic events with life-long anticoagulation to prevent recurrence.

### Intracranial Hemorrhage

Detection of intracranial hemorrhage before surgery is of obvious importance, as the cardiac surgery with cardiopulmonary bypass requires aggressive anticoagulation. At the time of birth, some amount of intracranial hemorrhage has been commonly found. These include subdural hemorrhages along the tentorial membrane and choroid plexus hemorrhages, which may have intraventricular extension. It is important to note that these hemorrhage types *do not* extend during the conduct of infant heart surgery with cardiopulmonary bypass despite the requirement for systemic anticoagulation.

Intraparenchymal hemorrhages found on preoperative head ultrasound or incidentally as part of a research protocol must be managed on a case-by-case basis because there is a paucity of information on the risk of hemorrhagic extension on cardiopulmonary bypass with this finding. At the Children's Hospital of Philadelphia, if an incidental parenchymal hemorrhage is found, surgical postponement is discussed with the surgeon and intensivist. This frequently results in the postponement of surgery. If the decision is made to postpone surgery, the patient is returned to the intensive care unit and surgery is rescheduled in 1 week with a second preoperative brain MRI.

Subdural hemorrhages are the most common clinically significant hemorrhages in the postsurgical patient, and these can occur acutely or subacutely after surgery. Anticoagulation, elevation in central venous pressures, and brain atrophy (from other injury) are all putative contributors to increased risk. Subdural hemorrhages requiring surgical intervention are uncommon in the cardiac ICU population.

Punctate microhemorrhages seen on brain MRI (Fig. 157-7) after heart surgery with cardiopulmonary bypass or after catheter-based interventional procedures are of unclear clinical significance. These microhemorrhages are unlikely to be hemorrhages at all and may be the result of micro thromboembolic material from bypass cannulation. The lesions are common, occurring in 30% to 50% of postsurgical patients. There is a single report that these lesions may contribute to the neurodevelopmental impairment that is seen in survivors of infant heart surgery.

### Cerebral Sinovenous Thrombosis

Cerebral sinovenous thrombosis has been described in the CHD population, particularly in children or infants with dehydration and/or protein loss through pleural effusions or protein losing enteropathy. Management is described in Chapter 110 and includes hydration, elevation of the head of the bed when possible to promote venous drainage, and systemic anticoagulation.

### Seizures

Seizures after infant heart surgery were identified as one of the significant predictors of a poor neurocognitive outcome in The Boston Circulatory Arrest Trial (BCAT). In that trial, electroencephalography (EEG) monitoring was performed on paper tracings, which were then read retrospectively. As a result, clinically silent seizures (electrographic only) were not treated. As a consequence of the findings in the BCAT, many centers have started to perform EEG monitoring (full montage or amplitude integrated EEG) after infant surgery. Seizure prevalence is quite variable after infant surgery and ranges from 5% to 26% of infants. The majority of seizures are electrographic

only (as was seen in the BCAT), and status epilepticus occurs in the majority of seizures detected by EEG monitoring (85% to 100% of patients with seizures detected). Most seizures that occur after infant heart surgery are acute symptomatic seizures, and neuroimaging commonly shows WMI or AIS. Recent results from one study showed that longer duration of DHCA and/or returning to the cardiac ICU with an open chest were the most predictive risk factors for postoperative seizures after infant heart surgery.

## Neurologic Sequelae of Heart Failure

Heart failure is the syndrome that results from the inability of the heart to meet the body's metabolic demands. Heart failure may be primary or secondary—that is, due to congenital or acquired cardiomyopathy or due to high flow states as seen in large hemangiomas, arterial-venous malformations (AVM), or severe anemia, among other causes. During heart failure, a child is at increased risk of neurologic injury: low cardiac output decreases cerebral perfusion, sudden arrests can lead to watershed infarction, hypoxic-ischemic brain damage, and secondary seizures or encephalopathy. Furthermore, decreased ventricular systolic function can result in stasis of blood in the heart chamber and increase the child's risk of cardioembolic events including AIS.

The degree of thrombotic risk associated with severe ventricular dysfunction is poorly defined in children. There are no guidelines to recommend the use of anticoagulation versus antiplatelet therapy. Current American College of Cardiology/American Heart Association adult heart failure guidelines (Monagle et al., 2008) suggest anticoagulating adults with heart failure and no history of atrial fibrillation or prior thromboembolic events (class IIb recommendation with level of evidence B). In children, recent guidelines suggest that anticoagulation should be considered in children with cardiomyopathy awaiting heart transplantation. Neither guideline specifies a threshold level of ventricular dysfunction where antiplatelet or anticoagulant agents would be strongly recommended. Further investigation is needed to help define the risk-to-benefit ratio of these therapies in various heart failure scenarios. At the Children's Hospital of Philadelphia, it is the clinical practice to use anticoagulation when the cardiac ejection fraction falls lower than 30%, unless there are contraindications such as a large AIS (i.e., greater than one-third of a specific vascular territory) or hemorrhage.

## Mechanical Circulatory Support Devices

Children with severe heart failure may require support devices to maintain cardiopulmonary circulation. These support devices often require maintenance on anticoagulation, antiplatelet agents, or both. Complications from the underlying cardiac failure, the device itself, or the medications used to maintain the device may arise, most commonly stroke.

## Extracorporeal Membrane Oxygenation (ECMO)

ECMO has been the most commonly used form of mechanical cardiopulmonary support and is a form of heart-lung bypass. There are two types of ECMO: veno-arterial ECMO supports both oxygenation and circulation and veno-venous ECMO supports oxygenation alone. For veno-arterial ECMO, a vascular cannula is placed into an artery (usually the right carotid artery, but it can also be the femoral artery) and a large vein. Systemic venous return is shunted into the pump and the blood is passed through an oxygenator that then returns the oxygenated blood to the arterial cannula in the patient. It is important to know that the carotid cannula is pointed down,

toward the aortic arch, so that blood flows away from the brain on the right side. An intact circle of Willis allows for collateralization of blood flow. Survival of "cardiac" ECMO is improving and is listed as 66% (<https://www.else.org/Registry/Statistics.aspx>) by the Extracorporeal Life Support Organization (ELSO), with 51% surviving to discharge or transfer (inferring heart transplant or other destination therapy). Neurologic complications can arise from ischemia due to carotid cannulation, hypoxic-ischemic damage, embolic arterial ischemic stroke, or intracranial hemorrhage. Sequelae including seizures and encephalopathy can arise in any of these settings.

There are many other types of ventricular assist devices (VAD) that support circulation only (without a membrane oxygenator). The FDA recently approved the Berlin Heart EXCOR Pediatric VAD under the Humanitarian Device Exemption Program. They can be used to assist the left ventricle only (systemic flow), right ventricle only (pulmonary flow), or both ventricles. Most cases involve direct cannulation of the ventricle for flow to the pump and aortic cannulation for systemic outflow. VADs are more compact than ECMO, thus providing a longer-term option for mechanical circulatory support so that the patient can be an active participant in rehabilitation. In pediatric centers, VADs are currently used almost exclusively as a bridge to cardiac transplantation, although newer impeller devices are beginning to be considered as "destination therapy" for special populations such as Duchenne muscular dystrophy and other nontransplantable cardiomyopathies and in patients in whom heart transplant is not an option due to anatomic considerations.

Similar to ECMO, children supported by VADs are at significant risk of neurologic complications including AIS and intracerebral hemorrhage. The prevalence of neurologic complications varies by case series. In one study, children with short-term VAD devices were significantly more likely to suffer a stroke than those with long-term VAD devices (35% versus 13%,  $p = 0.02$ ). In another series, children with left atrial cannulation were more likely to develop embolic arterial ischemic stroke than were those with left systemic apical cannulation.

There are relatively few studies of neurologic complications in children supported with ECMO versus VAD; one nonrandomized study reported a higher rate of neurologic complications with ECMO than for VAD. However, in a different study that compared an institutional experience between ECMO and the Berlin EXCOR device, the incidence of stroke was not significantly different between the two devices. A child placed on ECMO who is suspected of needing more long-term support is generally transitioned to a more mobile VAD device.

## NEUROLOGIC MANAGEMENT SPECIFIC TO CARDIAC CARE

The intensivist must choose medications and management with the child's underlying cardiac status in mind when managing neurologic complications of cardiac disease. For example, a child with acute arterial ischemic stroke or cerebral sinovenous thrombosis is often placed on isotonic fluids at 1 to 1.5 times the maintenance rate for age and weight. In the child with heart failure, the fluid rate may require modification in order to avoid iatrogenic worsening of heart failure. In the management of seizures with or without status epilepticus, anticonvulsant choices should take into account the child's cardiac status. Although phenobarbital is often the medication of choice for infants and phenytoin or fosphenytoin the choice for older children, these medications can cause hypotension. Furthermore, phenytoin is a class 1B sodium channel blocker

with both arrhythmogenic and antiarrhythmic properties. There are little data to guide anticonvulsant choice.

Indwelling vascular catheters are a likely source for most clots in patients cared for in the cardiac intensive care unit. For these patients, if ultrasound confirms the presence of a clot, a complete thrombophilia work up and consideration for anticoagulation is recommended in those patients with an arterial ischemic stroke (Chapter 109). An echocardiogram is helpful to evaluate for a residual intracardiac clot or fibrin stranding, as can be seen after removal of a right atrial catheter. Rarely is a transesophageal approach required for this assessment, as a transthoracic approach can usually provide adequate images in the pediatric population. For patients with significant residual right to left shunting (assessed by knowing the pulse-oxygen saturations in a patient without pulmonary disease), Doppler flow ultrasonography of the lower extremity venous system is also indicated.

## SHORT AND LONG-TERM OUTCOMES

### Postoperative Neurologic Findings

With improved surgical techniques and perioperative care, the prevalence of immediate postoperative complications has significantly decreased over the last decades. In the 1980s, the prevalence of perioperative neurologic abnormalities, mostly consisting of postoperative seizures, was as high as 25%. The significance of postoperative seizures as a risk factor for adverse long-term outcome has been documented already in the 1990s. Importantly, the prevalence of perioperative neurologic symptoms has dropped to around 2%, again mostly consisting of a decline in clinical seizures. However, despite this reduction, neurologic complications, often moderate to mild in severity, are still common when looking at early neurodevelopmental outcome.

The reported overall rate of neurologic complications developing in the postoperative period is quite broad, ranging from 2.3% to over 50%. This heterogeneity may be explained by different patient characteristics in the studies, including all different types of CHD or only severe ones, by the definitions of neurologic impairments, and by the variability across centers in surveillance. To address this, Bird and colleagues proposed a consensus list and definitions to help standardize terminology across centers (Bird et al., 2008). Preoperative abnormalities can persist after surgical repair or accentuate. Newly occurring neurologic abnormalities have also been described and manifest by changes of muscle tone, reflexes, or power or by movement abnormalities such as choreoathetosis.

Seizures are important neurologic symptoms that may occur preoperatively, but more frequently occur postoperatively. Postoperative seizures may have a significant influence on mortality and morbidity. The Boston Circulatory Arrest Trial demonstrated a negative effect of postoperative seizures on neurodevelopmental outcome in newborns with TGA. This has also been shown for children with a large variety of CHD diagnoses. Recently a study confirmed that postoperative seizures on amplitude integrated EEG (aEEG) predicted motor, but not cognitive, outcome at 2 years of age.

Cerebral MRI cannot always be performed during the immediate postoperative period. Thus studies have examined the use of functional bedside tools such as aEEG and NIRS to assess brain injury. Furthermore, the bedside clinical diagnosis of neurologic dysfunction may be complicated by their subtle manifestations, and further impaired by the use of sedating medications. These confounding factors can delay the accurate diagnosis of perioperative brain dysfunction. The aEEG is increasingly used as a routine monitoring, but its prognostic value for abnormal outcome remains unclear. One study

demonstrated a relationship between delayed recoveries of the background pattern on postoperative aEEGs and motor outcome.

When summarizing clinical outcome predictions for early childhood and school-age outcome, the strongest predictors are postoperative neurologic abnormalities, including seizures, as well as lower preoperative and postoperative head circumference.

### Short-Term Outcome

Recent reviews summarized neurodevelopmental outcomes in children with CHD, showing a consistent pattern of global developmental impairment, characterized by motor and cognitive delay in the first 2 to 3 years with motor delay and neuromotor abnormalities being more affected than cognitive and language functions (Marino et al., 2012; Snookes et al., 2010). Of note, children with genetic disorders are at particular risk for poorer neurodevelopmental outcome (Table 157-2).

In a recent large multicenter retrospective analysis, neurodevelopmental outcome of 1700 children from 22 institutions who had undergone cardiac surgery using cardiopulmonary bypass at ages less than 9 months showed significant neurodevelopmental impairments (Gaynor et al., 2015). At a mean age of 14.5 months, the Psychomotor Development Index (PDI) and Mental Development Index (MDI) of the Bayley Scales of Infant Development II (BSID II) were lower (PDI:  $77.6 \pm 18.8$ ; MDI:  $88.2 \pm 16.7$ ) than normative means. In that study, time trends over two decades were analyzed. The rate of survivors with more complex CHD and genetic/extracardiac abnormalities increased over time. Despite this, a modest improvement of motor and cognitive function was observed after correction for a variety of cofactors. However, this improvement is not substantial and is counterbalanced by the high rate of children with complex CHD and genetic comorbidities. Another study reported on children with various types of CHD who were assessed every 6 months until the age of 36 months. Of this group, 75% had scores in the "at risk" or "delayed" range in more than one domain at more than one assessment. Nineteen percent of children who had cognitive, language, and motor scores in the average range at 1 year of age were later found to be at risk or delayed in more than 1 area. In this study, parents reported that 74% of the children had received or were actively receiving early intervention services from the state-based "Birth to 3" programs or private therapy. Importantly, although motor delay improved in children without genetic syndrome, cognitive and language delay became more evident in nonsyndromal children. In addition, in children with syndromal disorders, developmental scores decline over time, and developmental delay become more apparent. The ability to successfully achieve oral feeding was an important clinical predictor for a favorable developmental course, indicating neuronal integrity. An increase of developmental delay within early childhood has also been shown in another study in which children were followed between 8 and 24 months. The most pronounced increase in the odds to have impairments was found in the problem-solving and in the personal-social dimension.

### Long-Term Outcome

School-age children with CHD may exhibit a wide range of long-term developmental impairments (Latal, 2016; Marino et al., 2012) (Table 157-7). They affect all areas of development, are most frequently mild to moderate in severity. Though they often occur in combination and can lead to significant school problems and academic difficulties. Mean IQ scores are in the low-average range, and motor difficulties

**TABLE 157-7** Potential Long-Term Neurocognitive and Behavioral Problems in Children and Adolescents With CHD

Developmental Domain	Impairment
Neurology	Cerebral palsy (rare, only if significant perioperative insult has occurred) Microcephaly Mild muscular hypotonia
Motor function and visuomotor function	Fine and gross motor coordination disorder Visuoperceptual and visuomotor problems
Cognition/intellectual function	Reduced overall IQ Working memory Processing speed Poorer academic achievement
Higher order intellectual function	Higher order language functions Executive functions
Behavior	Attention-deficit disorder Emotional disorders Social interaction problems

in gross and fine motor domains occur in around 20% to 40% of the children tested. Children with motor difficulties at school age will have a higher need of therapeutic support. Language problems may manifest themselves as impaired reading abilities. The Boston Circulatory Arrest Trial, one of the largest and most comprehensive studies of long-term neurodevelopmental outcomes, showed that at age 4 and 8 years after surgery, neurodevelopmental outcomes were independent of surgical strategy (ie DHCA). In addition, hearing problems and abnormalities on neurologic examination were more frequent than in the group that did not receive DHCA. This pattern of impairment seems to persist without much “outgrowth” occurring. When these children were reexamined at adolescent age, performance scores were lower in both treatments with a significant proportion of adolescents performing lower than average, who were in need of academic or behavioral services. The pattern of mild to moderate impairments in a variety of developmental domains has been shown also in other CHD populations with varying diagnoses, persisting into adolescence. These findings consolidate the impression that regardless of type of CHD, there seems to be an increased risk for long-lasting neurodevelopmental impairments in this population.

### Adolescent and Adult Outcome

The number of studies examining adolescent and adult outcome is small but growing. There is consistent evidence that with increasing academic challenges, children with CHD may be faced with more difficulties. One of the first studies examining long-term outcome demonstrated a persistence of lower IQ at 13 years of age in a small group of children with TGA. More studies followed and confirmed this finding in larger populations of children with TGA, TOE, after Fontan procedure or with mixed cardiac diagnoses. Overall IQ and other developmental domains such as executive functions and visuospatial, and motor performance remained affected (Calderon and Bellinger, 2015; Marino et al., 2012). These difficulties went along with an increased need for remedial academic or behavioral services. Of note, one study demonstrated flexibility and problem-solving executive skills to be impaired in all CHD patients in a large sample of patients aged 10 to 19 years, whereas visuospatially mediated executive

abilities were preserved in adolescents with TGA. Overall, adolescents seem to score worse on academic achievement tests, to need more supportive help, and to have a lower chance of completing mandatory schooling.

The transition into adulthood is an important phase and CHD survivors may be particularly vulnerable. There are very few studies examining this period. A recent study demonstrated that Swiss adolescents with a variety of CHD diagnosis had similar school educations and that patients were satisfied with their educational career. Only those patients with severe CHD were more likely to attend lower level education. One explanation for this favorable outcome may be the good educational support system allowing for a relatively easy transition into adulthood. Overall, the trend of poorer academic achievement described for adolescents with CHD seems to persist into adulthood, resulting in a higher rate of early unemployment and a lower rate of full-time employment. Patients with complex CHD seem to be at particular risk.

### SUMMARY

As mortality rates for children and adolescents with CHD have decreased significantly, the focus has shifted toward potential acute and chronic neurologic and developmental sequelae. Infants with CHD requiring cardiac surgery may show a combination of delayed intrauterine cerebral maturation and acute preoperative and postoperative brain injuries, associated with clinical neurologic symptoms such as seizures and abnormalities on neurologic examination. The mechanisms are complex and most likely multifactorial, consisting of altered fetal hemodynamics and cerebral perfusion, leading to a delay in brain maturation that in turn seems to be a risk factors for neonatal WMI. Children may present with mild neurologic abnormalities in early childhood (typically muscular hypotonia) and may continue to show motor deficits (balance and fine motor problems). In addition children with CHD may have cognitive impairments and attention problems, as well as deficits in working memory and higher language functions, which in turn influence school performance and academic achievement. Studies in this area of the long-term outcome up to adolescence and young adulthood are needed to shed light onto the full spectrum of potential problems, as well as their effect on personal well-being, on quality of life, and on societal financial burdens. Also, parents and caregivers need to be informed about the potential short-term and long-term neurodevelopmental and behavioral problems their children may face, and interdisciplinary follow-up clinics need to be established to detect developmental problems early in order to provide timely therapeutic interventions and parental guidance.

# 158 Neurologic Disorders Associated With Renal Diseases

Cheryl P. Sanchez, Rita D. Sheth, Robert S. Rust, Jessica L. Carpenter, and Stephen Ashwal

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Advances in the treatment of children with kidney disease with new antihypertensive medications, dialysis, transplantation, and immunosuppressive agents have resulted in improved long-term survival and quality of life. Still, children present acutely with neurologic symptoms, and they may develop long-term neurologic disorders because of currently available treatments. This chapter reviews various aspects of the complex interrelationships between the kidneys and the brain. Four areas are discussed: (1) renal diseases that secondarily affect the nervous system, (2) diseases that affect both the kidneys and the nervous system, (3) neurologic drugs that may affect renal function in individuals with normal kidneys, and (4) drug therapy in renal disease.

## RENAL DISEASES SECONDARILY AFFECTING THE NERVOUS SYSTEM

### Acute Kidney Injury

Acute kidney injury (AKI) is a common problem occurring in as many as 10% to 25% of all hospital admissions in the United States, and approximately 25% to 50% of these admissions may require critical care management. Neurologic decompensation occurs as a result of the following: (1) disturbances in water homeostasis, electrolyte abnormalities, and acid-base metabolism; (2) impairment in the blood-brain barrier (BBB); (3) changes in neurotransmitter activity; and (4) derangements in drug metabolism.

### Sodium and Water Disorders

Neurologic abnormalities associated with water intoxication may arise in AKI. The kidney's capacity to excrete water as dilute urine is the chief mechanism for prevention of water intoxication. In AKI, this mechanism is impaired, and neurologic dysfunction can develop within hours to days. Individuals with sodium values as low as 120 to 125 mEq/L can remain asymptomatic. Neurologic symptoms become more prevalent once the serum sodium is less than 120 mEq/L. Signs and symptoms of water intoxication are variable and include mental status changes (e.g., apathy, agitation, or confusion to obtundation), headache, nystagmus, vomiting, diaphoresis, weakness, generalized tremulousness, and seizures.

Children are at high risk for the development of brain edema from hyponatremia. Systemic aspects of water intoxication include cardiovascular compromise and pulmonary edema. These complications further jeopardize brain function. Hyponatremia may result in seizures, increasing cerebral energy demand and the rate at which toxic by-products of metabolism accumulate. Brain edema may increase intracranial pressure, further impairing cerebral circulation. Medical conditions that can lead to sodium disorders should be addressed (Table 158-1).

Hyponatremia can also be seen with acute neurologic disorders. Low serum sodium can result from excess renal sodium losses, as in cerebral salt wasting (CSW), or free-water retention, as in the syndrome of inappropriate antidiuretic hormone

(SIADH). CSW is characterized by a negative fluid balance, whereas SIADH is associated with a state of euvolemia or positive fluid balance. Distinguishing between these disorders is critical for management. Treatment of CSW is with sodium replacement and fluids and/or mineralocorticoids, whereas SIADH is treated with fluid restriction. A high index of suspicion for these disorders should exist for patients with acute brain dysfunction and down-trending or low serum sodium levels to minimize complications.

Correction of serum sodium should be done slowly to prevent complications associated with rapid osmolar shifts. Maintenance of circulation may require acute administration of fluid, in which case isotonic sodium is permissible. Volume expansion with hypotonic saline in a hyponatremic patient poses risks if the patient is actually in a sodium-depleted state. The decision to restrict fluids is appropriate if there is evidence of SIADH. Hypertonic saline should be administered in any symptomatic hyponatremic patient. Dialysis is often not necessary unless the patient is anuric or oliguric and fluid overload is the major cause of the sodium abnormality.

The rate of sodium correction is crucial. Excessively rapid correction poses the danger of central pontine myelinolysis. In children, correction at approximately 0.5 to 1 mEq/L/hour should be implemented, until the patient becomes alert and seizure-free, plasma sodium becomes 125 to 130 mEq/L, or the serum sodium level increases by 10 to 15 mEq/L, whichever occurs first. If seizures persist, or if there are signs of increased intracranial pressure (especially if these signs are worsening), the sodium concentration may be corrected at a rate of 4 to 8 mEq/L for 1 hour (if tolerated) or until seizures stop. Assuming that total body water comprises 50% of body mass, administration of 1 ml/kg of 3% NaCl solution will increase plasma sodium by approximately 1 mEq/L.

### Potassium Abnormalities

During the first 48 hours of anuric AKI there is loss of as much as 70% to 80% of renal outer medullary potassium secretory channels and 35% to 40% of the activity of potassium channel inducing factor. Cardiac and pulmonary manifestations of hyperkalemia generally precede and are greater threats to survival than neurologic ones. Cardiac dysfunction is usually the earliest and most ominous sign. However, there are rare instances of hyperkalemia that present with neurologic signs such as striated muscle paralysis.

Other important causes of acute hyperkalemia include rhabdomyolysis and succinylcholine administration to susceptible individuals in the setting of acute muscle damage. Catecholamine elevation in the setting of hypothermia may produce hyperkalemia. A list of causes of potassium disorders is given in Table 158-2.

### Calcium and Magnesium Abnormalities

Neurologic symptoms associated with calcium and magnesium disorders vary and depend on the rate with which these levels change. Typical symptoms of hypocalcemia include mental status changes, muscle irritability, and seizures.

**TABLE 158-1** Causes of Hyponatremia and Hypernatremia

Mechanism	Source	Causative Factor/Disorder
<b>CAUSES OF HYPONATREMIA</b>		
Excessive NaCl loss	Gastrointestinal tract	Diarrhea Cystic fibrosis
	Skin	Heat stress
Excessive water intake	Urinary tract	Salt-losing renal disease
		Adrenal insufficiency
	Diabetes mellitus	
	Psychogenic	
	Oral	Acute kidney injury
		Therapeutic error
	Parenteral	Coma
		Tap water enema
	Rectal	Improperly mixed formula
		Anesthetic drugs
Defective water excretion	Inappropriate antidiuretic hormone secretion	Craniocerebral trauma
		Infection
		Malignancy
<b>CAUSES OF HYPERNATREMIA</b>		
Excess sodium intake		Improperly mixed formula or rehydration solution
		Excessive sodium bicarbonate or chloride administration during resuscitation
Water deficit		Saltwater drowning
		Diabetes insipidus
		Diabetes mellitus
		Excessive sweating
		Increased water loss
		Adipsia
		Inadequate water intake
		Diarrhea
		Osmotic diuretics
		Obstructive uropathy
Water deficit in excess of sodium deficit		Renal dysplasia

Hypercalcemia can present with lethargy, weakness, and confusion. [Box 158-1](#) lists some of the common causes of hypocalcemia, hypomagnesemia, and hypermagnesemia.

The interactions between calcium and magnesium are complex, and each must be considered in situations where the other is present. Hypomagnesemia is a serious condition. Acute deficiency of magnesium is the cause of cramps and tetany. In critically ill patients, development of hypomagnesemia is associated with a twofold to threefold increased risk of death. Hypomagnesemia may be found in as many as 47% of patients with hypokalemia, 27% of individuals with hyponatremia, and 22% of those with hypocalcemia.

Hypermagnesemia may cause neurologic manifestations in AKI, although it is uncommon because normal renal magnesium regulation is efficient.

## Chronic Kidney Disease

Current estimates of the incidence of end-stage renal disease (ESRD) in children is approximately 16 per million in the United States.

### Uremic Encephalopathy

The syndrome of uremic encephalopathy is a spectrum of brain abnormalities resulting from the failure of the kidney to do the following:

1. Regulate fluids and electrolytes
2. Excrete protein catabolites and toxic substances
3. Balance endocrine secretion ([Seifter and Samuels, 2011](#))

**TABLE 158-2** Causes of Hypokalemia and Hyperkalemia

Mechanism	Causative Factor/Disorder	
<b>HYPOKALEMIA</b>		
Deficient intake	Protein-calorie malnutrition	
	Parenteral nutrition	
Renal loss	Distal tubular acidosis	
	Proximal tubular acidosis (Fanconi's syndrome)	
Renal disease	Barter's syndrome	
	Interstitial nephritis	
	Diabetes mellitus	
	Cushing's syndrome	
	Aldosteronism	
	Drug administration (diuretic, aspirin, steroids)	
	Hypomagnesemia	
	Hypercalcemia	
	Alkalosis	
	Drugs (insulin, catecholamines)	
Extrarenal disease	Parenteral nutrition	
	Vomiting, diarrhea	
Shift (extracellular to intracellular)	Fistula drainage	
	Laxative abuse	
	Ion-exchange resins	
	Congenital alkalosis	
	Increase urine output	
	Extrarenal loss	Potassium-containing salt substitutes
		Parenteral administration (excessive infusion, outdated blood)
	Gastrointestinal bleeding	
	<b>HYPERKALEMIA</b>	
Excessive intake	Potassium-containing salt substitutes	
Parenteral administration (excessive infusion, outdated blood)		
Gastrointestinal bleeding		
<b>DECREASED RENAL EXCRETION</b>		
Renal disease	Oliguric kidney injury	
	Chronic hydronephrosis	
Extrarenal causes	Potassium-sparing diuretics	
	Addison's disease	
	Congenital adrenal hyperplasia	
	Diabetes mellitus	
	Drugs (beta blockers, heparin)	
	Rapid cell breakdown (trauma, infection, cytotoxic agents)	
	Acidosis	
	Freshwater drowning	

In developed countries, severe uremia is rare because of the availability of dialysis or renal replacement therapy. Clinical symptoms usually do not occur until the estimated glomerular filtration rate (GFR) is less than 10% of normal. High levels of uremic toxins, advanced glycation end products, inflammatory mediators, excess of parathyroid hormone, and acid-base imbalance may contribute to the development of uremic encephalopathy. Brain edema is uncommon in uremic encephalopathy.

Disturbances of endocrine function occur in uremia, with elevations of parathyroid hormone (PTH), insulin, growth hormone, glucagons, thyrotropin, prolactin, luteinizing hormone, or gastrin. Secondary hyperparathyroidism may contribute to the development of uremic encephalopathy because elevated PTH levels have been clearly linked to the reduction of mental capacity.

**Clinical Features of Uremia.** Clinical symptoms include seizures, encephalopathy, poor feeding, lethargy, tremulousness, and gastrointestinal autonomic dysregulation. Twitching, muscular weakness or tetany, apnea, and paresthesias also may occur. Altered mental status, tremulousness, and muscle cramping tend to occur.

Uremic encephalopathy remains a complicated condition, the pathophysiology of which is likely multifactorial.

**BOX 158-1** Causes of Calcium and Magnesium Abnormalities**HYPOCALCEMIA**

- Vitamin D deficiency
- Hypoparathyroidism
- Pseudohypoparathyroidism
- Hyperphosphatemia
- Magnesium deficiency
- Acute pancreatitis
- Alkalosis
- Rapid correction of acidosis

**HYPERCALCEMIA**

- Vitamin D excess
- Hyperparathyroidism
- Malignancy
- Medications
- Infections
- Sarcoidosis

**HYPOMAGNESEMIA**

- Malabsorption
- Hypoparathyroidism
- Renal tubular acidosis
- Diuretic therapy
- Primary aldosteronism
- Neonatal tetany

**HYPERMAGNESEMIA**

- Decreased renal function
- Magnesium-containing laxatives or enema preparations
- Maternal magnesium sulfate treatment

Encephalopathy is more common in children than in adults with uremia and may present with subtle psychiatric manifestations such as moodiness or depression. Hypocalcemic tetany and a peculiar movement disorder termed “uremic twitching” occur more commonly in children.

Neurologic manifestations to which hypermagnesemia might contribute include lethargy, depression, paresthesias, muscle weakness, and neuropathic changes in cardiac conduction, autonomic cardiovascular regulatory abnormalities, and autonomic aspects of gastrointestinal function. Conditions that might worsen uremic hypermagnesemia are hypothyroidism, Addison’s disease, familial hypercalciuric hypercalcemia, and milk alkali syndrome. As with other electrolyte disturbances, clinically significant hypomagnesemia is found more commonly in infants and elderly individuals, usually in association with chronic kidney disease.

 **Pathophysiology of Uremia.** See online version of the chapter.

**Diagnostic Considerations in Patients With Uremia.** Most cases of chronic uremia are seen in those on dialysis for ESRD. In patients with new-onset renal failure and uremia, there is a wide differential diagnosis to consider for possible causes of neurologic deterioration.

Acute uremic encephalopathy produces deterioration of higher cortical function that varies from slowly progressive to fulminant. The earliest changes include inattention, irritability, and diminished intellectual agility and are often more apparent to caregivers than to the patient. Cognitive deficits may worsen as a consequence of the duration of hemodialysis.

Tremor and asterix are reliable early signs of uremic encephalopathy and should prompt careful mental status

evaluation. With progressive obtundation, encephalopathy becomes less intermittent, and severe disturbances of orientation, memory, cognition, judgment, and primitive reflexes (e.g., snout, root, grasp) may emerge. Transient loss of hearing or vision may develop. Seizures occurring in the later stages of acute uremia generally signify the development of other complications.

Muscle twitching or fasciculations, especially in the distal extremities, are common in acute renal failure. Such activity may be preceded by muscle aches or cramping. Restless-leg phenomenon is not uncommon in uremic encephalopathy. Tetany may develop and may not respond to calcium supplementation. Moderate to severe motor weakness may follow. Multifocal stimulus-sensitive myoclonus emerges as uremic stupor develops. In patients with chronic kidney disease, acute weakness must be distinguished from preexisting changes related to neuropathy or hyperparathyroidism. Endocrinopathies and vitamin deficiency states should be considered because most are treatable. Cardiovascular autonomic dysregulation in uremia is a cause of considerable morbidity and increases mortality risk. Some abnormalities (e.g., emotional and intellectual) may respond quickly to dialysis, whereas others (e.g., motor and sensory) respond more slowly.

Brain imaging is often normal. When present, abnormalities may be transient and of uncertain significance. Elevated lumbar cerebrospinal fluid (CSF) pressure may be found and usually resolves with dialysis. CSF protein concentration may be elevated, and pleocytosis may be found. These changes may occur without identification of any treatable process and may be a result of uremic alteration of BBB function.

**Management of Uremic Encephalopathy.** The primary treatment of uremic encephalopathy is dialysis. Seizures should suggest reevaluation for hypertension, electrolyte or water imbalance, infection, or intoxication (commonly, penicillin or a phenothiazine). Persistent seizures should be treated with antiseizure drugs.

### Congenital Uremic Encephalopathy

Most infants with congenital uremic encephalopathy have inherited forms of nephrosis, particularly congenital nephrosis of the Finnish type. It is possible that some of the neurologic abnormalities in these infants are independently inherited developmental abnormalities or a result of the prenatal metabolic effects of nephrosis. The appearance of abnormalities may present after a latent interval. Early provision of dialysis has not been shown to prevent development of congenital uremic encephalopathy.

Infants with seizures and developmental arrest in the first year of life are at a high risk for developing epilepsy and moderate to severe motor, cognitive, language, and psychosocial delay in later childhood. Neurologic abnormalities include ataxia, choreoathetosis, facial myoclonus, hypotonicity, weakness, and hyperreflexia. If language develops, it is often compromised by dysarthria and lingual apraxia. Renal transplantation may reverse progression of uremic encephalopathy.

### Stroke and Vasculopathy

Vascular accidents may cause acquired neurologic injuries in children with congenital nephrotic syndrome. Ischemic lesions appear to correlate with a history of pretransplantation hemodynamic crises and with greater duration of dialysis before renal transplantation. Attention devoted to ensuring hemodynamic stability in infants undergoing dialysis for chronic renal failure and early consideration of transplantation may improve

outcome. There may be a beneficial effect of folate, pyridoxine, and cobalamin supplements for the prevention of stroke in individuals undergoing peritoneal dialysis.

### Dialysis-Associated Complications

Dialysis is efficacious in the remediation or prevention of acute uremic encephalopathy and is also beneficial in the treatment of uremic peripheral neuropathy. Dialysis is associated with many potential complications. Problems related to the preparation of dialysis fluids are now seldom encountered. When they occur, they tend to manifest as seizures or decline in mental status. Dialysis side effects include headache, fatigue, allergic reactions, and hypotension. Mild to moderate headache is not uncommonly reported by older children. It is likely that dialysis headache is prompted by water and electrolyte shifts or by other aspects of dialysis disequilibrium. Risk can be reduced by adjustment of dialysis parameters. Patients with higher predialysis systolic and diastolic blood pressure may be at greater risk for headache, in addition to those who experience dialysis-related hypotension or weight loss. Metabolic abnormalities should be excluded. Headaches tend to occur after 3 to 4 hours of dialysis and often respond to acetaminophen. Hypertension or subdural hemorrhage should be considered when headache is more severe or persistent, particularly if mental status changes or new focal neurologic signs are present.

### Dialysis Disequilibrium Syndrome

Dialysis disequilibrium syndrome is a rare but serious complication mostly associated with aggressive hemodialysis. Manifestations include irritability, fatigue, headache, nausea, blurred vision, muscle cramps, and tremulousness. Hypertension, elevated intraocular pressure, and asterixis are sometimes seen. The syndrome is likely to occur with recently initiated dialysis, utilization of a rapid dialysis protocol, or dialysis with ultrafiltration, especially when initial serum osmolality is high.

The term *osmotic demyelination* has been applied to some patients who experience neurologic deterioration after dialysis and are found to have pontine abnormalities on T2-weighted magnetic resonance imaging (MRI). These changes may be found with dialysis-associated seizures or mild alterations of consciousness. Repeat scans usually demonstrate the rapid and complete disappearance of these changes. Dialysis removes osmotically active molecules from blood more rapidly than they can diffuse out of the brain. This movement results in an osmotic gradient that provokes net flow of water into the brain, resulting in cerebral edema, increased intracranial pressure, and encephalopathy.

Modifications in dialysis protocols have reduced the frequency of dialysis disequilibrium. The most important element in preventing dialysis disequilibrium is early diagnosis of uremia and initiation of dialysis, so that profound azotemia (blood urea nitrogen  $\geq$  200 mg/dl) is not encountered.

### Dialysis-Associated Seizures

Dialysis-associated seizures occur in 7% to 10% of children (newborn to 21 years) with ESRD. Most are generalized tonic-clonic seizures that occur during or shortly after dialysis. Risk factors include previous seizures, young age, malignant hypertension, uremic encephalopathy, dialysis disequilibrium, and congenital uremic encephalopathy. Seizures occur during the early phases of dialysis. Hemodialysis poses a greater risk for seizures than peritoneal dialysis because of more rapid clearance of electrolytes and other osmotically active solutes.

The efficacy of antiseizure drugs in treating or preventing dialysis-associated seizures is poorly defined. In individuals chronically treated with antiseizure medications, dialysis-associated seizures may be a result of dialysis-related reduction of antiseizure medication concentration.

### Aluminum Toxicity and Encephalopathy (Including Dialysis Dementia)

Aluminum toxicity and dementia related to dialysis and use of aluminum phosphate binding agents in chronic kidney disease have declined over the last decade; however, aluminum can still be found in total parenteral nutrition (TPN) and some drug preservatives. Infants, children, and adults with chronic kidney disease are at risk for aluminum toxicity. See the online chapter for further discussion. 

### Vitamin and Cofactor Deficiencies

The B vitamins are water soluble, and most are readily dialyzable. A single dialysis session may reduce plasma thiamine concentration by as much as 40%. Patients with ESRD continue to be at risk for thiamine deficiency, which causes Wernicke's encephalopathy. Symptoms include a triad of ophthalmoplegia, encephalopathy, and ataxia. Symptomatic thiamine deficiency has been reported rarely in children probably because stores of thiamine accumulated before the development of renal disease are only gradually depleted, and considerable effort is expended by parents and caregivers to ensure good nutrition. Response to intravenous thiamine may confirm the diagnosis.

Pyridoxine deficiency is a risk factor for seizures. Hyperhomocystinuria is an important indicator of vitamin B<sub>12</sub> deficiency. If found, it is associated with higher risk for preeclampsia, neural tube defects in offspring, atherosclerotic arterial disease, stroke, and venous thrombosis. Supplementation with B vitamins is routine to avoid these various complications. Chapters 46 and 47 review the vitamin and other micronutrient deficiency states seen in children.

### Intracranial Hemorrhage

Individuals requiring chronic dialysis for renal failure have an 11-fold greater risk for cerebral hemorrhage and 4-fold greater lifetime risk for subarachnoid hemorrhage. Replacement of generalized with regional anticoagulation and use of nonheparin-based anticoagulation have reduced the risk of this serious complication. Intracranial hemorrhage must be considered in renal patients with persistent drowsiness, headache, vomiting, persistent focal neurologic signs, or meningismus.

### Milder Forms of Encephalopathy

Neuropsychologic studies of children on dialysis have shown lower cognitive functioning. Abnormalities of performance IQ, short-term visual and auditory memory, attention span, memory, and speed of decision making have been documented. The risk is greatest if ESRD developed in early childhood (particularly during the first year of life) or if renal failure is of very long duration. Subtle intellectual and behavioral abnormalities, responsive to dialysis, have been detected. Sensorineural hearing abnormalities may occur in some patients with ESRD as a result of ototoxic medications given during the course of illnesses and multiple hospitalizations. Drugs used for treatment of ESRD and its complications may contribute to encephalopathy.

There is a high prevalence of depression, anxiety, and emotional stress in patients with chronic renal failure. Other

confounding effects include developmental dysmaturity related to chronic hospitalization. A long-term outcome study of individuals who started dialysis before 16 years of age reported good overall quality of life despite coexistent conditions and disabilities.

Poor intellectual function should lead to identification and scrupulous correction of metabolic abnormalities. Moderate uremia may result in disturbances ranging from mild encephalopathy to mild chronic delirium or psychosis. Intellectual dysfunction, deafness, and neuropathy, unresponsive to dialysis, may improve after successful transplantation.

### Uremic Peripheral Polyneuropathy

Peripheral neuropathy occurs in 65% of patients with ESRD. Somatic and autonomic nerves may be involved. As with other neurologic complications, the duration and severity of chronic kidney disease are important determinants of the occurrence and severity of neuropathy.

Electrophysiologic abnormalities consistent with neuropathy are detectable in two thirds of adults with long-standing chronic kidney disease, whether or not dialysis has been initiated. Restless-leg syndrome is among the most common presenting complaints of sensorimotor neuropathy, associated with an unpleasant sensation of crawling skin or a dull ache in the legs that is worse in the evening. Pruritus is common more likely in individuals who also complain of paresthesias.

Hearing is an important modality to be monitored in individuals with chronic kidney disease. Hearing loss may be the result of uremic axonal neuropathy, although other incompletely cleared endogenous or administered ototoxic substances may contribute to this and other neuropathic abnormalities.

Loss of deep tendon reflexes (especially the ankle jerk), diminished vibratory sense, and weakness of great toe extension are among the earliest signs of uremic neuropathy. Paradoxical heat sensation, the tendency to identify a low-temperature stimulus as being hot, is also a sensitive early sign of uremic polyneuropathy. Fully developed uremic neuropathy is a distal, symmetric polyneuropathy that involves sensory and motor modalities. Diminished sensitivity to all modalities in a glove-stocking distribution gradually develops. Pressure palsies, to which chronic renal failure/neuropathic renal disease patients are particularly subject, may alter the expected distribution of abnormalities.

In adolescents and adults on dialysis for ESRD, sudomotor changes and postural hypotension are common consequences of autonomic neuropathy. Delayed gastric emptying can occur in children with chronic kidney disease independent of age, gender, duration of disease, or blood urea nitrogen or creatinine levels. Successful renal transplantation may reverse sympathetic and parasympathetic dysfunction.

The mechanisms of nerve injury in association with end-stage kidney disease remain incompletely understood and are discussed in the online chapter.

### Uremic Myopathy (Myopathy of Chronic Kidney Disease)

Muscle weakness is common in patients with ESRD. The pathogenesis is incompletely understood, and the definition and diagnostic features of the term *uremic myopathy* remain controversial. Diagnosis is often made on the basis of loss of endurance or ability for muscular exercise without muscle physiologic testing or biopsy. Muscle enzymes and electromyography tend to be normal.

Chronic and progressive muscular weakness may be the secondary consequence of "uremic" neuropathy. Uremic vasculopathy is another cause of secondary myopathy. Vascu-

lar myopathy is a necrotic process that has been ascribed to severe hyperparathyroidism with calcification of blood vessels, rather than representing a consequence of autonomic neuropathy. Muscle biopsy abnormalities include atrophy, type grouping, lipidosis, glycogen depletion, and mitochondrial proliferation. Caution is needed to avoid excessive use of calcium-based phosphate binders and vitamin D analogs in the treatment of secondary hyperparathyroidism and hyperphosphatemia in patients with chronic kidney disease. Sudden cardiac death occurs in approximately 25% of adult dialysis patients as a result of multifactorial etiologies, including vascular calcification, calcium abnormalities, and high prevalence of arrhythmias. The rate in children is unknown.

### Malnutrition

Protein and energy wasting are a serious problem in children with chronic kidney disease. Tube feedings and special formulas have improved growth, although motor, speech, and fine motor delays remain evident, especially in the very young. Nutritional disorders are often difficult to dissociate from the metabolic and endocrine dysfunction of chronic kidney disease.

### Endocrinopathy

Secondary hyperparathyroidism with hypercalcemia or hypocalcemia may directly injure the nervous system. Parathyroid hormone excess may directly affect central neurotransmission. Studies in animals and human adults have found that encephalopathy may be prevented or ameliorated with parathyroidectomy.

### Complications Associated With Renal Transplantation

The quality of life, including certain aspects of neurologic function, is generally improved after renal transplantation. Dialysis-associated complications are avoided, and neuropathy usually improves. Cognitive function, head growth, and psychomotor development also improve in many children. Survival also has been extended with kidney transplantations from deceased donors and living relatives. Transplantation entails risk for a particular set of neurologic complications that are usually associated with infection, hypertension, and medications including immunosuppressive agents.

### Infection

Infections may be related to the donor organ, surgical procedure, or presence of a foreign body, including urinary stents. Infections can be severe as a result of immunosuppression during the first few weeks after transplantation. Common gram-positive bacterial infections include *Staphylococcus aureus*, coagulase-negative staphylococcus, and enterococcus; gram-negative organisms include *Escherichia coli*, *Pseudomonas*, *Klebsiella*, and *Enterobacter*.

Donor-derived or naturally acquired fungal infections can be fatal after renal transplantation. It is important to know the endemic areas where these infections can occur, travel history, and donor history. Central nervous system (CNS) infections account for 4% to 29% of CNS lesions in transplant recipients. Given the gravity of these infections, early biopsy of brain lesions and CSF collection for viral polymerase chain reaction (PCR) should be considered.

Meningoencephalitis in transplant recipients is often caused by viral infections, including Epstein-Barr virus (EBV), cytomegalovirus (CMV), West Nile virus, varicella zoster, polyoma virus JCV, and BK virus. EBV and CMV infections

in the first few months after renal transplantation are less common than previously because of the use of antiviral prophylaxis.

## Malignancy

Newer and more powerful immunosuppressants have decreased allograft rejection, but increased the risk of infections and malignancy. In adults, posttransplant malignancies are at least double in transplant recipients compared with the general population. The risk of developing a solid tumor is 6.7-fold higher in pediatric kidney recipients compared with the general pediatric population.

Posttransplant lymphoproliferative disorders (PTLDs) are more common in children than in adults who have received renal allografts and constitute the majority of neoplasms for which these children are at risk. Approximately 1% to 2% of pediatric kidney recipients will develop PTLT within 5 years. The use of lymphocyte-depleting antibodies has been associated with an increase in the incidence of PTLT in children, and CNS involvement carries a poor prognosis. Management includes reduction or cessation of immunosuppression and treatment with a combination of chemotherapy including rituximab (specific anti-CD20 monoclonal antibody), cranial irradiation, and intravenous (IV) ganciclovir. Approximately 72% of pediatric patients achieve CNS remission with the use of intrathecal/intraventricular rituximab in posttransplant EBV associated CNS lymphoma.

## Drugs

Drug-related complications include hypertension, immunosuppression, oncogenesis, and direct neurotoxicity. The use of corticosteroids and calcineurin inhibitors, cyclosporine A and tacrolimus, can lead to posterior reversible encephalopathy syndrome (PRES). Cyclosporine A is a calcineurin inhibitor most commonly associated with neurologic side effects, including paresthesias, peripheral neuropathy, ataxia, tremor, encephalopathy, sympathetic overactivation, headaches, and seizures. Cyclosporine neurotoxicity occurs more frequently in younger children and in those who develop hypertension.

There is evidence that tacrolimus, a more potent immunosuppressant than cyclosporine A, may also have a greater tendency to engender neurotoxicities of the same variety as that associated with cyclosporine use. Tacrolimus has been associated with a posttransplantation encephalopathy that includes MRI-discernible changes in gray and white matter. This syndrome may subside without discontinuation of tacrolimus. Patients who developed neurotoxicity with calcineurin inhibitors have been safely treated with mTOR inhibitors and mycophenolate mofetil without recurrence of their neurologic symptoms. Calcineurin-treated patients also have a higher prevalence and severity of neuropathy.

Administration of the CD3 monoclonal antibody, orthoclone OKT3, to prevent renal allograft rejection may provoke headache, fever, vomiting, a flulike syndrome, hypotension, seizures, or aseptic meningitis in as many as one third of patients. These changes may be severe and can progress to coma. Severe symptoms associated with OKT3 have precluded its use in the majority of renal transplant centers, in lieu of newer and safer medications and biologic agents.

## Hypertension

### Hypertensive Encephalopathy

The designation *hypertensive encephalopathy* is generally reserved for hypertensive patients with alteration of consciousness with diffuse or multifocal CNS dysfunction, in whom there is no better or more complex etiologic explanation. Malignant

hypertension leading to hypertensive encephalopathy can arise in association with a number of underlying illnesses, including aortic coarctation (30%) and polycystic kidneys (30%), nephritis (16%), and hemolytic-uremic syndrome (7%). The causes of malignant hypertension in children are age dependent. Increased sophistication in imaging has led to increased recognition of PRES and concomitant redesignation of cases that would previously have been designated as hypertensive encephalopathy.

More than 40% of patients with malignant hypertension develop significant neurologic complications. The risk for hypertensive encephalopathy is related to the rapidity and severity of blood pressure increases from any given baseline. Risk is higher in patients with acute renal failure. When hypertensive encephalopathy occurs in children, it carries a high risk of morbidity and mortality.

**Clinical Features of Hypertensive Encephalopathy.** Clinical symptoms include a combination of hypertension, headache, encephalopathy, and visual disturbances. The headache typically develops hours to days after the initiating blood pressure crisis and may be accompanied by lethargy, projectile vomiting, meningismus, or edema of the eyelids and ankles. Ophthalmoscopic findings include fundoscopic evidence of arteriolar spasm or ischemic nerve fiber infarction. Papilledema is present in one third of children with hypertensive encephalopathy.

Newborns and infants with hypertensive encephalopathy can present with irritability, lethargy, and unresponsiveness. Encephalopathy in older children may consist of fluctuating confusion, irritability, and restlessness that may progress to coma. Mental status changes typically develop 12 to 36 hours after headache onset. Seizures may occur and are more commonly generalized.

Focal neurologic signs may signify more permanent injury. Unilateral infarction of some portion of the anterior optic pathways is especially characteristic. Infarction may be more common in patients who have had long-standing unrecognized hypertension. It also may occur in individuals who experience hypotensive episodes as a result of overly aggressive management of blood pressure elevation.

**Pathophysiology of Hypertensive Encephalopathy.** The exact nature of the pathophysiology of hypertensive encephalopathy is not fully understood, but two major theories are advocated. Both propose dysfunction of cerebral autoregulation, with one favoring excessive vasoconstriction with secondary ischemia. The other theory proposes a vasoconstrictive threshold that is exceeded, resulting in the development of transudative perivascular edema, which then compresses the regional microvasculature. Microinfarction, edema, and loss of autoregulation can occur, necessitating caution in blood pressure reduction and manipulation of cardiac output because rapid changes may result in acute cerebral infarction.

**Diagnostic Considerations in Patients With Hypertensive Encephalopathy.** The differential diagnosis for hypertensive encephalopathy is broad. Structural CNS lesions, encephalitis (infectious or immune mediated), and seizures should all be considered in the initial evaluation. Focal lesions, such as infarction, intracranial hemorrhage, or tumor, may be the cause of the hypertension. Alternatively, focal lesions, such as PRES or cerebral ischemia, may be the consequence of the hypertension.

### Outcomes From Hypertensive Encephalopathy

Outcome in hypertensive encephalopathy is generally favorable. Encephalopathy and seizures resolve with correction of

blood pressure. Visual disturbances are typically reversible but occasionally can persist. The degree and duration of the hypertensive phase are important elements in the risk for visual dysfunction, underlining the importance of early diagnosis and treatment.

### Posterior Reversible Encephalopathy Syndrome

PRES is thought to represent a disorder of cerebral autoregulation occurring in the setting of acute hypertension and manifest as acute neurologic symptoms associated with stereotypical radiographic changes. The phenomenon was first described in patients with hypertension, but it is now thought to be associated with a variety of conditions and may occur in children with or without hypertension. Populations known to be at risk for PRES include children with autoimmune disease, renal or hematological disorders, and bone marrow or solid-organ transplantation. An increasing number of medications are associated with PRES. Risk is highest with immunosuppressive medications, including monoclonal antibodies, calcineurin inhibitors, steroids, and cytotoxic medications.

**Clinical Features of Posterior Reversible Encephalopathy Syndrome.** Clinical features of PRES include fairly sudden onset of severe headache, encephalopathy, seizures, and visual disturbance. Symptoms typically resolve spontaneously or after correction of blood pressure. Recurrent PRES is not uncommon.

Brain imaging usually illustrates fairly symmetric and extensive abnormalities within 24 hours of clinical onset that are much more apparent on MRI than on computed tomography. Changes are both cortical and subcortical and generally without diffusion restriction.

**Diagnostic Considerations in Patients With Posterior Reversible Encephalopathy Syndrome.** A broad differential diagnosis should be considered when making a diagnosis of PRES. Other considerations include vasculitis, hypoxic ischemic injury, infectious or immune-mediated encephalitis, acute disseminated encephalomyelitis, toxic leukoencephalopathy (e.g., methotrexate toxicity), and/or osmotic demyelination syndrome.

**Management of Posterior Reversible Encephalopathy Syndrome.** Management of PRES largely consists of supportive care. Severe blood pressure elevation should be treated aggressively. Blood pressure reduction is likely to be well tolerated except in the setting of chronic hypertension or cerebral vasculopathy.

Seizures should be treated aggressively, and continuous electroencephalogram (EEG) monitoring should be employed to assess for subclinical seizures. Medications should be renally dosed for children with renal insufficiency/failure. Electrolytes should be normalized, with close attention to sodium, calcium, and magnesium. Chronic anticonvulsant therapy is seldom required.

## DISEASES AFFECTING BOTH KIDNEY AND NERVOUS SYSTEM

Diseases that affect both the kidney and the nervous system can be divided into four general categories:

1. Inflammatory/vascular
2. Infectious
3. Toxic or metabolic
4. Heritable disorders with brain and renal anomalies

The inflammatory/vascular illnesses, which are considered first in this section, include thrombotic thrombocytopenic

purpura, hemolytic-uremic syndrome, and other thrombocytopenic microangiopathies. Additional disorders such as hepatorenal syndrome, Henoch–Schönlein syndrome, and familial amyloidosis are also reviewed. Systemic lupus erythematosus, polyarteritis nodosa, and Wegener's granulomatosis are examples of other illnesses that produce inflammatory changes in both the nervous and renal systems. The details of these illnesses are covered in Chapter 121.

Infections with a predilection for renal and neurologic involvement include bacterial infections, such as Shiga-toxin-producing *E. coli*-associated hemolytic-uremic syndrome (STEC-HUS) and *S. aureus* infections; infections with viruses such as adenovirus, enteroviruses, coxsackieviruses, and echoviruses; and infections caused by fungi such as *Candida* spp. and *Aspergillus*.

A variety of toxins ranging from metals (e.g., lead, mercury, aluminum) and illicit substances (cocaine and heroin) to household products (e.g., ethylene glycol) and insecticides such as malathion, chlorpyrifos, and dichlorvos are known to cause brain and kidney dysfunction. Rare inherited metabolic diseases are a vast category of diseases with potential for multiorgan involvement. Examples of subtypes with a predilection for kidney and brain disease include glycogen storage and lysosomal storage disorders (e.g., Gaucher disease and Fabry disease).

Many inherited disorders include brain and kidney involvement. Polycystic kidney disease is associated with an increased risk for cerebral aneurysms and arachnoid cysts.

Hereditary angiopathy with nephropathy, aneurysms, and muscle cramps syndrome (HANAC) includes kidney disease, cerebral aneurysms, and myopathy. Von Hippel–Lindau disease is a genetic disorder with a predisposition to malignancies, including CNS neoplasms, such as endolymphatic sac tumors and craniospinal hemangioblastomas, and renal masses, such as renal cysts and carcinomas. Sickle-cell disease is a chronic hematologic disorder with a high risk for cerebral vasculopathy, stroke, and kidney abnormalities ranging from proteinuria to ESRD.

### Thrombotic Thrombocytopenic Purpura

The clinical diagnosis of thrombotic thrombocytopenic purpura (TTP) requires at least two major (thrombocytopenia, Coombs-negative microangiopathic anemia, or neurologic dysfunction) and two minor (fever, renal dysfunction, or circulating thrombi) manifestations, permitting the diagnosis to be made in the absence of either renal or neurologic dysfunction. Determining the boundaries between TTP and a number of other microangiopathic conditions, collectively termed thrombotic microangiopathies, was challenging until recently.

It is now understood that TTP and HUS are distinct entities. TTP-associated thrombi are rich in platelets and are found in the heart, pancreas, kidney, adrenal glands, and brain, in decreasing order of severity. HUS-associated thrombi are rich in fibrin/red cells, and they tend largely to be confined to the kidney. TTP thrombi are found in the brains and kidneys of 50% to 75% of individuals with fatal TTP. Brain thromboses of TTP occur in small arterioles, capillaries, and venules and are associated with microinfarction. Small petechial hemorrhages may be widely scattered in gray matter. Diagnostic tests are available that reliably designate most heritable and acquired TTP cases. Classification of thrombotic microangiopathies is described in the online version of the chapter (James et al., 2014).

Signs and symptoms of acute TTP usually evolve quickly and quite noticeably over 7 to 10 days. Skin purpura is the initial manifestation in more than 90% of patients. Fever usually develops early. Hemorrhage (retinal, choroidal, nasal,

gingival, gastrointestinal, and genitourinary), abdominal pain, arthralgia, or pancreatitis may also develop. Neurologic findings include fatigue, confusion, headache, and varying degrees of dysfunction of vision or language. Significant laboratory findings include microangiopathic hemolytic anemia, thrombocytopenia, elevated lactate dehydrogenase, proteinuria, and microscopic hematuria. CSF chemistry, cell counts, and pressure are usually normal. Other findings associated with disseminated intravascular coagulopathy are not usually found. MRI of brain is often normal.

Plasma exchange is the therapy of choice. A survival rate of at least 80% has been found for plasma exchange, compared with 60% survival for patients randomized to plasma infusion. Plasma infusions may be used as a temporizing measure in patients with suspected TTP until plasma exchange can be instituted because of the high risk for morbidity and mortality if therapy is delayed. In addition to therapeutic plasma exchange, immunosuppressant therapy with corticosteroids is indicated in patients with acquired TTP (Blombery and Scully, 2014).

Most cases of TTP are monophasic, but 11% to 28% of patients experience one or more recurrences. Relapses can occur weeks to years after initial remission. For severe or recurrent cases, chronic plasmapheresis is useful. Rituximab can be used for initial therapy and in refractory or relapsing cases.

## Hemolytic-Uremic Syndrome

HUS is a Coombs-negative thrombocytopenic microangiopathy, the onset of which is typically in early childhood. Classic HUS, also known as D + HUS or STEC-HUS, occurs with a prodrome of diarrhea and is secondary to infections with Shiga-toxin-producing *E. coli*, although other bacterial infections have been associated with D + HUS. HUS that occurs in the absence of a diarrheal illness is labeled D-HUS or atypical HUS (aHUS). aHUS is considered to be a disorder of the alternate complement pathway involving dysregulation and increased terminal complement pathway activation. Multiple genetic mutations in the complement pathway have been identified as risk factors for the development of aHUS. Other forms of D-HUS include infection-related HUS that occurs with nondiarrheal illnesses, such as HUS associated with *Streptococcus pneumoniae* infections or drug-induced HUS. Most cases occur in children younger than 5 years of age; however, HUS associated with *E. coli* outbreaks can occur in patients at any age (Trachtman, 2013). HUS that presents in infancy is often noninfectious and is secondary to familial or genetic mutations. HUS can have multisystem involvement with associated cardiac, liver, and pancreatic dysfunction (Trachtman, 2013).

Neurologic manifestations of HUS—most commonly, seizures, stroke, and varying degrees of encephalopathy—are seen in 30% to 40% of patients. Occurrence of neurologic abnormalities predicts a worse outcome, with enhanced risk for ESRD or death. It is not always clear whether such neurologic changes are the result of cerebral microangiopathy or are secondary to metabolic disturbances and hypertension. MRI of the brain may disclose focal areas of infarction with swelling and, in some patients, hemorrhage.

## Treatment

Management of patients with D + HUS is supportive, with attention to fluid and electrolyte management, hypertension control, and judicious use of blood transfusions. HUS-associated renal failure usually persists for several weeks. Dialysis is required in 30% to 50% of patients and is indicative of a poorer prognosis. Patients with aHUS are more likely to

develop severe AKI requiring dialysis. Most patients with D + HUS will recover renal function, as opposed to patients with aHUS, who often develop chronic kidney disease or dialysis dependency.

Patients with aHUS have a more prolonged course with a higher incidence of morbidity and mortality. Eculizumab, a complement inhibitor, has been used successfully in the treatment of patients with aHUS and is considered the first line of therapy in patients with suspected complement-mediated aHUS (Loirat et al., 2016). Renal transplantation is indicated in patients with chronic kidney disease secondary to HUS; however, patients with aHUS are at a high risk for HUS recurrence posttransplantation.

## Vasculitic Diseases With Neurologic-Renal Presentations

Extended consideration of the various inflammatory disorders can be found in Chapters 109, 112, 121, 142, and 150.

## Hepatorenal Syndrome

Hepatorenal syndrome (HRS) is defined as the presence of functional, potentially reversible AKI that occurs in patients with various forms of liver failure in the absence of hypovolemia or other identifiable causes for AKI. It is divided into two types. Type 1 includes patients with AKI with rapidly deteriorating renal function in association with acute severe hepatic dysfunction. It can be fulminant and carries a high risk for death. Encephalopathy is common in type 1. Type 1 hepatorenal syndrome is rare in childhood. Type 2 includes patients who manifest the combination of less severe liver and renal disease with a slow progressive course and evidence of chronic liver and concurrent kidney disease. Encephalopathy is less common in type 2 cases. Some form of hepatorenal syndrome develops in as many as 20% of patients who are in their first year of acute or subacute hepatic failure.

Clinical features include ascites, jaundice, and low arterial blood pressure, despite increased plasma volume. The hepatorenal syndrome is often precipitated by infections such as spontaneous bacterial peritonitis or with aggressive diuresis or paracentesis. Laboratory findings consistent with AKI include a rise in serum creatinine from baseline values with concurrent evidence of a prerenal state in the form of a normal urine analysis, a low urinary sodium clearance, and a high urine osmolality.

Therapy is based on replenishing the low effective circulatory volume with fluids, albumin infusions, and correction of the vasomotor dysregulation with vasoconstrictors. Other supportive therapies include the institution of renal replacement therapies, such as hemodialysis in patients with severe hyponatremia, azotemia, or other metabolic disturbances. Combined liver-kidney transplantation may be considered when patients remain dialysis dependent or have evidence of chronic kidney disease (Sampaio, Martin, and Bunnapradist, 2014; Eason et al., 2008).

## Amyloidosis

Amyloidoses are a group of rare disorders of amyloid proteins that affect the kidney and the brain. They can be divided into the hereditary (primary) type and those that constitute the secondary (reactive) group. Renal amyloidosis is uncommon in children and is often secondary to chronic infectious or inflammatory diseases such as familial Mediterranean fever (Bilginer, Akpolat, and Ozen, 2011). These disorders are discussed in the online chapter.

## Metabolic Diseases Producing Generalized Renal and Neurologic Dysfunction

Both acute and chronic generalized nephron dysfunction may result from metabolic diseases that have primary effects on the kidney and nervous system. Diseases that are most likely to result in encephalopathy are those that produce the combination of chronic metabolic and catabolic dysfunction in association with acute renal failure. Under such conditions, the metabolic perturbation worsens more rapidly and often achieves greater severity. Systemic diseases that can provoke encephalopathy, even without renal failure (e.g., sepsis, burns, fever, ethylene glycol, lactic acidosis, or ketoacidosis), produce more fulminant, severe, and difficult-to-treat nervous system dysfunction when renal failure also occurs or was previously present. Therapeutic interventions must include attention to cerebrovascular dynamics because cardiac output is often low, and cerebral autoregulation is often compromised.

### Selective Tubular Dysfunction

Many inherited diseases and intoxications produce characteristic patterns of renal tubular acidosis in association with neurologic abnormalities; glomerular function is usually preserved in these diseases. Renal tubular acidosis is generally characterized by hyperchloremia and reduced plasma bicarbonate, and is further divided into proximal (bicarbonate-wasting) or distal (defective acid-excreting) renal tubular varieties. Selective tubular dysfunction itself produces far fewer clinical manifestations than are observed in uremia. In many instances, the neurologic dysfunction is more apparent than the associated renal dysfunction, which is often overlooked.

### Proximal Renal Tubular Acidosis

Proximal renal tubular acidosis (proximal RTA) refers to the condition characterized by urinary bicarbonate loss secondary to an isolated proximal tubular dysfunction, which leads to hyperchloremic non-anion-gap metabolic acidosis. Proximal RTA can occur as an adverse effect of medications, such as carbonic anhydrase inhibitors. It can occur transiently in infants and preterm babies as a result of lack of renal tubular maturation. Isolated proximal RTA can be primary in origin as a result of inherited genetic mutations, but it is more commonly seen secondary to medications or other systemic illnesses (Haque, Ariceta, and Batlle, 2011).

Clinical presentation includes a history of recurrent dehydration and failure to thrive, along with polyuria and polydipsia in older children. Laboratory evaluation will reveal a normal anion gap and metabolic acidosis. Urinary acidification will be impaired with a urine pH less than 5.5. Fractional excretion of urinary bicarbonate will be high, providing evidence of urinary bicarbonate loss. In patients with the Fanconi's syndrome, hypophosphatemia and hypokalemia may be seen. Urine studies will confirm the presence of generalized aminoaciduria along with glycosuria despite normal serum glucose.

### Nephropathic Cystinosis

Nephropathic cystinosis, caused by a defective lysosomal membrane transport protein, is the most common identifiable cause of renal Fanconi's syndrome in children. Mutations in the *CTNS* gene located on 17p13.2 result in defective cystinosis. Presentation is usually that of symptoms of failure to thrive and recurrent dehydration. Laboratory evaluation is consistent with Fanconi's syndrome with progressive renal dysfunction. The diagnosis is confirmed by detection of

elevated white blood cell (WBC) cystine levels, genetic analysis, and/or the presence of cystine crystals seen on slit-lamp examination (Emma et al., 2014).

Before renal transplantation was available, it was thought that neurologic abnormalities occurred only as consequences of renal dysfunction. With the prolonged survival, it has become clear that the infantile and juvenile forms may be associated with visual, intellectual, and motor abnormalities that result from cystine accumulation in the eye (cornea, conjunctiva, retina) or brain (choroid plexus, cortex). Other neurologic consequences develop at various ages from childhood to adulthood. They may include headache; autonomic abnormalities (heat intolerance, hyperthermia, abnormal sweating); poor vision and deficient visual memory; short, raspy, repetitive speech; tremor; pyramidal or extrapyramidal motor defects; and weakness. Selective impairment of visual processing is a frequent finding. Abnormal tactile recognition with astereognosis has been discerned in some patients. These subtle deficits are the likely basis of some of the school difficulties experienced by children with nephropathic cystinosis. Intellectual deficits are mild and may be static or slowly progressive.

Some patients experience severe and strikingly progressive neurologic complications. Cystinosis-related encephalopathy is an entity characterized by cerebellar and pyramidal signs, with ensuing mental deterioration, and then development of pseudobulbar or bulbar palsy with a prominent swallowing disorder. Evidence suggests that cysteamine may reverse cystinosis-related encephalopathy, improve the radiologic appearance of the brain, and prevent paroxysmal episodes.

One quarter of patients with long-standing nephropathic cystinosis develop distal lipid inclusion myopathy. This result may be the direct effect of cystine toxicity, although carnitine deficiency and other potential causes may contribute. Patients with cystinosis-related myopathy develop weakness and wasting of small hand muscles, facial weakness, and muscular dysphagia. Biopsies may indicate a vacuolar myopathy of lysosomal origin.

Additional heritable diseases that may result in a combination of neurologic and renal manifestations are listed in Table 158-6.

## NEUROLOGIC DRUGS THAT MAY AFFECT RENAL FUNCTION IN INDIVIDUALS WITH NORMAL KIDNEYS

Some drugs commonly used in the management of neurologic diseases may produce disturbances of renal function that range from mild transient effects on the regulation of free-water clearance to severe parenchymal kidney injury. Important effects of selected neurologic drugs on renal function are summarized in Table 158-7.

It is well known that carbamazepine and oxcarbazepine can produce hyponatremia. Prevalence with carbamazepine treatment is approximately 5%. Mild hyponatremia is seen in 18% to 25% of oxcarbazepine-treated children, with more severe hyponatremia (i.e., <125 mM/L) seen in no more than 3%. Symptomatic hyponatremia is found in 2% or less.

The mechanism of hyponatremia with either of these drugs is unknown. Although SIADH was formerly thought to explain the effect, it has recently been shown that this is not the case (at least for carbamazepine). Clinical manifestations of hyponatremia are rare in children treated with either carbamazepine or oxcarbazepine.

Lamotrigine use in children with centrally mediated diabetes insipidus has been found to induce hyponatremia as a result of change in desmopressin requirements. Acetazolamide

**TABLE 158-6** Syndromes With Kidney Malformation and Neurologic Disease

Syndrome (Inheritance)	Kidney	Neurologic	Syndrome (Inheritance)	Kidney	Neurologic
Bardet–Biedl (AR)	Congenital renal cysts Renal dysplasia	Mental retardation Visual abnormalities	Pallister–Hall (Sp)	Renal dysplasia	Tumors CNS migrational abnormalities

AD, autosomal dominant; AR, autosomal recessive; CNS, central nervous system; MURCS, Müllerian duct renal and cervical vertebral defects; Sp, sporadic.

may provoke a selective form of proximal renal tubular acidosis manifested by bicarbonate wasting without generalized proximal tubular dysfunction. Phenytoin, conversely, may inhibit the secretion of antidiuretic hormone, resulting in diabetes insipidus. Phenytoin-induced lupus may, in turn, produce lupus-related nephropathy.

Tricyclic drugs may interfere with the action of some anti-hypertensive medications and may provoke urine retention. Nifedipine may worsen the edema of renal failure.

Other drugs commonly employed for management of neurologic diseases can cause acute interstitial nephritis, including phenytoin, phenobarbital, carbamazepine, cimetidine, amphetamine, and interferon-alpha.

Valproic acid has direct effects on renal tubular ammonia metabolism. The increased renal ammoniogenesis may combine with valproate-related inhibition of hepatic ureagenesis to produce the hyperammonemia that is observed in some children with therapeutic serum valproate concentrations. Chronic valproate administration may result in proximal renal tubular dysfunction.

Acyclovir may result in acute renal failure. Coadministration of cephalosporins, which compete for tubular excretion, may increase the nephrotoxic risk of acyclovir administration.

## DRUG THERAPY IN RENAL DISEASE

Renal dysfunction may have significant effects on drug disposition, including many drugs administered to treat neurologic complications of renal disease. Renal dysfunction may affect drug binding, hepatic biotransformation, or renal clearance. Drug binding (especially of acidic drugs) may be affected by poor nutrition, protein loss, or competition with the weak organic acids that accumulate in uremia. Biotransformation may be affected by changes in the free fraction of a drug or, as is the case with phenytoin, by unknown mechanisms. Renal clearance is of little importance for some drugs but of great importance for others (e.g., barbiturates, levetiracetam, gabapentin). Drug penetration into the CNS or systemic clearance may be altered in renal failure.

## Drug-Induced Encephalopathy in Renal Failure

Encephalopathy is the most common consequence of pharmacologic changes with renal failure, with manifestations ranging from subtle intellectual impairment to hallucinations, agitation, confusion, delirium, or coma. Drugs most commonly implicated are antibiotics, antihistamines, antihypertensives, and neuropsychiatric medications.

**TABLE 158-7** Drugs/Toxins Affecting Nervous System and Kidney

Drug	Neurologic	Renal
Analgesics	Encephalopathy Headache	Proximal renal tubular acidosis Renal Fanconi's syndrome Distal renal tubular acidosis
Arsenic	Encephalopathy Headache Peripheral neuropathy and/or myopathy	Proximal renal tubular acidosis Chronic renal failure
Burn toxin	Encephalopathy	Proximal renal tubular acidosis
Cadmium	Encephalopathy Seizures Peripheral neuropathy and/or myopathy	Proximal renal tubular acidosis Renal Fanconi's syndrome
Chromium	Encephalopathy	Acute renal failure Chronic renal failure
"Ecstasy"	Encephalopathy Seizures	Acute renal failure
Ethylene glycol	Encephalopathy	Acute renal failure Chronic renal failure
Gallium	Blindness Peripheral neuropathy and/or myopathy	Acute renal failure Chronic renal failure
Indium	Encephalopathy Seizures Peripheral neuropathy and/or myopathy	Acute renal failure Chronic renal failure
Lead	Encephalopathy Peripheral neuropathy and/or myopathy	Proximal renal tubular acidosis Renal Fanconi's syndrome
Lithium	Encephalopathy Delirium	Distal renal tubular acidosis
Mercury	Encephalopathy Myopathy	Proximal renal tubular acidosis Renal Fanconi's syndrome
Mycotoxin	Encephalopathy	Proximal renal tubular acidosis
Pentazocine	Encephalopathy Delirium Headache	Distal renal tubular acidosis
Tellurium	Encephalopathy	Acute renal failure Chronic renal failure
Tetracycline	Pseudotumor	Proximal renal tubular acidosis Renal Fanconi's syndrome
Thallium	Encephalopathy Seizures Guillain-Barré syndrome	Proximal renal tubular acidosis Renal Fanconi's syndrome Distal renal tubular acidosis
Toluene	Encephalopathy Long-tract signs Seizures Delirium Pseudotumor	Proximal renal tubular acidosis Distal renal tubular acidosis
Xylitol	Encephalopathy Seizures	Acute renal failure Chronic renal failure

Although a careful drug history is often of greater importance in ascertaining the deleterious drug than the symptom pattern or serum levels, some clinical findings are relevant. Agitation, emotional lability, and anticholinergic signs suggest antihistamines or neuroleptics. Anticholinergic effects may include life-threatening cardiorespiratory impairment. Myoclonus may result from penicillins, chelated aluminum, cyclosporine, nitroprusside, tricyclic antidepressants, phenothiazine, or meperidine. Established "toxic levels" of medications may not always represent reliable guides in renal failure because unmeasured toxic metabolites may accumulate. Therefore trial withdrawal of expendable or especially toxic medications may be necessary. Recovery from medication effects may require weeks to months.

### Treatment of Seizures Associated With Renal Disease

Seizures are common problems in children with renal disease. Management generally involves treatment of precipitating causes and correction of metabolic disturbances. However, some individuals with renal disease experience prolonged seizures or develop epilepsy and require acute or chronic treatment with antiseizure medications.

Longer-term or even chronic treatment with an antiseizure medication must be undertaken when the risk for seizure recurrence is high. Usage is guided by medication level, known pharmacokinetics and pharmacodynamics of the antiseizure medication, the extent to which these are likely to be altered at a given level of reduction of renal creatinine clearance or by dialysis, and the degree of hepatic dysfunction.

### Concerns About Specific Antiseizure Medication Use in the Setting of Renal Failure

**Phenytoin.** Renal failure mandates adjustment of dosages and/or dosing intervals of many antiseizure medications. The effects of chronic renal failure on drug disposition are greatest for phenytoin. Protein binding may decrease by as much as threefold in uremia or nephrotic syndrome as a result of hypoalbuminemia and the presence of competitive or non-competitive inhibitors of binding (uremic or dialysis related). Conversely, the steady-state plasma concentration for a given dose of phenytoin also decreases by twofold to threefold as a result of an increase in the apparent volume of distribution and shortened half-time of elimination. It is particularly important to monitor phenytoin levels carefully in patients with renal failure because of the nonlinear kinetics of this drug and narrow therapeutic window. Levels should be followed with free-phenytoin concentrations because total phenytoin levels are unreliable. Dosing intervals should be 8 hours or less because administration of larger, less frequent doses may produce toxic symptoms. Hemodialysis has little effect on total serum phenytoin concentration but may decrease free-phenytoin levels to variable degrees. Heparinization for dialysis may displace bound phenytoin, resulting in transient toxicity.

Chronic phenytoin therapy may aggravate renal osteomalacia, especially in the setting of renal disease. Risk for osteomalacia is higher for individuals with reduced mobility.

**Valproate.** Although few good studies are available, valproic acid is subject to pharmacokinetic changes similar to phenytoin when administered to patients with renal failure. Valproic acid appears to be moderately dialyzable, and hence hemodialysis may be indicated with severe valproic acid poisoning. Development of valproate-associated pancreatitis with

hepatic dysfunction has been suggested as a condition for which there is greater risk in children with ESRD.

**Barbiturates.** Phenobarbital elimination depends in part on the GFR and urine pH, but there are few data on its disposition in renal failure. Over the short term, renal failure usually has little effect on serum phenobarbital levels. Long-term phenobarbital therapy in severe renal disease may require dosage reduction. Postdialysis doses are usually necessary because phenobarbital is readily dialyzed, especially by hemodialysis. Pentobarbital, on the other hand, is poorly dialyzable.

**Carbamazepine.** Carbamazepine bioavailability and clearance are unlikely to be greatly affected by renal disease because it is predominantly metabolized in the liver, and less than 5% is excreted unchanged in the urine. Studies have demonstrated removal with dialysis to a moderate degree, and hence hemodialysis is recommended for severe carbamazepine poisoning.

**Oxcarbazepine.** The glucuronide metabolites of oxcarbazepine may accumulate in patients with severe renal dysfunction, but the concentration of the monohydroxy derivative (MDH) that provides most of the antiseizure effect accumulates because only about 25% of this metabolite is renally excreted. Creatinine clearance is a useful index for estimating dosage adjustment in the setting of renal failure. There is limited information on the efficacy of hemodialysis for oxcarbazepine.

**Ethosuximide.** Ethosuximide has not been well studied, perhaps because it is seldom (although sometimes) used in patients with renal disease. It is likely to be readily dialyzable.

**Levetiracetam.** Less than 10% of circulating levetiracetam is protein bound, and as much as 90% is excreted in the urine—more than two-thirds unchanged and the remainder as inactive metabolites. It is not metabolized in the liver; hence, in patients with renal failure, dosage must be modified in accordance with the degree of decline in creatinine clearance.

**Zonisamide.** Approximately two thirds of zonisamide elimination is accomplished by the kidneys, either unchanged or as a glucuronide conjugate. Renal clearance also diminishes with diminished creatinine clearance. With severe renal failure (creatinine clearance < 20 ml/minute), zonisamide accumulation may result in serum concentrations approximately one-third greater than otherwise anticipated. It must be borne in mind that the very long elimination time of this drug means that steady-state elevation will not be achieved for a considerable interval after introduction or dose modification.

**Lamotrigine.** Lamotrigine inactivation is the result of hepatic conjugation with ensuing elimination of the predominantly 2-*N*-glucuronate adduct. At least 94% of elimination of this metabolite is renal; hence, accumulation occurs with renal failure. The mean plasma half-life of the drug is more than 40 hours in renal failure, compared with 26 hours in patients who do not have renal or hepatic failure. It has been suggested that lamotrigine (Lamictal) may elevate risk for renal stones by twofold to fourfold, compared with the expected risk of the underlying disease.

**Gabapentin.** Gabapentin is not appreciably metabolized, so elimination is achieved almost entirely as unchanged drug in the urine. The usual elimination half-life of 5 to 7 hours is increased to a mean of 132 hours for creatinine clearance less than 30 ml/minute without dialysis, or to approximately 50 hours in end-stage chronic renal failure with thrice-weekly dialysis. Published dosage tables for renal failure in adults receiving hemodialysis are available.

**Benzodiazepines.** Benzodiazepines (especially clonazepam) are useful in controlling uremic myoclonus and may not require dosage alteration for acute administration in renal failure, although protein binding may be reduced. Diazepam and lorazepam require reduction more often than clonazepam. Diazepam is not readily dialyzable. Little information is available concerning the dialysis of other benzodiazepines.

## Kidney Stones

The risk for urolithiasis is elevated with the utilization of carbonic anhydrase inhibitors, including acetazolamide, zonisamide, and topiramate. Risk may be particularly high with a positive family history of urolithiasis and elevation of the calcium:creatinine ratio, or if these medications are used in combination. The ketogenic diet is associated with risk for stones, and the diet is thought to double the risk for kidney stones associated with any particular carbonic anhydrase inhibitor.

## Other Neurologic Drugs

A number of other medications commonly used in the therapy of neurologic disease should be administered with caution in patients with renal failure. Both aspirin and acetaminophen require longer interdose intervals in renal failure. Aspirin should not be administered when the GFR is less than 10 ml/minute. Both of these analgesic drugs are readily cleared by dialysis.

Acetazolamide is entirely eliminated by renal mechanisms. The dosage should be reduced for renal failure and avoided in ESRD and in patients with acidosis, hypokalemia, or urolithiasis (all of which may be worsened by its administration). Tricyclic drugs are not dialyzed well but usually do not require dosage changes in renal failure. Alpha and calcium-channel blockers are not readily cleared by dialysis. Dosage may require adjustment in severe renal failure. Haloperidol is not well dialyzed and may provoke hypotension in patients with renal failure. Lithium is a dialyzable drug that requires a longer interdose interval in renal failure. It should be avoided in patients with renal disease because of potential aggravation of renal tubular acidosis or provocation of nephrogenic diabetes insipidus or chronic interstitial fibrosis. Considerably greater detail concerning the management of drugs pertinent to neurologic and other forms of medical practice in children with renal failure is available in several previous reviews.

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

The gastrointestinal (GI) tract and nervous system are inter-related. GI and liver abnormalities are associated with central nervous system (CNS) disease, and CNS abnormalities can cause GI dysfunction. The CNS depends on the GI system for the intake, absorption, and metabolism of important nutrients, including those required for normal brain function and for the removal of toxic metabolic wastes. GI impairment may interfere with these functions. Some neurologic complications of GI diseases are nutritional, such as those related to malabsorption of vitamin B<sub>1</sub>, nicotinamide, vitamin B<sub>12</sub>, vitamin D, and vitamin E. Other complications are related to the toxic effects of waste products (e.g., ammonia). Conditions affecting the GI tract may affect the CNS and the peripheral nervous system. For instance, cerebrovascular diseases can complicate hepatitis C infection and inflammatory bowel disease; encephalopathy can be caused by hepatic disease; antitumor necrosis factor alpha drugs may induce demyelination; and antigliadin antibodies, a marker of celiac disease, can be found in subjects with neurologic dysfunction of unknown cause, particularly in sporadic cerebellar ataxia, in addition to cerebral, brainstem, and peripheral nerve abnormalities. Characteristic movement disorders are key features of acquired hepatocerebral degeneration and of Whipple's disease. Multiple types of neuropathy can be found in association with hepatitis, inflammatory bowel disease, and gluten-related disorders. The severity of neurologic disease can vary—from minor cognitive changes in chronic portosystemic encephalopathy and hepatitis C to coma in acute liver failure and acute pancreatitis (Ferro and Oliveira, 2014; Datar and Wijidicks, 2014).

Conversely, central, peripheral, or enteric nervous system abnormalities may affect the GI tract. For instance, disorders of motility, such as achalasia and Hirschsprung disease, are the result of defects of innervation of the esophagus and distal large bowel or the result of primary muscle disorders or autonomic neuropathies, respectively. Dysphagia can be a symptom in many neurologic disorders, including strokes. Neurodevelopmental abnormalities are well known to be associated with gastroesophageal reflux. In addition, several drugs used to treat hepatic and GI diseases can have neurologic side effects. Likewise, drugs used in the treatment of neurologic disorders can cause hepatic dysfunction; thus, they may not be safely used or their dosage should be reduced in patients with hepatic failure.

This chapter reviews neurologic complications of the most common GI and liver diseases, including the enteric nervous system (see also Chapter 154 on the autonomic nervous

system, Chapter 46 on vitamin deficiencies, and Chapter 47 on nutritional disorders).

## DISORDERS ASSOCIATED WITH GASTROINTESTINAL DISEASE

### The Enteric Nervous System

The enteric nervous system (ENS) is the intrinsic innervation of the GI tract. It is an elaborate network of neurons, glial cells, and connections arranged in intramuscular plexuses, and it modulates the motility, microcirculation, sphincter tone and activity, hormone secretion, and immune and inflammatory responses of the GI tract (Obermayr, Hotta, Enomoto, and Young, 2013). Please see the online chapter for discussion of the development and modulators of the ENS. Developmental disorders involving the ENS in children including dysphagia, feeding intolerance, gastroesophageal reflux, abdominal pain, and constipation.

**Dysphagia.** Certain groups of infants with specific developmental or medical conditions are at higher risk for developing dysphagia, including those with neurologic conditions or structural deficits (e.g., cleft lip or palate). Left untreated, these problems can lead to failure to thrive, recurrent aspiration pneumonias, gastroesophageal reflux, or the inability to establish and maintain proper nutrition and hydration.

Inhibition of gastric emptying and stimulation of colonic transit are the most frequent dysmotility responses of the GI tract to acute short-term stress. Endogenous corticotropin-releasing factor (CRF) plays a significant role in CNS mediation of stress-induced inhibition of upper GI motor function and stimulation of lower GI motor function.

Sucking, swallowing, and feeding disorders are common. Several investigations help determine the mechanism(s) causing symptoms (e.g., fiber endoscopy, videofluoroscopy, facial and swallowing electromyography, esophageal manometry). The main causes of sucking, swallowing, and feeding disorders are lesions of the brainstem (malformations of the posterior fossa, neonatal brainstem tumors, agenesis of cranial nerves, destructive lesions of the posterior brain, craniovertebral anomalies, and syndromes that involve rhombencephalic development, such as Pierre Robin sequence, CHARGE syndrome, etc.). Suprabulbar lesions, neuromuscular disorders, and anomalies or dysfunction of the esophageal, digestive, and laryngeal systems also can cause these symptoms. Management of these disorders involves treating the underlying cause, facilitating the sucking reflex, preventing the deleterious consequences of aspiration and malnutrition, and preventing posttraumatic anorexia.

## Episodic Gastrointestinal Disease

### Recurrent Abdominal Pain and Irritable Bowel Syndrome

Episodic GI diseases resulting from ENS dysfunction include irritable bowel syndrome, functional dyspepsia, chronic abdominal pain, and motility disorders such as gastroparesis, constipation, gastroesophageal reflux disease, and cyclic vomiting syndrome.

Patients with inflammatory bowel disease (IBD) and irritable bowel syndrome (IBS) develop long-term neuroplastic changes in the brain–gut axis that result in chronic abdominal pain. These changes are driven by peripheral mechanisms within the intestinal wall, neuronal synaptic changes, and/or increased neurotransmitter release in the spinal cord and brain. Therapeutic interventions are mainly carried out using pharmacologic agents, although interventions involving electrical stimulation have been suggested. Psychological stress factors also may play a role.

### Cyclic Vomiting Syndrome and Recurrent Abdominal Pain

Cyclic vomiting syndrome (CVS; Online Mendelian Inheritance in Man [OMIM] No. 500007) is manifested by repeated episodes of vomiting lasting for hours or days, which can cause dehydration, hypochloremic alkalosis, and ketosis in an otherwise healthy-appearing child (Moses et al., 2014). Abdominal pain and fever may be present, and the patient may become pale, drowsy, and lethargic. In one study, annual incidence of CVS was 3.15 per 100,000 children per year, the median age at onset was 4 years, the median age of diagnosis was 7.42 years, and the median duration of an episode was 24 hours, with a range of up to 5 days. CVS and migraine share coexistent dysautonomias, including orthostatic intolerance and syncope.

Treatment of cyclic vomiting is by fluid and electrolyte replacement and treatment of esophagitis, which may be caused by the continued vomiting. Antimigraine, antiemetic, and antiepileptic agents have been used. Lorazepam has antiemetic and anxiolytic properties. Phenothiazines, butyrophenones, metoclopramide (Reglan), cyproheptadine, and trimethobenzamide (Tigan) may be effective as antiemetic agents but may cause extrapyramidal side effects. Ondansetron also may be considered. Beneficial effects of prophylactic therapy with propranolol and of oral or nasal sumatriptan have been described. Antiepileptic drugs (phenobarbital, valproic acid) have been suggested as ameliorating symptoms. Prophylactic therapy with valproate or amitriptyline has been described.

### Irritable Bowel Syndrome

IBS is characterized by abdominal discomfort, pain, and changes in bowel habits. It is the most common cause of recurrent abdominal pain in children, affecting 10% to 15% of older children and adolescents. It is defined by the 2006 Rome III criteria for functional GI disorders, which characterize symptoms as abdominal pain associated with a change in stool form and/or frequency, that is improved by defecation, and that is not explained by structural or biochemical abnormalities. The pathophysiology of IBS is not fully understood and is discussed in the online chapter.

The diagnosis of IBS is made based on the Rome III criteria together with the exclusion of other organic causes of recurrent abdominal pain, such as IBD and celiac disease. Diagnostic testing includes routine blood studies, stool testing, celiac disease serology, abdominal ultrasonography, and breath

testing to rule out carbohydrate (lactose, fructose, etc.) intolerance and small intestinal bacterial overgrowth. Colonoscopy is recommended if alarming symptoms are present or to obtain biopsies.

Management is based on a multifactorial approach and includes lifestyle modifications, stress management, behavioral and psychological treatment, dietary alterations, education, reassurance, and development of an effective patient–physician relationship (Chapter 160). Hypnotherapy and probiotics can be helpful. Antispasmodic and antidiarrheal agents may have a role in severe cases.

### Infantile Colic

Infantile colic is defined as a condition in which an otherwise healthy baby cries or displays symptoms of distress frequently and for extended periods. In these instances, there is no clear cause for the discomfort. Colic usually starts within the first month of life, and, in most babies, stops before the infant is 3 to 4 months of age. In some babies it can last up to 12 months. Infantile colic is thought to be a pain syndrome. Migraine is a common cause of headache pain in childhood. An association between these two pain syndromes has been suggested.

## Anatomic Gastrointestinal Disorders

### Gastroesophageal Reflux

Gastroesophageal reflux (GER) is present when reflux of gastric contents causes troublesome symptoms or complications. GER occurs in about one third of all children with severe psychomotor retardation and other neurologic conditions, including myopathies and cerebral palsy, and as a sequelae of birth asphyxia. Factors related to the frequent occurrence of GER with neurologic conditions include esophageal muscle weakness, hypotonia, incoordination of the swallowing mechanism, scoliosis, and immobility.

Symptoms include pain, discomfort, irritability, and vomiting. Anemia and recurrent aspiration pneumonia also may occur. Respiratory symptoms resulting from reflux, aspiration, and laryngospasm that cause apnea, cyanosis, and stiffening (Sandifer syndrome) may be confused with seizures. In children with severe neurologic impairment, self-injurious behaviors or considerable agitation may be a marker for GER.

Esophageal pH monitoring demonstrates intermittent periods of reduced pH. Esophageal manometry may show decreased sphincter pressure and reduced peristalsis. A barium swallow may determine the presence of anatomic or functional abnormalities that mimic reflux.

Medications that enhance GI motility (e.g., metoclopramide, cisapride, ranitidine, sucralfate) usually are beneficial. Those who do not respond may benefit from gastrostomy and Nissen fundoplication, which can be done laparoscopically. Postoperative complications or recurrent gastroesophageal disease occur more frequently in neurologically impaired children.

### Intestinal Pseudoobstruction

Intestinal pseudoobstruction is manifested by intestinal obstruction in the absence of mechanical blockage. Disorders causing chronic intestinal pseudoobstruction (CIPO) are listed in Box 159-1. Acute pseudoobstruction (paralytic ileus) usually occurs postoperatively or secondary to the use of medications, including anticholinergic agents, phenothiazines, tricyclic antidepressants, narcotics, and certain anticonvulsants, particularly benzodiazepines and barbiturates. Infant botulism can present as colonic ileus (Chapter 145).

**BOX 159-1** Causes of Intestinal Pseudoobstruction in Children**I. ACUTE**

- A. Postoperative
- B. Electrolyte disturbances
- C. Medication effects
- D. Acute infections or toxins

**II. CHRONIC****A. Disorders of the Myenteric Plexus**

- 1. Primary disorders of the myenteric plexus
  - a. Developmental abnormalities—neuronal immaturity and developmental abnormalities
  - b. Aganglionosis—Hirschsprung disease, segmental aganglionosis
- 2. Familial visceral neuropathies—multiple subtypes
- 3. Systemic disorders affecting the myenteric plexus
  - a. Infectious—Chagas's disease, cytomegalovirus infection, infectious mononucleosis, zoster
  - b. Neurologic disorders—familial dysautonomia
  - c. Endocrine disorders—diabetes mellitus
  - d. Gastrointestinal disorders—malabsorption syndromes

**B. Disorders of Intestinal Smooth Muscle**

- 1. Primary disorders of smooth muscle
  - a. Familial visceral myopathy—various inherited forms
  - b. Sporadic childhood visceral myopathies
- 2. Systemic disorders affecting visceral smooth muscle
  - a. Muscular and myotonic dystrophies
  - b. Hypothyroidism
  - c. Connective tissue disorders—systemic lupus erythematosus, polymyositis/dermatomyositis

**C. Small Intestinal Diverticulosis**

- 1. With myopathic changes
- 2. With neuropathic changes

(Modified from Scott RB: *Motility disorders*. In Walker WA, et al, editors: *Pediatric gastrointestinal disease*, St. Louis, 1996, Mosby.)

When no recognizable etiology is found, CIPO is referred to as idiopathic (CIPO). Clinical manifestations include recurrent episodes of bowel obstruction without a mechanical obstructive cause. Symptoms include poor feeding, vomiting, abdominal distention, megacolon, and constipation. Evaluation for pseudoobstruction requires exclusion of structural, mechanical, and pharmacologic etiologies, followed by additional studies to evaluate motor activity and motility, including breath hydrogen determination, scintigraphy, and manometric studies.

A mitochondrial neurointestinal encephalopathy may cause chronic pseudoobstruction in addition to cranial nerve abnormalities, ataxia, ophthalmoplegia, facial and limb muscle weakness, and pigmentary retinopathy. Brain MRI demonstrates diffuse leukoencephalopathy. Muscle biopsy may reveal neuropathic and myopathic changes, scattered ragged red fibers, and focal cytochrome oxidase deficiency.

Therapy and prognosis vary depending on the lesions identified by pathology; treatment includes diet modifications, parenteral nutrition, and use of cisapride.

**Hirschsprung Disease**

Hirschsprung disease (HSCR; OMIM 142623), or aganglionic megacolon, is a congenital disorder that is characterized by the absence of intestinal ganglion cells in the submucosal and

myenteric plexuses, which causes proximal bowel distention. It is the consequence of defective migration of neural crest cells to the colonic submucosa and is one of a spectrum of neurocristopathies, a group of diverse disorders resulting from defective growth, differentiation, and migration of neural crest cells, with a wide spectrum of neurologic abnormalities. HSCR, its variants, and the key genes that regulate neural crest cell development are described in the online chapter.

**Other Neurocristopathy Syndromes**

Several neurocristopathy syndromes are described in the online chapter, including Down syndrome in association with HSCR, Shah-Waardenburg syndrome or Waardenburg syndrome type IVB (OMIM 613265), Mowat-Wilson syndrome (OMIM 235730), and neuroblastoma (OMIM 613013).

**Other Pseudoobstruction Syndromes**

Children with muscular or myotonic dystrophies may have intestinal pseudoobstruction. X-linked recessive neuropathic forms of intestinal pseudoobstruction also have been described.

**Mitochondrial Neurogastrointestinal Encephalopathy (MNGIE)**

Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) is a rare autosomal-recessive mitochondrial DNA depletion syndrome with heterogeneous multisystem involvement and usually presents between the first and fifth decades of life (OMIM 603041). It is characterized by peripheral neuropathy, ophthalmoplegia, ptosis, deafness, leukoencephalopathy, and GI symptoms resulting from visceral neuropathy. Clinical manifestations include progressive GI dysmotility and cachexia, accompanied by ptosis/ophthalmoplegia, hearing loss, and a demyelinating neuropathy. Although symptoms can start between the first and fifth decades, they usually begin before age 20 years (60% of individuals). Confirmatory laboratory studies include an elevated plasma lactate level and elevated plasma thymidine and deoxyuridine concentrations and reduced leukocyte thymidine phosphorylase enzyme activity. Electron microscopy of rectal biopsy tissue may suggest a mitochondrial disorder.

MNGIE is caused by mutations in the *TYMP* gene encoding thymidine phosphorylase. The diagnosis of MNGIE is made by demonstrating reduced or absent thymidine phosphorylase activity and elevated serum thymidine and deoxyuridine, along with genetic identification of the *ECGF1* gene mutation on nuclear DNA (and also mitochondrial DNA deletions).

Clinical presentation may vary, and patients can be misdiagnosed with myasthenia gravis, chronic inflammatory demyelinating polyneuropathy (CIDP), and intestinal inflammatory disease. Electromyographic testing may demonstrate demyelinating sensory and motor polyneuropathy. The most common finding on MRI is that of a diffuse leukoencephalopathy. The extent and distribution of leukoencephalopathy may not correlate with disease severity or be related to the *TYMP* mutations, enzyme activity, or pyrimidine levels. Magnetic resonance imaging (MRI) apparent diffusion coefficient (ADC) maps have shown moderately increased diffusivity. The leukoencephalopathy can worsen over time, regardless of the clinical course.

Acute medical events such as infections often provoke worsening of symptoms, suggesting that careful monitoring and early treatment of intercurrent illnesses may be beneficial. Anecdotal reports suggest that allogeneic hematopoietic stem cell transplantation may be beneficial.

## Intussusception

Intestinal intussusception, with invagination of the gut into its distal segment, is the most common cause of bowel obstruction in children. Presenting signs and symptoms typically are abdominal, but encephalopathy with irritability, lethargy, obtundation, or coma has been described.

## Malabsorption Syndromes

GI disorders associated with malabsorption can cause selected nutritional, biochemical, and vitamin deficiencies, including vitamin E and vitamin B<sub>12</sub> deficiency. Neurologic involvement is present in some children. Neurologic abnormalities associated with nutritional deficiencies and specific vitamin deficiencies are reviewed in Chapters 46 and 47.

## Celiac Disease

Celiac disease is an immune-mediated malabsorption syndrome characterized by permanent gluten intolerance in genetically susceptible individuals, with symptoms of chronic diarrhea, failure to thrive, weight loss, and abdominal distention (OMIM 212750). Jejunal biopsy demonstrates villous atrophy, absence of surface mucosa, and crypt hyperplasia.

Extraintestinal manifestations are becoming increasingly more common. They include numerous conditions, such as dermatitis herpetiformis, anemia, dental enamel hypoplasia, recurrent oral aphthae, short stature, osteoporosis, arthritis, neurologic problems, unexplained elevation of transaminase levels, and female infertility.

Neurologic symptoms infrequently are the presenting manifestation of celiac disease (Diaconu, Burlea, Grigore, Anton, and Trandafir, 2013). In some patients, gluten sensitivity can be present with neurologic abnormalities without meeting the strictly defined criteria for celiac disease. The most common neurologic problems are ataxia and seizures. Peripheral nervous system involvement and acute disseminated encephalomyelitis are rare complications in children and may respond to diet modification. Specific syndromes of occipital calcifications and epilepsy, and cerebellar degeneration with or without epilepsy, also have been described in children. A significant percentage of patients with Down syndrome have celiac disease.

Psychiatric abnormalities include apathy, anxiety, irritability, depressive syndromes, schizophrenia, and psychosis. There are reports of immunopathological changes in the intestinal mucosa of autistic children, but a direct association between autism and celiac disease remains uncertain. Reports of behavioral improvement in autistic children on a gluten- and casein-free diet remain controversial. Untreated patients with celiac disease can have signs of ADHD.

The pathogenesis of nervous system dysfunction in gluten enteropathy remains unclear. It may be the result of malabsorption causing folic acid, vitamin B<sub>12</sub>, or vitamin E deficiencies. Hypocalcemia and hypokalemia also have been implicated. Although some patients have malabsorption, the majority of patients with neurologic symptoms do not.

Abnormalities of humoral and cell-mediated immunity suggest that celiac disease is an immunologic disorder caused by an inappropriate immune response to the gliadin component in dietary gluten. There is a genetic susceptibility, and 90% of patients have the human leukocyte antigen (HLA) DRG 3 DQ-2 haplotype. Antiendomysial, antigliadin, and antireticulin antibodies also are associated with the disease. Antitissue transglutaminase antibody assay has been used as a serologic screening test for celiac disease. Neurologic abnormalities in celiac disease may result from vasculitis

involving the vascular endothelium, possibly mediated by tissue transglutaminase.

Patients with celiac disease improve after dietary withdrawal of gluten. Neurologic abnormalities can be present before the appearance of celiac disease symptoms and may progress despite a gluten-free diet. In general, there is no evidence that a gluten-free diet or vitamin supplementation reverses the neurologic abnormalities, although, in an adult series, neurologic symptoms improved or disappeared in 7 of 13 individuals within 6 months of starting a gluten-free diet.

## Short Bowel Syndrome

Short bowel syndrome is a malabsorption syndrome that follows resection of a significant part of the small bowel, usually because of a congenital anomaly, necrotizing enterocolitis, inflammatory bowel disease, or ischemic injury. See the online chapter.

## Inflammatory Bowel Disease

IBDs, including Crohn's disease (regional enteritis) and ulcerative colitis, occur infrequently in children. Crohn's disease is a chronic, inflammatory process that affects any region of the GI tract, mostly the small bowel, in a discontinuous fashion. Patients complain of diarrhea, rectal bleeding, abdominal pain, vomiting, and weight loss. Therapy includes antiinflammatory agents, corticosteroids, and supportive nutritional therapy. Ulcerative colitis is a chronic relapsing inflammatory disease involving the mucosa of the colon and rectum in a continuous manner. Both conditions cause extraintestinal symptoms in about 25% to 35% of patients.

Neurologic manifestations are rare and are dominated by CNS vascular complications, including arterial occlusion, vasculitis, encephalopathy, mononeuropathies, and abnormalities of the white matter. The majority of patients experience the onset of neurologic symptoms within the first 5 to 6 years after the onset of IBD symptoms. Peripheral neuropathy is the most common complication of IBD and may be immune mediated or caused by antitumor necrosis factor-alpha (TNF- $\alpha$ ) therapy or metronidazole. Myelopathy, myopathy, myasthenia gravis, and multiple sclerosis also have been reported. Other symptoms that occur with higher frequency in children with IBS include headache, dizziness, and attention deficit hyperactivity disorder (Ben-Or, Zelnik, Shaoul, Pacht, and Lerner, 2015).

## Enteric Infections

Enteric viruses and bacteria that cause primary CNS infection are reviewed in Chapters 114 to 116. A variety of systemic viral and bacterial infections may cause an encephalopathy resulting from the presence of endotoxins or electrolyte and fluid disturbances. Some of the more well-recognized entities are reviewed in this section.

Seizures and encephalopathy in infants with enteric infections and diarrhea can be caused by hyponatremia or hypernatremia (Chapter 158). Hyponatremia may cause brain swelling because sodium and chloride ions cross the brain capillaries slower than water. Treatment consists of rehydration with adequate sodium salts and avoidance of more dilute fluids. Hypokalemia can accompany diarrhea and cause neuromuscular manifestations, including hypotonia, diminished bowel sounds, weakness, lethargy, abdominal distention, and, in severe cases, rhabdomyolysis and myoglobinuria. Neuromuscular manifestations become more prominent with serum potassium levels lower than 3 mEq/L. Severe hypokalemia occurs more frequently in children younger than 24 months

and in infants receiving dextrose-containing intravenous fluids without electrolyte replacement, and is related to the type of rehydration therapy.

Please see the online chapter for a discussion of the following infectious agents: *Escherichia coli*, *Campylobacter jejuni*, Nipah virus, infant botulism, shigellosis, and rotavirus infection.

## The Human Microbiome and Neurologic Disorders in Children

The human body contains more than 1 trillion bacteria, and it is estimated that the number of bacteria are tenfold greater than the number of human cells. There is increasing interest in the human microbiota (the body's entire microbial population) and the human microbiome (the body's collective genomes of all microorganisms) and their relation to nervous system function in health and disease (termed the *microbiota-gut-brain*, or *MGB axis*) (Mayer, Padua, and Tillisch, 2014).

### Development and Role of the Human Microbiota

Over the course of the first year of life, bacterial populations colonize the gut, skin, and other regions with the predominant phyla, including actinobacteria, bacteroidetes, firmicutes, and proteobacteria. Many factors affect the development of the infant's microbiota, including the state of maternal health, gestational age, mode of delivery, prematurity, exposure to being in an intensive care unit, the nature (e.g., breast milk vs. infant formulas) and amount of nutritional intake, use of antibiotics, prolonged hospitalization, and environmental factors. For a discussion of the changes in the microbiota prenatally, postnatally, and during childhood/adolescence, please see the online chapter and the review by Borre and colleagues (2014).

### Disease States and the Influences of the Microbiota and Microbiome

When there are conditions of pathologic stress or disease, intestinal dysbiosis can adversely influence gut physiology, leading to inappropriate MGB axis signaling and associated CNS dysfunction (Borre et al., 2014). The ensuing inflammatory response causes loss of intestinal integrity that promotes increased release of pathogenic bacterial constituents to the systemic circulation. These processes can activate the peripheral immune system to release proinflammatory/antiinflammatory cytokines/chemokines that alter the blood-brain barrier and impair multiple aspects of CNS function, involving the ENS and the sympathetic and parasympathetic (e.g., vagal) autonomic nervous systems. Other metabolic pathways (e.g., tryptophan-kynurenine) that participate in serotonin metabolism may mediate some of the affective behaviors attributed to alterations of the MGB axis.

**The Microbiota and Immune-Mediated Nervous System Disorders.** A number of immune-mediated diseases that affect the nervous system interface with the human microbiota.

**Multiple Sclerosis.** Translational studies have demonstrated that, in mice, commensal microbiota are essential for the development of experimental autoimmune encephalitis (EAE), a model commonly used to study CNS demyelination. Antibiotic administration modulates gut microbiota and affects EAE progression. Dietary patterns (e.g., high-fat diets) may increase EAE severity, whereas caloric restriction

attenuates EAE symptoms. Such data suggest the possibility that the human microbiota may contribute to the pathogenesis of multiple sclerosis and perhaps other CNS demyelinating disorders.

**Guillain-Barré Syndrome.** Guillain-Barré syndrome (GBS) is frequently seen in children and is reviewed in Chapter 161. Preceding infections with bacteria or viruses, such as *Haemophilus pneumoniae*, *Mycoplasma pneumoniae*, influenza, Epstein-Barr virus, and *Campylobacter jejuni*, have been associated with this disorder. GBS results, in part, from cross-reactivity between antibodies produced by the specific infectious agent to peripheral nerve tissues. *C. jejuni* has been associated with different types of GBS. The possibility exists that modifying this enteric pathogen could alter the effects of immune-mediated GBS.

### The Microbiota and Nonimmune-Mediated CNS Disorders

**Autistic Spectrum Disorder.** Of the neurodevelopmental disabilities, autistic spectrum disorders (ASDs) (Chapter 65) have attracted the most interest in studying the MGB axis relation (Mayer et al., 2014). Children with autism have a higher rate of GI symptoms. Numerous clinical studies in children with ASD have linked changes in the gut microbiota with behavioral disturbances, including irritability, inattentiveness, self-injurious behaviors, and mood disturbances.

Alterations in the gut microbiome composition and abnormal levels of microbial metabolites have been described in children with ASD. An imbalance of *Bacteroidetes* and *Firmicutes* phyla was seen in autistic children. Other reports provide conflicting evidence, and it remains unclear whether these are causal or associative phenomena. Certain diets (e.g., probiotics or gluten-/casein-free) that alter the microbiota appear to improve symptoms in individual patients. Recent rodent autism model studies have provided intriguing evidence that alteration in the gut microbiome and associated changes in serum metabolites play an important role in autism-like behaviors, and that these changes were reversible by ingestion of a probiotic. Therapeutic options that have been studied for treatment of autism include diet modulation, prebiotics, probiotics, synbiotics, postbiotics, antibiotics, fecal transplantation, and activated charcoal (Mayer et al., 2014).

**Attention Deficit Hyperactivity Disorder.** A few studies have addressed the potential relation of the MGB axis and ADHD. Genetic predisposition and environmental exposures to certain toxins and allergic triggers are linked to an increased risk of developing or of worsening ADHD symptoms. In contrast, factors such as sugar, artificial food colorings, zinc, iron, and  $\omega$ -3 fatty acids do not have established causality in ADHD, although in some children elimination diets have been shown to be effective.

**Cerebral Palsy.** Children with cerebral palsy have a wide range of GI symptoms, including feeding and swallowing disorders, sialorrhea, constipation, gastroesophageal reflux disease, recurrent respiratory infections secondary to aspiration, failure to thrive, and the need for gastrostomy. To date, there are no published reports of the MGB axis in affected children.

**Epilepsy.** GI complications frequently occur in children with epilepsy related to the genetic and metabolic diseases that cause the epilepsy or as side effects of anticonvulsants. There also are possible effects of recurrent seizures, diets such as the ketogenic diet, or vagal nerve stimulation on GI motility and function. There are no published reports of the MGB axis in children with pediatric epilepsy.

**Intellectual Disability.** As with cerebral palsy and epilepsy in which GI disorders are common, there is no literature on the human MGB axis.

**Depression, Anxiety, Stress and Schizophrenia.** The same general principles of the MGB axis as described previously have been examined in a variety of psychiatric disorders, including depression, anxiety, stress, and schizophrenia, and the reader is referred to several recently published reviews for more in-depth discussion (see the online chapter).

## Therapeutic Implications

Understanding the MGB axis should allow development of new complementary treatment strategies for a wide range of pediatric neurologic disorders. There are a large number of potential therapies that could alter the gut microbiota, and the extent to which such treatments could result in improved outcomes will require extensive translational studies and carefully controlled clinical trials.

## Other Gastrointestinal Diseases

### Whipple's Disease

Whipple's disease is a chronic, multisystem, bacterial, inflammatory disorder caused by a soil-borne, Gram-positive bacillus, *Tropheryma whippelii*. It is a rare disease that is misdiagnosed frequently, occurs primarily in adults, and is manifested by intestinal features that include weight loss, diarrhea, malabsorption, and abdominal pain, in addition to polyarthritides, lymphadenopathy, cardiomyopathy, hyperpigmentation, hypotension, and cardiovascular, pulmonary, and neurologic dysfunction. Up to one third of patients demonstrate signs of neurologic involvement, including progressive dementia, external ophthalmoplegia, myoclonus, seizures, ataxia, hypothalamic dysfunction (sleep disorders, hyperphagia, polydipsia), and meningitis. Oculomasticatory myorhythmia, possibly caused by brainstem tegmental abnormalities, is a movement disorder nearly unique to patients with Whipple's disease. It consists of rhythmic convergence of the eyes and synchronous contractions of the eyelids, jaw, face, and neck, with characteristics resembling spinal myoclonus. The disorder responds to antibiotic therapy. This disorder is very rare in children. Please see the online chapter.

### Turcot's Syndrome

Turcot's syndrome is the rare association of polyposis of the colon and malignant tumors of the CNS (glioblastomas, medulloblastomas, and anaplastic astrocytomas). See the online chapter.

### Porphyria

The porphyrias are a heterogeneous group of metabolic disorders characterized by abnormal heme biosynthesis and are rare in children. The abnormalities involve porphyrin metabolism in the metabolic pathway that converts glycine and succinyl-CoA to heme, which is reviewed in the online chapter.

Although all subtypes are rare, acute intermittent porphyria (AIP) is the most common form of the neuroporphyrias. It manifests with occasional neurovisceral crises resulting from overproduction of porphyrin precursors, such as aminolevulinic acid (ALA), which is released from the liver into the circulation. More than 60 mutations causing AIP have been found (OMIM 176000). Manifestation of neuropsychiatric symptoms in hepatic porphyria patients is triggered by precipitating factors, including various drugs, hormones, fasting, and other agents.

Acute porphyrias present with acute attacks consisting of severe abdominal pain, nausea, constipation, polyneuropathy mental symptoms, confusion, and seizures, and can be life-

threatening. In general, presentation in childhood is uncommon. Rare recessive porphyrias usually manifest in early childhood with severe cutaneous photosensitivity and chronic hemolysis, or chronic neurologic symptoms with or without photosensitivity. Symptoms include features of autonomic neuropathy, including severe abdominal pain, vomiting, constipation, hypertension, tachycardia, and bladder dysfunction. Other symptoms are those of peripheral axonal neuropathy and neuropsychiatric symptoms. Acute porphyric neuropathy predominantly involves the motor system and can be manifested by symptoms, signs, and CSF abnormalities resembling acute Guillain-Barré syndrome.

Acute encephalopathy in patients with hepatic porphyria is manifested as a combination of neuropsychiatric symptoms with seizures, syndrome of inappropriate antidiuretic hormone secretion, and, rarely, focal CNS deficits. Neuroimaging abnormalities are uncommon, although MRI ischemic lesions have been reported, as has a posterior reversible encephalopathy syndrome.

Diagnosis is based on detection of porphyrins and their precursors in blood, urine, or feces. Measurement of urinary porphobilinogen is the best screening biochemical test for AIP, although it is nonspecific.

Treatment is mainly symptomatic and includes supportive treatment with analgesia, monitoring for and treating complications such as hypertension, prevention and treatment of water and electrolyte disorders that may result from inappropriate antidiuretic hormone production, and a high-carbohydrate diet. See the online chapter.

## NEUROLOGIC DISORDERS ASSOCIATED WITH HEPATOBILIARY DISEASES

Neurologic abnormalities occur in patients with acute and chronic liver disease and include impairments of memory, attention, and executive and motor functions. These abnormalities vary in severity, being mild initially but later progressing to overt hepatic encephalopathy. Cognitive dysfunction also can be generalized or specific, including selective attention deficits and abnormalities of motor skills, language, or visuospatial skills. The etiology of the liver disease (e.g., hepatitis C virus, Wilson's disease, alcohol related) can influence the pattern of cognitive dysfunction.

### Hepatitis

Encephalitis, myelitis, Guillain-Barré syndrome, mononeuritis, and polymyositis are infrequent complications of hepatitis A and B. Associated nervous system involvement from Hepatitis C virus (HCV) infection includes cerebrovascular events, encephalopathy, myelitis, encephalomyelitis, cognitive impairment, psychiatric manifestations, and peripheral neuropathy.

Treatment includes use of interferon-alpha, steroids, and plasmapheresis. Treatment of chronic hepatitis with interferon may result in the onset of neuropsychiatric symptoms in some patients.

### Hepatic Encephalopathy

The most common etiology of hepatic encephalopathy (HE) in children is fulminant viral hepatitis, accounting for 50% to 75% of cases, followed by drug or toxin ingestion, including acetaminophen overdose, high-dose salicylate therapy, parenteral hyperalimentation, ingestion of isoniazid, rifampicin, halothane, alpha-methyl dopa, azathioprine, erythromycin, sodium valproate, and tetracycline. Other etiologies are end-stage chronic liver disease caused by biliary atresia,

$\alpha$ 1-antitrypsin deficiency, autoimmune chronic active hepatitis, Wilson's disease, and Reye's syndrome.

HE can complicate most liver diseases, whether acute, subacute, or chronic, and can occur with or without portosystemic shunting. It is characterized by an altered state of consciousness, abnormal mental status, and neurologic abnormalities.

 The pathophysiology of HE is described in the online chapter.

There have been several classifications of HE. A newer classification proposes three subtypes associated with (1) acute liver failure, (2) portosystemic bypass and no intrinsic hepatocellular disease, and (3) cirrhosis and portal hypertension or portosystemic shunting. The latter is subdivided into episodic HE (subtypes: precipitated, spontaneous, recurrent), persistent HE (subtypes: mild, severe, treatment dependent), and minimal HE.

### Neurologic Abnormalities

Neurologic examination may demonstrate mental status changes, motor abnormalities with pyramidal tract dysfunction, and an early parkinsonian syndrome. Other signs include ataxia, action tremor, dysarthria, and asterixis. Seizures are relatively uncommon, as are focal neurologic abnormalities and cerebral and retinal visual abnormalities. Patients with minimal HE usually have no overt neurologic abnormalities.

### Fulminant Liver Failure

Fulminant liver failure is present when HE occurs within one to several weeks of the first evidence of liver disease. Cerebral edema may develop and cause increased intracranial pressure. Ammonia concentration may be elevated, resulting in psychomotor agitation, muscle twitching, mania, delirium, or seizures, especially in children. It also may contribute to the pathogenesis of cerebral edema and raised intracranial pressure.

In affected patients, 70% to 80% of cases respond to antibiotic therapy. Although the mortality rate of acute hepatic failure is high, hepatic function can be restored completely in survivors. Children with moderate or severe electroencephalogram (EEG) abnormalities on admission are more likely to require a liver transplant or die, whereas children with a normal or only mildly abnormal EEG are more likely to survive without transplantation. Management includes monitoring and treatment of hypoglycemia and of intracranial pressure, along with maintenance of adequate cerebral perfusion pressure.

### Cognitive and Behavioral Abnormalities

The earliest changes of HE are subtle behavioral changes and mild impairments of intellectual function. Changes in activities of daily living; impairment of sleep-wake status, attentiveness, cognition, and consciousness; and deterioration in school performance and motor functions become increasingly apparent. Abnormalities occur in mental and motor status, including an abnormal level of consciousness; reduced attention; slow reaction speed; defects in orientation, memory, affect, perception, and judgment; and psychomotor slowing. HE is graded into four stages, with derangement of consciousness progressing from drowsiness to stupor and coma. These stages are as follows:

- Grade I: altered sleep cycle, altered affect (euphoria or belligerence), mild confusion, loss of spatial orientation
- Grade II: drowsy, responsive to simple commands
- Grade III: stuporous, responsive only to painful stimuli
- Grade IV: unresponsive to pain; decorticate or decerebrate posturing

### Minimal Hepatic Encephalopathy

MHE was known formerly as subclinical hepatic encephalopathy and refers to patients with chronic liver disease who have a normal neurologic examination but have milder subcortical cognitive impairments, including deficits in attention, executive function, immediate recall, visuospatial tasks, psychomotor speed, verbal learning, and long-term memory.

### Laboratory Tests

Liver function tests usually are abnormal, but derangements may not be as drastic as expected. Arterial blood ammonia may be elevated and correlates somewhat with the clinical state. Most studies have noted that the ammonia level does not correlate with the severity of encephalopathy. CSF glutamine concentration is more specific and correlates better with the stage of HE.

The EEG may assist in clinical staging. In the early stages, EEG shows reduction of the alpha rhythm with increased theta activity. With a more advanced encephalopathy and further clouding of consciousness, slower delta frequencies appear. Triphasic waves are characteristic but not specific and carry a poor prognosis. Subsequently, there is decreasing amplitude of the EEG waveforms and, finally, absent activity. CT may be normal early, and cortical atrophy may be seen later. MRI abnormalities include increased T1-weighted signal in basal ganglia regions. MRI does not correlate with laboratory indices of hepatic function, with histologic liver diagnosis, or with the neurologic status at the time of MRI acquisition. MR spectroscopy demonstrates depletion of myoinositol, preservation of N-acetylaspartate, and elevation of glutamine.

### Neuropathology and Pathophysiology

Please see the online chapter. 

### Treatment

The treatment of HE is directed toward removal or correction of any precipitating factors, diminishing the absorption of nitrogenous substances from the intestinal tract, and minimizing portosystemic shunting. Hyperammonemia may suggest poor functional reserves, malnutrition, and impending multi-organ dysfunction. Early provision of nutritional support; correction of hypokalemia, hypovolemia, and acidosis; aggressive treatment of infection; avoidance of sedatives; and modification of portosystemic shunts may contribute to reducing the production of ammonia and thus help to prevent its damaging effects (Tapper, Jiang, and Patwardhan, 2015).

All patients should be evaluated for secondary triggers of HE. Most effective therapies are directed at reducing the ammonia concentration and treating various complications, including infections, renal and cardiovascular dysfunction, and bleeding secondary to ruptured varices, hypersplenism, or clotting factor deficiencies. Probiotics can improve minimal HE and act as prophylaxis of overt HE. Therapy is more effective for portosystemic encephalopathy and much less so for fulminant hepatic failure. Ammonia production can be reduced by decreasing dietary intake of protein, treating constipation, controlling GI tract bleeding, and reducing bacterial intestinal growth. Ammonia also can be removed from the intestines by the osmotic action of nonabsorbable disaccharides, such as lactulose. Complications of lactulose therapy include dehydration and hypernatremia. Reduction of gut ammonia also can be achieved using antibiotics such as neomycin or rifaximin, which are active against urease-producing bacteria. Management of acute severe cerebral edema is important and is discussed in Chapter 105.

## Prognosis

Prognosis of hepatic encephalopathy is guarded, in spite of improvement in intensive medical support. One-year survival is 40%, and 3-year survival is 15%. Fulminant hepatic failure has a mortality rate of 75%, and severe hepatic coma carries a substantial risk of permanent neurologic disability.

## Neurologic Abnormalities Associated With Liver Transplantation

Patients undergoing liver transplantation can have serious postoperative neurologic complications, including encephalopathy, seizures, headaches, involuntary movement disorders, cortical blindness, brachial plexopathy, and peripheral neuropathy. Etiologic factors include air embolism, graft-versus-host reactions, coagulopathy-associated cerebral hemorrhage, seizures and central pontine myelinolysis resulting from severe electrolyte and metabolic changes, cerebral infarction resulting from perioperative hypotension, and meningoencephalitis or cerebral abscess resulting from opportunistic infection. Drug-induced neurologic disorders also may occur. Seizures can be the manifestations of ischemic or hemorrhagic strokes, CNS infection, or metabolic abnormalities. Neurologic complications also can be associated with cyclosporine A.

## Neurologic Abnormalities in Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) is a chronic cholestatic liver disease with an autoimmune etiology. In addition to chronic liver disease, patients have other symptoms, including fatigue and cognitive dysfunction, in particular, memory and concentration difficulties. Please see the online chapter for additional discussion.

## Reye's Syndrome

Reye's syndrome is a now-uncommon syndrome characterized by an acute encephalopathy with fatty infiltration of various organs, including the liver, kidney, and heart. The syndrome is associated with viral illnesses, such as influenza B and varicella, and salicylate therapy.

Several metabolic conditions, including fatty-acid oxidation defects (e.g., carnitine deficiency, organic acidurias, medium-chain acyl coenzyme A dehydrogenase deficiency), can cause recurrent Reye's syndrome-like episodes. In Reye's-like syndromes that are a result of inborn errors of metabolism, hypoglycemia, hypoketonemia, elevated ammonia, and organic aciduria often are evident. The most commonly diagnosed metabolic disorder has been medium-chain acyl coenzyme A dehydrogenase deficiency. Because Reye's syndrome is now very rare, any child suspected of manifesting this disorder should undergo investigations for inborn errors of metabolism.

Clinical presentation involves an antecedent viral infection, followed by vomiting and marked changes in sensorium that may start with a hyperexcitable stage and progress to lethargy and coma with decorticate posturing. The latter symptoms are secondary to increased intracranial pressure and central herniation as a result of brain edema. Clinical staging systems, consisting of four or five stages, are based on the cephalocaudal progression of brainstem dysfunction secondary to increased intracranial pressure, or EEG criteria. Laboratory abnormalities include marked elevations of hepatic transaminases, prolongation of the prothrombin time,

hyperammonemia, hypoglycemia, increases in plasma fatty acid levels, elevation of plasma lactate, and reduced phosphorus concentrations. Imaging findings and pathology are reviewed in the online chapter. The most important therapeutic measure is reduction of intracranial pressure, as reviewed in Chapter 105.

## Hepatolenticular Degeneration: Wilson's Disease

Wilson's disease (OMIM 27790) is a rare autosomal-recessive disease presenting in late childhood or adolescence and results from a defect in copper metabolism, secondary to ATP7B gene mutations on chromosome 13q14.3–q21.1, which codes for a copper-transporting adenosine triphosphatase. The basic defect in Wilson's disease is the impaired biliary excretion of copper, resulting in the accumulation of copper in the liver, cornea, and brain. Manifestations include liver dysfunction (acute or chronic hepatitis, cirrhosis, acute hepatic failure), neuropsychiatric disease, and Kayser–Fleischer rings.

Diagnosis is clear if two of the following symptoms are present: Kayser–Fleischer rings, typical neurologic symptoms, and low serum ceruloplasmin levels. Serum ceruloplasmin levels are low (<20 mg/dL), serum copper levels are decreased (<20 µg/dL), and 24-hour urinary excretion is increased (>100 µg/24 hours). Liver biopsy using radioactive <sup>64</sup>Cu or <sup>67</sup>Cu can be performed to determine hepatic copper levels.

Neurologic manifestations are gradual in onset. Dystonia is the most common feature. Dysarthria, tremors, and psychiatric manifestations start more commonly during the second decade of life. Three subsets of patients have been recognized: (1) pseudoparkinsonian patients with dilation of the third ventricle who have bradykinesia, rigidity, cognitive impairment, and an organic mood syndrome; (2) pseudosclerosis patients with focal thalamic lesions, ataxia, tremor, and reduced functional capacity; and (3) dyskinesia patients with focal abnormalities of the putamen and globus pallidus, dyskinesias, dysarthria, and an organic personality syndrome.

Psychiatric disorders are common and include mania, psychosis, depression, and schizophrenia. Almost all patients with neurologic and psychiatric manifestations develop corneal Kayser–Fleischer rings, a granular brown pigmentation of the cornea caused by copper deposition in Descemet's membrane, which can be visualized by slit-lamp examination.

Seizures are uncommon and can occur at any stage. In children, deterioration in school achievement and the development of behavioral and conduct disorders begin insidiously and progress slowly. Neurologic manifestations have been reported in children as young as 6 years of age, although, traditionally, children younger than age 10 years have the hepatic form of the disease, whereas children older than 10 years have neurologic involvement.

See the online chapter for a review of imaging abnormalities.

Treatment is directed at reducing systemic copper levels with a low-copper diet and with anticopper medications. The drugs used include zinc, which blocks intestinal copper absorption; penicillamine and trientine, both of which are chelators that increase urinary excretion of copper; and tetrathiomolybdate, which forms a tripartite complex with copper and protein and blocks copper absorption from the intestine or renders blood copper nontoxic. Because of its efficacy and lack of toxicity, zinc is considered by some to be the treatment of choice for maintenance therapy, for treatment of the presymptomatic patient, and for treatment of the pregnant patient.

For patients with mild liver failure, combined treatment with trientine and zinc is effective.

For patients with neurologic disease, tetrathiomolybdate is preferred to penicillamine by some groups because it provides rapid, safe control of copper. Patients treated with penicillamine are at great risk of serious permanent neurologic worsening or side effects. Pyridoxine should be given concurrently in those patients receiving penicillamine. A reduction of clinical symptoms usually is achieved with therapy, but the degree of recovery is variable.

## Progressive Hepatocerebral Disease

Alpers's syndrome is a heterogeneous group of disorders affecting young children, manifested by progressive neurologic degeneration with seizures, brain atrophy with neuronal necrosis, and sometimes liver disease; it is reviewed in Chapter 48.

## Bilirubin Encephalopathy: Kernicterus

Hyperbilirubinemia affects term and late-preterm infants in the first week of life, but is generally mild (Bhutani and Johnson-Hammerman, 2015). Chronic neurologic sequelae are seen in a subset of infants.

Many infants who now develop kernicterus are not those with Rhesus disease, and they often have no documented evidence of hemolytic disease. Rather, they are term and late-preterm infants who have been discharged from the nursery as "healthy newborns," yet returned with extreme hyperbilirubinemia and have then developed the classic findings associated with kernicterus. The term *kernicterus* describes the neuropathology of bilirubin-induced brain injury (including the yellow staining of the deep nuclei of the brain) and the clinical finding associated with this condition. Another term that can be used to describe the clinical condition is *bilirubin encephalopathy*.

Bilirubin is the end product of the catabolism of heme and is transported in plasma bound to albumin and converted in the liver to an excretable conjugated form, which is then excreted into the bile, transported to the small intestine, further degraded by intestinal bacteria, and excreted in the stool. A number of neonatal disorders may lead to much higher concentrations of unconjugated bilirubin. These include hemolytic diseases of the newborn caused by blood group incompatibility (but also some hemoglobinopathies), hemorrhage, polycythemia, inherited or acquired defects of conjugation, and hypothyroidism. Premature infants are more susceptible to hyperbilirubinemia. The risk for bilirubin encephalopathy also depends on the etiology of hyperbilirubinemia. The level of total serum bilirubin that may lead to acute bilirubin encephalopathy (ABE) and to kernicterus depends on a number of variables, including the gestational age and the serum albumin. In a full-term baby this level is equal to or more than 20 mg/dl, although in infants without risk factors neurotoxicity may be observed at higher bilirubin levels.

 **Pathophysiology of Hyperbilirubinemia.** This is discussed in the online chapter.

 **Neuropathology.** This is discussed in the online chapter.

**Clinical Manifestations.** The sequence of acute bilirubin encephalopathy (ABE) consists of three phases. Acute symptoms are characterized by lethargy, hypotonia, and poor sucking and swallowing responses. If untreated, the later stage of ABE is more severe and includes hypertonia, possible fever

(secondary to muscular contraction), and a high-pitched cry. The hypertonia is evident in the extensor muscle groups and is manifested by backward arching of the neck (retrocollis) and trunk (opisthotonos). The condition can progress to apnea, coma, seizures, and death. Central apneic events may be a sign of bilirubin-induced neurotoxicity. Clinical manifestations of ABE in preterm infants are similar but more subtle than those of term infants.

Chronic bilirubin encephalopathy (CBE, kernicterus) defines the permanent neurologic sequelae of bilirubin toxicity and is manifested by extrapyramidal motor abnormalities (e.g., chorea, dystonia, or ballismus) that may fluctuate—athetoid cerebral palsy, auditory impairment, and oculomotor impairment, especially paralysis of upward gaze.

Auditory impairment, usually high-frequency bilateral hearing loss, is common because the auditory pathway is the part of the nervous system most sensitive to bilirubin toxicity. Dental dysplasia is another complication of kernicterus and affects only the deciduous teeth. The permanent teeth may not be affected.

Intellectual deficits can vary from severe intellectual disability to isolated symptoms and also to subtle bilirubin-induced neurologic dysfunction (BIND). Characteristic features may not become apparent until after 1 year of age. Some patients may have a delayed onset of several years before developing a movement disorder. BIND is a constellation of more subtle neurodevelopmental abnormalities caused by bilirubin neurotoxicity, without classical kernicterus. These include abnormal central auditory processing, cognitive dysfunction, and alterations in muscle, sensorimotor and visual function.

**Laboratory Testing.** Determination of blood bilirubin, albumin, and pH levels may give an indication of the risk of kernicterus. Auditory brainstem response (ABR) testing provides early detection of bilirubin neurotoxicity. Neuroimaging hallmarks of kernicterus include high-intensity lesions in the globus pallidus and in the subthalamic nucleus on MRI T2-weighted imaging. These abnormalities are different from those seen with neonatal hypoxia-ischemia, which affects the cortex, thalamus, periventricular white matter, caudate nucleus, and putamen.

**Management.** The essential aspect of bilirubin encephalopathy management is the early detection of at-risk neonates. Phototherapy and exchange transfusion are the treatment of choice for hyperbilirubinemia (see the online chapter).

# 160 Counseling Children with Neurologic Disorders and Their Families

David J. Michelson and Robin D. Clark

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Clinicians treating a child with neurologic symptoms have the same fundamental goals as do the child's family: an accurate diagnosis and a plan for treating the disease; improving the child's symptoms, quality of life, and functioning; and minimizing the child's suffering. Good communication between clinicians and family members is vital to defining, clarifying, and meeting these goals, but in some circumstances, communication is difficult or breaks down, leading instead to confusion, misunderstanding, frustration, and dissatisfaction. Whether dealing with questions about a minor complaint in the clinic setting or with questions of critical importance in the intensive care unit, clinicians have a tendency to put themselves in the limited role of information providers—obtaining and conveying information about symptoms and treatment options. However, as the complexity and emotional intensity of discussions about illness increase, so too does the difficulty of maintaining clear communication.

Patients often express dissatisfaction with clinicians, saying that they did not feel listened to or understood during their interactions. Clinicians tend to interrupt, focus on the few symptoms initially elicited, and launch into biomedical explanations without exploring how the information fits with the patient's culture and perspective (Searight and Gafford, 2005). Patients and their families are often more capable of understanding medical issues and wish to play a more prominent role in decision making than clinicians estimate. Even discussions of informed consent are too often judged by patients to be hurried, limited, and unsatisfying (Elwyn et al., 2014). In situations where emotions run particularly high, such as giving bad news or negotiating differences of opinion, clinicians fare even worse.

Skills important to communication with patients can be taught through mentoring and focused practice, with self-awareness and self-reflection being the keys to success (Kern et al., 2005). Such efforts have shown positive and enduring results, particularly when integrated into training programs. A commitment to improved communication skills takes an investment of time and a willingness to engage with intense, often unpleasant emotional reactions, but ultimately leads to improved outcomes and a greater sense of satisfaction for both clinicians and patients.

## THE CLINICIAN–PATIENT RELATIONSHIP

Society invests physicians (and many allied health professionals) with the responsibility to use their knowledge and

experience for their patients' benefit, putting their patients' interests ahead of almost all other concerns. Trust is required if patients are going to provide clinicians access to their most private information and emotional states. Nevertheless, there has been a steady trend toward placing more emphasis on patient autonomy and self-determination. Paternalistic, doctor-centered approaches to directing patient care are increasingly giving way to more balanced and collaborative models.

Although trust is the foundation of good communication, patients may initially place only a small amount of trust in a clinician based solely on the clinician's professional title. Lower degrees of implicit trust may derive from a patient's own negative experiences or from a negative cultural perspective. A clinician can build on and solidify trust over time through use of communication skills that demonstrate interest, respect, and empathy.

## COMMUNICATION SKILLS

Even when a clinician focuses on information delivery, such as reviewing the results of a diagnostic test, the delivery is more likely to succeed if tailored to the needs of the family. Each family member may have differing levels of education, levels of trust in the medical profession, and perceptions of illness and death. The implications of a medical diagnosis, including the benefits and risks involved in testing and treatment decisions, depend greatly on the individual. Collaborative decision making depends on developing the interviewing and listening skills needed for understanding the perspective of each person involved.

Communication is easier and more efficient when relationships have developed and matured over time, but clinicians can engender trust in even brief encounters by paying attention to showing respect, interest, empathy, support, and a willingness to forge a partnership (Box 160-1). Compassionate care requires the clinician to be sensitive to the patient's immediate needs, rather than the clinician's agenda for the discussion (Epstein, Siegel, and Silberman, 2008).

## NONVERBAL COMMUNICATION

Clinicians show attentiveness, respect, and empathy, or lack thereof, through nonverbal behaviors as much as through words. Frequent eye contact, relaxed and open facial expressions and body postures, a warm and inviting tone of voice, and supportive head nods and encouraging semiverbal comments are important for conveying interest in what families have to say. Attentive silence also has a positive influence.

**BOX 160-1** Communication Skills**RESPECT**

- Introduce the medical team and have the family members introduce themselves, discuss the purpose of the meeting, and give the name of the child for whom the meeting is being held.
- Be “in the moment” and genuine, show interest, and take your time.
- Shake hands if culturally appropriate, sit down, and make eye contact.
- Use positive, engaged body postures, with your shoulders and head leaning forward, your hands relaxed on your lap, and with nothing in between you and the family.
- Consider leaving your pager and phone outside of the meeting space or turning them off so that calls and messages do not interrupt anyone.
- Acknowledge things the family is doing well and the family’s strengths.

**EMPATHY**

- Respond to emotions, identify and reflect them, and give them time to develop.
- Reframe emotional responses as communicating ideas.

**SUPPORT**

- Talk about the clinician–patient relationship as an ongoing partnership.

Postures that suggest emotional distance, disinterest, or disapproval (e.g., crossing one’s arms on the chest, standing by the door, frequently looking away) can undermine sincere efforts to establish rapport. The setting can also facilitate or detract from a sense of intimacy with the clinician. Clinicians should sit at a similar level to others, at a distance that is neither too close nor too far, and there should be as few distracting objects between the family and the clinician as possible. Some situations call for exceptions. Family members who are agitated or paranoid may perceive efforts to sustain eye contact or sit close to them as threatening or provocative.

**CONVEYING EMPATHY**

Demonstrating empathy is particularly important. Clinicians can communicate empathy through nonverbal expressions of attention and through the use of active listening techniques, encouraging comments, and repetition of things the patient says. Asking patients about nonmedical aspects of their lives, including their hopes and worries, gives the clinician important insights and communicates that the clinician values their feelings.

Identifying and affirming emotional responses also demonstrates empathy. Clinicians may be reluctant to address strong emotional responses directly, worrying that doing so will take too much time or be seen as an invasion of privacy. However, expressions of empathy can encourage patients to get to the heart of their concerns.

Responding to a strong emotion, such as fear, anger, or sadness, can be difficult, but a structured approach can be helpful (Box 160-2). Clinicians can use reflective statements to encourage patients and family members to express themselves and are particularly important when patients and family members are feeling guilt or shame about the subject matter. Clinicians can validate emotional responses as understandable and common. Such expressions convey understanding

**BOX 160-2** PEARLS for Difficult Conversations**PARTNERSHIP**

- *We will work together to deal with this.*

**EMPATHY**

- *I wish that things had turned out differently.*

**APOLOGY/APPRECIATION**

- *I’m sorry that I don’t have better news.*
- *You are handling this news quite well.*

**REFLECTION**

- *You seem upset by what I just told you.*

**LEGITIMATION (VALIDATION)**

- *It is understandable that you feel angry right now.*

**SUPPORT**

- *I will do what I can to help.*

without suggesting that the person’s response is one that the clinician agrees with.

Angry responses, especially those directed at clinicians, are difficult to handle. Validating such anger usually has the effect of diminishing it, rather than fueling it, and can be done in a supportive and respectful way. Clinicians should bear in mind that anger is a natural response to pain, loss, and fear, and that it can feel as if it is directed personally at the clinician even when the real cause is the situation. A defensive response from a clinician is likely to be counterproductive, escalating the person’s anger. It is important for clinicians to remain empathetic while also maintaining enough detachment from the interaction to monitor their own reactions.

Clinicians can demonstrate empathy and concern toward patients through promises to continue to be involved. Families appreciate hearing that clinicians are primarily interested in their child’s well-being and will provide them with support in whatever way they can.

**PROVIDING INFORMATION**

As with any interaction, advanced preparation is useful. Clinicians should consider their own emotional response to the situation, the patient, and the family and how best to make the discussion productive. For example, a clinician who had trouble with a particular family member in a prior interaction may choose to take a different approach in talking with the family, to speak to the difficult person individually, or even to ask another clinician to lead the discussion. Having time to prepare written information regarding the disease, treatment options, or support groups will help the family members recall the information they receive in the discussion.

It is helpful to provide preemptive counseling about diagnostic tests or procedures with highly consequential results. Families benefit from having at least a basic understanding of the possible results, including the ongoing uncertainty of an ambiguous or nondiagnostic result. The pretest discussion can build a solid foundation for the discussion of the test results. Clinicians should discuss important or ambiguous test results in person, in a dedicated counseling session whenever possible, rather than relay them over the phone. Optimally, posttest discussions should occur as soon as possible after results are available and be structured to allow other members of the medical team and family who wish to be involved in decision making to participate. Unanticipated medical problems can arise with such acuity that families and clinicians must discuss test results and treatments with little time to prepare and plan.

Clinicians should still do what they can to help families feel that they have time to consider their options. When families are uncertain of how to proceed with treatment, it may be possible in some cases to use temporizing measures to extend the time window for making a more definitive decision.

The location chosen for discussions should be as quiet, comfortable, and private as possible. In both the outpatient and inpatient settings, having a dedicated consultation room for such discussions is ideal. However, even when only the examination or patient room is available, sitting down before beginning discussions can increase relaxation and indicate that the clinician considers the conversation important enough not to rush. Facial tissues, paper and pens for taking notes, and water should be available.

Whether it is appropriate for minor children to be present during discussions of their diagnosis, prognosis, and treatment will depend largely on their age and maturity. Clinicians should strive to follow the parents' wishes. A child-life specialist may be an available resource for explaining medical procedures to children in an age-appropriate manner. Clinicians should also ask parents about whether they wish for members of their extended families to be included in discussions. Clinicians may wish to invite the participation of other staff members who have been involved in caring for the patient, including physicians, bedside nurses, therapists, social workers, and chaplains. All participants should introduce themselves by name and title and/or relationship to the patient.

Because family members may have heard or understood previously conveyed medical information differently from clinicians, from one another, or from other sources (such as the Internet), it is useful to begin discussions by asking family members to summarize the child's condition. This not only gives the clinician a sense of how much family members already know, what their concerns and beliefs are, and where further discussion needs to start, but also informs clinicians of the type of language the family members feel comfortable using to discuss medical issues. Clinicians should also ask, early on, what families are hoping to learn from the discussion. Clinicians may use this to propose an overview of their goals for the discussion, keeping expectations to a manageable size and offering to address other topics at another time.

Being mindful of an overall plan for the session can improve the consistency with which basic principles of good communication are followed. A six-step method, known by the acronym SPIKES, has proven to be an effective tool for delivering bad news (Kaplan, 2010) (Box 160-3).

Clinicians may find it quite natural to launch into long, complex discussions of medical issues, but it is unlikely that families will understand or retain what they hear. Families appreciate receiving information in small, digestible amounts expressed in words with which they are familiar. Clinicians can employ a number of methods to improve understanding and retention: telling a personal anecdote, drawing illustrations, or providing the family with written (or online) resources for later review. Clinicians should also ensure that families understand when and why important information, such as the patient's diagnosis or prognosis, is uncertain. Clinicians who use an "ask-tell-ask" paradigm with each new topic that they introduce find that it allows them to tailor the information provided to the needs of the family and to check for any misunderstandings or gaps that need correction. It is also generally helpful for clinicians to adhere to a consistent template for keeping conversations organized.

When clinicians anticipate that they are going to say something that will be emotionally difficult for the family to process, they should introduce the topic gradually, with frequent pauses to allow for questions. Before revealing information that may be distressing, an effort can be made to lessen

### BOX 160-3 The Six Steps of SPIKES

#### S—SET UP THE SESSION

- Arrange for privacy.
- Involve significant others.
- Sit down.
- Make a connection with the patient.
- Manage time constraints and interruptions.

#### P—ASSESS THE FAMILY'S PERCEPTION

- "Before you tell, ask"—ask the family members to summarize their current understanding of the situation.

#### I—OBTAIN THE PATIENT'S INVITATION

- Some patients do not want full information.

#### K—GIVE KNOWLEDGE TO THE FAMILY

- Warn the patient that bad news is coming.
- Speak at the level of comprehension of the patient.
- Use nontechnical words when possible.
- Avoid excessive bluntness.
- Give information in small chunks and check for understanding.

#### E—ADDRESS EMOTIONS WITH EMPATHY

- Observe for emotional responses.
- Identify the emotion and the reason for it; ask if unsure.
- Acknowledge emotions with empathic and validating statements.

#### S—STRATEGIZE AND SUMMARIZE

- Ask if the family is ready to discuss plans.
- Check for misunderstandings and unrealistic expectations.
- Frame treatment options in terms of specific patient goals.

their surprise through the use of a "warning shot" that allows them to better prepare to hear what you have to say. The expression "I'm sorry to tell you this" should be used cautiously because families may misinterpret the word "sorry" as an apology or as an expression of pity, causing them to react with anger or mistrust.

Pauses after statements with great impact give listeners time to process the information and their emotional response to it, whether disbelief, sadness, or anger. Clinicians should view a patient's silence after hearing bad news as an opportunity for them to show the patient empathy. Nonverbal signs of support can help to convey empathy better than words alone. In the context of difficult treatment decisions, clinicians should try to help families express their feelings about their goals for treatment, particularly whether they place more value on quality of life and avoidance of treatment side effects or on the child having the greatest possible chance of response to treatment. Clinicians can then frame their discussion of treatment options in terms of how each may or may not help the family achieve their goals. Medical decisions should be made based on scientific knowledge and standards of care, but they should reflect the personal, cultural, and spiritual values of the family. It is particularly important to check that families understand the purpose, risk, and potential for benefit of any treatments before they are considered mutually agreed upon (Jeoung, Yang, Bak, Lim, and Sim, 2014).

When the prognosis is uncertain, it can be difficult to make the risks understandable with the use of statistical descriptions alone, even when simplified. Using a diagram such as a single darkened circle out of 10 to convey the significance of a 10% risk can help avoid misunderstandings. It is also important to make it clear when the outcome is unclear. Families may come away from discussions believing that a clinician described the prognosis as absolutely positive or negative, despite efforts to convey uncertainty.

Understandably, families experience grief when they perceive that a child's diagnosis implies any chance that the child will not be healthy, not recover, or not survive. It is important to try to point out positive and negative aspects of the situation, even when the prognosis is dire, and to avoid statements that convey abandonment. Even when a child's condition is beyond hope of cure, the family will still be focused on hope that treatments can achieve other important goals, such as pain control and symptom relief.

## SPECIFIC CHALLENGES

### Low Health Literacy

Communication with one or more family members may be difficult because of a language barrier, low literacy, or impairments in receptive or expressive language skills. Nearly one fifth of adults living in the United States speak a language other than English at home, and many who speak English as a second language may only reluctantly admit to doing so less than fluently. Information given to patients and families, whether verbally or in written materials, is above their level of comprehension about half of the time. Asking family members for the highest grade they completed in school will often overestimate their reading comprehension level. Men are more likely than women to have lower health literacy but are less likely to identify as such when asked.

Several measures of health literacy have been designed for research purposes, but one tool that is particularly easy to administer quickly is the Rapid Evaluation of Adult Literacy in Medicine–Revised (REALM-R). This screening test asks subjects to read aloud the following list of eight words: *osteoporosis*, *allergic*, *jaundice*, *anemia*, *fatigue*, *directed*, *colitis*, *constipation*. Subjects unable to pronounce more than six of these words correctly are likely to have reading abilities at the sixth-grade level or lower. Other measures, which may take more time to administer, assess subjects for other aspects of health literacy, including numeracy and familiarity with medical concepts (Duell, Wright, Renzaho, and Bhattacharya, 2015). Clinicians can use information about health literacy to tailor how they convey spoken and written medical information.

### Family Discord

Family members may have differing opinions and values and struggle to agree on treatment decisions. When such conflicts arise, the clinician should try to express empathy for all points of view while looking for common ground. If the discussion threatens to become disruptive, the clinician may choose to restrict further discussion of that topic (Cannarella Lorenzetti, Jacques, Donovan, Cottrell, and Buck, 2013).

### Alternate Belief Systems

Families may ask that a child be shielded from some medical information or decisions, contrary to more prevalent views of patient autonomy, or may ask that medical decisions be made on the basis of an alternate belief system, such as faith healing or traditional medicine/folk remedies. The reasoning behind any treatment decision should be made clear through discussion—what initially appears to be lack of cooperation with recommendations may be a result of lack of understanding or fear of the unknown.

### Spirituality

Religious and spiritual faith play a major role in shaping the goals and values of many families, and it is usually helpful to

broach the subject when exploring a family's worldview and sources of support. Views on illness, medicine, death, and dying can vary greatly between religions and even within sects of a religion. Patients and families often derive comfort from the opportunity to seek counsel from spiritual leaders when facing difficult decisions. In many cultures, there is crossover between the roles of healthcare providers and spiritual leaders, and some families may look to a clinician as a source of spiritual support. It can be appropriate to accept offers to pray with families if clinicians are able to do so based on genuinely held faith, but it may be a violation of interpersonal boundaries for clinicians to spontaneously offer to do so (D'Souza, 2007). It is perfectly acceptable and appropriate for clinicians to decline such requests respectfully, instead referring families to spiritual support services.

### Difficult Patients

Clinicians may encounter family members with whom they find it especially difficult to build rapport and partnership. A family member's particular emotional response to grief, such as anger, may cause difficulties. It may be family members with disorders, such as alcoholism or hypochondriasis, with whom clinicians struggle to feel empathy. Clinicians should cultivate self-awareness of how they respond to patients and reflect on what they are responding to, whether it is reasonable, and whether they can overcome those reactions.

If a person becomes inappropriately angry during an interaction, a clinician may choose to attempt to continue to engage with the person, giving warnings and choices that indicate a willingness to continue listening if boundaries are respected. However, when there are reasonable safety concerns, it may be wiser for clinicians to avoid further confrontation and either walk away from the conversation or call for help from security officers. Demonstrations of extreme anger are unusual but can occur as a defensive reaction to other intense emotions, such as fear, or may reflect an underlying pathology in the person, such as substance abuse or a personality disorder.

Occasionally, frustration and anger boil over to the point of family members becoming verbally abusive or physically threatening toward one another, toward clinicians, or toward other staff. A family member with a psychiatric disorder or substance abuse problem is particularly likely to behave inappropriately. If clinicians are unable to defuse a potentially dangerous situation, they should put their own safety first, carefully withdraw from the room, and seek help.

### Uncertain Test Results

Communicating test results is difficult enough in general, and especially so when the interpretation is uncertain. Genetic tests are particularly likely to be of uncertain significance. There are common phenotypes with variable genetic bases (e.g., nonsyndromic global developmental delay), genotypes with highly variable phenotypic expression (e.g., Marfan syndrome), and genetic mutations with incomplete penetrance (e.g., *BRCA1* mutations). As genetic screening tests become more sensitive for previously unreported copy-number changes and mutations, these tests are reporting an ever-increasing number of genetic variants of unknown significance (VUIs). As with any test, it is important that the ordering physician understand and consider the sensitivity and specificity of a genetic test before it is ordered (see Chapter 161). For example, a patient with Angelman syndrome resulting from a *UBE3A* mutation in a splice site, detectable through traditional Sanger sequencing of the whole gene, might initially escape diagnosis when tested by whole-exome sequencing or

with a multigene panel using a next-generation sequencing platform.

When a screening test reveals a VUS, the initial step toward reducing the uncertainty of its significance is parental testing to determine whether the variant was inherited or arose *de novo*. If the VUS was inherited and the carrier parent is unaffected, it is more likely that the VUS is benign. However, it can still be the cause of the disorder if there is a second mutation elsewhere in the same gene or if the variation has reduced penetrance or expressivity in the parent.

The nature of genetic disorders also lends itself to parents experiencing shame and guilt. This may lead to denial—for example, a father refusing to be tested for carrier status, not wanting to know if he bears direct responsibility for his child's illness. Test results may also reveal unexpected information. When a patient with an autosomal-recessive condition is hemizygous for an uncommon mutation or has extensive homozygosity, it suggests consanguinity or even incest. Parental testing may reveal nonpaternity of the father. Ideally, clinicians should address these and other issues in pretest counseling.

## Terminal Illnesses

Discussing an illness that is likely to be terminal is uniquely challenging for families and for clinicians. Studies have shown that clinicians are more than twice as likely to overestimate a patient's survival as to underestimate it, and that their overestimates are greater when they are familiar with the patient. When discussing prognosis, it is best for clinicians to avoid giving a specific time frame, such as the average life expectancy, without also discussing the range of outcomes and the possibility of exceptions, including both shorter and longer survival.

Clinicians are also likely to offer treatments that they themselves believe to be futile and not discuss prognosis at all, not wanting to broach such anxiety-provoking topics or to deprive families of their hope for a cure. Understandably, clinicians tend to assume that families will want to pursue treatment options that will lead to recovery from illness, even when reaching that goal requires significant pain and suffering. It is always better to explore this upfront, so that the necessary trade-offs are clear. When no treatment options are likely to result in recovery, or survival, it is even more important to discuss this with families and help them focus on other goals for the patient. Families may or may not choose a second round of chemotherapy after relapse of a cancer; they may or may not want resuscitation performed if an attempt at extubation fails. There is not necessarily a path that suits all families, and by listening carefully, clinicians can guide families toward the path that best fits their values. Palliative care specialists are particularly experienced and comfortable with discussing these issues.

Avoiding difficult discussions about advanced care and resuscitation increases the likelihood that clinicians will maintain their default position, ready to make all efforts to prolong life, regardless of the potential for the child to return to an acceptable quality of life. If doctors find it difficult to discuss

the limited benefits of a test or treatment, patients and their families may have unrealistic expectations and make decisions that are not in the patient's best interest.

Clinicians may avoid having a full discussion about the short- and long-term consequences of an illness, even avoiding the topic completely, when they themselves are unused to dealing with grief. With training, clinicians can learn to remain supportive in the face of even the strongest emotional responses that patients and family members experience in response to bad news. Helping to guide people through their denial, depression, anger, and bargaining, leading them toward ultimate acceptance and peace of mind, can become a very rewarding aspect of medical practice (Back, Arnold, and Tulskey, 2009).

## E-BOOK FIGURES AND TABLES

The following figures and tables are available in the e-book at [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

**Box 160-4** Template for Discussions.

**Box 160-5** Discussing Complex Outcomes.

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

The idea of personalized medicine offers the prospect of customization of medical management with unprecedented precision (Collins and Varmus, 2015; Hamburg and Collins, 2010). This includes use of testing to precisely define a diagnosis, choose the most appropriate treatment, and tailor drug dosage to individual metabolism. In addition it entails development of new treatments based on knowledge of pathophysiology. It can also entail predictive testing and formulation of an individualized management plan to reduce risk.

Genomic testing permits diagnoses to be made that had previously been elusive in spite of intensive medical evaluation. In some cases this opens the door to treatments targeted at the disease mechanism and may reveal subgroups of patients who will respond particularly well or poorly to the treatment. It can also be used to guide administration of a drug at a dosage that will minimize side effects and maximize efficacy. In some cases, genomic testing may reveal individuals who are at risk of disease well in advance of signs or symptoms, allowing anticipatory guidance or even efforts to prevent or delay disease. This chapter reviews some of the applications of genomics to pediatric neurology and briefly considers the application of nongenomic approaches as well.

## GENOMIC DIAGNOSIS

The mainstay of the genomic approach is the ability to provide testing, either to diagnose a rare Mendelian disorder, to assess risk of a common multifactorial disorder, or to determine individual patterns of drug metabolism. Until recently, genetic diagnosis was limited to analysis at the two extremes of genetic variation: single-nucleotide changes and large-scale chromosomal abnormalities. Changes within a gene may alter the amino acid sequence of a protein, completely eliminate protein production, or alter patterns of splicing of the messenger RNA. Copy-number changes may occur on a larger scale, deleting or duplicating whole exons or groups of exons, or even entire genes or groups of genes, up to complete chromosomes. The major approaches to detection of genetic variants are summarized in Table 161-1.

The plummeting cost of genome sequencing has offered a new approach to genome-scale diagnosis (Bamshad et al., 2011). The protein-encoding portion of the genome, referred to as the *exome*, amounts to less than 1.5% of the 3.15 billion base pairs of the haploid genome yet harbors most of the known variants that account for disease. Exome sequencing can usually be performed for under \$1000, although the analysis of the tens of thousands of variants that are found in any individual may cost many times that amount. Further advances in sequencing are bringing the cost of whole-genome sequencing to a comparable level and may further increase the sensitivity of analysis. Exome or genome sequencing can reveal pathogenic mutations without prior knowledge of the target

gene (Yang et al., 2014). Interpretation can be complicated by the finding of variants of unknown significance. In addition, incidental findings of pathogenic mutations that predict disorders other than those that explain the phenotype also may result. These possibilities necessitate careful pretest and post-test counseling.

Although genetic counseling should be available when any genetic test is done, it is especially important when doing genome sequencing, given the complexity of the analysis and potential findings. Pretest counseling includes informing the patient about what the testing can and cannot accomplish, including the overall likelihood of achieving a diagnosis. The possibility of finding a variant of unknown significance must be discussed because patients are often unprepared for ambiguous results such as these. Testing also includes the possibility of incidental findings, such as discovery of unexpected genetic variants that predict medical problems different from those that prompted testing (Green et al., 2013). Some patients may decline to be informed of incidental findings, but such information offers potential for learning about potentially life-changing findings. There is also a need to inform patients about revealing potentially unexpected family relationships, for example, unexpected consanguinity. After the test results are available, counseling again should be provided to inform the patient of results and to put the results in perspective. There is the potential to identify multiple genetic variants of possible medical significance, so the session may be a long one, and most laypersons are not well versed in the concepts of genome sequencing. Findings may also have implications for other family members, which needs to be discussed and may require follow up.

## THERAPEUTICS

Genetic and genomic information can be used to guide drug therapy in three ways. First, precise definition of a medical condition at the genetic level can result in treatment that targets the underlying pathogenesis, with improved efficacy and reduced likelihood of side effects. Second, the manner in which drugs are absorbed, metabolized, and excreted is, to a large extent, under genetic control. Recognition of an individual's pattern of interacting with a drug can result in optimization of dosage, again improving efficacy and avoiding side effects. Also, some rare "idiosyncratic" side effects occur only in individuals with specific at-risk genotypes; recognition of such individuals allows the physician to avoid administration of the offending drugs, preventing potentially devastating adverse reactions.

### Targeted Treatment

Since the advent of molecular genetic approaches, the genes that underlie neurogenetic disorders have gradually come to light. This in turn reveals molecular mechanisms of disease

**TABLE 161-1** Major Approaches to Genetic Diagnosis

Mode of Analysis	Introduced	Applications	Limitations	Current Status
Unbanded chromosomal analysis	Late 1950s–1960s	Detection of aneuploidy	Unable to visualize small structural changes	Obsolete
Banded chromosomal analysis	Late 1960s–1970s	Detection of aneuploidy, large deletions, duplications, structural rearrangements	Limited resolution	Still in use
Fluorescence in situ hybridization	1990s	Detection of small deletions or duplications, characterization of unknown chromosomal rearrangements	Requires prior knowledge of region of concern	Still in use
Cytogenomic microarray	2000s	Detection of copy-number variants	Does not detect balanced structural rearrangements	First-line test for congenital anomalies, intellectual disability
Genetic linkage analysis	1980s	Determination of segregation of mutation in a family; does not require identification of specific mutation	Genetic recombination can lead to errors; requires family study	Rarely used clinically
Single-gene-mutation analysis	1980s–1990s	Identification of mutation in specific gene	Identification of variants of unknown significance; need to know target gene in advance; some mutations not readily detectable	Still in use
Exome/genome sequencing	2010s	Identification of pathogenic variants across genome	Variants of unknown significance; incidental findings; does not detect structural rearrangements	Emerging technology

that can guide the development of specific treatments. Medical treatment for some complications of tuberous sclerosis complex is now available, and clinical trials are under way for many other neurogenetic disorders, such as neurofibromatosis, Duchenne muscular dystrophy, and various forms of epilepsy. Some of these treatments target biochemical pathways involved in disease; some target the abnormal gene.

## Disease Stratification

Genetic studies also have the potential to inform drug therapy for common multifactorial disorders. Cancer is one area where this concept of disease stratification based on genotype has made significant progress. There are now increasing numbers of drugs that target specific tumor proteins that only are effective if those proteins are altered as a result of gene mutation. Genomic sequencing of tumors is now being done on a wide scale in an effort to identify other such targets; in some cases it is becoming routine clinical practice, and the information is being used to inform both prognosis and treatment.

## Pharmacogenetics

The study of genes that control drug metabolism is referred to as pharmacogenetics (*de Wildt, Tibboel, and Leeder, 2014*). Exogenous chemicals, including drugs, undergo metabolic changes in three phases. Phase I reactions are chemical changes in the drug, principally oxidation, reduction, or hydrolysis. These are carried out by multiple groups of enzymes, such as the family of cytochrome c oxidases, monoamine oxidase, and NADPH cytochrome P450 reductase. Phase II reactions involve conjugation of chemical groups onto the drug, such as glucuronidation, acetylation, methylation, and conjugation with glutathione. Phase III reactions involve active transport of the conjugated drug out of the cell, usually through action of ABC-type transporters, a family of ATP-dependent cell mem-

brane proteins responsible for pumping conjugated chemicals out of the cell.

Many of the enzyme systems involved in these reactions are encoded by genes that exist in various forms in the population (i.e., exhibit genetic polymorphism). These genetic variants may lead to either increased or decreased activity of the corresponding enzymes. The effect of such a variant on drug metabolism depends on the nature of the reaction and its role in metabolism of the drug. For example, some phase I reactions are required to convert a biologically inert drug to one that effectively interacts with its target, whereas others function to inactivate a drug. If the reaction activates a drug, a variant that increases activity will result in higher levels of the active drug in the system, and potentially toxicity; a variant that decreases activity will result in lack of sufficient active drug, and hence inadequate treatment. If the reaction inactivates a drug, the opposite will occur; reduced enzyme activity will lead to higher levels and potential toxicity, increased activity in rapid metabolism, and lower levels of the active drug. Some pharmacogenetic polymorphisms that are relevant to neurologic practice are listed in [Table 161-2](#).

## PREVENTION

Genomics offers the possibility of identification of risk factors for disease in advance of development of signs and symptoms, with the hope of maintaining good health as long as possible.

## Newborn Screening

The paradigm of newborn screening is that of detection of a treatable disorder before onset of symptoms to avoid irreversible damage. A successful program is predicated on the availability of an inexpensive but accurate screening test, an effective treatment, and knowledge of the natural history of the disorder. The advent of tandem mass spectrometry has

**TABLE 161-2** Major Pharmacogenetic Polymorphisms of Interest in Pediatric Neurology

Drug	Enzyme/Gene	Comments
Amitriptyline, desipramine, nortriptyline	CYP2D6/CPY2C19	Ultrarapid or slow metabolizers require dosage adjustment or alternative drug
Azathioprine	Thiopurine methyltransferase	Slow metabolizers at risk of fatal bone marrow suppression; rapid metabolizers may have inadequate treatment
Carbamazepine	HLA-B*15:02	Increased risk of Stevens-Johnson syndrome
Phenytoin	HLA-B*15:02 CYP2C19	Increased risk of Stevens-Johnson syndrome Dosage adjustment
Clopidogrel	CYP2C19	Intermediate or poor metabolizers: choose alternative drug
Warfarin	CYP2C9, VKORC1	Dosage adjustment based on genotype

allowed a significant increase in the number of disorders for which screening is possible without increasing the cost of testing. In the United States, state departments of public health run most screening programs, and the specific disorders to be screened are determined on a state-by-state basis. During the past decade, however, a systematic evidence-based effort has been under way to standardize at least the core panel. Recently the possibility of screening based on genomic sequencing has been in consideration. This offers the opportunity to vastly increase the numbers of conditions that could be detected but also raises significant challenges, such as the identification of variants of unknown significance or incidental findings. There is also the potential of discovery of variants that indicate a risk for a late-onset disorder. Typically, one does not do genetic testing of children for conditions that do not manifest until later in life. It is not known how such findings will affect the child and the parent-child relationship, or the way a child with such a risk should be followed by care providers. These issues are currently under study, and newborn DNA sequencing is not yet ready for routine clinical implementation.

## Risk Assessment

Genetic factors contribute to common disorders via a complex interaction of multiple genes and the environment. Approaches such as genome-wide association studies have revealed hundreds of gene loci that are associated with common disorders. There are several important caveats to keep in mind when genetic variants are used for risk assessment. First, in most cases the odds of disease in an individual who carries a specific variant usually are only modestly different from the odds for one who does not carry the variant. Second, the proportion of the genetic contribution to a disease accounted for by a specific variant may be small. Genome-wide association is based on the assumption that common variants (found in 1%-5% of the population) account for most of the genetic contribution to common disease. It is possible that at least some of the contribution is comprised of a constellation of rare variants

that may be almost unique to an individual—the “dark side” of personalized medicine (i.e., that risk is so personal it will never be possible to know for any individual). A third caveat is that case-control studies are done in specific populations, and results may not generalize to people of different ethnic backgrounds, a point that may not be appreciated by a layperson looking at information from a direct-to-consumer site. Fourth, genetic factors do not operate on their own to contribute to disease risk; thus there is concern that an individual could interpret risk to be low on the basis of genomic testing and ignore commonsense advice. Finally, the specific combinations of genetic and nongenetic factors that determine risk are not entirely known, and risk calculations may be based on proprietary algorithms, leading to different conclusions from the same data set. These caveats notwithstanding, individualized risk assessment has been marketed both through health professionals and to the public. Currently, the U.S. Food and Drug Administration is exploring the role it might play in regulating genetic testing, which has put a hold on direct-to-consumer genomic testing for disease risk assessment. It is likely that this landscape will continue to evolve in the coming years as the costs of genotyping decline, knowledge of disease associations increases, and the regulatory landscape is clarified.

## FUTURE PROSPECTS

The modern era of genomic medicine is in its infancy, and predictions are especially hazardous given the rapid pace of technological change along with changes in the context in which healthcare is provided. Indeed, some of the technologies that are fueling the personalized medicine approach are also catalyzing overall change in healthcare delivery.

## Genome Sequencing

As the price of genome sequencing decreases, it is likely that there will be increasing pressure to provide access on a routine basis. It should be noted that the cost of sequencing is only part of the overall cost of providing sequence-based genomic analysis. The informatics analysis currently exceeds the cost of sequencing itself, but that may change as approaches to analysis of genomic data advance. At least three issues will need to be addressed before routine genomic sequencing is offered: clinical utility, timing, and data storage.

## Patient Engagement

Although the focus in this chapter is on application of genomics to personalized medicine, there are many other areas of technology that may also be applied to the personalization of healthcare. These include imaging devices that provide highly precise data on both anatomy and physiology and may be placed in the hands of physicians or even patients at low cost. Advances also include portable and even wearable devices that track data in real time, such as physical activity, heart rate, and oxygenation (Topol, Steinhubl, and Torkamani, 2015). There is even a possibility of development of devices that will diagnose common conditions by themselves, without the need for intervention by a health professional.

These devices may be coupled with increasingly powerful and popular social networking and health-coaching systems. People already wear activity trackers and share their level of physical activity through social networking. Health coaches will be able to access real-time data and offer individualized advice on issues such as diet and exercise, and even optimal use of medical care. Social networking is also being used for patients to share their experiences with the healthcare system

and to assist one another in diagnosis and treatment of chronic illness. Although the quality of data that can be acquired by portable devices or self-reporting may be less than that obtained through more systematic professionally guided approaches, the sheer volume of data may lead to insights and even discoveries that would not have been made in conventional epidemiologic studies.

These approaches may supplant direct professional involvement in some areas of healthcare as less expensive and more accessible alternatives become available. This is exemplified by the availability of direct-to-consumer genomic data. It may be argued that the quality of care currently provided by such approaches is far inferior to that available with professional guidance. If the quality gradually improves, however, such models may eventually supplant existing approaches, along the lines of a “disruptive technology” that replaces traditional approaches because of lower cost, easier access, and comparable or better outcomes. Such a model raises complex questions regarding the ability to provide pretest and posttest genetic counseling, although new approaches to counseling may be developed as part of the model.

## FINAL COMMENTS

The revolution in healthcare represented by personalized medicine has been the subject of much hype and reactionary cynicism. The genome sequence was completed more than 10 years ago, and although there are tangible medical applications, such as cytogenomic microarray analysis and cancer sequencing, these advances are a long way from having transformed healthcare. It is clear that the path from sequencing

the genome to clinical application is arduous; some promised advances will prove to be unrealistic and some eventual applications will be ones we cannot dream of today. A statement that has become known as Amara’s law is apt here: We tend to overestimate the effects of a technology in the short run and underestimate its effects in the long run.

# 162 Pediatric Neurorehabilitation Medicine

Michael J. Noetzel and Nico U. F. Dosenbach

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Rehabilitation is the process of restoration after injury or disease, with the goal of maximizing an individual's ability to function in a typical manner. The application of rehabilitation extends far beyond the traditional bounds of medicine because one of its chief aims is to restore personal and social identity (Noetzel, 2003). The principles and challenges of pediatric neurorehabilitation are best understood in the context of the International Classification of Functioning, Disability, and Health. Impairment is the loss or abnormality of physiologic, psychological, or anatomic structure or function, whereas disability, the lack or restricted ability to perform a task, is dependent on the individual's environment. Thus one of the ways in which neurorehabilitation can be carried out is to modify or adapt the environment. Disability does not flow solely or directly from the type and degree of impairment. Instead, disability is a three-dimensional construct, consisting of functional impairment, activity limitations, and participation restrictions. Each dimension is the result of interaction between the biologic features intrinsic to the individual's medical condition and the physical and social environment (Noetzel, 2012). The concept of dependency also plays a fundamental role in rehabilitation. Degree of dependency is a critical element in the cost of rehabilitation care, as well as in quality of life.

The disablement/dependency paradigm in pediatric neurorehabilitation emphasizes progress toward appropriate functional outcomes (Noetzel, 2003). Thus therapeutic interventions should be based primarily on the disablement and resultant activity limitations, as opposed to the underlying pathologic process, and rehabilitation techniques should be transferrable from one child to another despite differences in diagnosis. Similarly, the process of neurorehabilitation logically involves a multidisciplinary team working in collaboration with the patient and the patient's family. Finally, the paradigm provides a framework that can be expanded to encompass all aspects of neurorehabilitation inherent in the practice of child neurology. For example, the paradigm works just as well in describing an adolescent with seizures (impairment) who is prohibited from driving an automobile (disablement) and relies on his parents for rides (dependency) as it does for a child with a spinal cord injury causing paraplegia and impaired ambulation.

## MECHANISMS UNDERLYING FUNCTIONAL RECOVERY IN THE NERVOUS SYSTEM

The degree of recovery after injury to the nervous system is variable but often incomplete. A better understanding of the cellular and molecular bases of neuronal dysfunction and the mechanisms by which recovery of function occurs is the framework upon which development of any pediatric neurorehabilitation program must rest (Noetzel, 2003). Based upon increasing scientific evidence (Johnston, 2009), we now recognize that significant biologic modification in response to injury and developmental aberrations exist within the nervous

system that are more dynamic than suggested by prior studies (Dosenbach and Noetzel, 2014). Additionally, meaningful recovery of function continues for an extended period of time, longer than previously recognized (Noetzel, 2012). These findings stand in contrast to former beliefs that recovery essentially was a biphasic process in that early improvement was due to reversibility of factors affecting dysfunctional, as opposed to dead, tissue. Later improvements in functional capabilities were attributed to behavior modification. Presently, however, there is strong evidence that changes in neuronal circuitry within the central nervous system (CNS) also mediate later recovery of function (Johnston, 2009), although there remains ongoing debate concerning the relative contributions of brain reorganization and functional adaptation.

## Resolution of Temporary Dysfunction

Rapid recovery of function within hours to days after CNS injury likely relates to resolution of temporary dysfunction caused by mild tissue hypoxia, elevated intracranial pressure, edema, small contusions, and reversible depression of metabolic activity in areas remote from the primary injury (Dosenbach and Noetzel, 2014). Focal brain injury results in depressed metabolic activity in noncontiguous brain areas, secondary to a decrease in transmitter synthesizing enzymes in regions of damage. The concept of diaschisis similarly has evolved to explain uninvolved brain areas that are rendered temporarily nonfunctional when deprived of appropriate input from a remote injured CNS region. Recovery of function presumably transpires as a result of increased neurotransmitter synthesis or elevated production of receptors. In addition, cellular and molecular mechanisms at the systems level are initiated within 1 to 5 days after injury to help mediate recovery.

## Plasticity of the Nervous System

Although, individual brain regions contribute specialized computations, all human behaviors are the emergent property of networks distributed through cerebral cortex, subcortical structures, and even the cerebellum (Dosenbach and Noetzel, 2014). Abilities such as executive control, attention, and movement are supported by widespread networks and not localized to specific brain areas (Carter, et al., 2012). The brain's organization into functional networks allows a certain degree of malleability both during development and in reaction to damage. Plasticity is a term that encompasses multiple capabilities of the nervous system to encode information in response to learning, as well as adapting to environmental changes (Johnston, 2009). In the context of rehabilitation, plasticity may relate both to redundancy within the brain's functional network architecture, as well as injury-driven reorganization of brain networks. These redundancies in connectivity and computational specialization allow functional networks to reorganize into new network states that enable the best possible performance (Dosenbach and Noetzel, 2014). For example, during the initial subacute recovery phase in adult stroke patients, widespread activations throughout

the motor system are observed. Patients with good functional recovery gradually develop activation patterns focused in perilesional areas—that is, patterns of more typical activation, even though task performance relies on different functional neuroanatomy (Dosenbach and Noetzel, 2014).

## Reorganization of Neuronal Connections

The proposed events of neural reorganization that emerge in response to injury are well-recognized, normal developmental processes, which are reactivated or potentiated in response to CNS damage (Noetzel, 2012). After the immediate postinjury period, functional recovery starts to occur through modification of active neural connections, three of which have been suggested as the most promising examples of reorganization mechanisms. Axonal regeneration, whereby damaged axons regrow to their normal target, serves as a dominant process of recovery in the peripheral nervous system, but its role in restoration of brain function is debatable. Axon retraction and synaptic pruning are the second mechanisms by which neuronal reorganization transpires. During early development, certain axons project branches that ultimately will be retracted. Similarly, maturation of the cerebral cortex in early postnatal life is characterized by an initial proliferation of synapse formation, followed by activity-dependent pruning of excessive synapses. Research now indicates that these normal retraction and pruning processes may not occur if nervous system injury is sustained early on, thus providing a mechanism for retention of function.

Collateral sprouting involves axonal outgrowth from undamaged neurons and the establishment of synaptic contact at sites vacated by degenerating neurons. This process typically is confined to brain regions normally innervated by nerve cells sharing common features with the injured neurons, and axonal growth cones rarely migrate into novel nervous system domains. Collateral sprouting is influenced by growth and apoptotic factors, in particular activation of genes responsible for molecular growth-promoting programs. As such the magnitude and rate of sprouting after acute CNS injury appears much greater in the immature brain.

A potential final mechanism involved in modifying neural connections consists of neural progenitor cells, which retain the capacity to proliferate, divide, and differentiate after injury. Damage in the CNS initiates a cascade of molecular signals that recruit migrating neuroblasts into the injured areas. Whether these cells actually promote restoration of function in humans has not been established.

## Functional Recovery Through Adaptation

Recovery long past the onset of injury primarily is dependent on functional substitution in which an altered strategy is adapted to achieve a goal. It is a recovery of the “ends” and not a restoration of the “means to that end,” in that the action performed is modified in order to fit the capabilities of undamaged nerve cells. The tissue subserving this recovery does not alter its intrinsic properties but utilizes novel strategies to complete the task. Because functional substitution is highly dependent on new learning and repetitive problem-solving, neurorehabilitation can influence greatly on this type of recovery.

## PRINCIPLES OF PEDIATRIC NEUROREHABILITATION

Pediatric rehabilitation has several guiding principles based upon the nature of recovery and reorganization mechanisms, as well as the age and developmental level of the patients requiring treatment (Box 162-1) (Noetzel, 2003). The

rehabilitation process requires a coordinated transdisciplinary team working to provide integrated evaluations and therapeutic interventions. Because injury to or malformation of the brain and spinal cord accounts for the majority of children referred for rehabilitation, child neurologists are uniquely positioned to contribute in a meaningful way to the discipline of rehabilitation (Noetzel, 2003). Issues such as home accessibility, psychosocial adaptation, and school reintegration mandate that the team include individuals who can address these all-important considerations. In addition, the rehabilitation process should concentrate on strategies designed to effect functional improvement. The team must have a clear understanding of the physical, emotional, cognitive, and social consequences of a child’s injury (Noetzel, 2012). The degree, extent, and rate of recovery, which varies significantly among children, as well as differences in functioning from setting to setting and task to task, mandate continual assessment. Neurorehabilitation is a spiral management process in which a treatment program is initiated and then constantly revised and updated, based on therapy-mediated improvements.

Another essential principle is that reassessments must be guided by a detailed understanding of normative maturation. Typical developmental milestones can be identified as sequential goals (Noetzel, 2003). In addition, as a result of injury or illness, the pediatric patient typically loses age-appropriate developmental capabilities. Thus the manner in which therapy can be provided and the individual’s ability to respond to it will be limited. This is most notable early on in patients who lack skills necessary to learn complex strategies upon which functional substitution is predicated (Noetzel, 2012). Finally, an understanding of cognitive development allows more accurate prediction of the long-term effects of cerebral injury sustained by young children, especially in cortical areas subserving functions that mature later such as executive functioning and emotional and attentional control.

Equally important in pediatric rehabilitation is the core principle of family-centered care, recognizing that the child’s family is a constant presence in the rehabilitation process, available to provide comfort and reassurance during times of stress (Dosenbach and Noetzel, 2014). Practical management decisions must be endorsed by the family, whose members should be expected to participate in therapy programs.

A final guiding principle is that intervention should begin as soon as possible. Coma is not a contraindication to the initiation of rehabilitation strategies, and once the patient is medically stable, therapy should be instituted (Noetzel, 2012). This early phase of intervention is designed to limit maladaptive movement patterns and to prevent, or at least minimize, complications that can take months to resolve if not promptly addressed.

## MEDICAL ASPECTS OF ACUTE PEDIATRIC REHABILITATION MANAGEMENT

In any child with an acquired nervous system injury, the risk for compromised nutrition is high. Causes include: a hypermetabolic state resulting from trauma and/or infection; delayed gastric emptying and intestinal dysmotility; oral pharyngeal dysfunction; and underestimation of caloric requirements necessary for repair and growth (Noetzel, 2003). Oropharyngeal dysfunction and swallowing difficulties mandate a detailed evaluation by a feeding team.

Fever and associated infection often affect acute management (Noetzel, 2012). In those with intracranial trauma, the possibility of CNS infection must be considered (Noetzel, 2003). Sinusitis is a relatively common infection

secondary to the frequent need for long-term nasogastric tube utilization.

Dysautonomia characterized by simultaneous and paroxysmal sympathetic and muscle overactivity typically follows severe traumatic brain injury, with an incidence of 5% to 12%. Autonomic changes include marked tachycardia, hyperventilation, hypertension, fever, and increased sweating; motor disturbances include posturing, dystonia, rigidity and spasticity. Evidence-based treatment paradigms for dysautonomia in pediatric patients do not exist. Bromocriptine, propranolol, clonidine, and midazolam may be beneficial, although intrathecal baclofen is clearly effective in children who are resistant to oral medications (Noetzel, 2012).

Damage to the pituitary and hypothalamic glands can produce the syndrome of inappropriate antidiuretic hormone secretion (SIADH), or conversely, central diabetes insipidus (Noetzel, 2012). Gastrointestinal disorders in acquired nervous system injury range from delayed gastric emptying and intestinal stasis to hemorrhage secondary to esophagitis and ulcers (Noetzel, 2003). In severe CNS trauma, long bone and other skeletal fractures are common. Such fractures may not be apparent early on in the comatose patient or in spinal cord injury (SCI) but reveal themselves during the course of treatment.

## COMPREHENSIVE PEDIATRIC REHABILITATION PROGRAMS

Once medical issues have stabilized, the direction in which the rehabilitation process should proceed must be addressed. In some children, recovery has been sufficiently rapid for discharge to outpatient or day treatment programs. For others whose progress has been very slow, a subacute nursing center with less intense therapy is reasonable. A dedicated pediatric rehabilitation program is indicated for most children and adolescents with moderate to severe acute neurologic injury whose management issues typically include:

- Inability to walk, climb stairs, or perform wheelchair transfers
- Dependence in self-care activities
- Receptive/expressive aphasia
- Cognitive or perceptual motor dysfunction
- Incontinence of bowel or bladder
- Limited functional performance due to pain
- Severe neuromuscular deconditioning secondary to prolonged ventilatory support

Eligibility criteria for admission to comprehensive neuro-rehabilitation services include: a primary condition that is medically stable, but mandates intensive rehabilitation; the premorbid physical and cognitive level of the child indicates potential for meaningful recovery; the patient is responsive to verbal or visual stimuli and has sufficient alertness to participate in rehabilitation; and the diagnosis allows an expectation for improvement with the potential to achieve clearly identifiable treatment goals within a reasonable time period (Box 162-2) (Noetzel, 2003).

A comprehensive pediatric rehabilitation program is a highly intensive service with an initial minimum of 3 hours of therapy each day. As recovery proceeds and endurance improves, treatment is expanded to a full day. The program is supervised by a physician with specialized training and experience in rehabilitation medicine. Rehabilitation nursing care/supervision must be provided 24 hours a day. In addition to physical and occupational therapists and speech-language pathologists, most teams also include social workers, child-life specialists, music therapists, chaplains, orthotists, and

dietitians. In any program with a large number of children with acquired brain injury, psychologists and neuropsychologists are essential, as psychological support and neurocognitive assessment and intervention will be required at frequent intervals. Written evaluations should: measure progress; determine impediments to recovery and potential solutions; readjust established goals; develop and implement discharge plans; and facilitate transition into the community (Dosenbach and Noetzel, 2014).

## REHABILITATION TREATMENT OF MOTOR IMPAIRMENT

### Overview

Almost every patient requiring acute neurorehabilitation will manifest motor impairments or alterations in tone (Noetzel, 2003). In pediatrics, spasticity is most commonly found in children with cerebral palsy, but spasticity can result from any brain or spinal cord disorder causing damage to or abnormal development of nerves or pathways controlling motor movement. In adults motor rehabilitation is predicated on long-standing therapies designed to improve performance (Dosenbach and Noetzel, 2014). Similar interventions are endorsed in pediatric patients despite lack of strong empirical evidence to substantiate or quantify the actual benefit (Noetzel, 2012). Pediatric rehabilitation includes physical, occupational, and speech therapy and utilization of assistive devices and/or medications to reduce elevated tone and facilitate postural alignment. Aerobic conditioning, muscle strengthening, and task-specific training strategies assume greater importance as recovery proceeds. Innovative techniques for improving motor outcome, such as constraint-induced movement therapy (CIMT) and direct stimulation of the CNS, recently have been introduced (Dosenbach and Noetzel, 2014).

### Treatment of Spasticity

In the early phase after CNS injury, reduced tone typically is encountered; over time, the pattern often evolves into spasticity as part of the upper motor neuron syndrome. Spasticity is characterized by excessive and inappropriately timed activation of skeletal muscles, which interferes with normal voluntarily movement. In most children, spasticity impairs passive movement and static postural alignment and is accompanied by deficient activation of voluntary movement, resulting in weakness, clumsiness, and reduced exercise tolerance. Invariably, these deficits cause excessive energy expenditure compared with able-bodied children (Noetzel, 2012). Spasticity eventually reduces protein synthesis in muscles and impairs longitudinal growth, causing contractures and bony deformities.

Treatment of spasticity should be predicated upon establishing goals that improve a child's functional capabilities, most commonly either upper-extremity use in activities of daily living or movement to achieve ambulation. Improvement of head, neck, and trunk posture by reducing spasticity may improve oral feeding and provide better breath support for speech. However, spasticity may impart advantages, including maintenance of muscle bulk and tone, support of circulatory function, and assistance in transfers and ambulation.

### Rehabilitation Therapy

Early on the focus of relieving spasticity is to minimize joint and muscle contractures with a secondary goal of eliminating painful spasms (Noetzel, 2003). Management in comatose or obtunded patients combines proper positioning, range

of motion exercises (ROM), and splinting (Fig. 162-1). As recovery ensues, specific affected muscles are targeted. Heat, cold, water, and electrical stimulation are effective adjuncts with few side effects or contraindications (Noetzel, 2012).

Positioning is designed to facilitate proper postural alignment and symmetry and to correct weight-bearing distribution throughout the body. Tone-inhibiting techniques can use gravity to stretch muscles and promote relaxation. In the latter stages of recovery, proper position facilitates active contraction of functionally weak muscles (Noetzel, 2003). Other mainstays are casting and splinting, designed to prevent formation or worsening of contractures in spastic extremities (Noetzel, 2012). Inhibitive casting also may lower tone via several mechanisms. Splints or orthotics may be utilized to produce functional benefits (Fig. 162-2). For example, an appropriately designed wrist/finger extension splint may improve hand activities such as keyboarding.

Equipment is an important adjuvant, especially in patients with chronic motor deficits. Standing frames allow a child with reduced weight-bearing ability to be placed in an appropriate position to minimize the development of contractures, improve bone maturation and increase pulmonary function. Deficits in static and dynamic balance may prevent independent ambulation, mandating the use of walkers and crutches (Fig. 162-3). For recreational activities, more creative assistive devices have further enhanced the independence of patients with motor disability (Fig. 162-4).

**Oral Medications**

Despite the fact that a large number of antispasticity medications have been available for many years, data currently available (Table 162-1) are too limited to conclude that any of these agents is truly effective in reducing spasticity in acutely brain-injured pediatric patients. In children with spastic cerebral palsy, data on tone reduction efficacy exist, but whether oral antispasticity medication can improve functional

capabilities has not been determined (Delgado, et al., 2010). Moreover, the side effects of antispasticity medication in children are concerning (Table 162-1). Thus antispasticity medication should be utilized only when severe spasticity cannot be managed by other modalities and continued use must be justified by ongoing demonstrable benefit. Finally, antispasticity medication should be prescribed in those situations

**Figure 162-2. Ankle-foot orthotics.** Ankle-foot orthotics often are appropriate for children starting to make gains in functional ambulation. (Courtesy of Dr. Janice E. Brustrom-Hernandez and Anna Marie Champion.)

**TABLE 162-1** Oral Antispasticity Medications

Drug	Mechanism	Dosage	Side Effects	Studies
Baclofen (oral)	GABA-B agonist inhibits at spinal cord level	2–7 yr; max 40 mg 8–11 yr; max 60 mg >12 yr; max 80 mg; divided three to four times a day; increase every 3 days	2 + sedation, confusion 2 + weakness, ± seizure control	DBPC (adult)
Clorazepate	Facilitates GABA	>9–12 yr; max 60 mg/day >12 yr; max 90 mg/day; divided twice a day to three times a day; increase weekly	1–2 + sedation 1–2 + weakness	DBPC (adult)
Clonazepam	Facilitates GABA	<10 yr or 30 kg; max 0.1–0.2 mg/kg/day >10 yr or 30 kg; max 20 mg/kg/day; divided twice a day to three times a day; increase every 3 days	3 + sedation 2 + weakness	Open trial only
Diazepam	Facilitates GABA	<12 yr; 0.1–0.8 mg/kg/day >12 yr; 6–30 mg/day; divided three times a day to four times a day; increase weekly	3 + sedation 2 + weakness, dizziness	DBPC (child/adult)
Dantrolene	Interferes with skeletal muscle contraction by interruption of calcium release from sarcoplasmic reticulum	>5 yr; 12 mg/kg/day divided twice a day to four times a day Adult; max 400 mg/day; increase every 4–7 days	1 + sedation 3 + weakness, hepatotoxicity, GI complaints	DBPC (child/adult)
Tizanidine	Alpha-2 adrenergic agonist with presynaptic inhibition	0.2–0.3 mg/kg/day divided three to four time a day; night dosing helpful for sleep Adult max 36 mg; increase weekly	2 + sedation 1 + weakness, hypotension	DBPC (adult)

DBPC: double-blind, placebo-controlled; GABA: gamma-aminobutyric acid; GI: gastrointestinal.

in which meaningful functional goals can be achieved, as opposed to mere clinical ones—i.e., decreased resistance to stretch. Exceptions to the above “rule” include medications to facilitate hygiene, improve positioning, reduce caregiver demands and ease proper fitting of orthotics.

Commonly employed medications treating spasticity in pediatrics include diazepam, baclofen, tizanidine, and dantrolene (Table 162-1). Baclofen usually is well tolerated and has been moderately effective in reducing spasticity in spinal cord injury, with lesser benefit in brain injury from trauma or stroke. In cerebral palsy, baclofen studies have demonstrated significant reduction in spasticity and improved use of extremities. Sudden withdrawal of the medication has been associated with seizures and hallucinations. Although there have been numerous controlled trials of tizanidine in adults with spasticity, studies in children are few (Table 162-1). The usefulness of clonidine is limited mainly to patients with acute brain injury resulting in hypertension, tachycardia, and autonomic dysfunction, given its propensity to cause hypotension and bradycardia. Dantrolene sodium is the least sedating of the antispasticity medications, but requires careful titration to minimize the potential for severe generalized weakness and a limited duration of treatment due to the risk of hepatic injury (Noetzel, 2012). Newer agents such as gabapentin and pregabalin, both GABA analogs, as well as modafinil lack convincing data to establish that any of them reduce spasticity or improve quality of life in children (Noetzel, 2012).

### Neuromuscular Blockade: Alcohol, Phenol, and Botulinum Toxin Injections

Neuromuscular blockade with phenol and alcohol causes axonal degeneration, with tone reduction lasting up to 1 to 3 years, but they are utilized relatively infrequently due to the need for sedation or anesthesia, as electrical stimulation is necessary to identify the target nerve (Noetzel, 2012). Intramuscular injection of botulinum toxin inhibits the release of the neurotransmitter acetylcholine responsible for transforming nerve impulses into muscle contraction. Studies on children with cerebral palsy have documented reduction in spasticity and modest functional improvement after injections in the arms and legs (Noetzel, 2012).

The limitation in movement must be the result of spasticity and not from a fixed contracture (Box 162-3). In addition, there should be sufficient underlying strength so that weakening of the problem muscle does not produce paresis. A clinically apparent effect is most notable 2 to 4 weeks after injection, and ongoing benefit typically lasts 3 to 4 months or longer. The total maximum dose of botulinum that can be administered at a single time is limited, and there must be appropriate spacing between injections in order to minimize antibodies developing to the toxin. Botulinum injections can be employed with other therapies and typically are coupled with an intensification of therapy and/or serial casting in order to secure maximum benefit (Fig. 162-1) (Noetzel, 2012). Pain on injection and transient flu-like syndromes have been noted; with increasing use, systemic botulism, resulting in deterioration in respiratory and oral-motor function, has occurred.

### Intrathecal Baclofen Therapy

In patients with more extensive spasticity, intrathecal baclofen pump (ITB) therapy can be employed. Components include: a pump implanted under the skin on the abdomen, which infuses the drug at a predetermined rate; a catheter, which delivers drug to the intrathecal space of the spinal cord (with

the tip placed between T2 and C6 for maximum efficacy); and a programmer for adjustable and precise dosing (Noetzel, 2003). ITB therapy should be considered in children whose spasticity interferes with function or care, those who have painful spasticity-related spasms, and individuals unable to tolerate side effects from oral medications (Box 162-4). Because intrathecal baclofen diffuses directly into the spinal cord, the doses are much smaller than those taken orally, and the potential for systemic side effects is reduced. ITB therapy is not the optimal treatment if: spasticity predominantly affects the arms or is focal; trunk control is poor; and families cannot fully commit to the requirements of therapy maintenance (Box 162-4) (Noetzel, 2012). The pump reservoir is refilled percutaneously every 2 to 6 months, and the battery life of 5 to 7 years mandates pump replacement at the end of that time. Contraindications in patient selection include hypersensitivity to baclofen, unrealistic expectations of benefit, and small size/low weight.

ITB therapy complications due to surgical implantation and refilling procedures include CNS infection and peritonitis; device-related complications also may occur (Box 162-5). Side effects, such as somnolence, dizziness, and hypotonia, have been reported. Signs of overdose range from itching, excessive weakness, and ascending low tone to respiratory depression, seizures, and coma. Withdrawal is a medical emergency, presenting as altered mental status, spasticity and rigidity that may advance to rhabdomyolysis, organ failure, and death. Management of withdrawal is predicated on prompt recognition, institution of oral baclofen or tizanidine, and, in severe cases, intravenous benzodiazepines or propofol. Cyproheptadine can be a useful adjunct in the management of serotonergic syndrome symptoms.

### Selective Dorsal Rhizotomy

Selective dorsal rhizotomy (SDR) is designed to reduce moderate to severe lower-extremity spasticity by minimizing aberrant muscle spindle input believed to trigger muscle overactivity. Bone covering the first two lumbar segments is removed. Afferent fibers in the dorsal roots from L1 to S2 are dissected, and those rootlets that demonstrate excessive activity are severed. Studies have demonstrated that the combination of SDR and intensive post operative PT is beneficial in reducing spasticity in children with diplegic cerebral palsy and produces gains in strength, gait speed, and overall gross motor function (Noetzel, 2012).

Patients most suitable for SDR are those between the ages of 4 and 10 with spastic diplegia or mild quadriplegia who have some degree of ambulatory capability (Box 162-6) (Noetzel, 2003). Most have a history of prematurity or evidence of periventricular leukomalacia on imaging studies. Those unsuitable for SDR include patients with spasticity from congenital or neonatal CNS infection and head trauma or hypoxic brain injury outside the newborn period (Box 162-6). In addition, children with very weak abdominal muscles and those with predominant dystonia or ataxia are less likely to benefit from SDR.

### Orthopedic Surgery

Even with optimal treatment, spasticity may progress to cause contractures and bony deformities necessitating orthopedic intervention such as tendon releases for fixed contractures at the ankle, surgery to correct hip subluxation or dislocation, and instrumentation for scoliosis. The benefit of orthopedic surgery is most pronounced in patients who have achieved some degree of skeletal maturation.

## Treatment of Dystonia and Other Hyperkinetic Movement Disorders

A number of movement disorders have been recognized in children after traumatic brain injury and stroke (Dosenbach and Noetzel, 2014). Management is predicated upon the type of movement disorder, but unfortunately most medications have proven to be ineffective or of minimal benefit. For children with acquired dystonia, trihexyphenidyl, tetrabenazine, and botulinum toxin injections often are utilized.

## ACQUIRED BRAIN INJURY

Traumatic brain injury, together with stroke, hypoxic/ischemic injury, brain tumor, and CNS infection, account for about 75% of all pediatric admissions to an acute neurorehabilitation service (Noetzel, 2012). Even though the primary injury may be focal, brain damage is typically widely distributed in most patients. Secondary injury from cerebral edema, hypoxia, or ischemia, often in the setting of elevated intracranial pressure, may inflict additional diffuse damage, especially in infants with nonaccidental trauma. Although the pathology of acquired brain injury is variable, certain neurorehabilitation issues require attention in almost every child recovering from this type of injury.

## Behavioral Disturbances

Behavioral aberrations are a nearly universal consideration and can be observed in all stages of recovery (Noetzel, 2012). Agitation, characterized as nonpurposeful, random, motor and verbal activity, is common early in recovery. Emotional regression and impaired information processing likewise often are observed and may persist for weeks or months. Sedative medications usually are without benefit and, in fact, symptoms may be aggravated by further clouding the sensorium. In the middle stages of recovery, patients often have limited understanding of their own deficits and intolerance to sensory stimulation (Noetzel, 2003). Hyperactivity and impulsivity are typical manifestations seen in a child 3 to 8 years old; in older children and adolescents, the behavioral theme is one of decreased motivation and poor initiation of action, combined with lethargy. Therapeutic intervention and management strategies require ongoing careful assessment of the patient's attention and arousal patterns. Medications with adverse cognitive or behavioral side effects should be withdrawn when possible. Careful modulation of a child's surroundings may be beneficial, avoiding either overstimulation or prolonged sensory deprivation. Alerting, orienting, and preparing a child for any therapy activity is important. In addition, it is essential to monitor the child's response so as to determine which environmental adaptations are beneficial (Noetzel, 2003).

In some children with acquired brain injury, aberrant behavior persists and medication may need to be prescribed, recognizing that the use of pharmacologic agents to manage behavior in this clinical setting has not been investigated in a scientifically rigorous manner. The most pressing behavioral issues of aggression and severe agitation have been treated with beta blockers, carbamazepine, and tricyclic antidepressants, as well as clonidine, amantadine, and buspirone (Noetzel, 2012). Stimulants may have a role in children with underarousal and slow cognitive processing.

## Communication and Cognitive Deficits

Deficits in communication and cognition are exceedingly common and represent the largest cause of long-term

disability, most often affecting memory and learning of new information. Agents acting upon the various neurotransmitter systems have been employed to establish an appropriate level of arousal and sustained attention. Although not overwhelming, the results do demonstrate a likely overall beneficial effect. Efficacy of pharmacologic intervention with respect to memory and learning has not been demonstrated (Noetzel, 2012).

Therapeutic interventions for communication and cognitive impairment should be initiated in the acute care setting, with the main focus on providing sensory modulation. Cognitive retraining should pervade all aspects of the therapy process. Finally, rehabilitation should be predicated not only on enhancing preserved function, but also on remediating residual deficits, utilizing standardized tests to establish a structured intervention program (Noetzel, 2003).

## Postinjury Seizures

Seizures resulting from brain trauma commonly occur within the first 7 to 10 days after injury. The risk is highest in children under the age of 3 years and those with a severe injury or any nonaccidental brain injury. The incidence of posttraumatic epilepsy (PTE) is less than 1%; severity of brain injury and the presence of early seizures are the most important predictive factors for PTE (Noetzel, 2012). Early seizures do not mandate treatment, but recurrent seizures can be treated with levetiracetam, especially in patients with raised intracranial pressure and those with risk factors for late seizures, such as intraparenchymal hemorrhage and penetrating cerebral injury. There is, however, no convincing evidence in children that prophylactic therapy prevents PTE. In contrast, epilepsy as a long-term complication occurs in 15% to 20% of childhood acute ischemic stroke patients, with large cortical infarcts imposing the highest risk. In patients with seizures at stroke onset, anticonvulsants are warranted, with the choice of medication dictated by seizure semiology and EEG findings.

## PEDIATRIC STROKE

There is increasing recognition of the incidence, severity, and functional impact of pediatric stroke and of the consequent rehabilitation needs of survivors. Disability caused by pediatric stroke and its influence on a child's quality of life endures over decades (Dosenbach and Noetzel, 2014). Although brain damage from a stroke is not progressive, the resultant functional deficits typically evolve over time, commensurate with nervous system maturation. Permanent motor and cognitive dysfunction is seen in the majority of pediatric stroke survivors, with deficits ranging from 50% to 90%.

## Novel Rehabilitation Strategies-Overview

Fueled by a growing understanding of brain reorganization strategies, various novel rehabilitation treatments are currently in different stages of development and efficacy testing, mostly in adults (Carmichael, 2010). Because stroke recovery utilizes some of the same systems-level, neuronal and molecular mechanisms as learning, therapeutic interventions demonstrated to improve learning are being applied to stroke patients.

Novel stroke rehabilitation treatments can be grouped into three basic categories. First, many are practice programs that build on existing therapy paradigms but incorporate novel technologies or vary some of the specifics of training. A second group has as its foundation electrical stimulation of the nervous system. Finally, medications are being tested in the hope that they might boost recovery from stroke. Although most novel rehabilitation treatments have focused on improving motor outcome, efforts are under way to extend

these therapies into other domains such as the restoration of sensory, language, attentional, and executive deficits (Dosenbach and Noetzel, 2014). However, these interventions have not demonstrated any lasting benefit over conventional therapies in the small number of pediatric patients enrolled. There is increasing interest in the potential use of stem cell therapy (Chapter 15).

### Practice Based Therapies—Constraint Induced Movement Therapy and Robot Assisted Therapy

In pediatrics, intervention with CIMT has focused on children with hemiparesis from presumed perinatal stroke, utilizing a bivalved cast to restrain the more functional arm (Fig. 162-5). CIMT can result in lasting improvements in motor function compared with standard, less intense treatment. A recent study found slightly better outcomes for CIMT compared with dose-matched bimanual intensive therapy immediately after the treatment period, but these differences were not sustained at 12-month follow up (Sakzewski, et al., 2011). Robot-assisted therapy may eventually allow convenient delivery of the high volume of repetitions needed to effect use-dependent neural plasticity (Noetzel, 2012) and currently is being investigated in children with cerebral palsy and stroke.

### Stimulation of the Nervous System to Improve Stroke Recovery

Numerous studies have demonstrated that functional neuroanatomy of the brain's distributed systems can be reshaped by task practice (Lewis, et al., 2009), but repetitive training is time consuming. Thus there is significant interest in directly stimulating the nervous system to bypass or at least enhance task practice. Transcranial magnetic stimulation (TMS), which uses rapidly shifting magnetic fields to induce small currents, has been well studied in pediatric patients. Repetitive TMS (rTMS) can increase or decrease the excitability of underlying cortex and appears to induce a local state of heightened use-dependent neuroplasticity via several molecular and cellular mechanisms, including both GABA and glutamate levels. Evidence for clinical efficacy of rTMS is limited to small-scale studies in children with chronic paresis after stroke (Kirton,

et al., 2008). More research is needed before it can become a mainstream treatment, but rTMS appears to have great potential.

### Medications to Improve Stroke Recovery

Efforts to find neurorehabilitative medications have focused on compounds shown to improve use-dependent neuroplasticity and learning, including selective serotonin reuptake inhibitors, stimulants, and agents that increase dopamine. In the best trial to date, adults with moderate to severe motor deficits who were randomized to 90 days of standard rehabilitative care plus 20 mg of fluoxetine daily had significantly better outcomes compared with standard care plus placebo. Thus it may be reasonable to consider fluoxetine treatment in teenagers who have suffered a motor stroke (Dosenbach and Noetzel, 2014). Stimulant medications and dopamine also induce neuroplasticity and improve stroke recovery in animal models, but no data exists to determine whether pediatric patients might benefit from their use during stroke recover.

### SPINAL CORD INJURY

About 20% of acute SCI patients are under 20 years of age. Although trauma accounts for the vast majority of SCI in children, demyelination, infarction, and tumors contribute to cases of myelopathy. The neurologic examination with suspected SCI entails a sensory evaluation of dermatomes and strength assessment in key muscles in the arms and legs. An understanding of motor movement and reflexes, as they relate to spinal level, aids in the examination (Table 162-2). The assigned level of injury is the lowest segment at which sensory and motor responses are intact bilaterally. The American Spinal Injury Association provides criteria defining the extent of injury that not only informs rehabilitation decisions (Box 162-7), but also has predictive value because mobility and independence in activities of daily living outcomes correlate with the level of functional motor activity.

### Medical Issues

Pulmonary complications such as ventilator failure, pulmonary edema, pneumonia, and aspiration are a major source of morbidity and mortality in the acute stage of SCI. Patients with high cervical injuries (C1–C4) typically require lifelong

**TABLE 162-2** Neurologic Examination to Determine the Spinal Level of Injury

Spinal Level	Cutaneous Sensation	Motor Function	Working Muscles	Reflex
C5	Lateral upper arm	Elbow flexion	Biceps, deltoid	Biceps
C6	Anteromedial arm/thumb	Wrist extension	Extensor carpi ulnaris/radialis	Brachioradialis
C7	Posterior forearm/middle finger	Elbow extension	Triceps	Triceps
C8	Fourth/fifth fingers	Finger flexion	Flexor digitorum sublimis	
T12	Lower abdomen	None	None	
L1	Groin	Weak hip flexion	Iliopsoas	
L2	Anterior upper thigh	Full hip flexion	Iliopsoas and sartorius	
L3	Anterior distal thigh/knee	Knee extension	Quadriceps	Knee jerk
L4	Medial leg	Knee flexion/hip adduction	Medial hamstrings	Knee jerk
L5	Lateral leg/medial knee	Foot dorsiflexion/eversion	Anterior tibial/peroneals	Ankle jerk
S1	Sole of foot	Foot plantar flexion	Gastrocnemius/soleus	Ankle jerk
S2	Posterior leg/thigh	Toe flexion	Flexor hallucis	Anal wink
S3	Middle of buttock	None	None	Anal wink

ventilator support because respiratory muscles are innervated by cranial nerve XI and C2–C4. Individuals with injuries from C3–C5 have varying degrees of ventilator compromise depending on diaphragmatic function, whereas damage at the C6–C7 level usually allows for eventual discontinuation of ventilator support.

Once spinal shock resolves, bladder spasticity with detrusor hyperreflexia produces elevated voiding pressures and impaired emptying, with the potential for renal damage. Treatment consists of intermittent catheterization and anticholinergic medications. Bowel dysfunction in SCI almost always takes the form of constipation and incomplete evacuation of stool, thus a bowel management program, with stool softeners and suppositories, as well as digital stimulation, is important.

Other concerns in children with SCI include heterotopic ossification, hypercalcemia, and deep vein thrombosis (DVT), the latter of which occurs in 10% of adolescents. In adults with SCI, thromboprophylaxis with low molecular weight heparin is recommended for the first 3 months; data are less compelling in children.

## Rehabilitation Strategies

Childhood SCI produces greater disability than a similar injury in an adult. In addition to the profound multisystem trauma that often occurs in an SCI, in a child there is secondary impairment created by the disruption of normal development, physical growth, and psychosocial maturation. Although rehabilitation goals are dictated by specific deficits in bodily function, the overriding aim is to treat the needs of the whole child and maximize the potential for future independence. Patients with C1–C4 injuries require significant adaptive equipment, typically with activating switches. In most cervical cord injuries, a power wheelchair is indicated, with the method of control determined by the level of injury. Appropriate splinting and orthotics may facilitate greater independence in feeding and upper-extremity dressing. With slightly lower injury levels, patients have adequate arm extension and improved hand function, which are critical for wheelchair propulsion (Fig. 162-6), the ability to self-transfer, and participation in bowel and bladder training programs. Programs and equipment designed to assist ambulation are predicated on residual muscle function in the trunk and legs. Finally, regardless of injury level, pressure relief is necessary, and patients, as well as their caretakers, need to be instructed in this maneuver to minimize development of decubitus ulcers.

## FUTURE DIRECTIONS

Pediatric neurorehabilitation has improved dramatically over the last quarter century. Our understanding of the mechanisms of recovery has accelerated, leading to the hope that this knowledge can be translated into specific neurologic therapies that can serve as the basis for restorative rehabilitation. The more immediate need is to upgrade the neurorehabilitation treatments we provide for our patients. Few of the currently employed interventions, medications, and physical modalities implemented in the rehabilitation of children have been subjected to rigorous scientific research with appropriate control subjects. Most investigations involve limited populations, with little regard for the influence of normal development on recovery; many fail to recognize that achievement of functional goals is the only meaningful outcome. Double-blinded protocols, utilizing quantifiable clinically relevant outcomes,

are essential for the growth of rehabilitation and improving the care we provide to neurologically injured children.

# 163 Pain Management and Palliative Care

John Colin Partridge and Elizabeth E. Rogers

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## PAIN MANAGEMENT

### Introduction

Pain has been defined as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage” from thermal, chemical, or mechanical stimuli. Nociception, or pain perception, is the series of electrochemical events after the tissue damage or injury, excluding any emotional correlates of the noxious sensation. Acute pain is common in pediatric medical encounters, and chronic pain affects an estimated 15% to 30% of children. Only 20% of patients achieve effective relief of chronic pain.

### Historical Background

Studies from the 1970s into the 1990s documented undertreatment of pediatric patients compared with adults undergoing uncomfortable diagnostic procedures (e.g., lumbar puncture) and even for major surgical procedures. Newborn infants have both the neurophysiologic basis necessary to experience and remember pain and an intact and functional opiate receptor system. Appropriately, routine pain assessment is now standard of care, and there is consensus on the need to prevent and treat pain in pediatric patients (Hall and Anand, 2014).

### Physiology

Nociceptors transduce a noxious stimulus into electrical sensory nerve activity, and the sensory information is projected to the central nervous system via several types of fibers to the dorsal root and on to the medial and lateral divisions of the dorsolateral fasciculus, then forming synapses within the laminae of spinal cord gray matter (Simons and Tibboel, 2006). Neurons within the spinal cord relay information via the long ascending tracts to various portions of the brain, including the locus ceruleus, thalamus, hypothalamus, anterior and posterior cingulate gyrus, amygdala, insular cortex, and somatosensory cortex, forming what has been termed the “pain matrix.”

### Developmental Differences

Fetal stress responses to pain have been documented as early as 18 weeks' gestation, with peripheral, spinal, and supraspinal capacity for afferent pain transmission by 26 weeks' gestation (Lee et al., 2005). Neonates demonstrate characteristic facial expressions, aversive body movements, alterations in cardiac activity, and changes in cry in response to painful stimuli. Nociceptive receptors are fewer in number in children; so tissue damage must be more significant before a pain response is elicited. Young infants may perceive pain more intensely than older children or adults because inhibitory pathways develop later than afferent excitatory pathways. Inadequately treated pain in premature infants is associated with adverse short-term effects (e.g., more postoperative com-

plications); the accompanying physiologic changes (increases in heart rate, blood pressure, cardiac variability, autonomic tone, venous pressure, cerebral blood flow, and intrathoracic and intracranial pressure) may augment the risks for intraventricular hemorrhage or white-matter injury in the immature brain. Repetitive pain may lead to accentuated neuronal apoptosis, wind-up, pain syndromes, long-term behavioral changes, and diminished visual-perceptual abilities at school age (Grunau et al., 2009).

### Clinical Assessment

Infants and children demonstrate nonspecific but consistent behavioral, physiologic, and autonomic responses to pain (Box 163-1). There is no single, uniform, standard technique for assessing pain in neonates or children. Biochemical responses to pain, (cortisol, catecholamines, beta-endorphins, insulin, glucagon, renin-aldosterone, growth hormone, and prolactin) are not specific to pain.

Self-report, usually by linear analog scale, is regarded as most reliable among children having sufficient cognitive capacity. For preverbal patients, pain assessment is best achieved using multidimensional scales, including behavioral, physiologic, and autonomic responses. Behavioral observational scales are used for pain assessment with children under the age of 4 or with cognitive impairment. Toddlers and preschool children can often use standardized, semiquantitative pain assessment tools (poker chips, cartoons of faces, a pain thermometer, and colors or words) to rate pain intensity. Children of 8 years or older can effectively use questionnaires or visual analog scales designed for adults. Newer studies are investigating the use of near-infrared spectroscopy and EEG to monitor neonatal cortical pain responses.

### Management

Pain, acute or chronic, should be assessed regularly and treated aggressively with nonpharmacologic methods and appropriate analgesics with around-the-clock dosing tailored to individual patient needs. In neonates, nonnutritive sucking (with or without sucrose), distraction, breastfeeding, swaddling, kangaroo care, contralateral tactile stimulation, massage, acupuncture, music therapy, and multisensorial stimulation can decrease the pain severity and needs for pharmacologic treatment. Nonpharmacologic interventions should be developmentally appropriate for older patients.

When pharmacologic management is required, regular doses should be ordered at appropriate intervals with added “as necessary” medication for breakthrough pain (Howard et al., 2008). Doses should be titrated according to response. Mild pain that is unresponsive to cognitive techniques or sucrose in neonates can be treated with nonsteroidal antiinflammatory (NSAIDs) drugs or acetaminophen. For moderate pain, oral “weaker” opioids or combinations of opioids and NSAIDs or acetaminophen can be used. Severe pain requires more aggressive parenteral opioids such as morphine or

Opioids may be administered subcutaneously, orally, rectally, transdermally, or intranasally, or by patient-controlled analgesia in children over age 7 years. For some procedures, oral transmucosal or transdermal fentanyl provides an alternative for conscious sedation, although emesis is a frequent side effect. Rectal administration can be utilized when oral dosing is contraindicated; intramuscular injection should be a last resort. Tolerance may develop more rapidly with continuous infusions and with use of synthetic opioids. Opiate withdrawal can occur when opioids are discontinued abruptly after several days of exposure. Although considered safe, bolus opioids are associated with an increased incidence of severe intraventricular hemorrhage, white matter injury, and short-term neurodevelopmental abnormalities.

### Procedural Sedation and Analgesia

Methods such as perioperative preparation, relaxation training, distraction, guided imagery, cognitive interventions, and hypnosis may reduce the need for pharmacologic treatment for minor procedures. More uncomfortable procedures require deeper sedation, more appropriately performed by anesthesiologists, intensivists, or emergency physicians experienced in deep sedation techniques and monitoring. The American Academy of Pediatrics has defined two levels of sedation for procedures that are less deep than general anesthesia: 1) conscious sedation, a medically controlled state of depressed consciousness that preserves protective reflexes, airway, and responses to physical stimuli or verbal commands; and 2) deep sedation, involving depressed consciousness or unconsciousness when the patient is not easily aroused, cannot protect the airway, or respond to physical stimuli or verbal commands (Committee on Drugs, 2002).

### Analgesia

Topical analgesia such as EMLA (eutectic mixture of topical anesthetics, prilocaine, and lidocaine) can reduce the discomfort of minor procedures. For very brief procedures, ethyl chloride or fluoromethane can provide limited analgesia. Local anesthetics or peripheral nerve blocks should be used for lumbar punctures, difficult intravenous cannulation, suturing, or procedures involving prolonged pain. For surgical procedures, fentanyl is preferable because of its faster onset, shorter duration, and lack of a histamine-inducing effect. For longer duration procedures, morphine remains the preferable agent. Ketamine induces profound analgesia while maintaining spontaneous respiratory activity, airway tone, and protective reflexes; it may be the drug of choice for emergency procedures when the patient has not fasted. When used in conjunction with propofol for short-term procedural sedation, doses and side effects are reduced.

### Sedation

Benzodiazepines are the most commonly used drugs for sedating children, particularly in pediatric intensive care. Midazolam is the preferred drug for procedural sedation given its rapid onset of action, short half-life, and potent sedative and anxiolytic effects. For painful procedures, benzodiazepine sedation should be accompanied by opioid analgesia, and patients should be monitored for hypoxia or respiratory depression. Barbiturates are regarded as the sedatives of choice for diagnostic imaging in children younger than 3 years of age but provide no analgesia. Chloral hydrate, an acceptably safe sedative without analgesic efficacy, can be used for nonpainful procedures such as electroencephalograms and diagnostic imaging in children younger than 3 years of age, although it has a long half-life and concerns about potential carcinogenicity.

Given at subanesthetic doses, intravenous ultrashort-acting agents (etomidate, methohexital, propofol, remifentanyl, and thiopental) can be used for procedural analgesias but should be used only by certified practitioners due to risks for over-sedation or rapid swings in consciousness.

## Types of Pain

### Neuropathic Pain

Neuropathic pain is seldom responsive to opioids, often requiring multiple modalities for effective pain relief. Analgesic agents recommended for first-line medications for neuropathic pain in pediatric patients are gabapentinoids, tricyclic antidepressants, and serotonin noradrenaline reuptake inhibitors. For moderate to severe pain, tramadol and controlled-release opioid analgesics are recommended as second-line medications, with cannabinoids now recommended as third-line treatments. Other drugs for management of neuropathic pain include methadone, less efficacious anticonvulsants (e.g., lamotrigine), tapentadol, or botulinum toxin. Phantom pain after amputation may respond to preemptive regional anesthesia, antiepileptics, tricyclic antidepressants, calcitonin, topical agents, or intrathecal medication. Nerve trauma may be treated with injected local anesthetics, steroids, neurolysis, antiepileptics, tricyclic antidepressants, or mexiletine. Neuropathies after chemotherapy can be treated with antiepileptics, tricyclic antidepressants, or mexiletine.

### Pain in Children With Significant Neurological Impairment

Children with cerebral palsy or developmental delays do experience pain despite some reports of blunted pain responses or insensitivity to pain. Pain from spasticity and muscle spasms can be treated with diazepam, dantrolene, oral baclofen, or botulinum toxin. Oral analgesia is the preferred route as intramuscular injections may be more painful in children with decreased muscle mass. Subcutaneous and transdermal administration can be used for chronic administration. Patients with neurologic impairment are more likely to have pain discounted or denied and thus may have pain treated ineffectively. In patients too impaired to communicate pain levels, behavioral responses should be regarded as effective surrogate indications for analgesic treatment. Analgesic needs must be balanced by the recognition that systemic opioids may have undesirable side effects such as respiratory depression or constipation.

### Migraine and Headache

NSAIDs or weak analgesics can be given for mild to moderate pain from tension headaches and to many children with migraine attacks. Once a chronic pattern is established, cognitive-behavioral techniques such as biofeedback and relaxation therapy may help alleviate headaches. Practitioners should be aware of the possible development of medication overuse headache when NSAIDs or opiates are used chronically (Lewis et al., 2002, Lewis et al., 2004). Sumatriptan is an effective and safe abortive treatment; dihydroergotamine and ibuprofen may help interrupt episodes. Other drugs studied for prevention of migraine include beta-blockers, calcium-channel blockers, and antidepressants. For migraine, the hallmark of effective control is treatment early in an attack.

## Summary

Pain in pediatric patients is often underrecognized and undertreated. Relief of pain is one of the most important aspects of

ethical pediatric care. Judicious use of nonpharmacologic modalities, analgesics, and anxiolytics to treat pain is recommended until further research indicates the medications and dosing schedules that relieve pain and pose the least side effects or neurodevelopmental risks.

## PALLIATIVE CARE

### Introduction

At least 500,000 children suffer life-threatening medical conditions such as extreme prematurity, heritable disorders, or acquired diseases warranting palliative care services; of these, 15,000 die each year (Feudtner et al., 2011; Himmelstein et al., 2004). Nearly half of pediatric deaths and over 70% of deaths from chronic complex conditions occur in hospital; of these, nearly half occur in an intensive care setting. It is estimated that only 5000 to 7000 children receive hospice care or formal palliative care services and that another 10,000 to 15,000 children could benefit from them. Recent population-based studies have documented that 15% of pediatric hospital deaths are from neurologic or neuromuscular diseases. Neuromuscular disorders cause 3% to 4% of childhood deaths in all age groups but account for 18% of deaths of children with complex chronic conditions (Feudtner, 2007). A third of the children referred for palliative care have neuromuscular conditions, and another 41% have genetic or congenital conditions that may have neurologic consequences (Ho and Straatman, 2013).

Children with neuromuscular disorders tend to be referred for palliative care earlier than those with other chronic diseases (cancer, human immunodeficiency virus, cystic fibrosis, sickle cell disease, or chronic lung disease); however, 30% to 35% of children with metabolic diseases, muscular dystrophy, severe cerebral palsy, and posttraumatic brain injury receive only end-of-life care. Some neurologists may feel they lack the training or experience in addressing the complex needs of dying children or communicating bad news to young patients and their families.

### Historical Background

Palliative care as an adjunct to modern medical care began with the founding of St. Christopher's Hospice by Cecily Saunders in 1967. Although the first pediatric hospices started in 1982, it is only recently that widespread institution of pediatric palliative care has been recommended, including in intensive care settings. Pediatric palliative care is a cost-effective way to care for dying children, decreasing procedures and intensive care days, increasing support, and facilitating withholding or withdrawing aggressive measures.

### Definitions of Palliative Care

Best provided by a multidisciplinary team (Box 163-3), the focus of palliative care is to provide comprehensive, compassionate, and developmentally appropriate care that optimizes the quality of life by meeting the physical, psychological, emotional, social, and spiritual needs of the child as the disease progresses. The intent is a decent or good death, free from avoidable distress and suffering for patients, families, or caregivers.

### Components of Palliative Care

#### Identifying the Need

Children with neuromuscular diseases and their family members have palliative care needs that differ from those of

#### BOX 163-3 Interdisciplinary Team for Palliative Care

- Primary care provider, community pediatricians, subspecialists
- Pediatric registered nurses/case managers
- Pediatric social worker
- Child life therapist
- Spiritual care counselor
- Home health aides
- Pediatric medical consultants
- Physical/occupational therapists
- Clinical pharmacist
- Clinical dietitian
- Volunteers
- Insurers/payers
- Other providers
- Regional centers
- Durable medical equipment companies
- Community pharmacies

dying adults. A series of questions can help inform the counseling process and considerations about the appropriateness of further interventions of changing the goals of care when necessary. First, what has been the child's health status and quality of life previously? Second, how likely is the child to survive the current life-threatening condition? Third, what degree of suffering is entailed if the child survives in the short term? Fourth, what is the anticipated quality of life in the future and how long is it expected to endure? Fifth, how likely are future crises or deteriorations? Discussions about treatment options should assist the child and parents in selecting which measures should or should not be done (Feudtner 2007).

Critically ill or dying children benefit from being with and comforted by their parents. Providers should allow time for the family to nurture their child and recognize the emotional stress of anticipating neurologic compromise or death. Providers should attempt to give parents and, when appropriate, children some sense of control in their care.

#### Transition in Goals of Care

Palliative care should not be restricted to children expected to die soon when therapeutic interventions fail or are withdrawn. Providers should learn to recognize when needs for palliative care become more salient with neurodegenerative diseases or progressive neuropathies or as complications from a static encephalopathy impinge on quality of life. In conditions associated with a predictably shortened life span (e.g., trisomy 13 and 18, neurodegenerative diseases, anencephaly, and many inborn errors of metabolism), the primary focus of care is limited to optimizing quality of life. For diseases with less certain prognoses (for example, traumatic or hypoxic brain injury, some central nervous system or spinal tumors, congenital myopathies and neuropathies), it is appropriate to introduce palliative care at an early stage that can soften the effect of nonintervention discussions *later* in the disease trajectory. With older children, it is important to address future choices for care before the neurologic status deteriorates and bars them from participating in healthcare decisions. Parents must be given the information necessary to decision making and be made aware of the limits of our prognostic ability. An essential step is to clarify, and reassess periodically, the goals of continuing, rather than limiting, ongoing interventions as the chances for cure lessen.

## Levels of Care

A shift from curative to palliative treatment goals does not imply that all ongoing medical interventions must be abandoned. It is important to clarify specific measures that will continue to be utilized, as well as what level of nonintervention appears most appropriate. An order proscribing all or selected resuscitative measures in the event of a cardiac or respiratory arrest (a “Do not resuscitate” or “Do not attempt resuscitation” order) is often an appropriate first step; it is not a half-hearted resuscitation (“slow code”) order. It should be discussed with parents and the healthcare team before being written. Withholding of life-sustaining measures involves an agreement not to institute medically indicated measures given that more aggressive interventions would not improve a grim prognosis or quality of life. Interventions deemed futile are not required and should be discontinued. Withdrawal of life-sustaining measures involves the discontinuation of current medical interventions deemed either futile or no longer appropriate to the child’s best interests.

## Communication

Patterns of communication sensitive to the child’s developmental status and to the parents’ emotional state are critical to good palliative care. The degree to which the child can participate in decision making increases as children develop sufficient cognitive capacity (over the age of 7). Pictures, stories, toys, music, or other family rituals can help younger children communicate their preferences. Whenever the child has the cognitive capacity to participate, it is important for providers to allow the child the time to express hopes, dreams, and fears. Infections of the nervous system, hypoxia-ischemia, neurodegenerative diseases, or traumatic brain injury may limit older children’s decision-making capacity.

Conversations about changing the goals of care when the disease progresses are best held by continuity providers over a period of time, allowing patients or parents time for questions, second opinions, reflection, and informed decision making. To minimize the sense of giving up or abandoning their child, it is critical that parents understand that the goal of care will be to do everything that *should* be done rather than everything that *can* be done.

The primary focus is what is important to the child and the family: longer life, pain-free, time with family members, specific desires, environment and setting, time to say goodbye in ways that respect family values. A structured approach can help physicians deliver difficult news and negotiate goals of care (Box 163-4).

Communications should be simple, direct, clear, and honest explanations that relate the expected outcomes of each treatment option. It is critical to avoid promising outcomes

that are not reasonably feasible, overwhelming the parents, or leaving them in despair.

## Healthcare Decision Making

Children usually have no previously documented preferences for healthcare decisions; the first issue is to identify who will be making healthcare decisions. In general, advanced directives are not relevant in pediatrics; parents are assumed to be the primary proxy decision makers for young children, although their discretion is not limitless. Older children themselves have the right to determine what quality of life means to them, with support from their parents and physicians.

Parents (or competent adolescents) determine the quantity of information necessary for to informed decision making. If decisions seem not to reflect a full understanding of the disease, the goals of care and expected outcomes should be readdressed. Decisions that do not concur with the provider’s choices should be respected when taken in the child’s best interests. Ethics committee consultation can help clarify impediments to decision making, the limits to parental decision making, or the need to advocate for the child or refer to child welfare. The resulting care plan should be disseminated to the healthcare team and any limitations to care clearly documented.

## Persistent Vegetative State

Although there is no consensus as to whether children in a persistent vegetative state experience pain and suffering, it seems prudent to treat suggestive signs and symptoms. Decisions to withdraw or withhold life-sustaining measures should be made only when neurodiagnostic testing and a sufficient period of observation suggest there is no chance for a meaningful recovery. Decisions involving the withholding of fluids or hydration remain controversial, even when deemed appropriate responses to the child’s medical situation.

## Environment for Death and Dying

When parents prefer continued inpatient care, a private space for families to gather before and after the child’s death is recommended (e.g., a separate comfort care room) but should not impede nursing medical attention to pain and symptoms. Elective transfer to a lower level of care or to a hospice may be preferred and feasible despite concerns about changing care providers late in their child’s disease. Death at home from neuromuscular disorders is preferred by an increasing proportion (25%) of children and parents. Plans for a death at home require a continuity provider skilled in managing pain and suffering and able to provide 24-hour coverage from discharge through the child’s death and the parents’ bereavement.

## Support During Dying

When death is near, providers can commit to aggressive treatment of pain or suffering and help parents envision the child’s imminent death and the likely timing. Overall support when a child is dying involves a balance between respect for privacy and close, but noninvasive, attention to the child’s and the family’s needs in collaboration with primary care pediatricians, social workers, clergy, and psychologists or psychiatrists.

## Assessment and Treatment of Symptoms

Providers should reevaluate the efficacy of pain and symptom management as the disease progresses. Many neurologists will feel comfortable treating seizures, insomnia, and depression in dying patients but may prefer to have primary care

### BOX 163-4 Protocol for Palliative Care Communications

#### SPIKES: A PROTOCOL FOR DELIVERING BAD NEWS AND NEGOTIATING GOALS OF CARE

- **S**etting: create environment conducive to communication
- **P**erception: determine what the family knows
- **I**nvitation: determine how the family would like information delivered
- **K**nowledge: provide information
- **E**motions: empathetically support patient
- **S**ummarize: set realistic goals, make a treatment plan, and follow through
- **R**epeat: review and revise frequently

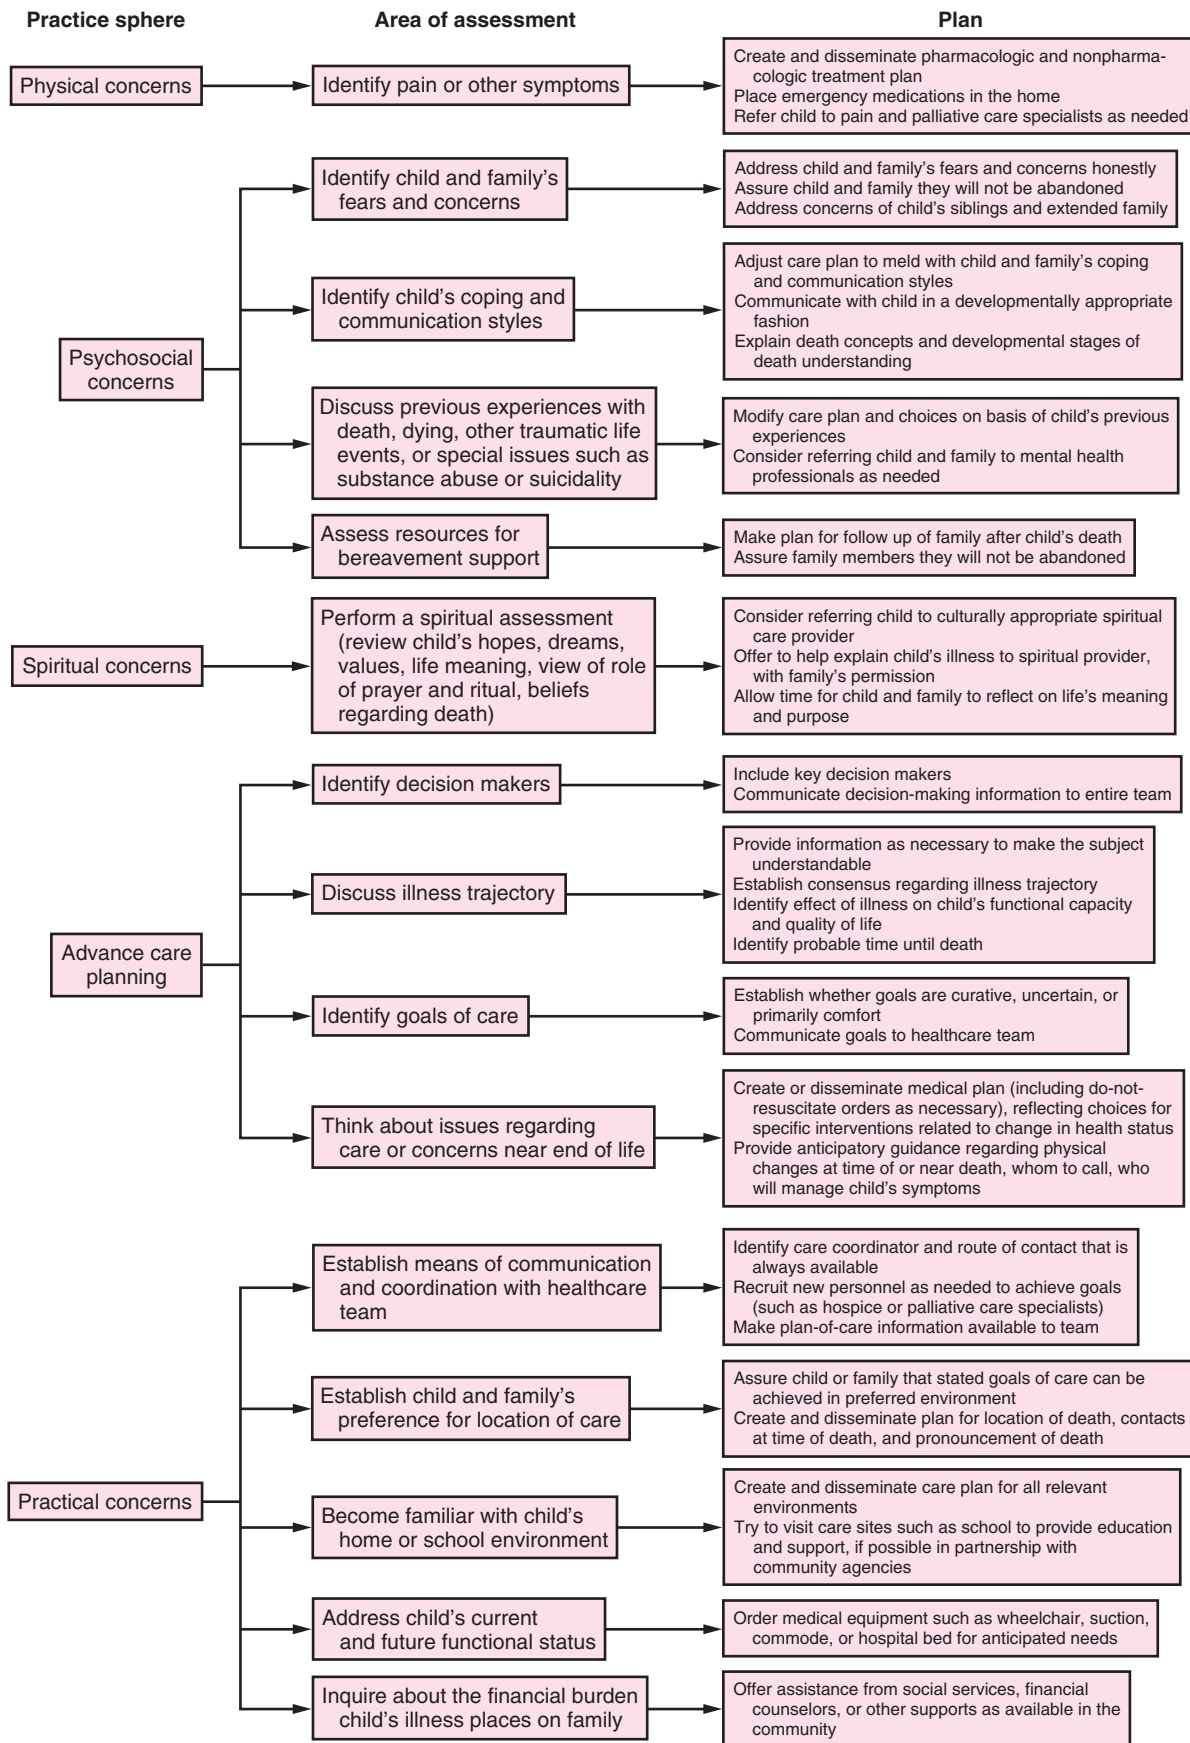

Figure 163-3. Essential elements in the approach to pediatric palliative care.

pediatricians or palliative care specialists manage other frequently encountered end-of-life symptoms (dyspnea, anxiety, fatigue, fever, bleeding, nausea, skin breakdown, anorexia, dehydration, and constipation).

Pain should be treated aggressively with analgesics. Terminal sedation with opioids is effective and justifiable in alleviating severe or unremitting pain at the end of life despite risks of suppressing respiratory drive and thereby hastening death. Fears of addiction to opioids are unwarranted. Paralytics are not appropriate when life support is being withdrawn. Anxiolytics may help terminal agitation and perhaps air hunger experienced in the terminal phases.

### Developmental, Emotional and Spiritual Concerns

Care for a dying child requires candor, openness, and an emotional availability to the child's experience of illness and imminent death in a developmentally appropriate manner. Children come to understand death as a change of being by age 3 and as a universal fact of living by age 5 to 6; by age 8 to 9, they have gained a concept of their personal mortality. Developmentally appropriate interactions that respect the children's spiritual nature will allow providers to explore issues of love, hope, security, loneliness, and concepts of the legacy that the child will leave to family and friends. Family routines and rituals add structure and a sense of normality and should be encouraged as the medical condition worsens.

### Bereavement

Children are aware of dying and disease; they understand much more about death and dying than adults often realize and do not need to be protected from death and dying as much as they need help making it understandable. Parents often regret not having talked with the child about death. Dying children may grieve about their impending death, the loss of functional status, or the inability to participate in current or future events. They may fear how their family members will cope after their death. When heritable neuromuscular disorders pose a future risk to affected siblings, particular care is necessary to deal with concerns about subsequent pregnancies or fears of future illness.

Providers should allow family members the opportunity to spend time grieving with their deceased child alone, with time to talk and time to be silent. It may be helpful to celebrate their child's life, recap the family's experience, value their loss and emotions, and help them contact family members and friends. Parents should be offered religious observances, social services support, family support groups, or other supportive measures to help them cope. Funerals can help siblings remember and value the dead child. Psychological counseling may help parents and siblings work through the emotional trauma.

### Follow-Up Conference

Many physicians arrange a postdeath conference to see how the parents are coping. Clarification of the diagnosis, etiology, end-of-life events, and (when relevant) autopsy results can provide solace, an opportunity to address parents' questions about their decisions, a method of reducing guilt, time to detail the implications of heritable neurologic disorders and to offer referrals for counseling or support.

### Barriers to Palliative Care

Providers may encourage treatments with little hope of a favorable outcome, abandoning them only when death seems inevitable. A late transition from curative care to palliative care is a frequent problem. For many pediatric neurologic diagnoses, it is difficult to predict which children will die of

their disease or the quality of life as the disease progresses. Parents' recognition that death is inevitable often lags behind their understanding of the diagnosis.

### Summary

Neurologists can offer children and their families the comprehensive palliative care that can improve children's and families' experience of end-of-life care (Fig. 163-3). Primary-care neurologists should develop expertise in the palliative care of children with life-threatening neuromuscular conditions. Consultant neurologists should coordinate their palliative care efforts with primary pediatric providers, palliative care specialists, and the interdisciplinary team.

## INTRODUCTION

The task of ethics in general is to understand how human beings should behave in regard to other persons and to society: to understand what is right and what is wrong. The philosophical study of ethics parallels the growth and development of human society. Morality is understood as the set of generally accepted rules and guidelines for acceptable conduct in society. These social conventions about what is right and wrong constitute the common morality (Beauchamp and Childress, 2012). Philosophic ethics can be thought of as the attempt to develop a rational basis for morality. Although ethics (as a form of philosophy) strives for universal truth, it is inextricably linked to the realities of the human societies whose morality it seeks to understand. Distinguishing between “moral” and “ethical” behavior is often difficult (Bernat, 2008). Perhaps moral behavior may be thought of as a personal attempt to conduct one’s life in conformity with the common morality, whereas ethical behavior may be thought of as a more theoretical or rational attempt to apply philosophical thinking to what is right and wrong. In other words, ethics is a systematic attempt to understand how to live and act morally in a social context.

Ethics addresses all aspects of human behavior. Bioethics considers the interaction between biology and ethics. It is defined as the systematic study of the moral dimensions of the life sciences and health care, and it includes consideration of the health- and science-related moral issues in the areas of public health, environmental health, population ethics, and animal care. Clinical ethics is a subcategory of bioethics that refers to the day-to-day moral decision making of those caring for patients. More specifically, clinical ethics refers to the identification, analysis, and resolution of moral problems that arise in the care of a particular patient (Jonsen, Siegler, and Winslade, 2015). Medical ethics is a subcategory of clinical ethics that refers to the moral behavior of physicians (and is thus distinguishable from nursing ethics, social work ethics, and pastoral ethics).

Neuroethics is a concept that cuts across most of these distinctions. As an area of bioethics, it considers the interaction between the neurosciences and clinical neurology and ethics in all of the same areas of study as for bioethics, noted previously. As a clinical discipline, it addresses the care of patients with neurologic disorders. As an area of medical ethics, it refers most directly to the moral behavior of neurologists and neurosurgeons. Thus child neurologists interested in ethics need to be knowledgeable about the general approaches to ethics, the emerging scope of bioethics, and the more specific approaches to ethics in medicine, nursing, and other health-related disciplines.

The goal of this chapter is to provide child neurologists interested in ethics with the tools they need to identify, analyze, and resolve moral problems they may encounter in the care of children and adolescents with neurologic disorders. The first part covers the most significant theoretical approaches to ethics as they apply to child neurology. The second part considers the varied duties of the child neurologist working

with patients with morally problematic issues. These tools should help child neurologists to frame the ethical problems that arise in their work. Developing a framework for the analysis and identifying the key ethical question or questions are the first step in approaching these cases. The next step is to consider the most relevant and appropriate ethical approach, which may vary considerably from case to case. The final step is to synthesize all of the available information (usually through discussion with colleagues, patients, and family) and attempt to answer the question as it was framed.

## THEORETICAL APPROACHES TO ETHICS

Philosophy may be a search for truth, but the fact is that there is no one, true, universal approach to ethics. Physicians who want to act ethically should be aware of the several major ethical theories that compete for attention in contemporary medical practice. Two ethical theories in particular dominate thinking in Western philosophy. Utilitarianism is derived from the writings of Jeremy Bentham and John Stuart Mill. Deontology is derived mainly from the writings of Immanuel Kant. Elements of both theories persist in modern ethical approaches to clinical problems, usually in somewhat modified form. Most physicians will find themselves using utilitarian thinking on some occasions and deontological thinking on other occasions, or using some combination of both when it is necessary to resolve an ethical dilemma in clinical practice.

A number of other ethical approaches have been developed more recently and also deserve consideration. As a general statement, probably no one theory or approach is optimal in every case in medical practice. A skillful physician will recognize which approach is best suited to the challenges of a specific ethical situation. Knowledge about these several ethical theories thus provides the physician with a kind of “ethical toolkit,” from which to select the approach that is most likely to be helpful in analyzing the specific issues present in a particular case.

## UTILITARIANISM

The essence of utilitarian theory is the idea that the morality of an action is determined mainly by its consequences: the morally right action is the one that produces the best result. Of course, the result of an action may be quite complex and challenging to identify. An action that helps one person may harm another person. Withdrawing support from a child in a vegetative state undoubtedly harms the child because it results in the child’s death, but the action may help the family grieve and may allow society to use limited medical resources to help other patients. The utility principle states that one should act to produce the best overall balance of positive and negative consequences of the act. This idea is embedded in the concept of balancing risks and benefits to achieve the best overall result.

Utilitarian theory is often cited to justify actions that are most likely to increase happiness, but other desirable results

are also possible. Individuals may wish to act in such a way as to increase personal quality of life, enjoyment of and satisfaction with life, success in a preferred career, and general knowledge and understanding, or to strengthen personal relationships. Lawyers and policymakers use the utility principle to produce the best overall balance of justice and fairness for society.

Utilitarian thinking is almost intuitive in many aspects of ordinary life. Understanding this form of thinking is important because it may help avoid the potential pitfalls that can result from uncritical application of the theory. Perhaps the most familiar situation is the use of utilitarian theory to justify the killing of defective newborns. Although theoretically logical, such arguments are morally repugnant to persons who apply a different moral standard based on some other approach to ethics. Another problem with utilitarian theory is its failure to protect minorities, which results from its emphasis on producing the greatest good for the majority. The needs of children with rare neurologic disorders can be overlooked if utilitarian thinking allocates scarce medical resources primarily to children with more common and less debilitating disorders.

## DEONTOLOGY

The term *deontology* is derived from the root *deon*, meaning “duty,” and deontological theory is based on the importance of duty. Duty is based more on the intentions that lead a person to act than on the outcomes or consequences of the action. Utilitarian thinking is mostly situational and depends on the specific aspects of a given situation; deontological thinking strives to be more universal and to emphasize decisions that would apply in all relevant situations. Thus Kant’s categorical imperative states that we should act only in a way that is consistent with a universal law or obligation. Using people as means to an end implies that different actions (or reactions) are needed, depending on the end or outcome that is desired; therefore, the actions are not universally applicable. For this reason, deontological thinking stipulates that we should treat all people as “ends” and not as means to an end. This could cause problems in thinking about the morality of organ transplantation if the organ donor is thought of only as a means to the end of survival for the recipient. Clearly, deontological thinking imposes a duty to respect the rights and value of the donor as much as those of the recipient because anyone could be either a donor or a recipient.

Deontological thinking emphasizes duties and obligations, but these may conflict. For example, physicians may have different and competing obligations toward patients, families, hospitals, insurance companies, and society. The attempt to describe duties leads to formulation of general or universal rules for moral action, but these rules may also conflict. Rules may be too abstract and impractical to apply to real-life situations. Deontologically based rules do not take into account the messiness of human relationships, a point that it is essential to keep in mind when considering the ethics of care discussed later in this chapter.

## Common Morality and Natural Law

What are the universal rules that spring from deontological thinking? Most Western philosophers would argue that these rules can be derived from the application of reason—from rational, logical thinking about the nature of human existence. The general argument is that all rational persons would agree that these rules are essential to govern and guide the moral actions of individuals in a cohesive society. The common morality represents the socially approved norms of human

conduct that form the basis of ethical theory. This common-sense understanding of what is needed for individuals to behave in society is not derived from theory, but rather forms the basis for potentially competing theories.

Natural law theory is an ancient approach to deriving universal rules through the application of reason. For Thomas Aquinas, natural law sprang from man’s participation in God’s eternal law and was brought into being by the application to action of human intelligence and reasoning. This application leads first to the principle that all things desire that which is good; therefore, good is to be pursued and evil is to be avoided. Good things are those to which man has a natural inclination, such as life (existence), social interaction, family life, and civil government. To pursue these good things, one should act fairly, love God, and love other persons. Secondary precepts or rules (such as the Ten Commandments) follow from these basic principles.

Secular interpretations of natural law are as old as Aristotle and are still used in some forms of legal theory. Beauchamp and Childress do not define any specific rules as part of their concept of the common morality, but they do define four principles that are not absolute and that need to be specified based on actual circumstances (Beauchamp and Childress, 2012). These four principles may be seen to correlate with the precepts of natural law:

1. Do good (beneficence).
2. Avoid evil (nonmaleficence).
3. Act fairly (justice).
4. Love one another (autonomy).

Whatever the source of the common morality, it is the basis for principlism, the ethical theory based on the application of principles to specific situations.

## Principlism

Principlism is an approach to ethical problems that is based on the application of the four principles of beneficence, nonmaleficence, justice, and autonomy. It is more of a practical guide than an abstract theory, and it has found widespread acceptance in a variety of settings. It was adopted explicitly in the Belmont Report, which forms the foundation for research ethics in the United States. Although principlism is perhaps the best-known approach to clinical ethical problems, it is by no means the only approach. Understanding principlism is necessary to consider these alternative systems.

The principle of autonomy has become preeminent in Western society, although it may be less prominent in Eastern or religiously oriented societies that place a greater value on social harmony. Physicians need to keep this in mind when caring for patients from other cultures. An autonomous choice is one that is based on sufficient knowledge of the facts involved, the ability to understand the situation, and the independence to choose without undue influence of other people. Autonomous individuals can determine for themselves what they think is best, and this principle states that other people should respect these choices, even when they do not agree with or approve of them. Autonomy is the basis for the concept of informed consent, which requires that a patient has the capacity or competence to understand the issues, full disclosure of all of the information needed to make a decision, and freedom from any coercion that might influence the decision.

In general, persons younger than 18 years of age are not considered to have the capacity to make fully autonomous choices, although their preferences should be considered and respected, if possible. American law recognizes that persons 18 years of age and older are fully competent, unless a judge

has determined otherwise. This recognition is critically important for young adults with neurologic disorders (such as intellectual disability) that may affect their capacity to make fully autonomous decisions. If capacity is in doubt, the family will need to initiate legal proceedings to obtain guardianship when the person becomes 18 years old. A young adult (over 18 years) with a neurologic disorder that results in limited competence is unable to give informed consent, but that individual's parents cannot give consent for him or her unless they have obtained guardianship. Failure to obtain guardianship when it is necessary can interfere seriously with timely medical treatment. It should be noted that this age threshold is arbitrary and may differ in other countries.

The principle of beneficence encourages physicians to do good or to act in the best interest of the patient whenever possible. This principle can also be interpreted to suggest that physicians should seek to promote an optimal quality of life or satisfaction with life. Considerable debate exists about how to define and measure quality of life. Objective measures are based on the judgments of others, whereas subjective measures are based on the opinions of the patient about what constitutes a satisfying life. In general, preference is given to subjective judgments when they can be known with reasonable certainty.

The principle of nonmaleficence encourages physicians to avoid doing harm to patients and dates back to Hippocrates ("*primum non nocere*"). It is related logically to the principle of beneficence. Both principles are considered when physicians attempt to strike a balance between providing a benefit for the patient (doing good) and not imposing a burden (avoiding harm). This balance may become especially problematic when the same action could produce a good, or desired, effect, along with a bad, or undesired, effect. The classic example is prescription of sufficient medicine to reduce pain while knowing that it may also cause the patient to stop breathing. This problem is known as the situation of double effect. In Catholic moral theory (which contains the most explicit analysis of such situations), an action that causes double effects is morally justifiable only if it meets all of the following criteria:

1. The action itself is not morally wrong (such as killing would be).
2. The intent is to produce the good effect, even though the bad effect may be expected.
3. The good effect is not based on achieving the bad effect.
4. The benefit to be obtained is greater than the harm that might occur.

This concept is admittedly difficult to apply in practice. Evaluation of each criterion may be arguable in a specific situation. Perhaps the best that can be expected is that physicians will make a good-faith effort to adhere to the principles involved and seek to obtain the optimal balance between benefit and harm for the patient and family.

The principle of justice requires that equals be treated equally, but the basis for an equal distribution of resources may be arguable. Should resources be distributed according to need, effort, merit, contribution to society, or some other factor? Utilitarian, libertarian, communitarian, and egalitarian approaches have been proposed to answer this question. Rawls suggests that resources should be distributed to ameliorate the effects of life's inherently unfair natural and social lotteries. It may be simply bad luck ("losing the lottery") that a child is born with a disabling condition or is born into poverty. If the child is not responsible for this condition, then society should act to remedy the situation. According to this rule, unfair situations would presumably have priority over merely unfortunate situations. How many resources should be provided to those who have been unfairly deprived? The limits

of this redistribution policy may be the extent to which it disables or impoverishes the rest of society.

Jonsen et al. (2015) suggest that ethical issues can be analyzed by asking the following four questions (which are, in fact, practical applications of the four principles discussed previously):

1. What are the medical indications for treatment? (principle of beneficence)
2. What are the patient's preferences? (principle of autonomy)
3. What effect on the patient's quality of life can be reasonably anticipated? (principle of beneficence)
4. What are the burdens and benefits that may affect the family and society? (principles of justice and nonmaleficence)

The questions may be somewhat hierarchic, in the sense that medical indications and patient preferences are usually more important than potential social burdens, but physicians should not be too rigid about this. In fact, asking (and answering) these four questions in a particular case is an excellent way to make sure that the relevant issues are identified and evaluated. These issues can then be considered by the caregiving team, patient, and family. Resolution of the issues may vary from case to case, but at least everyone involved will be able to see how the decision was determined.

## Virtue or Character Ethics

Virtue can be described as a trait that has positive moral or social value. According to Aristotle, virtuous behavior requires both the right motive and the right action. In other words, wanting (or intending) to do the right thing is not enough by itself. This idea is somewhat at variance with pure deontological thinking, as described previously. In virtue theory, following a presumably universal rule is not necessarily a moral or virtuous act if it produces a bad result. Similarly, doing right for the wrong reason is not necessarily a moral or virtuous act if the motive itself was not virtuous.

The catalog of virtues not surprisingly varies from one writer to another. Pellegrino and Thomasma (1993) suggest eight virtues that are necessary for sound medical practice:

1. Fidelity to trust (trustworthiness)
2. Compassion (understanding the patient's feelings)
3. Prudence (clinical judgment)
4. Justice (in the sense of love and altruism)
5. Fortitude (sustained courage in the face of difficulty or despair)
6. Temperance (balance in one's life, perhaps also Osler's sense of equanimity)
7. Integrity (personal honesty and wholeness)
8. Effacement of self-interest (putting the patient's interests first)

They argue that these eight virtues are necessary but not sufficient for physicians to practice ethically. Possessing these virtues provides evidence of good intent but they must be linked to ethical action. They suggest that principlism, although not specifically part of virtue theory, can provide a guide for virtue-based ethical action.

## Ethics of Care

Care-based ethical thinking is prominent in nursing practice but may be unfamiliar to physicians. It arose as somewhat of an alternative to deontological, rule-based thinking that depends on adherence to more or less rigid principles. It also arose from feminist research studies comparing male and female approaches to ethical dilemma. Gilligan (1982) found

that males were more likely to look for rules to follow and to insist on adherence to these rules. Females were more likely to look for some situation-based way to resolve a dilemma, taking into consideration the person's feelings and significant relationships. This "feminine" way is not exclusively reserved for women (or for nurses), of course. Rather, it provides an alternative and perhaps more subjective way to evaluate an ethical problem that is especially relevant when a rule-based approach seems to be inappropriate or unhelpful.

Somewhat obviously, care-based ethics does not have any fixed rules. In fact, this perspective challenges the idea that impartial or universal rules should guide ethical action. Instead, it looks at the particularity of the patient and the specific clinical situation and seeks to find answers that fit this unique case. Care-based ethics accepts the fact that emotions have important moral value and must be considered carefully. It also emphasizes the patient's human relationships and the mutual interdependence of the patient, family, and all members of the caregiving team. A care-based approach to an ethical dilemma would say something like, "That can't be the only possible ethical solution. There must be another way to resolve this problem that is acceptable to everyone here. We all want to do what's best for the patient, so let's think about what that means. Maybe we could start by understanding what the patient is feeling and by talking to the family. We should also talk about how we feel about all of this. Let's brainstorm some ideas and think about what they would involve. Maybe we need to talk to some more people and get more information. If we keep working at it, we'll find a way."

This approach will sound familiar to anyone who has been involved in difficult cases in the intensive care unit, which emphasizes the ubiquity and usefulness of this way of thinking in clinical practice. Perhaps an awareness of the sound ethical foundation of care-based ethics will also help clinicians give this way of thinking attention and consideration.

## Casuistry

Casuistry, or case-based ethics, is another alternative to utilitarian or rule-based ethical approaches. It rejects the very idea of a "moral calculus" that can be analyzed impartially, based on abstract concepts. Instead of a "top-down" approach, based on pure theory, it takes a "bottom-up" approach, based on the particularity of specific cases. Casuistry looks at specific cases and emphasizes points of agreement about those cases. It recognizes that moral intuition may be more important than adherence to principles. It is common knowledge that members of hospital ethics committees often agree on what needs to be done but cannot always say with clarity why they feel that way (or what ethical theory they relied on to make a particular judgment) or whether they share some degree of social commonality. This moral intuition may also reflect the influence of the "common morality" described previously. By looking at the particularities of a specific case, casuistry is also sensitive to contextual influences and individual differences.

The method of casuistry is somewhat analogous to the method of case law used in the United States. One first identifies several key cases about which there is a consensus regarding the proper ethical approach. These are cases that have had careful scrutiny in the past and are still believed to be instructive. New cases are then compared with these key cases, selecting those past cases that have the greatest similarity to the current case. One then seeks to develop a consensus about how to resolve the current case, based on how these past cases were resolved. Each new case that is resolved in this way goes into the body of case experience, so that the consensus is revised and modified incrementally in the light of evolving and accruing clinical experience.

One can see that casuistry is very similar to what an experienced clinician does naturally, drawing on his or her experience in past cases to sort out the issues in a new case. One has to be careful about which past cases to consider and to what extent the decisions made in those cases apply to the current case. Experience in past cases may also be conflicting, and it may be difficult to sort out the similarities and differences compared with the current case. One also has to be careful about how much weight should be given to one past case compared with another past case. In a very real sense, every new case is different (as every clinician knows), but there is still much to be learned from past experience. Casuistry provides a sound ethical foundation for using this clinical experience in resolving ethical dilemmas.

## Spirituality

Spirituality is variously defined, but it can be understood as a belief system that focuses on intangible elements that impart vitality and meaning to one's life. Because it is based on beliefs, or faith statements, it is not provable through logical argument. Spirituality in medicine is often based on religious beliefs but it need not be. As an expression of ultimate concern, it reflects the elements of our lives that are the most important and make life worth living. Most people have some spiritual beliefs that become prominent when their health is threatened; yet these beliefs are often not considered by physicians and other health-care providers. Physicians may anticipate that patients would have certain beliefs based on knowledge of their religious background, but individual differences exist, even within a religious tradition. A more direct understanding of the patient's spirituality would be preferable.

One approach to understanding the patient's spirituality is the "three ways of looking." The first look is to see the person subjectively as an individual human being. Compassion requires distance and objectivity, but this first look requires closeness and subjectivity. It is an attempt to understand the patient's spiritual beliefs. The second look is to recognize in the other person that which we know to be central to our own existence. With the second look, we can value in the patient that which we most value in ourselves. These values include living, freedom, tolerance, respect, happiness, and satisfaction with life. Physicians would then seek to protect for their patients the values that they would protect for themselves. The third look is more elusive and is an attempt to grasp, through our relationship with another person, the transcendence or divinity that is the basis of our spiritual existence. This third look comes when it is least expected, often in the vulnerability of a frustrating or challenging ethical situation. When we are open to it, it can provide insight, enrichment, and ethical guidance.

The three ways of looking can be the basis for a spiritual approach to medical ethics. Three precepts can be identified:

1. Respect in others what I value in myself. This precept is similar to the principle of autonomy but is based on the mutuality of spiritual sharing between physician and patient.
2. Do the most loving thing possible. When we love in the patient what we love in ourselves, we will strive to do that which is best for all. Love—not just duty, convention, rules, or cost containment—is the basis for action.
3. Seek guidance from the source of my own and the other person's being, through deep reflection, prayer, advice, or sharing. Thoughtful physicians often do this in difficult ethical situations but may not recognize the spiritual nature of these reflections.

These precepts do not appear to depend on any specific religious tradition and should be applicable in all cultures and religions. One need not be religious to apply them to one's practice. They avoid the relativity of accepting cultural practices at face value by providing a general structure for applying differing cultural beliefs to specific clinical situations. Spirituality cannot and must not be coerced or imposed on others, but physicians who are open to the role of spirituality in the lives of their patients may find these precepts useful in considering difficult ethical challenges.

## ETHICAL RESPONSIBILITIES

Child neurologists have duties as physicians, as pediatricians, and as neurologists. These categories overlap to some extent. Physicians in general have duties that are reflected in the Hippocratic Oath and the Code of Ethics of the American Medical Association (AMA). Pediatricians have duties as primary care physicians and as caregivers for minor children in a family context. Neurologists have duties as specialists to provide consultation and to maintain expertise in the field.

### Duties as a Physician

The AMA Code of Ethics is but one example of ethical codes that professional societies and organizations in many countries espouse. It is a document that has been revised over the years and includes opinions and statements on a variety of current issues. It is a good starting point for considering a physician's duties. Additional guidance may be found in descriptions of the virtues needed for medical practice. These include the need for trustworthiness, compassion, empathy, prudent clinical judgment, altruism, fortitude, temperance, integrity, and primacy of the patient's interest. Indeed, many of these virtues are implicit in the principles delineated by the AMA.

Many professional societies have developed ethical codes or guidelines that are specific for their field. The websites of the American Academy of Pediatrics ([www.aap.org](http://www.aap.org)), the American Academy of Neurology ([www.aan.com](http://www.aan.com)), and the Child Neurology Society ([www.childneurologysociety.org](http://www.childneurologysociety.org)) may be consulted for the most up-to-date statements about the ethical responsibilities of members of these societies.

Conflicts may arise in applying these principles during ordinary practice. For example, physicians should generally tell the truth, but what if truth-telling would appear to be harmful to the patient? There are no easy answers. The application of a care-based ethical approach may be useful in such situations. A carefully considered amount of information may be provided in such a way and in a particular context, taking into account the physician-patient relationship, so that all involved will understand the information being conveyed and be able to use it to benefit the patient.

Consider this example. A 5-week-old infant had severe neonatal hypoxic-ischemic encephalopathy and remains on a ventilator. The magnetic resonance image shows extensive brain damage. To maintain optimal care and plan for the future, the clinical team has recommended a tracheostomy and gastrostomy. The neurologist is asked to provide an estimate of the child's developmental potential, knowing that the family is also looking into withdrawal of life support and organ donation after cardiac death. The neurologist realizes the great difficulty in predicting outcomes in this context but also is aware of the literature that predicts severe neurologic disability in this case. How should the neurologist present this information? Emphasizing the small but real possibility of an outcome that might be better than expected could help the family choose to maintain support and plan

for rehabilitation. Emphasizing the greater possibility of a poor outcome will likely result in the child's death. Ultimately, it is the family's decision to make, but the neurologist's role in telling the truth, and how it is told, about the prognosis will have a significant influence on the family's decision and on the child's life.

Physicians are often called upon to write letters for patients. These letters may be used to secure benefits for the patient in school, work, or other settings. Letters may also be requested to assist the patient or family in obtaining insurance coverage for tests or treatments, or in obtaining help with housing and utilities (heat, electricity, or telephone services). In general, physicians would seem to be required to do what is best for the patient, but what if this seems to conflict with a duty to respect the law and to do what is best for the community?

Consider this example. A 10-year-old boy had Lyme meningoencephalitis 5 years ago and now is experiencing problems in school. The neurologist has recommended neuropsychological testing to help define the child's school-related needs, but the family's insurance company has stated that it will not cover testing for educational purposes. The neurologist is asked to write a letter to support the request for insurance authorization for the testing. Should the neurologist request the testing to define the cognitive implications of possible chronic Lyme encephalopathy (because the insurance company will cover neuropsychological testing for medical indications), even though the neurologist does not believe that the child has this condition?

In a more general sense, is it ever ethical to lie to an insurance company for the benefit of the patient? The question puts so many ethical principles in conflict that no single answer can be given that would apply in every case. One way to approach the question is through virtue ethics. Compassion and effacement of self-interest might support lying for the benefit of the patient, but following the virtues of integrity and fidelity to trust might indicate otherwise. In this context, each physician would have to develop a balancing of these virtues that he or she can live with in good conscience.

Physicians are often requested by insurance companies to prescribe older, cheaper drugs or to use generic products instead of new brand-name products. Indeed, in some insurance arrangements (such as full capitation), physicians may receive a financial benefit by limiting the cost of the patient's care. Should a physician order expensive tests or prescribe expensive treatments anyway, if they are believed to be in the patient's best interest? How much is a physician responsible for the overall cost of health care in society, and how should this responsibility be balanced against the responsibility to do what is best for the patient?

Consider this example. A 14-year-old girl with epilepsy had a breakthrough seizure after having been well controlled for several years. She had been taking brand-name oxcarbazepine but was recently switched to the generic equivalent. The neurologist checks the blood level and finds that it has dropped from 20 to 10 mg/dl. Should the neurologist rewrite the prescription to specify brand name only (which increases the cost of health care in general), or just increase the dose of the generic product?

Physicians are members of their community, and ethical questions can arise in the course of fairly ordinary activities. For example, suppose a physician is in church and observes a young child who is being presented for baptism. The physician suspects the child may be showing signs of autism, which the child's parents do not seem to recognize. Knowing the importance of early diagnosis and treatment of autism, should the physician say something to the family or to the minister? This may be a situation where spiritual ethics might help guide the physician toward an answer.

Clearly, application of general principles of medical ethics to complicated clinical situations is anything but straightforward. Nonetheless, physicians should make a genuine effort to do the best they can. The requirement to make the patient's interests paramount would appear to be the defining standard in most cases. In doubtful or difficult situations, consultation or discussion with one's colleagues (either formally or informally) is probably a good idea.

### Duties as a Pediatrician

Many (but not all) child neurologists have trained as pediatricians and have some experience with the roles and responsibilities of a pediatrician. Most also have frequent contact with referring pediatricians who provide primary care for the patients seen in neurologic practice. The role of a pediatrician often involves primary care in the United States, but in other countries and other settings the pediatrician is a specialist who manages diseases involving other parts of the body. Child neurologists interact regularly with pediatric specialists involved in the care of children with complex disorders. Thus there is an overlap between the duties of the child neurologist and the pediatrician that warrants some exploration.

Primary care involves the longitudinal management of all of the health issues of the child and family and requires a commitment to being accessible, available, and capable. Effective primary care is compassionate, culturally competent and sensitive, and comprehensive, and includes coordination and oversight of all of the child's health problems. Most child neurologists do not provide this type of primary care. Many do, however, provide many of the same elements of care for children whose neurologic problems constitute the main health issues. These include older children and adolescents who are otherwise healthy but have ongoing neurologic problems and patients with complex neurologic problems whose general health problems are fairly straightforward. Child neurologists have no obligation to take on this role and may confine their role to that of a consultant. Those who do take on this role would seem to have the same duties as those of a primary care physician, as listed earlier, except that their duties are limited to management of the child's neurologic problems.

All physicians who care for children (including pediatricians and child neurologists) have a duty to understand and respect the child's status as a minor. This duty has two elements: one involves promoting the child's emerging development into an adult, and the other involves protecting the child from harm. Promoting the child's development involves an understanding of normal child development and helping the child succeed as much as possible. Child neurologists ordinarily monitor the child's progress in school and provide whatever assistance is possible to secure special education and therapeutic resources needed to promote the child's development. Although the primary responsibility rests with the parents and the school, the child neurologist should be available and capable of providing help when needed.

Because children are not capable of making sound judgments about their own best interests, others must judge for them what is in their best interests. Social convention and the law generally recognize that parents are the best judge of what is in the child's best interest, but this recognition is not absolute. A substantial body of law and regulation governs when and in what circumstances a parent's rights may be superseded. Consideration of these laws and regulations is beyond the scope of this chapter. Child neurologists may be called upon to give an opinion about what medical care is in the child's best interest. They may also be asked about whether they believe the child is capable of independent judgment. Persons

who are 18 years old are usually assumed to be fully autonomous adults who are capable of giving informed consent for medical treatment. Many neurologic patients with significant intellectual disabilities are not capable, however; therefore, others must be designated as guardians for them. The child neurologist should be aware of what is involved in determining the need for guardianship and assist the patient and family in whatever way is appropriate.

The United Nations has formulated a declaration on the rights of children, the Convention on the Rights of the Child, which contains 54 articles that stipulate the rights of the child to life, safety, health, education, and a decent standard of living. Article 23 states that a mentally or physically disabled child should enjoy a full and decent life in conditions that ensure dignity, promote self-reliance, and facilitate the child's active participation in the community. It further recognizes the rights of the disabled child to special care. Article 24 states that the child should have access to quality health services, including primary care, preventive health care, and treatment of health conditions. Although the Convention's declaration is not legally binding, it provides a strong moral statement about the internationally accepted obligations of states to protect the best interests of all children. Awareness of this international consensus may be helpful to physicians who are advocating for children under their care.

### Duties as a Neurologist

Child neurologists are specialists or subspecialists and have duties that correspond to this role. They provide longitudinal care for children and adolescents with chronic neurologic disorders, and this includes corresponding duties that resemble those of primary care, as described previously. They also provide consultative opinions about diagnosis and treatment, both in outpatient and inpatient settings. As a consultant, the child neurologist has a duty to provide a fair, impartial, accurate, and (as much as possible) evidence-based statement about the facts of the case. The child neurologist's principal role in evaluating ethical dilemmas is to clarify the facts. This is a critical role because accurate data are essential for making sound ethical decisions. Indeed, poor or questionable ethical decisions often are attributable to inadequate specialized medical information regarding the diagnosis, treatment, and/or prognosis of a case. This problem is illustrated well in cases when the patient is in a vegetative state. Some may consider such a state permanent and hopeless after only a few weeks and seek to withdraw life-sustaining treatment. The child neurologist, acting as a consultant in such a case, would inform the family and caregivers about the published data indicating that the vegetative state is not considered permanent until 3 months after an anoxic injury and 12 months after a traumatic brain injury. The family may be given some slim hope for possible recovery of consciousness before these time periods, which may call for continued treatment and rehabilitation.

The role of an expert consultant has certain limitations. For the most part, child neurologists are experts in child neurology and not in ethics. The child neurologist should distinguish between opinions regarding the neurologic data and opinions regarding the ethical issues involved in cases that present ethical dilemmas. The child neurologist's opinion about the ethical issues is one voice among many and is not necessarily the most important or determining opinion. Normally, the family's opinion about the ethical issues is the most important. The views of the extended family and the family's religious or faith or cultural community are often important. In many cases, the views of individuals who have had long-term, close, and personal relationships with the patient (e.g., friends,

personal attendants, or group home staff) also deserve consideration. Child neurologists, in addition to other physicians and nurses involved in such cases, should be careful not to impose their own ethical opinions or attempt to override the expressed opinions of the patient's family and friends.

The child neurologist also has a duty to maintain expertise in the field. This is a duty that is shared with all medical specialists. Expertise is maintained through continuing education, which may involve reading journals, attending conferences, and discussing issues or cases with colleagues who may have more knowledge or experience regarding the issues in question.

## Research

Many child neurologists are involved in research, which carries additional ethical duties. One of the challenges for child neurologists involved in clinical research is to separate their ethical obligations as investigators from their ethical obligations as physicians responsible for treating patients who may be enrolled as subjects in the neurologist's research study. This challenge is harder than it may seem. In the United States research ethics is based on the Belmont Report, which adopted the principles of autonomy, nonmaleficence, beneficence, and justice (see earlier discussion) as the basis of research ethics. In general, the researcher's principal ethical obligation is to protect the rights and welfare of the research subject. Poorly designed research studies are inherently unethical because they are not likely to produce sound scientific results, and thus they place the patient subject at risk for harm without the prospect of benefit. The researcher's ethical obligation as an investigator to pursue well-designed scientific studies is secondary to his or her obligation to protect the subject involved in the research. When the research subject is also a patient, this means that the child neurologist investigator's clinical duties to the patient are ordinarily stronger than his or her duties to enroll subjects in the research study.

In the United States federally sponsored research is governed by the Code of Federal Regulations, which stipulates the roles and responsibilities of researchers and institutions involved in clinical research. Researchers are required to obtain review and approval of the research study by a properly constituted Institutional Review Board for the Protection of Human Subjects in Research (IRB). Child neurologists involved in clinical research have legal and ethical obligations to follow these rules and regulations. In general, ethical issues in research should be considered when the study is being designed, not just at the end of the process when IRB review and approval are formally requested. The researcher should be knowledgeable about ethical issues in research. If the researcher has questions about ethical aspects of study design or protocol development, most IRBs will provide assistance. Building ethics into the study from the beginning will usually prevent problems later during the process of IRB approval and during continuing review and oversight of the study.

## SYNTHESIS

The child neurologist striving to do the right thing and to avoid doing the wrong thing will listen to many voices

conveying a variety of messages. Some of these voices are internal and reflect the several theoretical approaches that provide a "best fit" for the patient's problem. The neurologist's mind will hear different ways of conceptualizing the problem, perhaps from an ethics of care or a utilitarian perspective, or some other approach. Experience teaches that clinical ethics is not procrustean, that no theory or approach will fit every clinical situation. Every case is unique and provides lessons that can be stored away in memory and called upon another day. Drawing upon his or her knowledge about ethics derived from careful study and the knowledge that can only come from having been at the bedside of many sick children over the years, the neurologist will struggle to derive a sense of harmony that will be helpful when a decision must be made.

The child neurologist also listens to the external voices of others who are involved in the clinical situation. Foremost among them is the voice of the family. When love is present, families usually find a way to deal with whatever life hands them. It may not be the "right" way (the way others want them to take), but it is a way that works for them and deserves respect. At any given point in time, most people are doing the best they can, given their skills and abilities and the pressures and limitations they face. When physicians seek to understand the situation from the family's point of view, they may be able to help them do the best they can for themselves and for their child. The neurologist will also hear the voices of other patients and families he or she has treated and followed over the years, who were in a similar situation in the past and whose subsequent history speaks to the wisdom of decisions that were made. The child neurologist also will hear the voices of other caregivers involved in a particular case, especially those of the nurses who have a more intimate relationship with the patient and family. In some cases, the voices of long-time friends, pastoral ministers, and staff who have cared for the patient before the present situation arose will need to be heard and considered carefully. The soft but insistent voices of insurance administrators and utilization reviewers may also be softly or stridently audible.

Synthesizing all of these arguments and perspectives is never easy and perhaps benefits most from a deep sense of humility.

# 165 Transitional Care for Children with Neurologic Disorders

Carol S. Camfield, Peter R. Camfield, and Lawrence W. Brown

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Neurologic disorders of childhood often persist into adulthood. Although many have a good medical and social outcome, 20% to 30% are complex with physical, psychiatric, or developmental problems complicated by societal stigma. The problem is compounded as more children with chronic neurologic diseases now survive into adulthood with advances in diagnosis, treatment, technology and management that continue to create a new “natural history.” Child neurologists need to facilitate the transition of all youth with neurologic disorders as they enter to adult healthcare (Brown and Roach, 2013).

The distinction between transfer and transition is important (Camfield and Camfield, 2011). Transfer is the formal handing over of care from a pediatric to an adult healthcare system. The relationship with the child neurologist ends with a detailed referral letter to an adult care provider and responsibility for care is transferred. Transition is a long-term, purposeful, planned process beginning in childhood to prepare youth and their families for the adult healthcare system. Over a period of years the adolescent becomes knowledgeable about his or her medical condition and as independent as possible. Ideally, they become able to evaluate the adequacy of their care. The child neurologist actively participates in the transition process and develops and maintains a relationship with the adult healthcare team to prepare for the eventual transfer.

Pediatric care includes intensive involvement with the family. Adult medical care is focused firmly on the individual, not their caregiver(s). Adolescents and young adults move from family-centered pediatric care dominated by their parents, a change that they may find difficult after years of a well-established relationship. Many of these young people have never developed full knowledge about their neurologic disorder, may not even know their diagnosis or treatment plan, and are unprepared to cope with the adult healthcare system.

In 2014 the Child Neurology Society convened a panel to identify common principles underlying the process of transition to adult care that could help to clarify the process for neurologists and caregivers. The panel outlined eight critical points that are shown in Box 165-1.

This chapter attempts to outline: 1) barriers to transfer; 2) the natural history of several disorders that evolve during or after adolescence; and 3) models that have been used for “transition.”

## BARRIERS TO CARE

The family, patient, pediatric neurologist, and adult neurologist have an underlying inertia to initiate the process of transition. Legal issues of confidentiality and age of consent are encountered. Electronic interchange of patient information currently is often awkward with differences in computing technology. Changes in insurance coverage in some countries (especially the United States) are of grave concern.

Many worries cause barriers to transition (Box 165-2). Families may fear the unknown and the passing of their own responsibility to their child and new adult healthcare team. They are attached and comfortable with the pediatric service (often described as holistic, attentive, understanding, and knowledgeable). Parents of an adolescent with significant physical or intellectual disability understand that normal independence is precluded (he or she remains a “child”). They may fear that this reality will not be respected by the adult healthcare team. Interestingly, parents are typically more anxious about transition than the adolescent.

For the child neurologist, transition/transfer means a loss of the long-term attachment associated with years of working with these families. There is often a nagging feeling of not having done everything possible to “cure” the child during the pediatric years. Adult service may be viewed as less holistic, particularly for management of comorbidities. Discussion of transition takes time and reimbursement may be inadequate for “nonmedical” counseling. There may be difficulty finding appropriate expert adult primary or subspecialty care.

The adult neurologist faces other challenges. No professional wants to convince reluctant youths and families of their “credentials” or justify their model of care. It may be difficult for them because many child neurologists have not dealt with issues from sexuality and relationships to vocational challenges, from potential of death from the neurologic illness to end-of-life issues. Some patients have disorders that are rarely seen in adulthood; a whole new set of information is needed. The expectations for psychosocial care may be very difficult to meet, especially in a setting with little help from other professionals such as social workers. These issues cannot be easily addressed in a short visit.

An American study documented barriers to transition by a Delphi survey (Peter et al., 2009). Internal medicine providers (n = 241) rated highest concerns about lack of training in congenital and childhood-onset conditions, lack of family involvement, difficulty meeting patients’ psychosocial needs, needing access to a super specialist, lack of training in the care of adolescents, facing disability and end-of-life issues during youth, financial pressures limiting visit time, and families’ high expectations.

Other issues in adult care relate to the setting. The office is rarely set up for youth who are intellectually disabled or disruptive, and consultation rooms are often inadequate for parents or a power wheel chair. Young people with intellectual disability present a special problem for the adult healthcare system, even if the adult provider is comfortable with their limitations in providing a clear history or cooperating with the examination. Unless there is guardianship, does the patient or parent decide what is best? Office visits may need to be longer than usual for good cooperation.

The pediatric model of care emphasizes a “medical home” that is optimal especially for those with rare, complex, difficult to treat medical problems involving multiple specialties. This is less common for adults who may suffer if there is no designated individual with overall responsibility for care. In

**BOX 165-1** Principles for Transition for Child Neurologists (from the Child Neurology Society ref 16)

1. The pediatric neurology team should start to discuss the expectation of future transition to the adult care system beginning at an early age, no later than early adolescence.
2. This discussion should be continued annually and documented in the medical record and communicated to other healthcare providers. Reassessment of self-management skills can help to gradually allow the adolescent to assume more responsibility for his or her own care.
3. This phased transition planning should occur at scheduled visits rather than acute care visits and allow for sufficient time to deal with emerging issues such as sexuality, driving, and graduation from secondary education.
4. For those with intellectual disability, the child neurology team should begin the discussion of the youth's expected legal competency by age 14, support interventions to maximize this decision-making ability, and support caregivers who must address the legal implications of the assessment. This might include guardianship and power of attorney.
5. The child neurology team should collaborate with the youth and family, primary healthcare provider, and others on an annual basis to address comprehensive needs. Although the child neurologist is not responsible for healthcare finances and legal concerns, education, employment, and community-based adult services, he/she is obligated to make sure that a comprehensive transition plan is developed and updated.
6. The child neurology team is responsible for the neurologic component of the transition plan and should update it yearly.
7. Appropriate adult providers, whether neurologists or others, should be identified in collaboration with the youth and family before the anticipated time of transfer. The child neurology team coordinates the transfer, preferably utilizing a transition packet that documents the diagnosis, supportive testing, previous drug trials and past procedures, current management, and any protocols for emergency care.
8. The child neurology team should directly communicate with the identified adult providers to ensure successful transfer and document the youth's transfer (i.e., completion of transition) into the medical record.

addition, multidisciplinary clinics are common in pediatrics but rare in adult medicine, which may lead to fragmented, incomplete care.

In the next section, we provide examples of transition/transfer issues for a variety of childhood neurologic disorders.

### Disorders that May be Dangerous to Society if Untreated

Attention deficit with or without hyperactivity (ADHD or ADD) is important because it is so common and persists into adulthood in approximately 30% of individuals. It may exist as a single diagnosis or as a comorbidity of other disorders. For example, 20% of children with epilepsy also have ADHD, as do more than 50% with Tourette Disorder, possibly 20% with cerebral palsy, and 40% of survivors of some brain tumors. The symptoms have a profound effect on adult functioning, including accidents, substance abuse, and suicide. In 2012 Montano noted, "The current literature reveals a number of barriers to continuity of care of ADHD, including disparities and inadequacies in ADHD education in primary care and internal medicine residencies, prohibitive prescribing practices with respect to stimulants, inadequate clinic staffing, lack

**BOX 165-2** Barriers to Care

1. Family
  - Fear of the unknown
  - Comfort and attachment to pediatric service
  - Personal negative past personal experiences with adult care
  - Behavioral/psychiatric difficulties within family
  - Cultural and racial barriers attached to the family's financial and socioeducational background
  - Child with intellectual handicap or severe disabilities perceived always as a "child"
2. Child neurologist
  - Loss of long-term professional "friendship" and sharing relationship with family members
  - Adolescent and family resistance to transfer
  - Nagging feeling that care was not as complete as possible
  - Difficulty identifying appropriate adult healthcare providers perceived as excellent and compassionate
  - Long wait lists for entrance into the adult system
  - Financial reimbursement, institutional support for transition/transfer services
  - Reminder of personal mortality
3. Adult Neurologist
  - Reluctance of family and adolescent to change
  - Insufficient time and reimbursement for complex care
  - The challenge of dealing with "taboo" subjects such as sexuality, potential of death, and longevity
  - Possible insufficient of knowledge of the natural history and management of rare, chronic neurologic diseases of childhood
  - Unease with youth with intellectual disability and the complexity of deciding who is the decision maker
  - Lack of multidisciplinary clinics

of support by college health services, inadequate health insurance coverage, and failure to conduct transitional planning. Without improved continuity of care and adherence to medication, adolescents and young adults with ADHD are at greater risk of academic, social, and vocational difficulties, as well as behavioral problems, including substance abuse, unsafe driving, and criminal activity." (Montano et al., 2012.)

Barkley compared 149 children with ADHD who were followed into young adulthood to a matched cohort of "community" controls. Only two thirds with ADHD completed high school compared with all of the controls. ADHD subjects were more likely to have been involved with a pregnancy (38% versus 4%) and have a driver's license suspension (41% versus 26%). Automobile accident rates in those with ADHD are alarming, and the effect of ADHD is similar to moderate alcohol intoxication according to studies using driving simulators. The combination of mild alcohol intoxication and ADHD is even more striking. Adults with ADHD are more competent drivers if they take stimulant medication. Effective management of ADHD in young adults can dramatically reduce the rate of substance abuse. Therefore sophisticated adult care is needed to continue to optimize treatment for ADHD.

### Disorders that are Potentially Lethal in Childhood and Young Adulthood and Have Emerging Treatments Leading to Increased Survival Well into Adulthood

Treatment advances have allowed improved function and prolonged survival in some conditions such as boys with

Duchenne muscular dystrophy. Affected boys can now walk well into their teenage years and 85% survive to age 35 years or longer since the addition of positive pressure ventilation. However, the burden of disease increases with longevity and is further complicated if there is significant learning and/or intellectual disability. Sleep-related breathing disorders, cardiomyopathy, and progressive restrictive lung disease from scoliosis are among the challenging issues. Adult neurology, rehabilitation, pulmonary medicine, and cardiology all need to be involved along with many allied health professionals and social workers. These services are typically well coordinated in a pediatric hospital, but it is rare to find comparable adult comprehensive programs. As more youths are surviving with formally fatal disorders, “taboo” issues such as sexuality management, life-threatening cardiopulmonary complications, and end-of-life care need to be discussed more fully (Barkley et al., 2006). Goals for young adult life require innovative solutions as do satisfying daily activities, acceptance by peers, coping with difficulties, and establishing optimism.

### Disorders that Are Problematic and “Static” in Childhood but Progress in Adulthood

The brain lesions causing cerebral palsy (CP) are not progressive. They are permanent and associated with evolving movement disorders that limit activities (Backman and Conaway, 2014). Comorbidities are frequent: 50% of patients have intellectual disability and/or epilepsy. Over 90% live beyond 18 years of age, and many are able to successfully adapt to adult life; however, others face monumental challenges. Learning or behavioral problems often become troublesome as the child reaches school age and may persist into adulthood, resulting in low educational attainment, decreased employment, limited finances, living with family, reduced social opportunities, and overall poor quality of life. Limitations in coordination, strength, and mobility gradually lead to curbing activities with peers. Associated epilepsy may be intractable. Unfortunately, there is increasing evidence that mobility for children with cerebral palsy worsens in adulthood. An initial survey of 226 adults with cerebral palsy was repeated after an interval of 7 years. Depending on the type of CP, one-third to three-fourths of patients reported increased walking difficulties that included pain, fatigue, and decreased balance. Others have noted a variety of progressive orthopedic problems in adults with cerebral palsy frequently complicated by musculoskeletal pain. Young adults with cerebral palsy between ages 20 to 22 years were twice as likely to rate their health as poor (21%) compared with those who were 15 to 16 years old (9%).

Some studies have been more optimistic. A cohort of patients who underwent dorsal rhizotomy in early childhood seemed to have stable gaits 20 years later. Nonetheless, a comprehensive program that includes adult neurology would appear to be necessary to optimize management of a myriad of needed services, including orthopedic surgery, gastroenterology, pulmonary medicine, pain management, physical, occupational and speech therapy, and social services.

### Disorders Diagnosed in Childhood with Their Most Serious Manifestations in Adulthood

Neurofibromatosis 1 (NF1) is a complex disorder for transition/transfer. Most patients are diagnosed in childhood and followed by child neurologists without progressive problems unless they have an optic pathway glioma; however, the effect of NF1 in adulthood may be profound. A recent meta-analysis

of eight studies relating NF1 with adult health-related quality of life found that NF1 decreases all aspects of quality of life compared with the general population. Medical complications and visible cosmetic effects were strong predictors of quality of life.

During the school years, learning/behavior problems, sometimes autistic spectrum disorder, headache, and epilepsy are the focus of clinicians. Schwannomas become increasingly prominent with age, but many of the really serious complications begin in adulthood with sarcomas, renal failure and cerebrovascular disease. In our experience, referral is infrequent between the pediatric and adult neurology services. Primary care physicians are left to provide overall medical care but may not have the detailed knowledge to coordinate comprehensive care. Most guidelines for NF1 management have focused on children and have not been recently updated nor have they recognized that life expectancy now approaches the seventh decade.

Different issues exist for children with tuberous sclerosis complex (TSC) (De Waele et al., 2015). Recent improved understanding of the pathophysiology has led to new therapies. One of the most promising is mTOR inhibitors which have potential for treatment of subependymal giant cell astrocytoma as well as renal angiomyolipoma, lymphangiomyomatosis, and facial angiofibromas, all problems that span the ages between childhood and adulthood.

Renal disease is the most common cause of mortality after the age of 30 with renal cysts, angiomyolipomas, fat-poor lesions, and malignant tumors causing chronic renal disease. These problems become nearly universal in adulthood.

Epilepsy is typically a persistent problem. In infancy, TSC may present with infantile spasms. During childhood and adulthood seizures are focal or secondarily generalized. Autism, learning disorders, intellectual disabilities, ADHD, or other psychiatric disorders ordinarily present in childhood but persist.

There are few “birth-to-death” programs for neurocutaneous disorders that ensure optimal long-term care, and such multidisciplinary clinics are unusual. The need for TSC patient advocacy along with an awareness and knowledge of the upcoming treatment advances underlies the requirement for continued lifelong surveillance. There are presently no clinical guidelines for patient management of TSC; however, a recent consensus statement by international experts describes a standardized, routine “surveillance” program for life.

### Disorders that Are Cured in Childhood but Have Neurologic Sequelae that Persist into Adulthood

An increasing number of children survive brain cancers due to improvements in early diagnosis, surgery, radiotherapy and chemotherapy. Oncologists may continue to follow these patients for problems related to the late effects of chemotherapy and second malignancies, but many continue to have significant neurologic problems. It is critical to have neurologic involvement in their care. Ongoing surveillance by adult neurologists is increasingly important now that so many children with brain tumors survive into adulthood. Unfortunately, long-term survival does not necessarily equate to optimal outcome; a large cohort of childhood brain tumor survivors was compared with their siblings. Over 1800 cases were followed for a median of 19 years; survivors were much less likely to graduate from college, more likely to be unemployed, and much less likely to be married than their siblings. Of those with medulloblastoma, more than 40% of survivors had neuropsychiatric problems. One other study from a single center

suggested that about 50% of survivors of childhood brain tumors were “disabled.” The long-term neurologic issues may be complex and include intractable epilepsy or remote vasculitis from radiation. Clearly, adult neurologic expertise is required.

### Disorders that May/Not Remit in Childhood but Have Persistent Effects on Adult Social Function

As a group, children with epilepsy have very high rates of poor social outcome in adulthood, rates that are higher than other pediatric chronic disease comparisons and population controls (Borlot et al., 2014; Geerlings et al., 2015). Adult consequences of pediatric epilepsy are reviewed in Chapter 62. A critical observation is that social outcome appears to be independent of seizure remission, although those with persistent seizures may have even greater problems. Although the main focus is always seizure control, optimizing quality of life is critical if children with epilepsy are expected to live fulfilling lives. Identifying and treating comorbidities must begin in childhood but is a lifelong concern.

### Disorders that May Be Uncomfortable for Adult Care

Youth with intellectual disability are at particular risk for care discontinuity as they approach adulthood. Lack of communication skills, disruptive behavior, and inadequate medical insurance are particularly challenging for adult neurologists. As these young people become adults, their parents age, and siblings move away. When placed in an institution or a group home with high rates of staff turnover, many intellectually handicapped adults soon become “well known by no one.” The link with their medical records may be broken, and the original diagnosis and management become unfamiliar or unknown to their caretakers and physicians.

Caretakers may not be aware of new approaches to diagnosis or treatment. For example, profoundly handicapped adults with untreated phenylketonuria may still benefit from a low phenylalanine diet with improved quality of life. Organizing transition and transfer for this type of patient is a major challenge. A strong case can be made for a birth-to-death clinic, although institutional barriers are to be expected.

### Disorders in Childhood Treated in a Way that is Difficult to Replicate in Adult Medicine

Adult care rarely uses the “medical home” model that brings together specialists working together with families and community resources. Such care is ideally suited to the many children now surviving with neurologic disorders who would have died 20 to 30 years ago. Without major efforts at coordination, their complex care easily becomes fragmented and suboptimal. For example, gastrostomy tubes are well accepted in pediatrics and have been a major contributor to longevity. Dietary/nutrition support for tube feeding may not be available in adult care settings nor is there often familiarity with the ketogenic diet or other special diets for metabolic disorders. There are many young people with disorders in this category; examples include progeria, craniosynostosis syndromes, Ondine’s curse, Down syndrome, serious head injury, and neural tube defects.

## POOR OR LITTLE DEVELOPMENT OF THE TRANSITION PROCESS YIELDS POOR OUTCOME

There is very little literature about the unsatisfactory transition for youth with neurologic disorders. Examples from other chronic diseases suggest that the effect may be devastating. For example, youths with type 1 diabetes dropped attendance rates within 2 years of transfer to adult clinics from 94% to 57%; 21% were lost to follow up. Only 40% of those with asymptomatic ulcerative colitis adhered to their medication regime after transfer to the adult setting. Renal transplant patients are another example. One study tracked 20 young adult kidney transplant recipients and found that medical outcomes sharply deteriorated in the 36 months after transfer. One third lost their transplant; nonadherence to immunosuppressant medications was suspected as the primary cause.

### Models of Care for Transition

An optimal model of transitional care has not been identified in general or specifically for neurologic patients. The Kaiser Permanente Patient Risk Stratification Pyramid is a method to stratify patients with long-term health conditions and defines the appropriate level of required care. This approach divides the population of patients with chronic conditions into three groups based on their level of risk and degree of need.

For those with relatively low healthcare needs (Level 1), adult care might be provided by a family physician with sufficient knowledge, skills, and confidence; this may encompass 70% to 80% of youths with chronic neurologic conditions. A multidisciplinary team, including a nurse practitioner, might be optimal. Level 2 indicates a need for more structured assisted care or care management for a single or multiple conditions. These youths have increased risk because their condition is unstable or is likely to deteriorate unless they receive specialist disease management. Transfer from the pediatric neurologist to adult specialist care is appropriate.

For the most complex conditions (Level 3), management of multiple, high intensity conditions through case managers, nurse practitioners, and super specialists should be provided along with care from an array of professionals to plan and coordinate services. As suggested in the Child Neurology Foundation report, this does not have to be an adult neurologist, but it is essential to have a designated “captain.” Beyond medical needs, additional issues to be addressed over time include the individual’s cognitive function and level of competence, personal and family psychosocial issues, the degree of support from family and friends, community resources, capacity to navigate and engage with the medical system, ethnicity and language that may create barriers/challenges, and end-of-life care, power of attorney, and creation of wills and trusts.

A variety of transition/transfer models has been described in [Box 165-3 \(Carrizosa et al., 2014\)](#).

#### 1. Abandonment of Specialized Care or “Fend for Yourself”

This approach places the burden for ongoing care entirely on the youth’s pediatrician or family physician. Unfortunately, this physician may have had limited involvement in the child’s chronic disorder and is unlikely to have full, current knowledge of the disease. The youth and family may not be particularly attached to the provider or may doubt his or her competence.

An alternative is a group of family physicians who might develop a special interest in chronic neurologic disorders (preferably with an able nurse practitioner as a case manager)

**BOX 165-3** Models for Transitional Care

1. Abandonment of specialized care or “fend for yourself”
2. Referral to adult rehabilitation program
3. Referral to adult neurologist or internist
4. Referral to an internal medicine/pediatric subspecialist
5. Referral to a nurse-run transition clinic
6. A formal transition clinic with pediatric and adult neurologists and other professionals
7. Referral to a professionally moderated Internet support group

(From: Carrizosa, J., An, I., Appleton, R., Camfield, P., Von Moers, A., 2014. Models for transition clinics. *Epilepsia* 55(Suppl 3), 46–51.)

and, as a group, follow transferred youth with neurologic problems. To be successful, multidisciplinary consultation would need to be available with financial compensation adequate for the additional time needed.

## 2. Referral to an Adult Rehabilitation Program

These programs are typically oriented toward a single consultation or short-term intervention. Examples would be management for gait difficulties, repetitive strain injury, or wheel chair assessment. Care in this setting is generally multidisciplinary, but long-term follow up is unusual. “Botox” treatment for spasticity may be an exception. Rehabilitation programs are found in large tertiary centers and cities more often than in smaller hospitals or communities.

## 3. Referral to an Adult Neurologist or Internist

This is generally a consultation model with follow-up visits. It begins with a request for consultation to an adult specialist. Although follow-up visits may be scheduled with the specialist, they may require a new referral from the primary care physician.

There are limitations to this approach. Few adult internists or neurologists are trained or interested in the long-term care of developmental brain disorders. Financial pressures limiting visit time and high expectations of the family are particularly problematic. Many adult neurologists and internists are uncomfortable treating patients with intellectual disability and worry about not having easy access to appropriate subspecialists.

## 4. Referral to an Internal Medicine/Pediatric Subspecialist

We are unaware of published literature about the effectiveness of a neurology transition program that uses the United States model of a fully accredited Internal Medicine/Pediatrics residency program. The concept is that during a “med/peds” residency, training is offered in comprehensive care for children, adolescents, and adults with chronic health disorders. This model allows for 2 to 4 years before transfer to an adult specialist or return to the family physician. During this period, the youth has time to mature, gain skills to manage medical care, and recognize when and where to seek additional help for health issues. Families have time to establish estate planning and learn to relinquish their responsibility for their child, allowing the young adult to “grow up.”

## 5. Referral to a Nurse-Run Transition Clinic

This model was described in Edmonton, Alberta. A pediatric epileptologist completes a referral to the adult care team. The

patient and family meet jointly with the pediatric and adult epilepsy nurses for several visits to prepare for their initial and long-term visits with the adult epilepsy team.

## 6. A Joint Pediatric/Adult Transition Clinic

We favor this approach (Camfield et al., 2012). Careful initial review in such a transition clinic may revise the original diagnosis, reconsider medications, investigate surgical options, and address comorbidities. Adherence can be addressed along with potential side effects to medications and potential lifestyle alterations. Counseling may include sexuality, life expectancy, newer treatments, and ways to improve quality of life with the opportunity for increased maturity and self-esteem in addition to realistic long-term goals. In 1997 Appleton first described such a program for youth with epilepsy in the United Kingdom. There were 120 “transitioned” patients—37% with intellectual disability. Patients were seen several times by the clinic staff of a pediatric and adult neurologist, as well as a nurse practitioner. During these visits a new diagnosis emerged for 10%, and medication was changed 22% of patients. After an average of two visits, the pediatric neurologist bowed out leaving the youth to be followed in the adult care system. The pediatric neurologist continued to be available for consultation to the adult staff.

## 7. Internet-Based Support Groups

Encouragement for youth and families to align with a professionally moderated, disease-specific online support group or organization will hopefully permit very long-term access to new developments in treatment. Such a connection is not a replacement for a transition process.

## CONCLUSIONS

More information is needed about the long-term outcome of neurologic diseases in children and the best way to manage transition and transfer. The optimal age to begin the transition process is not known, but starting in early adolescence seems appropriate. The best time for transfer may vary from high school graduation to completion of college or when the young adult is fully emancipated. The success of any transition program will surely be strongly related to the enthusiasm and commitment of the physicians and other healthcare professionals who are involved. Personal contact between providers in the pediatric and adult settings is likely the most important ingredient to success. Given the intensity of treatment for children with chronic neurologic disorders, it is essential to transition satisfactorily to adult medicine.

## INTRODUCTION

Clinical practice guidelines (CPGs), practice parameters, and practice advisories are documents developed to address the need of practitioners for guidance in making medical decisions. High-quality CPGs are written by panels of authors, including topic experts, using a formalized process to reach consensus recommendations based on a systematic review (SR) of available clinical evidence regarding the benefits and harms of different treatment options. The last half century has seen CPGs evolve along with the field of evidence-based medicine and come to play an increasingly important and highly scrutinized role in medical practice and health care policy.

## HISTORY

The first SRs were efforts to analyze the combined data from multiple small clinical trials. Concurrently, authors began to use SRs of evidence as the basis for practice recommendations. Evidence-based medicine (EBM) emerged from work done in the 1970s that uncovered wide geographic variations in care received by seemingly similar groups of patients. An EBM Working Group report in 1992 advocated for a greater emphasis on rigorous and systematic evaluation of high-quality scientific medical evidence for understanding causation, prognosis, diagnostic accuracy, and treatment effects (Eddy, 2005).

Within a few years, dozens of medical specialty societies and disease-specific societies began publishing practice guidelines. However, these guidelines continued to rely more heavily on the beliefs of the authors, or on expert consensus, than on empirical evidence. Governmental agencies and insurance providers, acting on their interest in improving patient outcomes and slowing the rising cost of healthcare, began to take an active role in the guideline development process. In 1989 the U.S. Congress established the Agency for Health Care Policy and Research (AHCPR), later renamed the Agency for Healthcare Research and Quality (AHRQ), which currently provides support for a network of centers that produce systematic reviews for public and private groups and maintains the National Guideline Clearinghouse (<http://www.guideline.gov>), a searchable online CPG database.

Private and international organizations have also been significant contributors to the field in EBM development. The Cochrane Collaboration produces systematic reviews following protocols that emphasize transparency and scientific rigor. The Scotland-based Guidelines International Network (GIN) library has collected more than 6000 guidelines from around the world (<http://www.G-I-N.net>).

Several dozen guidelines with particular relevance to child neurologists have been developed in the last 20 years, mostly through the work of what is now called the Guideline Development, Dissemination, and Implementation (GDDI) subcommittee of the American Academy of Neurology (AAN), often with involvement and endorsement by the Child Neurology Society (CNS) (Table 166-1) (Hurwitz et al., 2015).

## DEVELOPMENT PROCESS

Over the years, guidelines have come to play a more prominent role in healthcare practice, administration, and law. Private and government insurers are supporting guidelines for their potential to reduce practice variations, improve the quality of care, and reduce healthcare costs by discouraging ineffective or harmful practices. Hospitals are using guidelines as the basis for quality assessments and computer-based decision support tools. Lawyers working both sides of malpractice suits are attempting to introduce guidelines into evidence as the accepted standards of appropriate care.

Many previously published guidelines fall short because of limitations in the scientific evidence upon which they are based. Even when developers can overcome the difficulty and expense involved in reviewing all available studies, there may still be a lack of sufficiently rigorous, unbiased, consistent, and generalizable evidence to support more than vague recommendations. CPG development groups may only be able to produce specific recommendations by relying on expert opinion.

The process of guideline development may also suffer from a lack of transparency, inclusiveness, or consistency, diminishing the actual or apparent reliability of the result. Perception that one or more authors of a guideline are biased by self-interest can diminish the acceptance of a guideline by both practitioners and the public.

Conflicts of interest (COIs) can be academic, intellectual, and financial. The American Thoracic Society defined COI as “a divergence between an individual’s private interests and his or her professional obligations such that an independent observer might reasonably question whether the individual’s professional actions or decisions are motivated by personal gain, such as financial, academic advancement, clinical revenue streams, or community standing” (Schünemann et al., 2009).

The evidence available to guideline developers may also suffer from COIs. Many published clinical trials are industry sponsored and conducted to obtain U.S. Food and Drug Administration (FDA) approval for a new medication or clinical indication. Although these studies tend to be of high quality, they are more likely to show favorable results than independently done studies and to use socioeconomically homogenous populations, exclude patients with important medical comorbidities, utilize relatively brief follow-up periods that may underestimate risks, and rely on surrogate endpoints that may overestimate benefits (Avorn, 2005). These shortcomings have reduced the generalizability of even very recent guidelines. With evidence lacking, imperfect, or disputed, and guideline developers making recommendations based on some estimation of expert consensus, multiple guidelines on a subject have been published with conflicting recommendations.

Concerns about CPG quality prompted the U.S. Congress to direct the Secretary of Health and Human Services to contract with AHRQ and the Institute of Medicine (IOM) of the

**BOX 166-2** Institute of Medicine (IOM) Standards for Developing “Trustworthy” Guidelines

1. Transparency
  - a. Details regarding clinical practice guideline (CPG) development and funding should be explicit and public.
2. Conflict of Interest (COI)
  - a. Potential guideline development group (GDG) members should declare all potential COIs.
  - b. COIs should be reported and discussed by the GDG before any member joins the group.
  - c. Each member should explain how COIs could influence their work.
  - d. Members should take steps to minimize their current and future COIs.
  - e. Ideally, members should not have COIs, but when necessary, those who do should be a minority of the group and should not serve as the chair or cochairs of the group.
  - f. Funders should have no role in CPG development.
3. GDG Composition
  - a. GDGs should be multidisciplinary and balanced.
  - b. Patient and public involvement should be facilitated.
  - c. GDGs should adopt strategies for increasing effective participation of patient and consumer representatives.
4. CPG–Systematic Review (SR) Intersection
  - a. CPG developers should use SRs that meet standards set by the IOM.
  - b. When SRs are conducted specifically for a CPG, the GDG and SR team should interact regarding the scope, approach, and output of both processes.
5. Establishing Evidence Foundations for and Rating Strength of Recommendations
  - a. Each recommendation should be accompanied by:
    - i. the reasoning underlying the recommendation, including
      1. a clear description of potential benefits and harms;
      2. a summary of relevant available evidence (and evidentiary gaps), a description of the quality (including applicability), quantity (including completeness), and consistency of the aggregate available evidence; and
      3. an explanation of the part played by values, opinion, theory, and clinical experience in deriving the recommendation.
    - ii. a rating of the level of confidence in (certainty regarding) the evidence underpinning the recommendation;
    - iii. a rating of the strength of the recommendation in light of the preceding bullets; and
    - iv. a description and explanation of any differences of opinion regarding the recommendation.
6. Articulation of Recommendations
  - a. Recommendations should be articulated in a standardized form that makes clear what actions are recommended and under what circumstances.
  - b. Strong recommendations should be worded to facilitate evaluation of compliance.
7. External Review
  - a. External reviewers should include scientific and clinical experts, interested organizations (e.g., healthcare, specialty societies) and agencies (e.g., federal government), patients, and representatives of the public.
  - b. The confidentiality of authorship of external reviews by individuals and/or organizations should be maintained unless waived.
  - c. The GDG should record its responses to all reviewers' comments.
  - d. A draft of the CPG should be made available to the general public for comment and reasonable notice of impending publication should be provided to interested public stakeholders.
8. Updating
  - a. The CPG publication date, date of pertinent SR, and proposed date for future CPG review should be documented in the CPG.
  - b. Literature should be monitored regularly to evaluate the continued validity of the CPG.
  - c. CPGs should be updated when new evidence suggests the need for modification of clinically important recommendations.

(Adapted from Institute of Medicine (IOM). Clinical Practice Guidelines We Can Trust. Washington, DC: The National Academies Press; 2011.)

National Academy of Sciences to research the most objective, scientifically valid, and consistent methods for producing SRs and CPGs. The IOM's report “Clinical Practice Guidelines We Can Trust,” published in 2011, outlined eight recommendations for improving the transparency and validity of the guideline development process (Box 166-2) (IOM, 2011).

## THE AMERICAN ACADEMY OF NEUROLOGY PROCESS

The AAN GDDI subcommittee produces guidelines according to a process manual that has incorporated each of the IOM report's recommendations (AAN, 2011).

### Choosing Topics and Panelists

AAN guidelines may be written to address any number of the decision points facing practitioners in the management of patients with neurologic disorders, including how diagnostic tests should be used, how to choose the most appropriate medical and surgical treatments, and how to apply test results to counseling about prognosis.

Topics for AAN guidelines can be suggested by anyone, but typically come from physicians interested in serving as guideline authors, physician or patient interest groups and organizations, and members of the AAN GDDI and Practice committees. These nominations are rated by a topic expert designated by the GDDI based on relevance, prevalence, degree of practice variation or controversy, financial implications, feasibility of the project, and the potential for changes in treatment to improve patient care and outcomes.

Once a topic is selected, the GDDI then uses the same factors to decide whether the topic and its time-sensitivity warrant the production of a full SR, a more focused SR, a full CPG that uses a full SR, or a practice advisory focused on one or two clinical questions, based on a focused SR.

Next, a writing panel made up of volunteer subject experts and GDDI members serving as process experts is assembled, with careful attention to minimizing and balancing COIs. For full systematic reviews and guidelines, the panel includes at least one patient or patient representative. The writing panel formulates a protocol with an introduction to the topic, the clinical questions the panel will try to answer, and the search strategy the researchers will use for collecting scientific

evidence. Clinical questions are written in PICO format, specifying the population (P) or type of patient involved, the intervention (I) experienced by the patient (e.g., treatment, risk factor, or positive test result), the co-intervention (C) that serves as a comparator to the intervention (e.g., no-treatment or different treatment, lack of the risk factor, or negative test result), and the outcome (O) by which the effect of the intervention is being assessed.

For fully IOM-compliant products, the panel protocol is posted for public review and the framework and PICO questions are revised based on the comments received.

## Collecting and Grading Evidence

The search strategy for fully IOM-compliant products must query more than one database, including the so-called “gray literature,” which refers to results of clinical studies and literature reviews that are never published as articles in medical journals, but are nonetheless available ([www.graylit.org/about](http://www.graylit.org/about)). Including data from unpublished studies may help to counter some of the bias that leads to studies showing less benefit and more harm from treatments or tests being more likely either to be rejected for publication or to never be submitted in the first place. Most clinical trials performed in academic centers are now registered with the National Institutes of Health (NIH), and their protocols are published and maintained on an online site ([www.clinicaltrials.gov](http://www.clinicaltrials.gov)) so that the investigators can be asked for study data even when the study is never completed or never published.

The AAN process calls for an explicit search strategy to be laid out, for the abstracts of all papers identified by that search to be reviewed by at least two people for relevance, and then for the full text of all remaining papers to be reviewed by at least two people for relevance and stratification of the evidence into one of four classes based on characteristics of the study design that are relevant to bias. Different criteria are applied to studies addressing different clinical questions. For randomized, controlled clinical trials (RCTs) pertaining to the effectiveness of a treatment, studies can receive the highest rating (lowest risk of bias), class I, only when they are done in a sample of patients representative of the population, use masked or objective outcome assessments, exclude or adjust

for substantial differences between treatment groups in relevant baseline characteristics, use appropriate concealment allocation, prospectively define no more than two primary outcome measures, have clearly defined exclusion and inclusion criteria, and follow at least 80% of enrolled subjects to completion of the study, adequately accounting for dropouts. Studies that fail to meet one or more of these criteria will be downgraded to class II (moderate risk of bias) or class III (high risk of bias). Uncontrolled case series are given the lowest rating (very high risk of bias), class IV (Table 166-4).

The rationale for classifying evidence relates to the likelihood that given methods will affect the internal and external validity of the study's results and conclusions. When there are multiple studies pertaining to a question, particularly when they reach conflicting conclusions, greater weight should be given to studies providing stronger evidence (i.e., ones that because of their methodology are more likely to accurately reflect reality). For treatment trials, biases affecting internal validity lead to an underestimation or overestimation of the effectiveness of interventions. These biases frequently involve improper use of control groups, blinding, and randomization. External validity is lower when a study's results cannot easily be generalized to real-world patients and clinical settings, as a result of such factors as the exclusion of representative patients, high costs, and onerous burdens on patients and caregivers.

## Drawing Conclusions

Each study is then abstracted for a measure of the strength of the association between the intervention and outcome pair. For treatment trials, such association measures might be relative or absolute risk or odds differences between the treatment and control groups, with the precision in measurement shown by 95% confidence intervals (CIs) or by *p*-values (from which the 95% CI can usually be estimated). For relative risks or odds, a 95% CI that does not cross the value 1 is statistically equivalent to a *p*-value of less than 0.05. A study may or may not show a statistically significant association between interventions and outcomes, but the width of the CI should also be considered. A study may have great precision (narrow CI) and show significance ( $p < 0.5$ ) but still lack clinical relevance

**TABLE 166-4** American Academy of Neurology Process

CONFIDENCE IN EVIDENCE				
Confidence	Evidence			
High	At least 2 consistent class I studies			
Moderate	1 class I or at least 2 class II studies			
Low	1 class II or at least 2 class III studies			
Very Low or Unknown	Insufficient for a higher rating			
LEVELS OF RECOMMENDATIONS				
Recommendation Level	Level U	Level C	Level B	Level A
Wording	None	May	Should	Must
Adherence expected to affect	Few	Some	Most	Nearly all
Variation in patient preferences	Large			Minimal
Cost	Prohibitive			Minimal
Availability	Limited			Universal
Value of benefit relative to risk	Too close to call	Small	Moderate	Large
Confidence in evidence	Very low	Low	Moderate	High
Strength of principle-based inferences	Not plausible	Plausible	Convincing	Compelling

The recommendation level is anchored by the lowest of the confidence in evidence and the strength of principle-based inferences. The recommendation level can be decreased for any factor. The recommendation level can be increased only for a value of the benefit relative to risk that is moderate or large and can only increase by one level. With the exception of the unusual circumstance of recommendations derived solely from first principles, the level of recommendation can never attain level A without high confidence in evidence.

(Adapted from AAN. Clinical Practice Guideline Process Manual. 2011 Ed. St. Paul: The American Academy of Neurology; 2011.)

because of actually small or clinically irrelevant differences in outcome. A study lacking both precision (wide CI) and statistical significance ( $p > 0.5$ ) may be inconclusive, rather than negative, suggesting that an intervention could be clinically important if measured more precisely. If a great deal of the identified evidence suffers from lack of precision, a meta-analysis to combine the results of comparably performed studies may be appropriate.

The AAN uses the Grading of Recommendations Assessment, Development and Evaluation (GRADE) process for determining the confidence in the evidence, modified by using the class of the supporting evidence as an anchor point. First, interventions are assigned an initial level of confidence based on the class of evidence supporting their association with an outcome. This serves as an anchor limiting how much a recommendation can be upgraded or downgraded based on other factors that are then considered. The confidence can be downgraded by one level if the panel feels that there are additional factors limiting confidence in the evidence, including biological implausibility, the number and consistency of studies, their statistical precision, their generalizability, and their potential for being skewed by reporting bias. Similarly, the panel members may decide to raise their confidence in the evidence by one level if supporting factors are present, such as a large effect size, a dose–response relationship, and a bias that tends to minimize effect size.

To complete an evidence report or systematic review, the writing panel must summarize the collected evidence for each PICO question into conclusions that account for the class of evidence found, the strength and precision of the measures of association, the populations to which the findings apply, and the consistency, or lack thereof, between studies. The AAN uses language in writing its conclusions that is directly tied to the confidence in the evidence. For example, if there are multiple, consistent class I studies showing a clinically meaningful association between a treatment and improved clinical outcomes supporting high confidence, the panel is prompted to conclude that it is “highly likely” that the treatment is effective. If there is a single class I study or there are multiple class II studies showing a similar association supporting moderate confidence, the panel will conclude that it is “likely” that the treatment is effective, and so on. The panel may exclude negative studies lacking the precision to exclude a meaningful association (high risk of random error) when drawing conclusions, even if those studies were rated highly for class of evidence (low risk of systematic error).

## Writing Recommendations

If the writing panel had intended to draft a clinical practice guideline or advisory, and the evidence review was able to identify evidence of good quality and consistency, the writing panel then begins the process of formulating recommendations. Each recommendation is rated according to the level of the panel’s confidence in making it. The levels imply the obligation of practitioners to follow the recommendations. High-level (level A) recommendations direct practitioners toward things that they “must” or “must not” do. Moderate-level (level B) recommendations suggest to practitioners things that they “should” or “should not” do. Low-level (level C) recommendations imply that practitioners “may” or “may choose not to” decide to follow them. The lowest-level recommendation (level U) is assigned when there is insufficient evidence and rationale for choosing between available options (Table 166-4).

The author panel then drafts a set of recommendations, starting with the clinical questions and considering the available evidence in a realistic context. Each recommendation is

rated for the strength of deductive inference behind it, based on how well it can be related to accepted principles of medicine, related clinical evidence, and deductive reasoning. Recommendations considered at this stage can be based on this deductive process alone, rather than on conclusions from the evidence review. Each recommendation is assigned an overall rating based on the lower of the two ratings, the level of confidence (high, medium, low, very low) and the level of plausibility (compelling, convincing, plausible, or not plausible). The panel then systematically considers additional factors affecting the relative value of an intervention (the benefits [effect size], risks [tolerability and safety], availability, cost, and presence [or lack] of alternatives) and the variation expected in patient preferences. Only a large relative value can raise the level of confidence in a recommendation, and even then it can do so by only one level and cannot raise a recommendation up to level A. Interventions that might otherwise be worthy of a level U recommendation may also be designated level R (research-only) if concerns about costs or risks are such that the panel feels that patients should only receive the intervention in the context of ongoing research.

Often, the AAN uses a modified Delphi technique to reach consensus between the guideline development group (GDG) members regarding the wording and rating of the level of recommendations. The Delphi process involves GDG members anonymously answering a series of questions intended to determine the soundness of the recommendation and the relative importance of the factors that might influence the strength of the recommendation. The GDG responses are summarized and then presented to each member again, along with any commentary, and another round of rating is carried out. This rating and summarization process is repeated until consensus is obtained ( $\geq 80\%$  agreement), up to a maximum of three voting rounds. Because the process maintains participant anonymity, it reduces some negative group dynamics, including the tendency for opinion to be strongly influenced by participants with greater authority, reputation, or personality, and the tendency for participants to avoid changing their opinions out of fear of appearing inconsistent.

Some important clinical questions cannot be answered with current data, and some studies, even if conceivable, are unlikely to ever be financially or ethically feasible. Clinical context sections in some recent AAN guidelines have provided discussions by the authors of what is common in clinical practice without making specific recommendations. In the absence of sufficient evidence to support strong recommendations, the AAN has typically opted to lay out the limitations of the evidence and leave decisions regarding the best course of action to individual neurologists, who are those with the best understanding of their patients’ values and circumstances.

Once the author panel has finalized the wording and grading for its recommendations, the guideline is vetted by the AAN staff working with the GDDI subcommittee, including the staff EBM methodologist; reviewed by other members of GDDI committee; posted online with invitations for public comments; reviewed by the AAN Practice committee; and finally submitted for publication to the AAN’s official academic journal, *Neurology*. At each step, the feedback received and the reasoning behind any modifications made or not made in response are documented. Finally, the manuscript is submitted to the AAN Board of Directors and to any cooperating professional and patient-centered organizations for endorsement.

Dissemination efforts beyond publication in *Neurology* include press releases and official AAN written and electronic announcements directed at AAN members and the public. An archive of prior guidelines and educational materials for

patients and practitioners, including summary pages and slide sets, are freely available for download on the AAN website (<http://www.aan.com/Guidelines>).

The GDDI considers whether or not to update previously published AAN guidelines every 2 years, based on whether sufficient and compelling new evidence is identified by an interim literature search that would significantly change prior recommendations. If a guideline appears to still be valid, the panel may vote to reaffirm it. If a guideline no longer appears to be valid, the panel may decide to either retire it or nominate it for revision.

## LAW AND ETHICS

Many clinicians have a reflexive objection to the idea of being obligated by a clinical practice guideline to take specific actions in the care of their patients, feeling that rote application of “cookbook” standards of care cannot adequately substitute for their use of their own clinical judgment, incorporating their experience, their knowledge of disease pathophysiology, and their understanding of the nuances in their patients’ characteristics and individual values and preferences.

There has been little demonstrable effect of guidelines on the frequency with which defensive medicine is practiced. It has been suggested that CPGs would be more widely accepted, and that greater improvements in the cost-effectiveness of care could be realized, if it was clear that CPG recommendations could serve as an effective defense against malpractice claims. However, most malpractice trials take place in state courts, which tend to look to customary local practices, rather than to recommendations from a CPG, for the standards of care to which they will compare the actions of physician defendants (Avraham and Schanzenbach, 2010). Courts in most states will not hold practitioners liable for care that is judged customary, even if it is not optimal or evidence-based.

However, the U.S. federal legal system has allowed the submission of CPGs as expert testimony even if not as evidence. CPGs have been introduced into court proceedings both to defend a practitioner’s actions and to suggest negligence. In one case, a court ruled a physician’s care negligent for following a guideline without consideration of his patient’s specific circumstances (Recupero, 2008).

Because of ongoing concerns about their legal implications, all guidelines produced by the AAN carry a general disclaimer that their recommendations, even when worded as strongly as possible, should be considered suggestions rather than explicit directives. Nevertheless, some specific AAN guidelines anticipated to be controversial or upsetting to particular interest groups have been submitted to the AAN’s legal team before their publication to be vetted for wording that might be unnecessarily provocative.

## GUIDELINE UTILIZATION

There have been several studies done regarding awareness and acceptance of guidelines; these studies suggest that practitioners value them, but do not follow their advice (Davis and Taylor-Vaisez, 1997). A general obstacle to guideline utilization is the consideration of how decisions for real patients must usually account for far greater complexity, nuance, and specificity than clinical trials, meta-analyses, or guidelines can cover. Financial incentives to order unnecessary tests and treatments probably play a smaller role in the overutilization of services than do inclinations to perform defensive medicine out of concern for potential lawsuits. Guidelines may adversely affect their own adoption by lacking clearly actionable language or simply because they rely on a weak base of evidence.

It is clear that the most successful strategies for changing practitioner behavior use financial incentives, such as those that can be directed by hospitals and insurers (Rosenthal and Dudley, 2007). The pay-for-performance incentives and penalties incorporated into the 2008 Affordable Care Health Care law are driving sweeping systematic changes in physician participation in electronic health record (EHR) systems, registries, and quality improvement (QI) measurement efforts. Guidelines can suggest improvements in standards for practice when based on evidence of benefit versus harm that is clear, strong, and generalizable. For example, studies have shown that patients treated in accordance with CPG recommendations for asthma (Licska, Sands, and Ong, 2012) tend to have better health, shorter hospital stays, lower short-term costs, and lower rates of early rehospitalization.

Ongoing research in measuring the impact of guidelines will involve the use of electronic medical records (EMRs) to assess implementation and outcomes. Additional research will address the most effective ways for hospitals and practice groups to integrate guideline recommendations into the care of patients, such as through prompts generated in EMRs and assignment (especially of noncontroversial and strongly supported recommendations) to physician extenders such as nurse practitioners.

## CONCLUSION

When developed using methodologically sound processes, clinical practice guidelines can provide clinicians, researchers, and administrators with a clear picture of the state of the art in the evaluation, diagnosis, and management of a disease. In addition, systematic reviews and guidelines, by providing a clear accounting of the quality of the existing evidence, can suggest where the need for additional information is greatest. Because recommendations can only be as strong as the evidence will support, the growing interest in evidence-based guidelines is naturally stoking interest in creating a stronger evidence base. In 2010 the U.S. Congress established the non-profit Patient-Centered Outcomes Research Institute (PCORI), which has already provided more than \$1 billion to fund comparative effectiveness research projects to “provide information about which approaches to care might work best, given [patients’] particular concerns, circumstances, and preferences” (<http://www.pcori.org>).

The methods used for disseminating and implementing CPGs are undergoing rapid changes, with some trends having unintended consequences. Healthcare providers share the interest of consumers and payers in identifying and minimizing practices that are questionable or outright harmful. However, institutions must take care to ensure that practitioners do not end up feeling overburdened with levels of regulation of unproven value. The coming years, with additional insights from studies assessing the impact of CPGs on outcomes, will see these competing interests brought into better balance.

# 167 Special Education Law as it Relates to Children with Neurologic Disorders

Kathleen A. Hurwitz

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## HISTORY

Special education case law carried out by individual states and the federal legislation for the education of children with disabilities has its roots in the Fourteenth Amendment of the U.S. Constitution. This post-Civil War proposal insured that no state could deprive a person of life, liberty, or property without due process of law. Defining educational laws for children with special needs took its next big leap during the civil rights movement in the 1950s and 1960s. The equal rights amendments and the desegregation laws opened the door for children with disabilities to fall under the umbrella of antidiscrimination legislation. Educators, families, physicians, and disabled children have lobbied for education provisions that provide the best possible learning environment for special needs children.

Physicians and allied healthcare providers who deliver diagnostic and prognostic information to patients and families are compelled to understand current special education laws. In 1992 the American Academy of Pediatrics put forward a policy statement that called upon all pediatricians and pediatric subspecialists to provide a “medical home” for their patients. The medical home concept is particularly relevant for children with special needs. The statement advocates that physicians develop a “coordinated, comprehensive plan” for each child and involve community resources, including schools and educators in that plan. The physician needs to “claim responsibility” and oversee the implementation of the child’s care plan. Expansion and inclusion of healthcare services during school hours is increasingly falling under the jurisdiction of public education. Children with complex medical needs who frequently are sustained on technological devices require physician input for their care during school hours. In anticipation of the clinician’s changing role, a working knowledge of the evolution of the legislative process as it pertains to special needs education is presented in this chapter.

## SPECIAL EDUCATION CASE LAW

Special education law developed in state courts. A chronologic review is presented to give a historical perspective. These changing state rulings are precursors to federal legislation (Table 167-1).

*Brown v the Board of Education (1954)* was a class action suit that was a plea for racial desegregation. African American parents who had attempted to enroll their children in neighborhood schools with Anglo American students had been refused. They were required to attend segregated schools. Previously, “separate but equal” facilities were acceptable as long as they were equivalent. The Supreme Court ruled that in “the field of education separate but equal has no place. Separate educational facilities are inherently unequal.”

In *Hobson v Hanson (1969)*, the first objection to the use of standardized testing as part of tracking students was challenged. Ninety percent of students in Washington, DC, were African American. However, they were given Intelligent Quotient (IQ) testing benchmarked to Anglo American standards. Children were placed based on socioeconomic and race as opposed to their learning aptitude. The legal decision abolished Washington, DC’s tracking system. IQ testing in a child’s native language was first tested in *Diana v State Board of Education (1970)* (Reynolds, 2007). Civil rights groups brought suit on behalf of a bilingual student who was placed in a classroom for the mentally retarded. The child, Diana, had been tested in English and not in her native language, Spanish. The case never was heard because a decree was issued that IQ testing must be performed in the child’s primary language.

*Lau v Nichols (1974)* was a case involving Chinese-speaking students who claimed that they could not take advantage of certain educational opportunities because instruction was only in English. The court ruled that supplemental English be provided or instruction be carried out in the native language.

In 1979, *Larry P. v Riles* clarified testing of African American children. Larry P., one of six African American children, brought suit against the California Superintendent of Schools, claiming overrepresentation of African American children in classes for the mentally retarded. The children were placed in these classes solely on IQ testing. The court’s ruling favored the plaintiffs and restricted IQ testing for African American children. It was ruled that testing could only be performed if: 1) the court had received a request; 2) the test was validated for identifying cognitive delays; 3) the test was not racially or culturally biased; 4) the test was administered in a nonbiased environment; and 5) an open public hearing was held regarding the test.

Stanford Binet and WISC-R testing procedures were evaluated in the Illinois case, *PASE v. Hannon (1980)*. Cultural bias was on trial for each test question. Very few biased questions were found. The case never became historically significant because the state of Illinois banned the IQ testing of African American children as part of a settlement in a desegregation case.

High school competency testing as a requirement for graduation has been challenged in Florida. *Debra P. v Turlington (1984)* challenged the fact that a disproportionate number of African American children were failing their exit examinations. Because students taking the test started school when Florida was still segregating students, the court found for the plaintiffs. The courts also placed an injunction and the test was not required for graduation.

*Mills v Board of Education of the District of Columbia (1972)* is a landmark case for special needs children. Seven children brought suit against the schools because they were excluded

**TABLE 167-1** Summary of Case Laws

Case	Complaint	Ruling
<i>Brown v Board of Education (1954)</i>	Unable to enroll African American students in neighborhood school	Separate schools are inherently unequal
<i>Hobson v Hanson (1969)</i>	Objection to using Intelligent Quotient (IQ) testing for tracking students	Abolished tracking system
<i>Diana v Board of Education (1970)</i>	IQ testing in nonnative language	IQ testing must be in native language
<i>Lau v Nicholas (1974)</i>	Instruction not in native language	Supplemental English or instruction in native languages required
<i>Larry P. v Riles (1979)</i>	Overrepresentation of African Americans in EMR classes	Courts severely restructured IQ testing
<i>PASE v. Hannon (1980)</i>	Cultural bias in IQ tests	Very few culturally biased questions
<i>Debra P. v Turlington (1984)</i>	High school competency testing for graduation	Requires adequate notification to student before enforced
<i>Mills v Board of Education (1972)</i>	Excluded from school based on behavior, hyperactivity, and mental retardation	Free and appropriate education to all children regardless of disability type
<i>Pennsylvania Association for Retarded Children v Pennsylvania (1972)</i>	Excluded from classroom	Must include all children in education process and attempt to educate alongside nonhandicapped children if possible
<i>Pennsylvania v Battle (1980)</i>	Related service terminated at end of school year	Must be continued year round if a negative or regressive effect would result from termination
<i>Board of Education of the Hendrick Hudson Central School District, Westchester County, et al. v Rowley (1982)</i>	Deaf student requested an interpreter even though meeting IEP goals	No; the program in place was adequate
<i>Timothy v Rochester (1989)</i>	Severely handicapped and thought to be uneducable	Free and appropriate education upheld
<i>N.B. v Warwick School (2004)</i>	Parents wanted a different education program for autistic child and not the school-offered program	School providing program with a reasonable prediction of success was adequate

from public education based on their disabilities. These were issues of behavior, hyperactivity, and mental retardation. Many of the students excluded had not received a fair hearing. The court found in favor of the children; thus began “a free and appropriate education” for all children regardless of the disability. The case predated but greatly influenced the federal 1965 legislation called the “Education for all Handicapped Children Act” of 1975.

Defining a free and public education in the least restrictive environment became clearer from the case, *Pennsylvania Association for Retarded Children v Pennsylvania*. Thirteen mentally retarded children on behalf of all such children sued for a free and appropriate education under the equal protection clause. The court developed the concept of a least restrictive environment. A regular public classroom was a better choice for educational training than a special education classroom, which in turn, was preferable to a separate educational facility.

*Battle v Pennsylvania (1980)* extended benefits and services to disabled children beyond the traditional 180-day school year. The court supported the claim that discontinuing special education and programs, particularly self-help skills during recesses, could have a negative, regressive effect on children. This legal precedent protects interruption of much needed services.

The *Board of Education of the Hendrick Hudson Central School District, Westchester County, et al. v Rowley (1982)* was ultimately heard by the Supreme Court and interpreted the legal language of a “free and appropriate education” more clearly. Amy Rowley, a deaf student with two deaf parents, was enrolled in a regular classroom with an Individual Education Plan

(IEP) in place. She thrived in her environment, yet her parents requested an interpreter. The lower courts supported her parents because of a discrepancy between her performance and potential. However, the Supreme Court felt the program in place was “benefitting” her and fell under the definition of a free and appropriate education.

Accessibility of education for children with disabilities was tested in the courts in 1989. In *Timothy W. v Rochester*, it was ruled that the severity of a disability was not at the interpretation of the state. Timothy was severely mentally retarded, a spastic quadriplegic, cortically blind, and thought to be uneducable. Timothy’s right to a free and appropriate education was upheld (Murdick et al., 2007).

*N.B. v Warwick School Committee (2004)* has important ramifications for child advocates. The parents of an autistic child brought suit against a school district. The child in question had an IEP that supported a program called Treatment and Education of Autistic and Related Communicatively Handicapped Children (TEACH). The parents preferred a program that promoted “discrete trials” and enrolled their child at their own expense into such a program and were requesting reimbursement. The court found in favor of the school. The school was not required to provide the requested program but rather any program as long as it had a “reasonable prediction” of success.

## Federal Legislation

Federal legislation for children with disabilities emerged from a combination of social, political, and legal pressures. In the late 1960s and early 1970s, over 8 million disabled children

attended U.S. public schools (Wright et al., 2007). However, the special education needs of each child were not being provided in any consistent manner. Some states had exclusionary practices whereas others were struggling to meet the demands without appropriate classification procedures in place. Parental advocacy groups, education leaders, and lawmakers realized the need for federal legislation.

The first program of federal assistance to local school districts was defined in the Elementary and Secondary Education Act of 1965 (P.L. 89-10). Title 1 of this statute provided federal funding for schools based upon the number of students living at or below the poverty level. The No Child Left Behind Act of 2002 replaced this legislation.

The Handicapped Children's Early Education Assistance Act of 1968 (P.L. 95-538) provided for educational programs for disabled young children. Demonstration projects or educational models were to be funded, established, and measured for their success in providing educational services. This act also funded research institutes to study behavioral, cognitive, and emotional functioning of children. In 1982 funding was also provided for the evaluation of children with autism.

The Vocational Rehabilitation Act of 1973 (P.L. 93-112) provided services for the educationally handicapped (physical or mental) to promote independent functioning or employability. Section 504 of this act protected against discrimination of services. It ensured that children who may not meet "special education" definitions can have appropriate classroom modifications. This is important for children with medical conditions who cannot meet the full demands of a classroom. Children with attention deficit disorder or attention deficit hyperactivity disorder are an example of those needing a "504" in place. This "504" can provide extra time for testing, frequent breaks, etc. (Osborne and Russo, 2006).

Access to a minor's academic records is defined in the Family Education Rights and Privacy Act (1974). Parents of minors or 18-year-old students must provide a written request to review their records. If they believe the record to be incorrect they can request that the record be amended. A hearing can be called if the school disputes the amendment. Law enforcement records must be maintained separately and are not included in a student's file (Family Education Rights and Privacy Act, 1974, Pub. L No. 93-380).

In the early 1970s, Congress recognized that over 1.5 million children were excluded from school based on their disabilities. Therefore P.L. 142, known as The Education of All Handicapped Children Act (1975), was passed. This act included the all-important inclusion of an Individual Education Plan (IEP) for every child in special education. It was mandated that the child's education be carried out in the least restrictive environment and that parents be given informed consent regarding testing and evaluation results. Testing and reports were to be conducted and discussed in the child's native language. Due process must be provided for conflict and disagreement, and placement in special education must be nondiscriminatory. The concept of "zero reject" was established in P.L. 142. No child regardless of the disability could be excluded (Murdick et al. 2007).

This act was expanded as P.L. 101 to 476, as the Individuals with Disabilities Education Act of 1990 (IDEA). Just before this, the Americans with Disability Act of 1990 (P.L. 101-336) was passed. The Americans with Disability Act mandated the elimination of discriminations for individuals with disabilities. It prevented the disabled from being discriminated against in employment and required that public school services (e.g., field trips, after school activities, and school facilities) be physically accessible to all disabled students. Passage of this act also required private entities to provide public services to all disabled individuals. Effective telecommunications and

### BOX 167-1 Summary of Individuals with Disabilities Education Act

1. Age 3 to 21 that are disabled
2. Free and appropriate education
3. Least restrictive environment
4. Related services
5. Public school must search and find children who qualify
6. Nondiscriminatory testing
7. Individual Education Plan (IEP) for every qualified child
8. IEP's are transferable
9. Transition program from infant to preschool
10. Personnel development
11. Transition programs for after high school graduation
12. Confidentiality

closed-captioning services were also mandated for the speech and hearing impaired.

### Individuals with Disabilities Education Act (IDEA)

The seminal legislation in protecting disabled children's educational rights is embodied in federal statutes 101 to 426, 102 to 119, 105 to 17 and 108 to 445, the Individuals with Disabilities Acts of 1990, 1991, 1997, and 2004. This act is divided into four sections. The first, Part A, is composed of definitions. Part B houses the important laws and bulk of the legislation. Part C refers to infants and toddlers, and Part D refers to the national activities that exist to improve special education.

The essence of this act, Part B, contains the legislative components important to physicians. Any state that receives federal funding must include these essential components (Box 167-1). The act states who qualifies for special education in Section B. Any child between the ages of 3 to 21 who has been evaluated under this act's standards who is mentally retarded, speech or hearing impaired, deaf, a victim of traumatic brain injury, visually impaired, orthopedically impaired, autistic, possesses another health impairment, or is learning disabled qualifies for special education if the preexisting impairment influences the learning potential of the child.

Children with disabilities are entitled to a free and appropriate education. Free literally means "no charge." The child and his parents cannot be refused a service or billed for a service if it is covered under this act or if it is part of the child's IEP. The school can provide the least expensive form of the service. Medicaid or MediCal or private insurance can be billed for services covered under this act as long as it does not financially injure the family. Schools cannot charge for transportation to public or private facilities if the service is part of an agreed IEP. Appropriate education has been tested at the court level. In *Board of Education of the Hendrick Hudson Central School District, Westchester County, et al. v Rowley (1982)*, an appropriate education must have "a reasonably calculated benefit to the child's education." A child's "educability" and prognosis does not exclude him from the process as seen in *Timothy v N.H. (1987)*. Section 504 of the Rehabilitation Act of 1973 included modification and support for children with "other health impairments." Children with allergies, asthma, diabetes, attention deficient and hyperactivity disorder, etc., who do not qualify for an IEP are entitled to accommodations to protect their right to a free and appropriate education.

The term "least restrictive environment" is the general education classroom. A classroom with an aide for the child is less

restrictive than a special education classroom, followed by a special school. The most restrictive setting would be a home environment.

The Individuals with Disabilities Education Act includes “related services” and covers a child’s need for services as long as the child qualifies for special education and the services are necessary to meet the education goals set forth in the IEP. The services covered are transportation, counseling, physical, occupational and speech therapy, recreation and enrichment programs, and school nurse services. Transportation includes “door to bus” assistance but not transportation from school to after-care programs unless it is a part of the IEP. Counseling services do not include psychiatric services because these services fall under medical need unless they are required for the achievement of educational goals. Equal opportunity to participate in extracurricular activities must be provided, if appropriate. Health or nursing services such as intermittent catheterization, suctioning, etc., are included. Medical services that must be performed by a licensed physician are not provided. Drug abuse programs are not considered related services. Various classroom modifications, for example an air conditioner, are covered if maintaining body temperature in a brain-injured child is required for that individual to meet their IEP goals.

Public schools and educational agencies must search, find, and identify children with special educational needs as per the Individuals with Disabilities Education Act. Children in private schools and homeless children are included. Nondiscriminatory testing and assessment is guaranteed by this act. The testing process must be free of cultural or language barriers and be administered by a person who is trained and speaks the student’s native language. Importantly, no single testing modality can be used solely to qualify a child for special education. Multiple evaluations and inputs must be performed before a child qualifies for special education.

An IEP must exist for every child that qualifies for special education. The IEP is a legal document that must be followed or the local public agency (school) can be cited for noncompliance. The IEP is reviewed every year and evaluated every 3 years. All confidential material must be made available to parents. The IEP team includes the child’s parents, the child if appropriate, one regular education teacher (only if the child will be participating at some level in a regular classroom), a special education teacher, an individual from the school who is responsible for overseeing the performance of the others, an individual (usually a school psychologist) who can interpret the testing tools and their instructional implications, and, lastly, persons who also may contribute to the IEP process. Current (2004) amendments to the IEP do not require, for example, the presence of a physical therapist, an occupational therapist, etc., unless that particular service is being provided. The IEP, as an education plan for the disabled child, needs to include the following: a general statement regarding the child’s current capabilities, annual goals, a statement regarding “related services,” the approximate time spent out of a “regular” classroom, modifications needed for mandated assessments, the projected date of commencement of the plan, how progress will be measured, and a method to keep parents regularly informed.

An IEP is transferable. It travels with the child between schools and between states. This continues until a new plan is adopted or the current one is accepted. Provided services can be continued through summer recesses. The summer IEP is separate from the school year and may be completely different. The student must be at risk for “substantial regression” if recess services are to be provided.

Children with disabilities, at the age of 14, need an IEP that includes transition planning. By age 16, the transition process

must be in action. Transition IEPs include vocational planning, assessment of activities of daily living, employment plans, and access to community services. Credentials and diplomas should be offered to special education students. An IEP diploma, the minimum requirement for armed services vocational training, can be earned. The diploma also can be used for seeking employment.

Part C of this act addresses infants and toddlers (up to 2 years) with disabilities. The Individualized Family Service Plan (IFSP) must be adopted, planned, and implemented by the local public agency and carefully mirrors an IEP. Federal grants are available for developing interagency systems in individual states for these services. The IFSP is a legal document specifying: the current status of the child’s abilities; a statement of a family’s resources and concerns; a plan for measurable treatment outcomes; a specific early intervention service plan based on research evidence; the location of the services; dates of commencement; and the name of the “service coordinator” who will oversee the IEP.

Part D of this act includes national activities to improve education of disabled children. Parent training, personnel improvement, and preparation and grants for research fall under this portion of the act.

## HEALTH INSURANCE PORTABILITY AND ACCOUNTABILITY ACT OF 1996 (HIPAA)

The Health Insurance Portability and Accountability Act (HIPAA) was enacted to protect health-insured individuals from preexisting penalties and privacy violations when changing jobs and hence health insurance carriers. Schools that provide health services that are federally funded (catheterization, tracheostomy care, suctioning, and medication administration) are under HIPAA law guidelines.

## No Child Left Behind Act (NCLB)

The No Child Left Behind Act was signed into law in 2002 ([No Child Left Behind Act 2002](#), Pub. L No. 107 to 110). The Individuals with Disabilities Education Act of 2004 aligns itself with this act. The No Child Left Behind Act replaced the Elementary and Secondary Education Act of 1965 and is a huge paradigm shift from previous legislation. Federal funding to schools, based on the Education Act of 1965, was preferentially given to schools with the greatest number of children whose family incomes were near or lower than the poverty level. The No Child Left Behind Act distributes federal funding to schools that are in need of improvement based on student performance. Children with disabilities were expected to be included in this annual progress assessment of academic proficiency. Adequate progress must be made, and if a school fails for two consecutive years, the students and their parents may transfer to a nonfailing school. The sending school district must provide transportation until it is no longer a failing school for two consecutive years. This applies to all children in the school, regardless of disabilities.

## INTERNATIONAL SPECIAL EDUCATION

Educational programs for children with disabilities vary widely internationally and approaches in several different countries are described in this section.

### Canada

The Constitution Act is the legal document that gives the provinces of Canada the control of educational policies and

their funding. Within the act, the Canadian Charter of Rights and Freedoms is the highest law of the country. So, the laws of any province regarding special education cannot be in violation of these fundamental rights outlined in the Charter of Rights and Freedoms. Passage by a province of their Education Act outlines the powers, responsibilities, and specific education laws for that province, and the minister of education enforces these laws. In the Education Act, special education, suspension, and expulsion resolutions are defined. Special needs schools are available for children with physical, mental, behavior, and communication disorders, as well as for gifted children.

## China

The United States special education laws have been adopted by China in many ways (Kritzer, 2012). The 1975 Education for All Handicapped Children Act and IDEA Act have served as models for China. Interestingly, despite the large number of children with disabilities in China, the percentage of children receiving services in China is much lower than in the United States (Worrell et al., 2009). China excludes children who have learning disabilities, emotional behavioral disorders, language impairments, and other health impairments from receiving special education services. A lack of experienced professionals, of diagnostic technology, and of delivery systems decreases the number of children who are properly identified and who ultimately receive services.

China's law, The Compulsory Education Law (CEL) issued in 1986, demands that all children attend school at the age of 6. However, in remote areas of China, the CEL-2006 requires only children from the age of 7 to attend. The length of mandated education in China is 9 years. Children with disabilities are entitled to the same number of years of education (Worrell, 2009). Unfortunately, China's legislation does not guarantee financial support for schools or for the agencies that provide services for disabled children. Class size can reach 70 to 90 students per class, preventing special education children from having their needs met (Worrell, 2009).

Infants and toddlers are excluded from special education services unlike in the United States. Some large cities in China, however, do have programs to teach parents with challenged infants and toddlers on how to provide services. China's beliefs and ideology are contradictory to an IEP so that the unique needs of a child are not readily defined and addressed.

## India

Special education has moved from segregation to integration through government laws and policies. India's Integration and Education of Disabled Children (IEDC) law was written in 1974. In 1991 there were 1200 special schools for disabled children that included children with visual impairments, intellectual disabilities, and orthopedic problems. In 1992 a new IEDC program was approved, and financing was provided to integrate disabled students into regular classrooms. Teacher training began and intensive teacher education was undertaken. Selected teachers at a given school were given a 1-year training program. They were then designated as resource teachers. In 1996 the government of India enacted the Persons with Disabilities Act, ensuring opportunities for, protecting the rights of, and allowing for full participation for all citizens. Education, employment, and rehabilitative services were covered for the blind, those with cured leprosy, and those with hearing impairment, motor disability, intellectually disability, and mental illness. Free and appropriate education until the age of 18 was included (National Policy for Persons with Disabilities, 2006).

Challenges occurred with attempts to integrate students and implement education. Because of poverty, access, and religious beliefs, many children did not receive services. The prevailing belief among many Hindus in India is that the disabilities a child or individual possessed were the result of past deeds in a former life and assisting the disabled could interfere with "karma." Therefore many disabled students did not receive education and inclusion.

## Israel

Israel has very comprehensive special education programs for its citizens. The Special Education Law (SEL) of 1988 provided landmark legislation. A child with special needs is defined as "a person aged 3 to 21 whose capacity for adapted behavior is limited due to faulty physical, mental, psychological, or behavioral development and is in need of special education." A special education placement committee decides a child's educational needs. The committee includes a social worker, pediatrician, psychologist, minister of education services, and a representative of the National Special Education Parents Organization. A parent has no legal right to attend the meeting, but if the parent does not agree with the placement committee's decision, he or she has 21 days to request an appeal. Individual Educational Programs are developed for each child (Gumpel, 1996).

## Italy

Since 1977, children with special education needs in Italy have an opportunity for inclusion with an Individual Educational Program. Special needs schools, separate from the parent school, have essentially been discontinued. All students, since 1987, are entitled to secondary education. In 1992 the Italian Parliament approved the Disabled Persons Bill (L.104/92), which allows inclusion education from preschool to university. A functional dynamic profile is developed utilizing public health doctors. Infants and children with disabilities are involved in education from birth to 19 years of age. Classrooms are composed of 20 students, and no more than 25 students are allowed in a classroom that contains a disabled student.

## Japan

Japanese laws for special education began after World War II. The School Education Law of 1947 stated that special needs children should receive education with similar expected goals of ordinary children. Ultimately, the School Education Law made school attendance for all disabled children mandatory. In 1994 the law extended compulsory education to all students between the ages of 6 to 15 years.

Multiple school arrangements are available in Japan. The severely disabled attend special education schools, and students are given individual education plans. The National Institution for Special Education (NISE) was founded in 1991 and oversees the education of special needs children. Furthermore, special classes exist as well as resource learning classes for students with milder disabilities. Schools exist for children with vision, hearing, or orthopedic impairment as well as for those who are intellectually disabled and children who fall under the category of being "sickly" (Ministry of Education, Culture, Sports, Science and Technology, 2015).

# 168 Measurement of Health Outcomes in Pediatric Neurologic Disorders

Annette Majnemer and F. Virginia Wright

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

This chapter focuses on outcome measurement from the perspective of rehabilitation specialists such as occupational therapists, physical therapists, speech language pathologists, and psychologists. The general principles described apply to all outcome measures; however, specific examples and considerations for specialized areas such as educational or psychiatric assessment are not provided. Most standardized measures require either formal training according to the tool's guidelines and certification protocols or expertise in child development, in addition to clinical experience in the components that are being assessed.

## OUTCOME MEASURES: PURPOSE, PROPERTIES, PRIORITIZING

An outcome is something that follows as a consequence or result of a process, which may be a disease, treatment, or service. An outcome measure is a tool that evaluates or determines the result of a disease, activity, or program. Outcome assessment using the appropriate tool(s) enables objective determination of changes in a neurologic condition over time or changes related to an intervention or program.

Identifying the purpose of outcome measurement in a given situation is essential because this will guide the selection of the most appropriate outcome measure(s). Whether in clinical practice or research, the evaluator must first consider what areas (domains) are most important to measure. These considerations always need to be accompanied by the question "why" to ensure that the outcome results will have direct relevance. Once what needs to be measured has been determined, the assessment tools that best align with the concepts (constructs) of interest within the targeted domains can be chosen.

It also is essential when selecting an outcome measure to know the intended purpose of the tool itself. With the recognition of the strong importance of being able to measure outcomes, tools have been created to measure particular outcomes and are typically identified as such in the corresponding validation literature that pertain to them. Examples include the Gross Motor Function Measure (observational measure) and Pediatric Evaluation of Disability Inventory (parent-report questionnaire). For an outcome measure to be used for change detection, the tool must contain items that have potential for change in the clinical group being measured and also have a response-option format that will permit change detection. Dichotomous (yes/no) response scales are not sufficiently sensitive to change, whereas response sets with five to seven options, although more difficult to score, enhance detection of small but potentially meaningful changes (Streiner, Norman, and Cairney, 2014).

There are two other categories of measures that users need to be aware of. *Discriminative measures* differentiate children as

having or not having a particular characteristic or skill level (e.g., delayed or not delayed). Most of these measures have normative values for comparison. Although these can be useful at the initial assessment (e.g., Bruininks-Oseretsky Test of Motor Proficiency, Battelle Developmental Inventory), their application to outcome measurement needs to be approached with caution because they may lack item and response characteristics needed to detect change. Predictive tools are meant to classify children into categories with respect to their future status (Streiner et al., 2014). For example, the Alberta Infant Motor Scales and the General Movement Assessment are used to predict future motor ability in young infants. These measures are typically not well suited to evaluate change.

As part of this selection process, the properties of candidate measures need to be considered. They need to be age appropriate and applicable to the child's condition, appropriately scaled, and psychometrically sound and feasible. Measures must produce consistent and reproducible results (reliable), whether tested by independent evaluators (interrater reliability) or repeatedly by the same evaluator (test-retest reliability). The tester's experience or training or the child's level of attention or lack of engagement can contribute to measurement error. Subscales items should aggregate well together to represent particular attributes of interest (internal consistency). It is imperative that assessment tools are actually measuring what they are intending to measure (valid). Content may be verified by experts to ensure it has the attributes of interest (face validity), and results may be compared with other gold-standard measures of a similar construct (concurrent validity) or a gold standard in the future (predictive validity). Gold-standard measures often do not exist for children, and therefore the potential correlations will be less than perfect.

Validity also can be estimated by determining that the measurement tool behaves as expected. It may differentiate between children with low and high performance levels (discriminant validity). Finally, if an outcome measure is to be used to evaluate change over time, it must have evidence of being sensitive to change (responsiveness). This is important to verify when clinicians want to use the tool to evaluate treatment effectiveness; it is also important for researchers who are conducting an intervention trial (Streiner et al., 2014).

The clinical or research priorities for outcome measurement should also influence the selection of measures. In clinical practice, the functions of the clinician will guide the choice of the best-fitting outcome tools. In acute hospital-based care, providers focus on diagnosis and need to consider the health-related attributes they must identify. In a rehabilitation center, specialists provide intensive interventions and need to focus on the child- and family-related attributes they expect to change. In the home or community setting, the focus is on integration and child/family adaptation to the real-life context, and therefore assessment will focus on the activities/areas in which the clinician can make a difference.

Assessment results should inform clinical decisions and promote greater accountability and a reflective practice approach. The outcome measures selected by providers should inform their goals for intervention plans that are unique and specific to the child and family and their needs and priorities. After treatment or following a period of evolution of the neurologic condition, reassessment is helpful in determining whether there are clinically meaningful changes and whether treatment goals should continue in the same direction or need to be realigned. For the family, the findings on their child's assessment offer objective quantitative information regarding abilities (strengths), areas of challenge, and changes documented over time.

In research endeavors, investigators need to select valid outcome measures to address their hypotheses. In pediatric neurology, these questions could relate to the underlying biologic mechanisms of disability, determinants of brain recovery or brain organization, validation of new diagnostic tools, treatment efficacy, quality and benefit of services, or knowledge-translation efforts (Majnemer and Limperopoulos, 2002). Researchers need to be specific in formulating their questions, and may use a patient intervention comparison outcome (PICO) format for question formulation (Thebane, Thomas, and Paul, 2009). For example, if the researcher wanted to evaluate the efficacy of botulinum toxin, the PICO question might be: Will there be a significant improvement (the *comparison*) in range of motion, gross motor function, participation, and quality of life (the *outcomes*) in preschoolers with spastic diplegia (the *patients*) 3 months after treatment with botulinum toxin (the *intervention*)? The researcher may want to determine which children benefit most, and may evaluate how specific attributes of the child (e.g., age, baseline motor/cognitive function) or environment (e.g., family support, access to interventions) affect the outcomes. These attributes would also need to be specifically measured.

One other priority is that the outcome measurement process and the actual measures selected need to reflect and support a child- and family-centered philosophy of practice. This means using tools that elicit information directly from participants themselves about what they experience and do (performance) in their daily lives in addition to using observational measures that show what the child can do (capability) in the clinical setting. With respect to parent or child report questionnaires, it is important to ensure the measures will be acceptable as far as content, format, and wording. For example, a validated measure of family stress created 30 years ago, developed for a context that is very different from today's extended-family and multicultural environment, may no longer be optimal from the standpoint of response comfort or relevance.

Being family centered requires that the clinician think carefully about the relative burden of assessment to ensure that the measurement that is done is worth the time and effort expended and also fits with the information needs of the child and/or parent. It is important to explain to families the rationale for measurement and to discuss the measurement approach(es). This information sharing helps to optimize family engagement in the outcomes process at the outset of a new intervention block. Sufficient time needs to be provided to allow for discussion of results as they occur. This ongoing dialogue helps families develop realistic expectations regarding their child's progress, outcome, and goals. The well-targeted intervention planning that results from this collaborative and systematic process is expected to result in a more efficient intervention-delivery process and potentially better outcomes.

It is important to recognize that standard items within measures "typically focus on selected aspects of health and

frequently do not include items that directly reflect a client's unique needs and goals" (McDougall and Wright, 2009, p. 1363), even though they may be valuable in providing an overall picture of the child's abilities and be sensitive to change. Integration of standard item measurement tools and individualized measures such as the Canadian Occupational Performance Measure (COPM) and/or Goal Attainment Scaling (GAS) (Cusick et al., 2006) is a powerful way of bringing child and family outcome priorities into a comprehensive and collaborative measurement approach. For these two goal measures, the child or caregiver (for younger children) selects the specific activities that he or she feels are problematic and important to improve. The child's present abilities are rated preintervention using the measure's specific scoring approach, and re-evaluated using the same goal-specific rating scale is done at targeted follow-up periods.

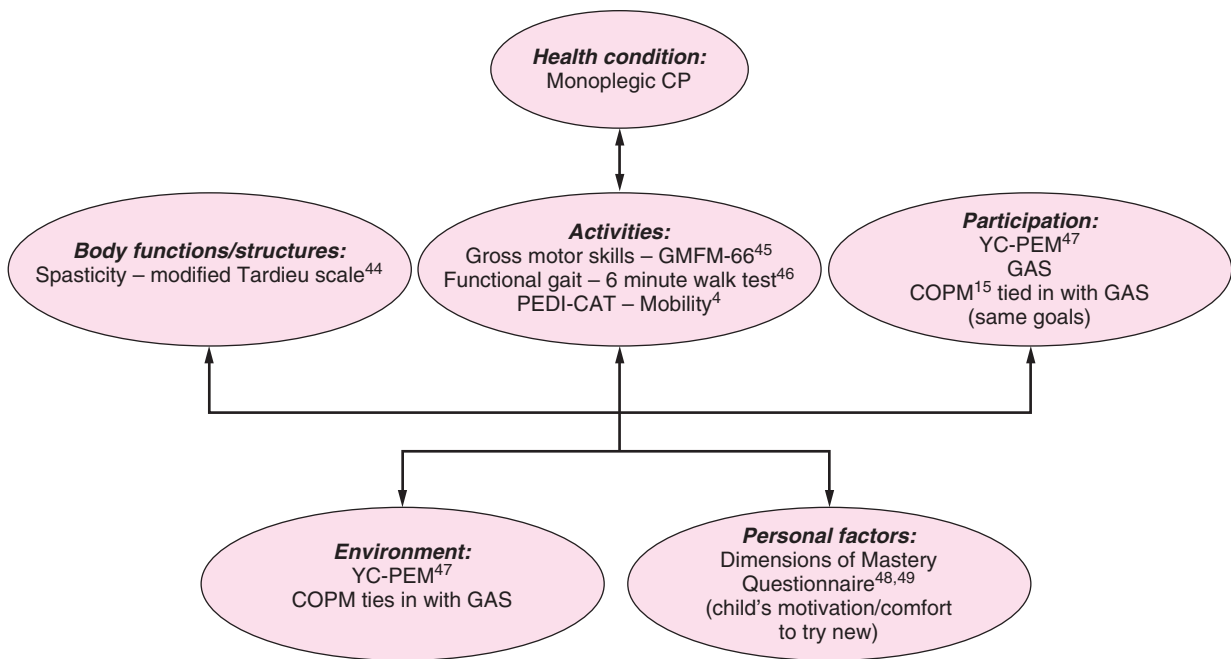

## ICF AS A FRAMEWORK FOR OUTCOME MEASUREMENT

Given the breadth of areas and domains that can be measured, the number of measures available, and the growth in the number of new measures being developed, it can be daunting to determine which areas to measure and to examine how the measures interrelate in terms of a child's health and functioning. These relationships are critical in understanding how a child and family are doing and will influence goal setting and planning of interventions. The International Classification of Functioning, Disability and Health (ICF) framework developed by the World Health Organization (2007) serves well as a template for conceptualizing the priority outcome areas to measure for a given child and family. The ICF language offers a way of moving beyond the notion of disability (formerly thought of as the absence of health) and reframing it as functioning (in terms of body functions/structure, activity and participation) and the relationship to health (Table 168-1). The ICF framework looks at the child's abilities and the effects of the social and physical environment on a child's functioning and health. Use of an ICF diagram (as illustrated in the following scenario describing a 3-year-old with cerebral palsy) to plan the measures used by a clinician/team for a child provides awareness of the current emphasis (and relative balance) of a measurement/goal/intervention focus and added clarity on how one might adjust the focus and balance at times of re-evaluation.

As an illustration of the use of an ICF-based outcome measurement approach, consider the scenario of a child who is age 3 and has monoplegic cerebral palsy (right leg) with spasticity in her right calf muscles resulting in mildly impaired walking and running (consistent with a definition of mobility in Gross Motor Function Classification Level I [GMFC I]). The parents describe an increasing tightness in her ankle when they put her socks and shoes on, a tendency to toe walk that has become more pronounced, tripping and occasionally falling, and a reluctance to try new physical activities. It is this last observation that worries the parents most because they fear she is starting to be excluded from activities in her preschool class and neighborhood. Physical examination by her pediatric neurologist revealed that she is an ideal candidate for botulinum toxin injections. Although the area of outcome measurement pertaining to this intervention relates directly to changes (gains) in body function/structure (spasticity, range of motion) (Fig. 168-1), the parents' observations make it clear that evaluating changes in gross motor skills (activities such as running, going down hills, ascending/descending stairs) and doing new activities/keeping up with peers (participation

**TABLE 168-1** Components of the ICF–Children and Youth Version (ICF-CY)

Components of the ICF	Description	Abnormalities	Examples
<b>1. FUNCTIONING AND HEALTH</b>			
Body structure	Anatomic parts of the body	Impairments	Periventricular leukomalacia, spinal muscular atrophy
Body function	Physiologic functions of the body or psychological functions	Impairments	Spasticity, decreased attention span, poor short-term memory
Activities and participation	Activity (A)—execution of a task/action Participation (P)—involvement in life situation or role	Activity limitations and participation restrictions	Walking (A), mobility in all environments (P); reading (A), education (P); brushing teeth (A), self-care (P)
<b>2. CONTEXTUAL FACTORS</b>			
Personal factors	Internal influences on functioning and health	Can be facilitator or obstacle	Lifestyle preferences, age, gender
Environmental factors	External influences on functioning and health	Can be facilitator or obstacle	Family functioning, peer support, health-care services, policies, resources,

**Figure 168-1.** An example of the application of the ICF framework to a child with cerebral palsy. (Based on the WHO International classification of functioning, disability and health. Geneva, Switzerland: World Health Organization; 2001.)

or mobility in the playground and in gym activities) is also critical as evidence that the intervention is working. Two well-validated measures that physical or occupational therapists can administer are the Gross Motor Function Measure-66 (GMFM-66) and the Pediatric Evaluation of Disability Inventory’s (PEDI-CAT’s) Mobility Domain, parent-report questionnaire that directly address gross motor skills and functional abilities in young children with cerebral palsy. Collectively these provide measurement of what the child can do (GMFM-66: ICF Activity) and how the child is able to integrate those skills into daily life (PEDI-CAT: ICF Activities and Participation). There is also a recently published parent report measure that delves more deeply into a young child’s participation in the environment, the Young Children’s Participation and Environment Measure (YC-PEM), which was adapted from the Participation and Environment Measure for Children and Youth (PEM-CY). This measure was incorporated into the assessment because

it considers the role of the environment as a facilitator or barrier to participation. Finally, GAS could be used with these measures to highlight two or three well-operationalized individualized goals focused on important everyday activities, with outcome specifications tailored directly to the parent’s hopes and expectations.

A word of caution in using the ICF framework for the linking of outcome measures is that there is a lack of incorporation of the overarching concept of quality of life (QOL) in the model (McDougall et al., 2010). Although enhancement of a child’s QOL is at the core of the care clinicians provide, there will be times when changes in QOL will be seen as a direct goal of an intervention, whereas in other scenarios, higher QOL/life satisfaction may be an outcome of a series of interventions over a longer time frame.

Tables 168-2–168-6 provide examples of measures that can be used to assess children with physical disabilities (Table 168-2), intellectual disabilities (Table 168-3), and global

developmental delays (Table 168-4), and generic measures of activities and participation (Table 168-5) and health and quality of life (Table 168-6). These tables are available in the online version of this chapter.

## CHILD'S AGE AND STAGE AS A DETERMINANT OF MEASUREMENT FOCUS

Child development is a dynamic process marked by ongoing change. When evaluating a child, it is essential that relevant activities and life roles are evaluated based on the stage of the child's development (i.e., chronologic age), not the level of functioning or mental age. A second important principle is that evaluation of the outcomes of children with neurologic disorders requires periodic assessment at key transition points because their development, functioning, and health are continuously changing and evolving, even if their health condition is static. Difficulties at each stage of development may be identified, with the expectation of periodic utilization of additional services to enhance outcomes (Majnemer and Mazer, 2004). Finally, evaluators should seek to identify strengths within the child at a particular developmental stage because capitalizing on these strengths can enhance motivation, takes advantage of the child's abilities and competencies, and is more solutions-focused. This would include strengths within the family as well. In rehabilitation interventions, there is increasing interest in applying a strengths-based approach to promote positive youth development, meaningful participation, and resilience. The following websites offer additional information on these concepts:

<http://www.acywr.org/2011/09/the-strength-based-approaches-background/>

[http://humanservices.ucdavis.edu/academy/pdf/strength\\_based.pdf](http://humanservices.ucdavis.edu/academy/pdf/strength_based.pdf)

In practice, a uniform template of specific measures is not applied to all children of all ages. Rather, the child's stage of development will influence the scope and focus of assessment, and the neurologic disorder and its associated impairments that manifest at each stage of development will guide selection of the most important measures. For example, in a 3-year-old with Down syndrome, it would be appropriate to ask the child to build a block tower to examine fine motor control (e.g., grasp, release, eye-hand coordination, proximal control, motor planning); however, at 13 years of age this activity would not be age appropriate. Rather, observations carried out during assessment of everyday tasks such as dressing, writing, and eating would be helpful in evaluating fine motor control, and use of standardized measures such as the Purdue Pegboard Test can provide objective and age-appropriate measurement of unilateral and bilateral manual dexterity.

For *newborns*, the primary focus is sensorimotor, such as the neonate's response to auditory and visual stimuli; the quality and symmetry of the infant's movements in prone, supine, and supported sitting; muscle tone; primitive reflex patterns; and behavioral state (e.g., lethargy, irritability). Many standardized neonatal neurobehavioral assessments (see review in Majnemer and Snider, 2005) are available and can be used in the neonatal intensive care unit. Feeding efficiency, an emerging life skill with important consequences for growth and development, may also be assessed.

In *infancy*, standardized evaluation tools such as the Bayley Scales of Infant and Toddler Development (Bayley-III, 3rd edition) are meant to assess the developmental abilities of infants and toddlers (up to 42 months), focusing predominantly on gross motor and fine motor skill development and cognitive abilities but also expressive and receptive

language skills, social-emotional development, and adaptive behavior. At this stage, all domains of development begin to unfold, and delays in particular areas may gradually manifest themselves.

*Preschool age* is marked by rapid changes in developmental abilities across all domains, and children also become independent in basic self-care activities such as eating, toileting, and dressing. Children are able to communicate their needs and participate in conversations. At this developmental stage, important preacademic skills are also achieved, such as listening to instructions and attending to task demands, basic writing and copying, interacting socially with other children, and separating from caregivers. Measurement must be holistic and cover the spectrum of developmental and functional expectations.

At *school age*, there is increasing emphasis on functioning and health. Outcome measurement focuses on educational achievement, oral and written communication, independence in daily living skills to include domestic chores, mobility in all environments, socialization, and community engagement. By *adolescence*, personal identity formation, preferences and motivation, and life choices shape these areas, influencing functional potential. Environmental resources and supports, such as availability of aids and adaptations and accessibility of and participation in adaptive programs and activities, exert important influences on functioning and health. Therefore measurement at school age and adolescence is increasingly focused on activities and participation and personal and environmental factors, as framed by the ICF, and less on developmental impairments.

Reflecting back on the scenario of the 3-year-old child receiving botulinum toxin injections, and thinking instead about a school-aged child (e.g., an 11-year-old) with the same diagnosis and similar body function/structures issues in her right leg, although the areas of priority for measurement are likely similar, the actual measures that are used will need to differ to ensure that the measurement focus and perspective are optimal. First, it would be of value to use activity and participation measures that allow self-report by the child herself (instead of or in addition to the parent). In this regard, although the PEDI-CAT would apply as far as content for evaluating the aspect of gross-motor-related functional abilities, at the time of writing this chapter, the child report version had not been validated, and therefore it would still be necessary to have the caregiver as the proxy reporter of the child's abilities on the PEDI-CAT. An alternative might be use of the well-validated Activities Scale for Kids questionnaire. This outcome tool is a good content fit from the viewpoint of advanced motor skills and has a validated version that allows school-aged children to self-report on abilities. Second, although the GMFM-66 will serve well to capture the child's stand and walk/run/jump abilities in the 3-year old child, the ceiling effect that is present with children in the category of GMFC I who are ages 7 and up is a key issue. Hence, to be able to measure this area, an outcome measure for advanced gross motor skills is necessary. At present, one of the few possibilities in this outcome-measure category is a new observational tool known as the Challenge. Third, a shift from the YC-PEM to the PEM-CY (which the YC-PEM was modeled after) would allow age-suitable measurement of the participation and environment outcome areas. Finally, it will be important to capture priority goals directly from the child using the COPM or GAS and then work with the child and parent together to allow these goals to guide the intervention offered.

Irrespective of age or stage of development, a holistic view of the child's functioning and health in the context of

the personal (e.g., lifestyle, intrinsic motivation, sociodemographic factors) and environmental (e.g., family functioning and well-being, peer support, resources in the community, societal attitudes) factors that can positively or negatively influence functioning is needed. This enables the clinician to capture a complete picture of the child's abilities and disabilities, which will then inform the next steps in intervention and health promotion.

## NEW DIRECTIONS IN OUTCOME MEASUREMENT

One of the important considerations in using outcome measures that relates to the psychometric properties of the measures is the actual clinical meaning or interpretation of the changes that are observed. Change-score magnitude needs to be considered in light of the measure's reliability and the estimated measurement error. As the awareness of the importance of this concept has grown, recent outcome-measure validation studies have tended to place greater emphasis on reporting the minimum detectable change (MDC) or minimum detectable difference (MDD) estimates. For example, the MDC<sub>95</sub> estimate for the GMFM-66 is 2.5 points, meaning that the user can have 95% confidence that a change of more than this will reflect true change and not measurement error. These estimates are still emerging for many of the commonly used pediatric outcome measures.

A related concept pertains to the minimum clinically important difference (MCID) (Streiner et al., 2014). Although it is often confused with MDC (Stratford and Riddle, 2013), this concept relates to what children, parents, and clinicians deem to be a meaningful change. Thus although it is fully reliant on the strength of the measure as far as reliability and related MDC, it goes a step beyond and takes child/parent priorities into account. There have been attempts to establish the MCID within different diagnostic groups for measures such as the PEDI and GMFM, and when these values are available, they at least give users some benchmarks to consider. However, at this point, caution is advised when using these values to signify intervention success because these estimates are at best only an average value across a group of parents/children and have been based upon statistical or consensus methods that are still in early conceptual stages (Copay et al., 2007).

An important new direction in outcome measurement is the concept of patient-reported outcomes (PROs). PROs include any report of the status of a patient's health condition that comes directly from the patient, without interpretation of the patient's response by the clinician or anyone else. These are self-report measures that are completed by the youth or by a proxy, typically a parent. PROs allow patients (or their proxies, if they cannot report for themselves) to describe and assess a number of attributes, such as symptoms, functional status, participation in life roles, health perceptions and quality of life, environmental facilitators and barriers, and satisfaction with services.

Numerous global initiatives promote the use of PROs as an emerging priority for clinical and research measurement. At the National Institutes of Health (NIH) in the United States, person-centered medicine and outcome research (PCOR) emphasizes the conduct of research that compares the benefits and harms of interventions to prevent, diagnose, and treat health conditions, and researchers are expected to apply PROs in the real-life context. NIH has funded research programs such as PROMIS, which is focused on PROs in health care and rehabilitation. In Canada, the strategy for patient-oriented

research (SPOR) has been launched by the Canadian Institutes of Health Research; PROs are integral to SPOR programs. The United Kingdom has policies in place to promote the use of PROs and a focus on patient experience frameworks. In reality, PROs are not often used in clinical practice but can be instrumental to allow patient voices to be heard and to identify outcome status or factors influencing outcomes, and they can be influential in setting goals and making treatment decisions based on patient priorities and values.

Finally, a challenge for selection of outcome measures is that this is a growing area in which new measures will continue to be developed to address identified measurement gaps or issues related to existing measures. The concept of a toolbox of measures (Koene et al., 2013) that can apply to a clinical group or intervention has been advocated across rehabilitation settings, providing a cohesive approach and common language to outcome measurement across the international community. The reader is referred to an earlier paper for an example of how this concept pertains to cerebral palsy (Wright and Majnemer, 2014). Within any outcomes toolbox, there will also need to be space for a few new emerging measures (e.g., the Focus on the Outcomes of Communication under Six and the YC-PEM) that may fill important measurement gaps and have foundational evidence of psychometric strength; current work on responsiveness and MCID may also be worth considering for the toolbox, either as a replacement for or addition to the measures for given clinical situations (e.g., the use of the Challenge mentioned earlier to replace the GMFM-66 for children with cerebral palsy at GMFC I).

In summary, outcome measurement is essential to characterizing a child's functioning and health. The ICF provides a universal framework to ensure that outcomes are viewed holistically, across the spectrum of the child's functioning and in the context of personal and environmental factors that can influence outcomes. Outcome measurement provides essential individualized information to children and families regarding the child's current status and how it evolves over time; it also provides clinicians objective feedback about the changes that can be documented in response to interventions. Managers also benefit from outcome measurement as part of quality improvement, and researchers use standardized measures to answer their research questions. Selecting the most appropriate measures can be a daunting task and is best achieved in collaboration with patients and families and team members across health disciplines.

# 169 The Influence of Computer Resources on Child Neurology

Michael M. Segal and Steven M. Leber

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

As computer technology becomes more integrated into our lives, much of the information that we use now, including summarization of knowledge in textbooks, will be accessed primarily electronically. This chapter examines how such changes are unfolding in the ways we communicate and discuss information, in the ways we marshal information to diagnose and treat patients, and in the ways we educate newcomers to the field and keep experienced clinicians up to date.

Table 169-1 in the online version of the chapter lists websites of interest to child neurologists.

## CLINICAL DISCUSSIONS AND GROUPS

Throughout medical history, doctors have talked to one another, patients have talked to one another, and doctors and patients have talked to each other. With the advances in information technology, such communications have become faster, cheaper, and, in some situations, more anonymous. For over a century, doctors have used conferences, journals, and textbooks to exchange information. Recent innovations in technology have moved such discussions to the Internet and made them more instantaneous. These have used listservs (discussions sent by e-mail to groups of subscribers) and web-based forums that are organized by topic, in which people post questions, answers, and news.

Speeding up communication is no small thing. It can take one or two decades for therapeutic advances to become part of routine clinical practice (<http://archive.ahrq.gov/research/findings/factsheets/translating/tripfac/trip2fac.html>). The ability to learn of such advances and hear considered responses from leaders in the field within days, results not only in an increased speed of learning of new advances but also in attention directed to potential problems in published interpretations of research. Web forums and listservs are also popular, in part, because they have created an environment that encourages spontaneity and sharing of hypotheses.

The specifics of the technology of listservs versus forums seem not to matter much. What matters most is the community. The Child-Neuro listserv (<http://www-personal.umich.edu/~leber/c-n/e-mailUM.html>) was established in 1993, using what is now antiquated technology—using text-format messages distributed individually or in daily digests. Nevertheless, the Child-Neuro listserv continues to be the core Internet discussion group in the field, whereas more technologically sophisticated web-based discussion services, such as Sermo (<http://www.sermo.com/>), have less influence because they do not have the same presence of experts. It is too early to be able to assess the utility of the Child Neurology Society's new "Open Forum" web-based service.

The technology for discussions among patients is often newer, since the communities are newer, the numbers are greater, and the needs for privacy are lower. In the past, patients had much less contact with one another due to difficulty finding each other and the reluctance to disclose illness to people they knew personally. As a result of the anonymity of the Internet and the ability to find others with similar problems through search engines, patient-to-patient discussions have proliferated. Since these discussions are new, they have tended

to use newer Web-based forum technologies. Communities such as PatientsLikeMe (<http://www.patientslikeme.com/>) and Brain Talk (<http://braintalkcommunities.org/>) have become meta-sites for people with neurologic diseases. Some forums offer advanced community capabilities. For example, PatientsLikeMe allows users to search for others with similar symptoms, an ability that can be used for identifying hypotheses to test in controlled studies. In addition to these meta-sites, there are communities for individual disorders, such as attention deficit disorder (<http://www.addforums.com/forums/index.php>) and periodic paralysis (<http://www.periodicparalysis.org/>).

Another innovation enabled by the Internet is medical blogging. Blogs, the shorthand term for "weblogs," are websites on which articles, commentary, and other forms of textual, graphic, or multimedia content are posted. Blogs are often run by a single individual, providing a personal perspective and a top-down structure. As the costs associated with blogging have fallen essentially to the cost of the time involved, blogs have proliferated. In medicine, blogs have tended to cover medical practice and common diseases; blogs covering rare diseases would have very small audiences, and online communities make more sense as forums for such communication. However, there is quite a continuum. Blogs are sometimes a group effort and typically include some discussion in each thread, and discussion groups often have several regulars who sustain the discussion. So, in actuality, there are hybrids between pure blogs and pure discussions that have evolved to meet the needs of individual communities.

One of the important innovations in online discussions is the breaking down of the separateness of doctor-to-doctor and patient-to-patient discussions to create doctor-to-patient discussions. Doctor-to-patient discussions are of course the core of medical practice, but sharing such discussions among wider communities has value. An advantage of the Internet is the ability to have doctor-to-patient discussions with anonymity that one cannot achieve by group visits to doctors. The main barriers to doctor-to-patient discussions on the Internet are the absence of physical examination and medical records from other doctors, making the doctor less confident about giving advice, as well as the lack of incentives for physicians to provide such assistance with commitment and consistency. However, this may be merely an issue of creating the proper incentives and structures. One of the authors of this chapter has spent a significant amount of time in recent years interacting with patients on a variety of sites as part of an effort to uncover the molecular mechanism of attention deficit disorder (Segal, 2014). The patients would make little progress by themselves because they lack the deep expertise of the doctors in understanding the biology of disease. The doctors would stagnate without the patients' descriptions of their clinical symptoms. The combination is much more effective. In the past, progress could be made by studying the patients in a large clinical practice and hearing their observations personally, but such a process is difficult to arrange for less common diseases. Now, the ability to have such interactions is much accelerated. A doctor can post a query and get responses from many patients within days and, furthermore, can get a sense

of how many of the regular participants respond in a particular way. Such interactions allow patients to partner with doctors, not only in decisions on treatment, but also in advances in understanding pathophysiology.

A patient-centered movement that calls itself “Health 2.0” has touted patient-to-patient discussions as a replacement for many types of doctor-to-patient interactions and replacing top-down “information therapy.” Health 2.0 is the exchange of information in Internet forums “that get richer as more people use them” by “harnessing collective intelligence” ([http://patients.aan.com/news/?event=read&article\\_id=5277](http://patients.aan.com/news/?event=read&article_id=5277)), whereas information therapy involves more traditional instructional materials provided by doctors. However, drawing a distinction between Health 2.0 and information therapy may be more theoretical than real. For example, the patients in the listserv of a prototypical Health 2.0 group, the Periodic Paralysis Association, asked the doctors associated with the listserv to write an “owner’s manual” for hypokalemic periodic paralysis (<http://simulconsult.com/resources/hypopp.html>), a prototypical information therapy type of resource. The patients used the listserv to collect questions for which they wanted answers, both for their own education and to educate physicians caring for them. Yet the patients made very clear that they wanted the responses—that is, the content—to be written by people whom they and their physicians trust as experts. Far from guarding their realm as a patient-to-patient self-empowerment organization, the patients encouraged two doctors to participate in the listserv, one motivated by a research interest in the area and the other motivated by having one of the diseases himself. This ability to add doctor-to-patient interactions and mix Health 2.0 and information therapy shows how some of the rigid conceptions of the types of medical information on the Internet are evolving into more flexible approaches that are better at meeting the needs of patients. There is an important need to institutionalize resources valued by patients such as “owner’s manuals” into a meta-site covering many diseases and thus known widely and trusted in the field.

The discussion groups described previously involve groups of patients, groups of doctors, and sometimes a few doctors and many patients. Yet in medical practice, a different type of exchange predominates: discussions about one patient in a clinical chart. With only a bit of exaggeration, one could characterize an electronic health record (EHR) as a privacy-protected blog about one patient. Despite the simplicity of blogs, they have the ability to incorporate a wide variety of types of external content. Currently, however, EHRs have a lot of standardized, nonpertinent material that distracts the reader from the main points. However, one should expect improvements in the EHRs of the future; as discussed later in “Diagnostic Decision Support,” it is possible to use computerized tools to reintroduce pertinence to EHRs and do so in ways that leverage large amounts of information.

There is much discussion about automating some types of doctor-to-patient interactions using e-mail and telemedicine. This is most extensively implemented so far in radiology, in which the subtleties of patient interaction are largely absent and reimbursement issues are most clearly defined. It is widely expected that such techniques will expand. Using telemedicine in radiology and psychiatry, however, is more practical than in some areas of neurology in which physical examination plays a much larger role. In other areas, however, such as epilepsy and movement disorders, the history and observation of the patient is more important than hands-on examination, and telemedicine may be boon for patient-centered health care (Joshi, 2014). Over the years, it is expected that telemedicine will increase, driven by provisions for reimbursement, technology and services for physical examination and patient monitoring, and secure options for such online interactions.

On a more basic level, many patients already are using e-mail to communicate with their physicians. Electronic communication between patients and healthcare providers is advantageous, in that the communications can be thought out carefully in advance, posted and read at convenient times, and saved for future reference and for the medical record. Supplemental information (e.g., medication instructions and handouts going from doctors to patients, or videos of patients’ events going from patients to doctors) can be attached or linked. “Asynchronous communication” also avoids “phone tag,” long telephone queues and holds, and long distance phone charges, a difficulty for many patients. However, the use of e-mail to convey sensitive information raises numerous security and privacy concerns, particularly given the legal right of employers to access their employees’ e-mail. A potential solution to many of the problems posed by e-mail lies in the development of comprehensive, password-protected patient portals for doctor-to-patient interaction. Most commercial EHRs have built-in portals with secure messaging; having at least 5% of a provider’s patients use the portal is now a requirement of the Centers for Medicare and Medicaid Services (CMS) Meaningful Use Stage 2 requirements ([http://www.cms.gov/Regulations-and-Guidance/Legislation/EHRIncentivePrograms/downloads/Stage2\\_EPCore\\_17\\_UseSecureElectronicMessaging.pdf](http://www.cms.gov/Regulations-and-Guidance/Legislation/EHRIncentivePrograms/downloads/Stage2_EPCore_17_UseSecureElectronicMessaging.pdf)).

## WIKIS

Wikis are a type of web content with no real analog in the precomputer age. A wiki is a document that can be edited independently by many people using a simple set of web page formatting tags. The prototypical and dominant wiki is the collection called Wikipedia.

The advantage of Wikipedia is that the wide participation has resulted in millions of pages of content, with many popular articles having material contributed by many different authors, none of whom is paid. The disadvantage of Wikipedia is that battles can erupt over controversial issues and editing of pages can be banned by editors with a particular perspective despite the existing information being false or misleading.

In medicine, a key concern about Wikipedia is that articles are often written by people who are not medical professionals, sometimes resulting in content that is dubious or very incomplete. Although Wikipedia has articles on thousands of diseases, many physicians will prefer wikis with authorship restricted to doctors, but there is not much content of this sort for child neurology.

As with traditional narrative content, a promising future direction for wikis is finding some way of getting doctors and patients “on the same page.” One such example is having a doctor who has a particular disease write material that combines both the doctor’s and patient’s perspectives, resulting in a full understanding that comes from living with the disease from both perspectives.

As with Internet forums, the chief difficulty in achieving the desired doctor-to-patient collaboration is creating financial and professional models for inducing the doctor to write patient-directed material. Due to the value of such material, it seems likely that this will be achieved, but it remains to be seen what incentives will get doctors involved in such patient-directed materials. Such helpful but hard-to-monetize resources are an example of the benefit of large, integrated health organizations (Christensen et al., 2008).

## DIAGNOSTIC DECISION SUPPORT

The basic difficulty with diagnosis is that medical information is typically organized by disease, yet the process of diagnosis begins with a collection of findings and considers which diseases best fit with these findings. Some of the resources for

diagnostic decision support, such as flow charts and diagnosis confirmation protocols, existed long before computers. These approaches are very useful in situations in which a particularly salient finding is present or a particular diagnosis is being considered. However, for the more general case, we now have access to novel approaches to decision support that did not exist in the precomputer age and can improve both diagnostic accuracy and cost-effectiveness of workups. These new approaches include automated search and diagnostic software. Although in the past people argued about whether such resources were useful, with the proliferation of newly recognized genetic disorders and the advent of inexpensive genome sequencing, little doubt remains that such computerized approaches are needed.

The advantage of automated search is the ability to process huge amounts of information collected in an inexpensive, automated process of searching accessible web pages (e.g., Google; <http://www.google.com/>) or adding some natural language processing (e.g., Isabel; <http://www.isabelhealthcare.com/>). The disadvantage of search is that many of the subtleties of the information are lost or jumbled, including information about timing and onset, absent findings, frequency of findings, and treatability. Such subtleties can be used in a diagnostic software approach, but a “curation” process of collecting information manually in a standardized format is needed to characterize diseases, and tradeoffs must be made as to level of granularity to characterize findings (e.g., SimulConsult: <http://www.simulconsult.com/>; and Phenomizer: <http://compbio.charite.de/phenomizer/>). Furthermore, there are many subtleties to how we think of patient findings such as how we group them (e.g., including orthostatic changes in blood pressure as part of the disease or considering it incidental) and with what level of granularity the clinician should describe findings (should weakness be described as proximal vs. distal, rapid vs. slow onset, and so forth).

Another advantage of diagnostic software is the ability to offer advice prospectively on which findings or laboratory tests would be most useful and cost-effective to distinguish among likely diagnoses. This is important in getting doctors and insurers to focus on evidence relevant to decisions about whether a test should be covered by insurance. Software also offers the ability to link such recommendations about useful tests to resources such as the Genetic Testing Registry (<http://www.ncbi.nlm.nih.gov/gtr/>) and the NextGxDx gene test shopping service (<https://www.nextgxdx.com/>). The ability to suggest useful findings is also important in promoting communication among medical specialties. For example, a radiologist can begin from a diagnostic software session begun by a neurologist, using a display of useful radiologic findings to ensure that the findings most useful to the neurologist are commented on explicitly.

One area in which doctors need help is in interpreting genetic tests. Increasingly, we face situations in which a mutation is found in a gene or an abnormality is found on a chromosomal test, but it is not clear whether the result is pathogenic or incidental. Such information is a key proprietary resource of companies that have interpreted many genetic tests, but such information is being increasingly centralized in the ClinVar database (<http://www.ncbi.nlm.nih.gov/clinvar/>), which allows genome interpretation software to tap into such listings via automated queries.

A basic philosophic issue is developing about interpretation of whole exome and whole genome testing. Is this similar to a single gene test, in which the laboratory returns an answer, or is it more similar to an MRI, in which the neurologist provides detailed information to the radiologist, and the ultimate diagnosis is made by the neurologist, not the radiologist? Clinical diagnostic decision support software that can also do genome analysis in a clinical context can be a crucial way of

empowering the neurologist to interpret genome results with appropriate clinical correlation (Segal, 2015). Clinicians who know the patient can often check findings (such as crying without tears or a molar tooth sign on MRI) that were not recognized as useful to check until results became available from genomic analysis of the patient.

## TREATMENT DECISION SUPPORT

Treatment is a more straightforward software task than diagnosis because one already knows the diagnosis. If the disease is unfamiliar, software simplifies access to narrative text, calculators, and flow charts to help with treatment. Even when the disease is familiar, integration of computer programs into the workflow can enhance fine-tuned management and increase safety and improve outcomes.

Examples of freestanding or integrated applications include calculators (such as automated anticoagulation calculators), drug information and interactions, flowcharts, look-up tables, nomograms, and automated guidelines and protocols (e.g., an online ordering system that might recommend deep vein thrombosis prophylaxis in an adult in bed for longer than 2 days, or a patient-controlled anesthesia pump that puts an upper limit on the amount of morphine infused).

The difficulties in deciding about treatment typically arise from lack of data and from conflicts between data sources. Perhaps the most useful recent advance in treatment decision making has been the ability of groups of healthcare professionals to address specific treatment questions, review the medical literature, and make these systematic reviews widely and easily available via the Internet ([http://en.wikipedia.org/wiki/Systematic\\_review](http://en.wikipedia.org/wiki/Systematic_review)). The best known collection is the Cochrane Database of Systematic Reviews section of the Cochrane Library (<http://www.cochranelibrary.com/>). Yet even when clear recommendations have been formulated, they often are not used (McGlynn et al., 2003). Why is this the case?

First, even when guidelines exist, it takes extra effort for the practitioner to look for them and remember to use them. However, “guideline execution engines” are being developed to address this issue; these are programs integrated into EHRs that translate clinical guidelines into recommendations ([http://en.wikipedia.org/wiki/Guideline\\_execution\\_engine](http://en.wikipedia.org/wiki/Guideline_execution_engine)). Examples might include alerts about drug interactions and dosage errors, disease management pathways (e.g., reminders to obtain surveillance laboratory tests in patients on certain medications or renal ultrasounds in patients with tuberous sclerosis) and automatic retrieval of relevant systematic reviews. A meta-analysis of clinical decision support systems for treatment or screening revealed that 68% of these support systems improved clinical practice and that the only ones that did so were those in which decision support was automatically supplied to the clinicians as part of their normal workflow; none of the support systems in which clinicians were required to seek out the help of the support system improved clinical practice (Kawamoto et al., 2005). Other features associated with improvement in clinical practice for treatment and screening were:

1. Computerized systems compared with manual systems
2. Systems integrated into the charting or order system, rather than acting as standalone applications
3. Systems that prompted clinicians for reasons when they chose to override automated recommendations, rather than allowing bypass of recommendations without recording a reason
4. Systems that provided recommendations rather than those that simply assessed risk (e.g., “Patient is at high risk of coronary artery disease; recommend initiation of beta-blocker therapy” rather than simply “Patient is at high risk of coronary artery disease”)

5. Systems that provided decision support at the location and time of decision making compared with those providing support away from the point of care

Some 94% of clinical support systems that incorporated these key features were associated with improvement in clinical practice. Paper-based clinical guidelines do not have the influence of guidelines that are integrated into a clinical management system.

The second reason why these clinical protocols are not used is that there are so few of them, and even the ones we have are based on limited information and often do not give definitive guidance. For example, the American Academy of Neurology and Child Neurology Society have a total of only 12 treatment guidelines for child neurology on their websites (<https://www.aan.com/Guidelines/home/ByTopic?topicId=14> and <http://www.childneurology.org/resources/practice-parameters>; accessed 11 April 2016). Moreover, guidelines frequently do not exist for or apply to the individual patient in front of us and the specific clinical question being asked (Gronseth and French, 2008). The patient in front of us is not the “average patient” addressed in the study and may have secondary diagnoses that affect treatment. Establishing recommendations can be very difficult (e.g., Smeets et al., 1999; regarding initiation of anti-epileptic medications), particularly for rare diseases. We are hopeful that, as medical records are digitized, medical information will become more easily abstracted, coded, and shared, aiding generation of better information about diseases, treatments, and outcomes. However, the complexities of coding information at appropriate levels of granularity are far from trivial, particularly because medical knowledge is in a constant state of flux.

## EDUCATION

Education is an area likely to be transformed in major ways by computer technology. Many of the information resources discussed previously, from narrative resources to wikis to decision support, are already being used in education. The ability of the web to disseminate video is of huge importance to teaching areas of neurology that are very visual, such as movement disorders and epilepsy; even the ability to provide still images at low cost is very helpful for neurocutaneous diseases and neuroimaging. The ability of diagnostic decision support software to highlight useful findings and link to resources about them is crucial to enabling such just-in-time education.

Several online educational resources relevant to child neurology are listed in the table accompanying the online version of this chapter.

The web has also facilitated case-based education by allowing many training programs to share interesting clinical cases. The Child Neurology Society and the Professors of Child Neurology have been running such a program since 2008 (<http://www.childneurology.org/resources/continuing-education/cns-case-studies>), making use of the web to include images and to hyperlink the cases directly to articles in the literature and to diagnostic software.

Decision support software is also useful in teaching in a very concrete context how we approach differential diagnosis. Typically, medical students are taught to make diagnoses by collecting all relevant information, thinking about it, and constructing a differential diagnosis. In reality, the process is far more iterative (Bowen, 2006). One collects a bit of information, forms hypotheses, and then collects more information based on the hypotheses and continues in this manner, refining the differential diagnosis iteratively. Using diagnostic software, one can show this process in a very concrete way and illustrate other factors that are important in diagnostic thinking such as frequency of findings, treatability, and time information. Diagnosis turns out to be far more complex than the

way it is presented in medical schools, and the ability to demonstrate this in a very concrete fashion with diagnostic software makes it easier to convey these complexities to students.

## PERSPECTIVES

One of the big questions about computerization in medicine is whether the new medium will change the type of medical information used. For new tools, such as diagnostic software, the use of the tool at all is a real change. But the wider question is how traditional narrative material will be changed by the Internet. Will we move away from authoritative sources and toward a social networking approach in which information is amplified by the community of users? The examples discussed in this chapter suggest that both doctors and patients want some mix of certification and social networking approaches and that the successful resources will be those that merge these to combine the solidity of expertise with the nimbleness of a vigorous community.

It seems clear that most of our information will be on the Internet, and new approaches to information will become common. We expect a rapid move toward interoperability among information resources, jumping not only from software to narrative resources but also from narrative resources to software to obtain advice tailored to an individual patient.

## CONFLICT OF INTEREST

Dr. Segal is the founder of SimulConsult. He acknowledges that his interest in promoting use of the software poses a potential conflict of interest. Dr. Leber has no conflicts of interest.

# 170 Education and Training of Child Neurologists and Workforce Issues

David K. Urion

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

This chapter considers two interrelated issues: how should child neurologists ideally be educated and trained in terms of their early development and introduction to the field, and how do these issues of education and training have an influence upon the workforce for the first half of the current century? Consideration of the issues of education and training, as well as the workforce in child neurology, directly affects the very nature and identity of child neurology. How we educate and train those who will follow us, to whom we are accountable for the content and outcome of that education, and how we deploy the workforce we thus prepare define our very essence as child neurologists.

The term most frequently used these days is “training,” but we must consider this in a broader sense. We are not limiting the notion of “training” to the acquisition of a set of skills and knowledge, a craft. Skills and knowledge are necessary but not sufficient. The training of child neurologists must also include the development of habits of mind, ethical and moral considerations, and the cultivation of certain virtues. Russell Gruen and his colleagues have argued quite persuasively that the evolution of the profession of medicine has been one of the constant extensions of domains of professional obligation into what had previously been domains of professional aspiration. Individual patient care was the sole domain of professional obligation for a long period of time. As time passed, he argues that access to care becomes a domain of professional obligation—whether or not all children have access to child neurology care becomes our professional obligation. Direct socioeconomic influences then became our professional obligation—do our patients have access to insurance coverage, and does their family’s socioeconomic status have an influence upon their health? Gruen then argues that broader socioeconomic influences and global health issues are still in the domain of professional aspiration, not currently normative for us, but that this will likely change as time goes on.

This concept of “training” is more akin to the notion of “formation” that was prevalent in the 19th century among the so-called liberal professions—medicine, law, the clergy, and the military. In those days, “formation” meant taking individuals and engaging them in a process in which they obtained not only the knowledge and skills necessary for a profession, but also a world view, a set of attitudes and beliefs, a common set of reference values and virtues, which were all recognized as essential to the profession. Another central feature to this calculus was the independence of the profession: it determined its own standards for becoming a member of the profession, as well as that which was needed to remain a member of the profession. The profession argued that it was the guarantor of skills and proficiency, ethical behavior and practice, and the public could, and should, be reassured by that. Although the use of the term “formation” has fallen out of currency, the broadness of the concept it embraces is one we should still

continue—it allows us to consider historical approaches before formal programs in child neurology evolved and to contemplate a generation of our forebears that became child neurologists through pathways other than our current mode of education and training, the residency program. It also allows us to think more broadly about the nature of child neurologists and what skills, attributes, and virtues they need to be successful, competent, and compassionate practitioners of the art and science of child neurology for the 21st century.

This chapter will use the framework of the development of child neurology training from the vantage point of how training evolved in the United States. It is but one example of the development of the field as a paradigm for consideration. Child neurology training has evolved differently across the globe based on how regional socioeconomic, cultural, and religious factors have influenced the development of different medical specialties.

## HISTORICAL ASPECTS

Unlike most other pediatric subspecialties, child neurology in the United States emerged from the evolution of certain adult neurology practitioners, who became particularly interested in the problems and disorders that were particular to children in the context of their discipline. This contrasts with most other pediatric subspecialties, whose history is one of pediatricians becoming increasingly interested in a specific set of disorders and a subspecialty organizing itself in that emergent fashion. This maintains itself today by the organization of the certifying bodies of pediatric subspecialties. Most derive their authority from the American Board of Pediatrics. Child neurologists are certified instead by the American Board of Psychiatry and Neurology. Even the preferred name for our discipline subtly demonstrates this. One is a pediatric cardiologist and is board certified as such. Our discipline is populated by people who usually refer to themselves as child neurologists and whose certification is in neurology with special competence in child neurology. The distinction is not merely semantic but is foundational in terms of identity.

It is beyond the scope of this chapter to consider in detail the founders of child neurology; the reader is referred to the excellent text by that name for a biographic compendium (Ashwal, 1990). We can, however, note several pathways that emerged in the evolution of the discipline. The vast majority of the early practitioners of what became our discipline began as adult neurologists who developed abiding interests in the neurologic disorders of children. They, in turn, began to gather like-minded younger physicians around them and what we can consider the first era of child neurology formation ensued. Informal and centered around one or two charismatic teachers, these schools of child neurology emerged at some of the larger university teaching hospitals of the early 20th century. The disciples of these schools then moved out across the country, taking their traditions, interests, and approaches with

them. The late Dr. David Clark likened this era of child neurology to tracing bloodlines in racehorses. One could trace many of these early leaders back to their original progenitor. Thus one could say that Charles Barlow, for example, personified the education he received from Douglas Buchanan, and the Boston Children's Hospital child neurology program could have been considered in the mid-20th century as a branch of the University of Chicago tree. The American schools of child neurology emanated from individuals such as Philip Dodge in Boston and then St. Louis and Sidney Carter in New York.

The argument could be made that during this period, individuals chose places in which to be formed in child neurology based upon the leadership and the school of child neurology that was represented there. Although this was undoubtedly fruitful for the development of career interests, it did not assure the public that formation in child neurology would be broad, inclusive, and comprehensive in all places in which it was being undertaken.

As child neurology emerged as a distinctive discipline within neurology, it was argued that it represented a competence sufficiently separable to be distinguished from adult neurology. Thus whereas adult neurologists were being certified by the American Board of Psychiatry and Neurology (ABPN) by 1935, it was not until the late 1950s that a set of examinations were promulgated by the ABPN to determine the competence an applicant had in that field.

In response to this, we can see that places in which child neurologists were being prepared began to respond to these early standards. The ABPN has argued since its inception that one of its chief fiduciary responsibilities is to the public; the standards for board certification create a body of persons in whom the public can trust in terms of competence, ethics, and professional behavior. The emergence of a separable competence in child neurology extended that approach. The ABPN was thus a public guarantor of the general competence of an individual to practice child neurology.

Supported by efforts from the United States government, child neurology programs took on a sort of mixed self-organization—some in response to the mandates of the certification examination of the ABPN, some in response to the mandates inherent in various parts of federal funding, particularly training grants which incentivized research into large domains such as intellectual disability. The meeting of those standards, however, was left to the individual programs with great leeway.

The disadvantages of this relatively unstructured approach became obvious, not just in child neurology but across almost all domains of medicine. Thus the last quarter of the 20th century saw increasing requirements of programs on the part of bodies such as the ABPN and the Accreditation Council for Graduate Medical Education (ACGME). Most of these requirements, however, were time-based; that is, the chief metric was so many months of a given type of rotation. One needed to do 1 year of adult neurology, for example, and rotations in psychiatry, to be eligible for the ABPN examination. Theorists of professional education refer to this as an industrial model of education. So much time on the assembly line assures the product.

## CURRENT APPROACHES

Among child neurology educators, this led to a general dissatisfaction with the variability in training that could still occur with this time-based, examination-referenced approach. In addition, there was a feeling that the public needed to be assured that there was sufficient consistency across child neurology programs that they could be confident that any child neurologist their child saw was well prepared and

broadly informed. Robert Rust edited an issue of *Seminars in Neurology* (Rust, 2011), which attempted to describe the corpus of knowledge that a child neurologist should have in a broad spectrum of domains of clinical practice. Each section was authored by a recognized expert in that domain. One could thus argue that the community of scholars was making a statement about what was essential to the practice of child neurology at the beginning of the new century.

The Professors of Child Neurology subsequently formed a working group that undertook to convert this set of essays and outlines into a framework of the knowledge that was viewed as essential to the practice of child neurology, a so-called "Universal Curriculum." The name cited the normative nature of the material—that is, an organization representing the academic training programs and departments, divisions and sections of child neurology across the country had endorsed this as the corpus of knowledge and skills required to practice child neurology in the new century.

A similar process is also happening in Canada. The Royal College of Physicians and Surgeons has embraced this concept under the rubric "competency by design." Competency is to be demonstrated in each of the CanMEDS roles: medical expert, communicator, collaborator, manager/leader, scholar, advocate, and professional. From a pedagogic viewpoint, this effort shifts the emphasis from time-based, rotation-based metrics of training to the achievement of mastery in a given domain, independent of the time spent on a rotation devoted to that area of expertise.

This happened in parallel to the movement by the ACGME to create "Milestones," a developmentally oriented approach to specific domains of performance for persons in training, which would chart their progress from absolute beginner to mastery of a given domain. Each recognized specialty represented in the ACGME was asked to convene a group that would work with the staff to draft a set of milestones relevant to that specialty. The child neurology milestones which were developed (*Child Neurology Milestones, 2015*) were very pragmatic and focused by and large on observable, verifiable behaviors. Other specialties, such as pediatrics, created Milestones frameworks that were oriented toward pedagogic theory such as Bloom's taxonomy of adult learning (*Pediatrics Milestones, 2015*).

The authors of the Universal Curriculum subsequently demonstrated how it could project onto the child neurology milestones. This allows the more granular Universal Curriculum to be used for the mandated reporting of resident progress through the milestones, which all programs must report to the ACGME on an annual basis (Urion et al., submitted). Child neurology therefore has two interrelated metrics to assess the progress of individuals through the course of their formation toward the established goal of being capable of the independent practice of child neurology. For those programs that find using the milestones themselves convenient, this can be done directly. For those who find that they think along the lines of the Universal Curriculum, this can be used and then translated into milestones.

Table 170-1 demonstrates some examples of the child neurology milestones; it should be noted that the levels do not correspond to years in training, but rather steps along a road toward basic competence to practice independently (level 4 in any given milestone) or the further step of contributing to the scholarly literature in a given domain (level 5). It is anticipated that graduates of child neurology training programs will achieve level 5 competences in perhaps one or two domains, likely to be the focus of their careers. One of the further implications of the milestones system would be a gradual move toward more individualized models of formation. In the past, residency has been viewed as a time-based

*(With permission from the Child Neurology Milestone Project, a joint initiative of the Accreditation Council for Graduate Medical Education and the American Board of Psychiatry and Neurology, 2015.)*

progression: so many months of ward or consult services, so many months of elective rotations in allied disciplines, and the like, with everyone spending equal amounts of time on all rotations. The milestones would allow individuals to progress at rates commensurate with their own achievement of expertise and would ideally spend time in various areas of clinical work commensurate with their need for the development of expertise in that area. The implications of this for organizing clinical services with a workforce within a hospital thus not automatically placed on a given service for a set length of time are profound and potentially disruptive to long established modes of health service delivery in teaching hospitals.

Table 170-2 demonstrates examples of goals established within the Universal Curriculum. These are perhaps more familiar in appearance to most child neurologists and represent identifiable goals of instruction and mastery of various parts of clinical child neurology practice. They are, in a sense, agnostic to means of instruction and learning, as well as the organization of that learning. Thus although they can be associated with the milestones, they might also readily map onto another structure being discussed by medical educators and certifying bodies, the Entrustable Professional Activities (EPA) (ten Cate, 2005).

In the EPA model, one considers an activity such as performing a lumbar puncture. The activity, from its start to finish, includes many elements. The resident must know that the lumbar puncture results are essential to the diagnosis of the patient at hand (medical knowledge and a sound differential diagnosis). The resident must be able to explain the rationale for this test to the family (communication skills and professionalism in conduct). The resident must assemble the needed personnel (working in multidisciplinary team), and then be able to execute the procedure skillfully (technical skills). It has been argued that an EPA model of education

**TABLE 170-2** Two Examples of the Universal Curriculum

<b>Example 1: Demyelinating Disorders</b>
<ol style="list-style-type: none"> <li>Recognition of patterns of lesion localization identified on brain, optic nerve or spinal cord MRI characteristic of multiple sclerosis (MS), neuromyelitis optica (NMO), CNS vasculitis, other inflammatory CNS disorders (e.g., infection, sarcoidosis), and disorders of cerebral white matter that are metabolic or malignant in origin</li> <li>Identification of clinical "red flags," including persistent headache and raised intracranial pressure that should prompt consideration of central nervous system (CNS) vasculitis</li> <li>Appropriate use of diagnostic tests including brain, optic nerve, and/or spinal MRI, CSF examination, and multimodal evoked potentials</li> <li>Familiarity with intravenous corticosteroid use and appreciation of second-line therapies including IVIG, plasma exchange, and other immunosuppressant or immunomodulatory therapies</li> <li>Referral for rehabilitation services as appropriate</li> </ol>
<b>Example 2: Relapsing CNS Inflammatory Diseases</b>
<ol style="list-style-type: none"> <li>Knowledge of current diagnostic criteria for multiple sclerosis (MS), neuromyelitis optica (NMO), and CNS vasculitis</li> <li>Familiarity with established MS treatments including interferon beta 1a, interferon beta 1b, and glatiramer acetate</li> <li>Recognition of new and emerging MS therapies including natalizumab, fingolimod, teriflunamide, and dimethyl fumarate</li> <li>Knowledge of treatment algorithms for MS, NMO, and CNS vasculitis</li> <li>Appreciation of key genetic and environmental risk factors for pediatric MS (e.g., HLA-DRB1 haplotype, vitamin D deficiency, and viral exposures)</li> <li>Recognition of emerging biomarkers (e.g., anti-MOG antibodies) and neuroimaging advances (e.g., DTI and OCT) in CNS inflammatory diseases</li> <li>Appropriate involvement of a multidisciplinary care team</li> </ol>

more closely captures what goes on for a child neurologist in actual practice, given the synthetic nature of multiple separate skills and attributes which must come into play, and thus is a more proximate and direct measure of an individual's readiness for clinical practice. Recent investigations have supported this assertion (Johnston, 2003).

Regardless of the measures used to determine a resident's progress through formation, the previously-noted Universal Curriculum and Milestones represent the current state of the conversation in the profession about what constitutes the body of knowledge, skills, and professional attributes that are considered necessary for the effective, compassionate, and ethical practice of child neurology.

## EDUCATION AND TRAINING PRECEDING CHILD NEUROLOGY

It is worth considering, for a moment, the current dialogue regarding the necessary formation that precedes child neurology formation. At present, the ABPN requires 2 years of formation before child neurology formation itself can begin. The most common pathway is 2 years of general pediatrics, organized in such a fashion that the person will be eligible for board certification in general pediatrics (that is, certain critical rotations must be accomplished in those 24 months). A less frequently used path is 1 year of general pediatrics and 1 year of internal medicine, the latter in a program that leads to board eligibility in internal medicine (that is, rotations must be supervised by board certified internists and not by family medicine specialists, for example). A so-called third path, with 1 year of general pediatrics and 1 year of neuroscience research, approved at the discretion of the local child neurology residency program director, requires approval at the ABPN as well. This latter pathway was designed to both assist individuals with significant research interests and also to help address a perceived lack of child neurologists with basic, clinical, or translational science expertise.

## CURRENT WORKFORCE ISSUES

This leads us into the consideration of workforce issues. After a period of substantial growth in the last quarter of the last century, child neurology approached and then reached what we might consider "zero population growth"—as many people were leaving the field annually through retirement or death as were entering.

This steady state, however, is a bit deceptive. Numbers of persons in practice or board certified is a less important measure from the standpoint of the families served by a child neurologist; access to child neurology care is more closely determined by the amount of time a given person spends seeing patients. This is the "full-time equivalent" measure of which organizations are so fond. Despite its provenance as a term, we might consider what the implications of this are for child neurology.

Recent surveys have shown that the mean clinical FTE (that is, the average amount of time spent seeing patients) of a retiring child neurologist was just lower than 0.7; that is, most people leaving the practice were spending more than two-thirds of their time seeing patients. The average clinical FTE of persons joining child neurology is slightly over 0.4. (*Child Neurology Society/American Academy of Pediatrics survey on Child Neurology, 2015*) This means that in order to keep the same amount of clinical time available across the country, we would need to add nearly two child neurologists to the roster for every one that dies or retires. Thus our "zero population growth" actually represents a likely progressive decline in the

number of available clinical child neurologists expressed as clinical FTE across the country. Given the nature of the disorders that child neurologists see, the increasing acuity reported on most hospital services, and the increasing number of treatment options available for previously untreatable diseases, our current staffing and training models would seem to be on a collision course with access to care.

A separate issue is that of the distribution of child neurologists. Child neurologists are generally unequally distributed across the country, tending to center in urban/exurban/suburban areas, often close to the children's hospitals in which they trained. This geographic distribution creates huge challenges for access to child neurology care, with families from rural areas of the country having to travel great distances in order to see a child neurologist. In addition, urban populations often have very poor access to specialty pediatric care, including child neurology, despite geographic proximity. Given the observation that urban and rural populations bear a greater burden of conditions that predispose to neurologic disorders (higher rates of premature births and lower birth weights of full term infants), this makes this lack of access all the more problematic.

United States programs that provide incentives to primary care physicians to practice in medically underserved areas (primarily through loan forgiveness) do not apply directly to child neurologists. The federal calculation of medically underserved is based upon all physicians in a region, weighted toward primary care providers. The calculation is not made in a specialty-specific fashion. Thus one could be in an area that is adequately staffed by primary care providers but be the only child neurologist serving that jurisdiction, and still not be considered in a medically underserved area. Yet anyone who practices as the only child neurologist, or part of a very small group, covering all of a state on the high plains or in northern New England, might disagree. Recent surveys show that practicing in such settings is viewed as stressful by those who do and undesirable by those who are starting. Incentivizing work in such areas through loan forgiveness might not be an entirely sufficient means of helping with this issue of maldistribution, but it is a necessary one. Experience in primary care settings suggests it can be very helpful in establishing a sustainable medical community.

Regardless of issues of distribution, is the workforce we are creating likely to meet the needs of the country? If we assume for a moment that child neurologists are likely to work as parts of larger treatment teams as changes occur in the practice of medicine in this century, we need to consider what patients need to be under the direct care of a child neurologist, what patients are likely to need a single or intermittent consultation by a child neurologist with care being shared with a primary care provider, and what patients might be effectively managed within a primary care provider's office if there were sufficient transfer of information and knowledge from a child neurologist to that primary care provider.

No matter how much primary care can be optimized, it is unlikely that patients with certain disorders will ever have anyone except a child neurologist responsible for that portion of their care. Children with complex neurogenetic disorders, multiple sclerosis, intractable epilepsy, brain tumors, or neuromuscular disorders, for example, will continue to require their care come from child neurologists.

There are children with other disorders that are likely to prompt a consultation with a child neurologist because they are not seen frequently enough by a primary care provider to produce clinical comfort and expertise. We could consider entities such as tic disorders, more readily controlled epilepsies, language disorders, cerebral palsy, or neurodevelopmental disabilities in this realm. Once a diagnosis has been

established, it is conceivable that a child neurologist could transfer the care of this patient back to a pediatrician, with some suggestions for the next steps, along with a willingness to either consult remotely with the provider or see the patient again if something does not go as predicted.

Then there are disorders that are sufficiently prevalent that we would expect them to be the domain of a primary care provider, yet in many parts of the country are now routinely sent to child neurologists with minimal attempts by the primary care provider at management. Disorders such as attention deficit-hyperactivity disorder (present in 5% to 7.5% of the childhood population), headache (25% of the childhood population will seek medical consultation at least once for a headache), or febrile seizures, now prompt child neurology referral in many parts of the country. Given the prevalence of these disorders, no rational system of child neurology formation or workforce could possibly meet such a demand; it inevitably leads to issues of access, justice, and quality.

These three domains interact in terms of access issues. If a child neurology practice or clinic is receiving large numbers of referrals for the third category, then access to appointments for the first category and sufficient time to manage the second category will inevitably suffer.

There are certain experiences that suggest this might be changed. Intentional instruction, targeted continuing medical education, and mutually developed treatment paradigms with built-in specialists support for primary care providers have been demonstrated to decrease the rate of specialist referral, produce noninferior or better clinical outcomes, and enhance family satisfaction and engagement. In one study, overall costs were also driven down, thus meeting the so-called “triple aim” of the Institute for Healthcare Improvement (Berwick et al., 2000).

The challenge with such models is one of scale (could these be extended over larger segments of the population) and compensation. (These studies were done under experimental conditions, and child neurologists were compensated for their time by the study; if these initiatives were to be extended, a way for third party payers to compensate child neurologists for information transfer without actually seeing a patient would need to be developed.) The evolution of Accountable Care Organizations, beyond the scope of this chapter, is likely to create incentives for such approaches.

Shifting dynamics in demographics of child neurologists are also likely to change issues of access. The child neurology workforce is an increasingly female one, and this raises issues of work-life balance and the challenges of raising a family while practicing a demanding specialty. Recent studies have suggested that despite assertions of sharing domestic responsibilities in dual professional couples, greater than 50% of those tasks are usually performed by the woman in a different-gender couple. This, in turn, often leads to less than full-time employment, which for our considerations here would have influence upon total FTE in child neurology, and access to care.

## FUTURE WORKFORCE ISSUES

If we do some basic calculations, we can estimate the number of child neurologists that might be needed for the most optimistic model of distributed or shared care (which makes

the lowest use of direct patient visits and maximizes the sharing of child neurology knowledge across various treatment paradigms as noted previously). If we assume that the average child neurologist in this second decade of the century is 0.6 FTE clinical (which would be the average based upon recent survey data), given a current membership of 1800, we have 1080 FTE child neurologists in terms of clinical practice. If we imagine that workforce seeing patients 5 days a week for 48 weeks each year, we have 240 patient-seeing days per FTE. The current childhood population of the United States is roughly 74 million. If we estimate that roughly 10% of that population will seek neurologic consultation at least once per year (given numbers of persons with intellectual disability, epilepsy, cognitive disorders, headache, and neurogenetics disorders), we find that the average child neurologist would need to see just over 28 patients per day in order to accommodate those needs ( $7.4 \text{ million} \div (1080 \times 240) = 28.5$ ). If we are more conservative in that number and say that only 5% of the population will need to be seen by a child neurologist, this still leads to over 14 patients being seen each day. Both of these models presume a single annual visit, not currently viewed as sufficient for most neurologic disorders under the care of child neurologists.

Thus our current workforce is not sufficient to cover the needs of the country. If the workforce continues to evolve in the direction of less than full-time clinical practice for most child neurologists, this gap will continue to grow.

It is beyond the scope of this chapter to address means of addressing this situation. Although we have made enormous progress as a profession in terms of training that meets individual learning needs and through assessment can assure the public of the high quality of child neurologists, we face enormous challenges in access.

 associated with paralysis and muscular  
 rigidity *e2684b*  
 insecticides 1195, 1196b  
 sensorium changes *e2682b*
- Carbamazepine 493, 511, 601t–602t, *e1176t*,  
*e1178–e1179, e1475, e2825t*  
 for antiseizure drug therapy in  
 children *e1398–e1399, e1399f*  
 behavioral and cognitive effects of  
 639  
 for familial hemiplegic migraine 409  
 mood disorders in 638  
 myoclonus and *e2685b*  
 pharmacogenetics 1246t  
 pharmacokinetics of 604t–605t  
 rectal administration of 606t  
 for renal disease *e2763–e2764, e2767*  
 in renal failure 1226  
 toxicity 1199b
- Carbamoyl-phosphate synthase 1  
 deficiency 298–299, *e711*
- Carbamoyl phosphate synthetase (CPS)  
 deficiency 482t–486t
- N-Carbamyl-L-glutamate *e718*
- Carbidopa  
 for afferent baroreflex failure 1178  
 for hereditary sensory and autonomic  
 neuropathies type 3 1181  
 indications, tyrosine hydroxylase  
 deficiency 358  
 sepiapterin reductase deficiency  
 358
- Carbinols  
 sensorium changes *e2682b*  
 toxicity 1196b
- Carbohydrate metabolism  
 diseases associated with primary  
 abnormalities in 305–315,  
*e723–e748*  
 fructose metabolism 306–307,  
*e726–e727*

- Carbohydrate metabolism (*Continued*)  
 galactose metabolism 305–306, *e723–e726*  
 glycogen storage diseases *e727–e741, e728t*  
 disorders of *e660t*
- Carbohydrate stores 1131
- Carbon monoxide  
 in ataxia *e2685b*  
 causing peripheral neuropathy *e2684b*  
 Parkinsonism *e2684b*  
 sensorium changes *e2682b*  
 toxicity 1196*b–1199b*
- Carbon tetrachloride  
 associated with tremor *e2685b*  
 in ataxia *e2685b*  
 toxicity 1199*b–1200b*
- Carbonic anhydrase inhibitors 852  
 for hyperkalemic periodic paralysis 1154
- Carbonic anhydrase VA deficiency 482*t–486t*
- Carboplatin-etoposide chemotherapy 1003
- Carboplatin toxicity 1202
- Card agglutination trypanosomiasis test 913
- Cardiac abnormalities, in sudden infant death syndrome *e1548–e1549*
- Cardiac arrest 804, *e1839, e1840t*  
 cardiopulmonary resuscitation 805*t*  
 etiology of 805*t*  
 delayed postanoxic myoclonic seizures 810  
 delayed posthypoxic injury 809  
 hypoxic-ischemic encephalopathy and *e1839, e1845–e1847*  
 major disorders causing 808–809, *e1845t*  
 abusive head trauma 808, *e1845*  
 drowning (submersion injury) 808–809, *e1846*  
 electrical shock 809, *e1847*  
 lightning and electrical injuries 809, *e1846–e1847*  
 strangulation injury 809, *e1846*  
 sudden infant death syndrome 808, *e1845–e1846*  
 neurologic complications after 809–810, *e1847–e1848*  
 delayed postanoxic myoclonic seizures 810  
 delayed posthypoxic injury 809  
 paroxysmal sympathetic hyperactivity 810  
 postischemic seizures 809–810  
 neurologic prognosis after 810–811, *e1848–e1850*  
 electroencephalography 810  
 neuroimaging 810–811  
 somatosensory-and auditory-evoked potentials 810  
 postcardiac-arrest syndrome 804  
 sudden, in children and adolescents 809, *e1847*  
 ventricular fibrillation and 809
- Cardiac arrhythmia, periodic paralysis with *e2610–e2612, e2611f*
- Cardiac mechanism, in proposed mechanisms for sudden unexpected death in epilepsy *e1485*
- Cardiomegaly, in Pompe disease 310
- Cardiomyopathy 427  
 DMD and 1110, 1161, *e2477–e2478*  
 ketogenic diet and *e1456*  
 lysosomal storage diseases and *e782*
- Cardiopulmonary resuscitation (CPR)  
 cardiac arrest and 805*t*  
 cardiovascular support and 811
- Cardiopulmonary resuscitation (CPR) (*Continued*)  
 drowning and 808  
 extracorporeal membrane oxygenation and 812  
 for hypoxic-ischemic encephalopathy *e1852–e1853*
- Cardiovascular drugs, in myasthenia gravis 1103*b*
- Cardiovascular manifestations, mucopolysaccharidoses and 327–328
- Cardiovascular-mediated syncope 660, *e1512*
- Cardiovascular support 811
- Care, transitional, for children with neurologic disorders *e2871–e2879*
- Carisbamate, for infantile spasms *e1287*
- Carnitine, for fatty acid oxidation disorders 1136, *e2553–e2554, e2563*
- Carnitine acylcarnitine translocase deficiency *e2551*
- Carnitine deficiency 292
- Carnitine disorders 279*t, e659t*
- Carnitine palmitoyltransferase deficiency type II (CPT II) 1132*b, e2350–e2351*  
 peripheral hypotonia and 1055*t–1056t*  
 Carnitine supplementation, ketogenic diet and *e1455–e1456*
- Carnitine uptake studies, in fatty acid oxidation disorders *e2555*
- Carvedilol *e2755b*
- Case-based ethics 1266
- Case studies, special education law and *e2897*
- CASK, mutations in 514
- Castor oil, sensorium changes *e2682b*
- Castor oil toxicity 1196*b*
- Casuistry 1266, *e2862*
- Cat scratch disease (CSD) 892, *e2023*
- Cataplexy  
 narcolepsy with 674–675  
 treatment of 675–676, *e1533*
- Cataracts  
 congenital *e73*  
 hypomyelination with 749*f, 750, e1685f, e1688*  
 galactokinase deficiency and 306
- Catastrophic spinal cord injuries 825–826
- Catathrenia 670, *e1526*
- Catecholamine-secreting tumors 1178, *e2651*
- Catecholamines  
 synthesis and catabolism of *e876f*  
 urinary, in acute cerebellar ataxia 704
- Cathepsin A 330
- Catheter angiography (CA)  
 for intracranial hemorrhage *e1974*  
 for sinovenous thrombosis 862
- Cathinones (bath salts) 1200
- Catholic moral theory 1265
- Cat's eye syndrome, with kidney malformation 1224*t, e2764t*
- Cauda equina injuries 825, *e1883*
- Caudal vermal lesions 689
- Caveolae 1116
- Caveolin 1034, *e2307*
- Caveolin-3 1116
- Caveolinopathy 1116, *e2489f, e2494*
- Cavernous malformations, in intracranial hemorrhage 868–869, *e1976–e1978, e1977f*  
 epidemiology of *e1976–e1977*  
 evaluation of *e1977–e1978*  
 genetic syndromes of *e1971t, e1977*  
 outcome of *e1978*
- Cavernous malformations, in intracranial hemorrhage (*Continued*)  
 pathogenesis of *e1976*  
 presentation of *e1977*  
 treatment of *e1978*
- Cavum septum pellucidum *e462*
- Cayman type cerebellar ataxia *e1569*

 angiogenesis *841, e1921*  
 blood-brain barrier *842–843, e1922–*  
*e1923, e1923f*  
 endothelial differentiation *842–843,*  
*843f, e1922–e1923, e1923f*  
 smooth muscle differentiation *841–842,*  
*842f, e1921–e1922, e1922f*  
 vasculogenesis *841, e1921*  
 calcium handling and contractile  
 apparatus of *e1924*  
 cerebrovascular contractility  
 of *e1923–e1925*  
 contractility in *843–845*  
 calcium handling and contractile  
 apparatus *844*  
 ion pumps and channels *844*  
 vasoactive ligands and  
 receptors *844–845*  
 development and function  
 of *e1921–e1930*  
 flow-metabolism coupling of *e1925*  
 hypercapnic vasodilatation of *e1925*  
 hypoxic vasodilatation of *e1925*  
 ion pumps and channels of *e1924*  
 neurovascular mechanisms of *846–847,*  
*e1926*  
 reactivity in *845–847*  
 autoregulation *846, 846f*  
 flow-metabolism coupling *845*  
 hypercapnic vasodilatation *845*  
 hypoxic vasodilatation *845–846*  
 vasoactive ligands and receptors  
 of *e1924–e1925*  
 whole brain cerebrovascular reactivity  
 of *e1925–e1926*
- Cervical cord neuropraxia *823,*  
*e1880–e1881*
- Cervical nerve root neuropraxia *823,*  
*e1880*
- Cervical seat-belt syndrome *820*
- Cervical spine immobilization *827, e1889*
- Cervicocephalic arterial dissection *873–874,*  
*873t*  
 for cerebral arteriopathies *e1989–e1991,*  
*e1990f, e1990t*
- Cervicomedullary syndrome *823–824,*  
*e1881*
- Cestodes *914–916, e2080t, e2101–e2104*  
 coenurosis *915, e2104*  
 cysticercosis *915, e2102–e2104*  
 diphyllorbothriasis *e2101*  
 echinococcosis *914–915, e2101–e2102*  
 paragonimiasis *916*  
 schistosomiasis *915–916*  
 sparganosis *914, e2101*

- Cethrin (BA-210), for spinal cord injury *e1888–e1889*
- Chagas disease 912–913, *e2093–e2094*
- Challenge Module 1292
- Chance fracture 820
- Channelopathies 405–411, 1148–1156, *e977–e985, e978t, e2595–e2615*  
 associated with clinical syndromes in pediatric neurology 406*t*  
 epilepsy syndromes 405–408, *e977–e980*  
 childhood absence epilepsy 408  
 developmental delay, epilepsy and neonatal diabetes 407–408  
 juvenile myoclonic epilepsy 408  
 familial pain syndromes 408–409, *e981–e982*  
 clinical features of 408  
 congenital indifference to pain 408  
 erythromelalgia 408  
 genetics/pathophysiology of 408  
 inherited erythromelalgia, primary erythromelalgia 408  
 paroxysmal extreme pain disorder 408  
 primary erythromelalgia 408  
 treatment of 408–409  
 generalized epilepsy with febrile seizures plus 407
- KCNQ2 encephalopathy 407, *e980–e981*
- migraine/ataxia syndromes 409–410, *e982–e983*  
 familial hemiplegic migraines 409
- myotonic dystrophies 1148–1149  
 acetazolamide-responsive sodium channel myotonia. *see* Acetazolamide-responsive sodium channel myotonia  
 mode of inheritance of 1148  
 myotonia congenita. *see* Myotonia congenita  
 type 1 1148, 1149*t*  
 type 2 1148–1149, 1149*t*
- periodic paralyses 1152–1156, 1153*t*  
 Andersen-Tawil syndrome 1155–1156  
 hyperkalemic 1153–1154  
 hypokalemic 1153*t*, 1154  
 paramyotonia congenita 1154–1155  
 thyrotoxic 1156
- Chaperones, for fatty acid oxidation disorders *e2563*
- Charcot-Marie-Tooth (CMT) disease 1073, *e2390*  
 classification of 1073, *e2391t–e2393t*  
 clinical sequelae of 1073  
 definition of 1073  
 diagnostic strategies of 1074, 1075*f–1076f*  
 genetic testing of 1074, 1075*f–1076f*  
 pathophysiology of 1073–1074  
 prevalence of 1073  
 serum CK levels found in 1039*t*  
 specific forms of 1074–1080, *e2396–e2405*  
 type 1 1074–1076  
 type 1A 1074  
 type 1B 1074–1075

 clinical features of 1154  
 genetics 1154  
 laboratory tests for 1155  
 pathophysiology of 1155  
 treatment for 1155
- Hypoketotic hypoglycemia 1134,  
 e2549
- Hypokinesia 713–714
- Hypomagnesemia 1216, 1217b, e2741–  
 e2742, e2741b
- Hypomelanosis of Ito 371, 586t, e906
- Hypomelanotic macules 427

- Hypomyelinating white matter disorders 747–751, *e1680–e1691*, *e1684f*  
 with atrophy of basal ganglia and cerebellum 750, *e1688–e1689*
- Cockayne syndrome and trichothiodystrophy *e1690*  
 with congenital cataract 749*f*, 750, *e1685f*, *e1688*
- cytoplasmatic tRNA synthetase defects and *e1687–e1688*
- 18q minus syndrome in *e1690*
- 4H syndrome in *e1685f*, *e1686–e1687*, *e1687f*
- fucosidosis in *e1689*
- oculodentodigital dysplasia in *e1688*
- Pelizaeus-Merzbacher disease in *e1683–e1686*, *e1685f*
- Pelizaeus-Merzbacher-like disease in *e1685f*, *e1686*
- serine synthesis defects in *e1689–e1690*
- sialic acid storage disorders in *e1685f*, *e1689*
- SOX10-associated disorders in *e1690–e1691*
- Hyponatremia 131, *e2738*, *e2740t*  
 AKI and 1215, 1216*t*  
 bacterial meningitis and *e2013–e2014*  
 causes of, postmeningitis 885–886  
 enteric infections cause by *e2785*  
 metabolic encephalopathies and *e404–e405*, *e406b*  
 sodium balance disturbances 171
- Hypophosphatasia, congenital 377, *e926*
- Hypophysial stalk 1165
- Hypoplasia, optic nerve *e75*, *e75f*
- Hypoplastic left heart (HLHS) 1205, 1207*f*, *e2713*, *e2715f*  
 fetal circulation in 1206–1207, 1208*f*, *e2714–e2716*, *e2716f*  
 white matter injury in *e2719*
- Hyporeflexia *e22–e23*
- Hyposmia 63
- Hypotension, trauma-induced 794–795
- Hypothalamic dysfunction, in craniopharyngioma 1007–1008
- Hypothalamic hamartoma, gelastic seizures with *e1369*
- Hypothalamic-pituitary-adrenal (HPA) axis 799, 1168, *e2632*
- Hypothalamic/pituitary disorders  
 appetite regulation and energy balance 1170–1171, 1170*f*, *e2635f*  
 disorders of appetite regulation and energy balance *e2635–e2636*, *e2635f*  
 glucocorticoid production 1168–1169, *e2632–e2633*  
 adrenocorticotrophic hormone (ACTH) deficiency 1168–1169, *e2632–e2633*  
 adrenocorticotrophic hormone (ACTH) excess 1168, *e2632*, *e2633f*  
 hormone deficiencies, hypogonadotropic hypogonadism associated with *e2630–e2631*, *e2631f*  
 organogenesis of *e2627*  
 prolactin secretion 1168, *e2631–e2632*  
 pubertal development 1165–1168, *e2628–e2631*  
 age of onset 1166  
 delayed/arrested puberty 1166–1168  
 normal physiology 1165–1166  
 sexual precocity 1166
- Hypothalamic/pituitary disorders (*Continued*)  
 statural growth 1169, *e2633–e2634*  
 growth hormone deficiency 1169, *e2634*  
 growth hormone excess 1169, *e2634*  
 thyroid function 1169–1170, *e2634–e2635*  
 central hyperthyroidism 1170, *e2635*  
 central hypothyroidism 1170, *e2635*  
 physiology 1169–1170  
 water balance 1171–1172, *e2636–e2638*  
 diabetes insipidus 1171–1172, *e2637*  
 syndrome of inappropriate antidiuretic hormone secretion 1172, *e2637–e2638*
- Hypothalamic-pituitary-gonadal (HPG) axis 1165–1166
- Hypothalamic-pituitary-portal system 1165
- Hypothalamic syndrome 986, *e2236*
- Hypothalamus *e2627*  
 anatomic and physiologic aspects of 1165, *e2627–e2628*, *e2628f*  
 development of 1165
- Hypothermia  
 coma and 776  
 intracranial pressure and 789, 818  
 for refractory status epilepticus 549*t*  
 spinal cord injury and 823, *e1886*  
 therapeutic 811  
 outcome and 141  
 traumatic brain injury and *e1787*
- Hypothyroidism 427, 1178  
 central 1170, *e2635*  
 congenital 487, *e1154–e1155*
- Hypotonia 689, *e1556*, *e2332*  
 algorithm 1051, 1053*f*  
 and ASD 465  
 central 1054, 1055*t*  
 definition of 1051, *e2341*  
 examination for 1052–1054, *e2342–e2344*

 localization of 1051, 1052*t*, *e2341*, *e2342t*, *e2343f*  
 muscle tone in *e2341*  
 onset and progression of 1052  
 peripheral 1054–1056, 1055*t*–1056*t*  
 popliteal angle in, measurement of 1052–1054  
 pull-to-sit test for 1052  
 scarf-sign in 1052  
 selected conditions associated with *e58b*  
 shoulder suspension test for 1054  
 ventral suspension test for 1054
- Hypotonic (atonic) cerebral palsy *e1656*
- Hypoxemia, in drowning 808–809
- Hypoxia  
 cerebrovascular system and 845–846  
 trauma-induced 794–795
- Hypoxia-ischemia, abusive head trauma and 794–795
- Hypoxic-ischemic brain injury 112, 1052, *e282*  
 cell death and *e331*  
 cerebral blood flow and *e327–e329*  
 clinical syndromes *e321–e322*  
 and natural history *e321–e325*  
 energy metabolism and *e327–e329*  
 etiology of *e321*  
 future directions of *e333*  
 neuroinflammation in *e331*  
 neuroprotection strategies in *e331–e332*  
 neurotrophic factors of *e332*
- Hypoxic-ischemic brain injury (*Continued*)  
 outcomes of *e325–e327*, *e326t*  
 cognition *e326*  
 motor function *e325*  
 prediction of *e327*, *e328f*  
 and therapeutic  
 hypothermia *e326–e327*  
 vision and hearing *e326*  
 oxidative stress and *e330–e331*  
 pathophysiology of, and  
 neuroprotection *e327–e331*, *e329f*  
 in preterm infant *e333*  
 scope of problem *e321*  
 stem cells and *e332–e333*  
 in term newborn 138–146, *e321–e338*  
 cell death and 145  
 cerebral blood flow and energy metabolism 143  
 clinical syndromes of 138–140  
 cognition of 141  
 etiology of 138  
 future directions for 146  
 inflammation in 143*f*, 144–145  
 motor function of 140–141  
 natural history of 138–140  
 and neuroprotection 143–145, 143*f*  
 neurotrophic factors 145  
 outcomes of 140–141, 141*t*, 142*f*  
 oxidative stress and 144  
 pathophysiology of 143–145, 143*f*  
 patterns of 140  
 progression of 140  
 scope of problem 138  
 stem cells in 145  
 therapeutic hypothermia and 141  
 vision and hearing of 141
- Hypoxic-ischemic encephalopathy 130, *e310*, *e321*  
 current treatment options for *e302–e303*  
 neonates with, treatment options for 124–125
- Hypoxic-ischemic encephalopathy, in infants and older children 804–812, *e1839–e1857*  
 cardiac arrest and 804, 805*t*, *e1839*, *e1845–e1847*  
 abusive head trauma 808, *e1845*  
 drowning (submersion injury) 808–809, *e1846*  
 electrical shock 809, *e1847*  
 lightning and electrical injuries 809, *e1846–e1847*  
 neurologic complications after 809–810, *e1847–e1848*  
 neurologic prognosis after 810–811, *e1848–e1850*  
 strangulation injury 809, *e1846*  
 sudden, in children and adolescents 809, *e1847*  
 sudden infant death syndrome 808, *e1845–e1846*  
 cardiopulmonary resuscitation for *e1852–e1853*  
 cardiovascular support for *e1852*  
 cerebral blood flow and metabolism after resuscitation in *e1844–e1845*  
 clinical pathophysiology of 808, *e1844–e1845*  
 cerebral blood flow and metabolism after resuscitation 808  
 dilemma of neurologic morbidity 812  
 extracorporeal membrane oxygenation for *e1852–e1853*

- Hypoxic-ischemic encephalopathy, in infants and older children (*Continued*)  
mechanisms of brain injury 804–808, e1840–e1844  
activation of intracellular enzymes 806, e1841  
activation of nitric oxide synthesis 806–807, 807f, e1842–e1843, e1843f, e1843t  
autophagy 808, e1844  
brain energy failure 804–806, 805f, e1840–e1841, e1841f  
calcium-mediated injury 806, 806f, e1841, e1842f  
excitotoxic injury 806, e1841  
formation of oxygen radicals 807, e1843–e1844, e1844f  
genetic damage and regulation 808, e1844, e1846b  
neuroinflammation, glia, and neurovascular unit 807–808, e1844  
phospholipase release of free fatty acids 806, e1842, e1842f  
neuroimaging, injury and outcome assessment of e1849–e1850, e1851f  
neurologic morbidity of e1854  
postcardiac-arrest syndrome and 804, e1839–e1840  
temperature control for e1853  
treatment of 811–812, e1850–e1854, e1852t  
cardiovascular support 811  
extracorporeal membrane oxygenation-cardiopulmonary resuscitation 812  
glucose homeostasis 811  
intracranial pressure monitoring and control 811  
postcardiac-arrest brain injury 812, e1853–e1854  
postresuscitation interventions as e1851–e1853  
resuscitation 811–812, e1850  
temperature control 811
- Hypoxic-ischemic insults, prognosis after, EEG and e238
- Hypoxic vasodilatation 845–846, e1925
- Hypsarrhythmia 95, e233–e234, e234f, e1229, e1278–e1284, e1279f  
in infantile spasms 540, 540f
- I**
- I-cell disease 331, e752t–e760t, e772t–e773t, e813–e814, e813f–e814f

- Immunotherapy  
brain inflammation and e2153  
for CIDP e2437  
in CNS tumors 961  
effect of, on brain inflammation 940  
for GBS e2433–e2434  
for opsoclonus myoclonus syndrome 941–943, 942t, e2154–e2157, e2156t  
side effects and safety monitoring 943  
for tumors e2197–e2198
- Impaired upgaze, intracranial pressure and 816t
- Imprinting 261
- Impulsivity  
and ADHD 451  
in childhood epilepsy 636
- In-hospital management, of febrile seizures e1244
- Inadequate response e2157, e2158f
- Inborn errors, presenting in the neonatal period e1029t–e1030t
- Inborn errors of metabolism (IEMs) 131, 171–177, 172b, 277, 286, 424, 481–487, e402t–e403t, e405–e419, e406t–e408t, e657, e660t, e2655–e2656, e2723–e2725
- acute fulminant metabolic diseases 172–175  
fatty acid oxidation defects 174–175  
fructose-1, 6-biphosphatase deficiency 174  
glutamine synthetase deficiency 174  
maple syrup urine disease 172  
organic acidopathies 172–174  
primary lactic acidosis, resulting from defects in oxidative phosphorylation 174  
urea cycle disorders 175
- arterial ischemic stroke and 854  
as cause of neonatal seizures e311
- chronic encephalopathies, with multiorgan involvement 176–177  
cholesterol biosynthesis defects 177  
congenital disorders of glycosylation 176–177  
peroxisomal disorders 177
- chronic encephalopathies, without multiorgan involvement 176  
glutaric aciduria 176  
hyperphenylalaninemia 176  
succinic semialdehyde dehydrogenase deficiency 176
- classification of 277–278  
by pathway and organelle e659t
- clinical presentation of 278–282  
abnormal development associated with congenital anomalies and dysmorphic physical features 280–281  
acute encephalopathy 278–279  
in childhood 282–284  
epilepsy 279–280  
neuromuscular weakness 282
- inheritance of 277
- intellectual developmental disabilities 481–486, 482t–486t
- laboratory evaluation of 277  
nonneurologic features of e661t  
by pathway and organelle 279t
- secondary leukoencephalopathies to 758
- subacute epileptic encephalopathies 175–176  
asparagine synthetase deficiency 176  
glycine cleavage defects 175  
L-amino acid decarboxylase deficiency (L-ADD) 176  
purine biosynthesis defects 176  
pyridoxine-dependent and pyridoxal phosphate dependent 175  
serine biosynthesis defects 175–176  
sulfite oxidase and molybdenum cofactor deficiency 175

 antenatal corticosteroid exposure in *e383*  
 candidate genes for 162–163, *e375–e377*  
 clinical studies implicate candidate genes in coagulation, inflammatory and vascular pathways *e376–e377*  
 preclinical studies suggest variants in microvascular proteins *e375–e376*, *e376t*
- cerebral blood flow alterations  
 contributing 162, *e375*, *e375b*
- cerebrospinal fluid studies for *e380*
- clinical findings of 164, *e379–e380*
- clinical manifestations of *e380*
- clinical risk factors of 161, 162*b*, *e373*, *e374b*
- coagulation candidates of *e376*, *e376t*
- cognitive outcomes in neonates  
 with *e382*, *e382f*
- as complex disorder 161, *e372–e373*, *e373f*
- gene-by-environment interactions *e377*
- incidence of *e379–e380*
- inflammatory factors of *e376–e377*
- long term outcome of 164, *e382–e383*  
 alterations in brain  
 development *e382–e383*  
 cerebral palsy *e382*
- maternal race and healthcare disparities  
 influence risk for *e373*
- neonatal outcome 164, *e380–e381*
- neuroimaging of 163, *e378*, *e378f*
- neuropathology of 163, *e377–e378*, *e377f*
- pathophysiology of 161–163, *e372–e377*
- prevention of 164–165, 164*t*, *e383–e384*, *e383t*  
 environmental strategies *e383–e384*  
 pharmacologic *e383–384*  
 timing of *e380*
- vascular genes and *e377*
- white matter injury and 166, *e387*
- Intrinsic connectivity networks (ICNs) 97, 100, *e259–e260*, *e259t*
- Intrinsic nervous system 1190, *e2672–e2673*
- Intussusception 1231, *e2782*
- Invasive intracranial electroencephalography  
 monitoring 616–617  
 for epilepsy surgery, in pediatric population *e1429*
- Inversion-duplication 15 syndrome, and infantile onset epilepsies 558*t–560t*
- Inversions *e637–e638*  
 paracentric 270  
 pericentric 270  
 “Inverted comma” position 27, *e56*
- Iodinated contrast agents, in myasthenia gravis 1103*b*
- Iodine 386  
 deficiency 386  
 developing brain and *e943t*, *e945*  
 as nutrient 384*t*
- Ion channels 405, *e1211*, *e1211t*, *e1213f*  
 in cerebrovascular system 844, *e1924*  
 development of, and membrane properties 509–510  
 ligand-gated 405  
 in seizures and epilepsy 506, 507*f*  
 voltage-gated 405

 mtDNA disease, management of e2562–e2565  
 myoadenylate deaminase deficiency in e2567  
 myoglobinuria in 1132, 1132b, e2538
- Metabolic neuropathies 1082–1083, e2412–e2417  
 abetalipoproteinemia 1082–1083, e2414–e2415  
 acute intermittent porphyria 1082, e2413–e2414  
 alpha-lipoprotein deficiency e2415  
 Chédiak-Higashi syndrome e2416–e2417  
 congenital pernicious anemia 1082, e2414  
 diabetes mellitus 1082, e2412  
 Krabbe's disease 1083, e2415–e2416  
 metachromatic leukodystrophy 1083, e2416  
 peroxisome biogenesis disorders 1083, e2416  
 Refsum's disease 1083, e2416  
 Tangier disease 1083  
 uremic neuropathy 1082, e2412–e2413  
 vitamin deficiency 1082, e2414
- Metabolism, inborn errors of 171–177, 172b, 1181–1182, e402t–e403t, e405–e419, e406t–e408t
- Metabotropic glutamate receptors 508
- Metachromatic leukodystrophy 327, 482t–486t, 752f, 753–754, 1083, e795–e797, e795f–e796f, e1692f, e1694–e1695, e2416  
 variants of 754
- Metachromatic leukodystrophy-like variants e1695
- Metaiodobenzylguanidine (MIBG) 85
- Metaiodobenzylguanidine (MIBG) scintigraphy, for acute cerebellar ataxia 704, e1589
- Metaldehyde  
 associated with tremor e2685b  
 in ataxia e2685b  
 sensorium changes e2682b  
 toxicity 1196b, 1199b–1200b
- Metals 1195–1198, e2688–e2689  
 associated with Parkinsonism e2684b  
 and inborn errors of metabolism 482t–486t
- Metamorphopsia 901
- Metastatic disease, in DIPG 992, e2245
- MetCbl defects e928
- Methadone, for pain management 1257t
- Methanol  
 associated with Parkinsonism e2684b  
 toxicity 1198b
- Methaqualone  
 associated with myoclonus e2685b  
 toxicity 1199b
- Methcathinone 1196b  
 sensorium changes e2682b
- Methionine 292
- Methionine synthase deficiency e686–e687
- Methotrexate e2695  
 for CIDP e2436–e2437  
 in CNS leukemia 1017
- Methotrexate (*Continued*)  
 for dermatomyositis 1144t  
 high dose, for AI/RT 998  
 for multiple sclerosis 764  
 neuroteratology 1203t  
 for opsoclonus myoclonus syndrome 942t, 943, e2157  
 toxicity 1202
- Methsuximide 601t–602t
- 3-Methylglutaconic acidurias e1382
- l-Methyl-4-phenyl-1,2,3,6,-tetrahydropyridine (MPTP)  
 associated with Parkinsonism e2684b  
 toxicity 1198b
- Methylation studies 261, e618t, e619–e620
- 2-Methylbutyryl-CoA dehydrogenase deficiency 297, e699
- 3-Methylcrotonyl-CoA carboxylase deficiency 295, e693
- 3-Methylcrotonyl glycinuria 482t–486t
- Methylidopa e2755b
- Methylene tetrahydrofolate dehydrogenase deficiency 380, e934
- Methylenetetrahydrofolate reductase 163  
 deficiency 380, 596, e687, e933
- 3-Methylglutaconic aciduria 295, 482t–486t, e695–e696
- 3-Methylglutaconyl-CoA hydratase deficiency e695–e696
- Methylmalonic acidemia 292–295, 482t–486t, e691–e692, e1380–e1382  
 clinical manifestations of 292–294  
 inherited metabolic epilepsies 594–595  
 laboratory tests of 294–295  
 pathophysiology of 292  
 treatment of 295
- Methylmalonic aciduria 424
- Methylphenidate 476  
 for ADHD 450, 453, 455t–457t, e1085, e1087t–e1089t  
 for ASD 467t–468t  
 for excessive daytime sleepiness 675
- Methylprednisolone  
 for acute demyelination 760–761  
 in dermatomyositis 1143  
 for spinal cord injury 826–827, e1884–e1885
- Methylxanthines  
 sensorium changes e2682b  
 toxicity 1196b
- Metoclopramide  
 for cyclic vomiting syndrome 1229  
 for gastroesophageal reflux 1161
- Metoprolol e2755b
- Metronidazole  
 associated with Parkinsonism e2684b  
 for brain abscess 893–894  
 causing peripheral neuropathy e2684b  
 toxicity 1197b–1198b
- Mevalonate kinase deficiency 297, e700
- Mexiletine  
 in ataxia e2685b  
 for familial pain syndromes 408  
 for paramyotonia congenita 1154  
 toxicity 1199b
- MFN2 gene, mutations in 1077
- MFSD8 e951t–e952t, e964–e965
- MG. *see* Myasthenia gravis (MG)

 Minimally conscious state 770*t, 771, 790, e1737–1740, e1737t, e1739b*  
   diagnostic criteria for 771*b*  
 Minimally conscious states, in traumatic brain injury *e1796*  
 Minimally invasive surgical techniques, in epilepsy surgery 617  
 Minimum clinically important difference (MCID) 1293  
 Minimum detectable change (MDC) 1293  
 Minocycline 480  
   for spinal cord injury *e1885–e1886*  
 Minoxidil *e2755b*  
   associated with myopathies *e2683b*  
   toxicity 1197*b*  
 Mirtazapine *e1171t, e1172–e1173*  
 Mirtazapine, for ADHD 455*t*–457*t*  
 Miscellaneous vasculitic disorders *e2182*  
 Mismatch negativity *e1733*  
   disorders of consciousness and 767  
 Missense mutation *e614t*  
 Mitochondria  
   adenine nucleotide translocator 342  
   genotype 334  
   and inborn errors of metabolism 482*t*–486*t*  
   metabolism 336*f*  
 Mitochondrial biogenesis, for mitochondrial diseases 1139  
 Mitochondrial citrate carrier SLC25A1, defects in, myasthenic syndrome associated with 1096, *e2448*  
 Mitochondrial deafness 49, *e104*  
 Mitochondrial diseases/disorders 279*t, 334–346, 1044, e659t, e839–e857, e1383–e1384, e2326*  
   classification of 334–336, *e839–e841, e841b*  
   and developmental language disorders 435–436  
   epilepsies and 596  
   genetic and biochemical classification of *e2563t*  
   histopathologic disturbances and 337–345, *e841–e843, e843f*  
   history of *e839, e840f, e841t*  
   and infantile onset epilepsies 560*t*–562*t*  
   Krebs cycle, defects of *e843–e851*  
   metabolic disturbances and 336–337, *e841, e842f*  
   pyruvate metabolism, defects of *e843–e851*  
   respiratory chain 338–340  
   Mendelian defects of *e845–e851*  
   therapeutic approaches in *e2567*  
   therapy for 345–346, *e851–e852*  
 Mitochondrial DNA depletion syndrome 7 (hepatocerebral type) 695, *e1569*
- Mitochondrial DNA (mtDNA) 335*f, e841t, e844f*  
   depletion of *e2566*  
   maintenance, defects of 342, *e848, e849f*  
   multiple deletions 343–344  
   mutation, diseases due to primary 344  
   translation, defects of 341  
 Mitochondrial dynamics  
   alteration of 346  
   defects of 342  
 Mitochondrial dysfunction *e2777*  
 Mitochondrial encephalomyopathies 1137–1139, *e2557*  
   biochemical classification of 1137–1138, *e2558, e2561f–e2562f*  
   clinical considerations in 1137, *e2558*  
   genetic classification in *e2558*  
   historical considerations in *e2557–e2558*  
   morphologic considerations in 1137, *e2558*  
   MRI abnormalities in 338*f*  
   mtDNA, defects of *e2558*  
   management of *e2562–e2565*  
   mitochondrial protein synthesis, defects in *e2558*  
   point mutations *e2560*  
   protein-coding genes *e2560–e2561*  
   mutations in nDNA, diseases caused by *e2562–e2565*  
   mitochondrial DNA, depletion of *e2566*  
   multiple mitochondrial DNA deletions *e2566–e2567*  
   respiratory chain, defects of *e2564*  
   substrate oxidation, defects of *e2562–e2565*  
   substrate transport, defects of *e2562–e2565*  
   physiologic considerations in 1138, *e2558*  
   therapeutic approaches in 1138–1139  
 Mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS). *see* MELAS  
 Mitochondrial fatty acid oxidation defects *e2725*  
 Mitochondrial genetics *e839*  
 Mitochondrial genome, replicative segregation 334  
 Mitochondrial inheritance 334  
 Mitochondrial membrane associated disorders *e696*  
 Mitochondrial motility, alterations of *e2566*  
 Mitochondrial neurogastrointestinal encephalomyopathy 343–344, 1230  
 Mitochondrial neurogastrointestinal encephalopathy *e850, e2782*  
 Mitochondrial nucleotide pool 343*f*  
 Mitochondrial protein importation, defects of *e2565*  
 Mitochondrial protein synthesis, defects in *e2558*  
 Mitochondrial replacement therapy (MRT) 345  
 Mitochondrial respiratory chain 335*f*  
   diseases/disorders *e2351–e2352*  
   genetic classification of *e2563t*  
   peripheral hypotonia and 1055*t*–1056*t*  
 Mitochondrial transfer *e851–e852*  
 Mitochondria, defects of 341  
 Mitosis 268  
 Mitotic centromere-associated kinesin 993  
 Mitotic segregation 334  
 Mitoxantrone, for multiple sclerosis 764  
 Mixed cerebral palsy *e1656*

- Mixed connective tissue disease 851, 947t, 952, e2175
- Mixed-density hematoma, abusive head trauma and e1816f–e1817f, e1817, e1819f
- Mixed episodes 656
- MKRN3* gene e2628
- MLIS Barth-type e519
- MLIS MOPD1-type e519
- MMR vaccine, autistic spectrum disorders and e1099
- Möbius syndrome e15f, e2382–e2383, e2383f, e2383t
- Modafinil 675  
for ADHD 455t–457t
- Moderate-level (level B) recommendations, writing 1279t, 1280
- Modified Ashworth Scale 472, 473t, e58t, e1128t
- Modified Atkins diet 625
- Modified Checklist for Autism in Toddlers (M-CHAT) 4, 5f, e5, e8f, e1103
- Moebius syndrome 207
- MOGS-CDG (IIb) e761
- Molar tooth-related syndromes, prenatal diagnosis of 254, e609, e610f
- “Molar tooth sign” 202
- Molecular cytogenetics e635–e637, e636f
- Molecular epilepsy genetics 581–582
- Molecular studies, in fatty acid oxidation disorders e2555
- Molecularly targeted treatment e2823–e2824
- Mollaret’s meningitis 889, 900
- Molybdenum cofactor deficiency 131, 175, 482t–486t, e311, e415–e416, e416f, e1383, e1705–e1706  
and infantile onset epilepsies 560t–562t  
inherited metabolic epilepsies 596
- Monoamine oxidase deficiency 356t, 358–359, e876t, e881–e882  
monoamine oxidase A 358  
monoamine oxidase A and B 359  
monoamine oxidase B 359
- Monoamine oxidase inhibitors (MAOIs), for ADHD 455t–457t
- Monoaminergic neurotransmitter deficiency states  
with hyperphenylalaninemia 355–357, 356t, e875–e878, e876f, e876t–e877t  
without hyperphenylalaninemia 357–359, e878–e882
- Monoclonal antibody therapy  
for CIDP e2437  
for opsoclonus myoclonus syndrome 942, e2156
- Monomelic amyotrophy 1072, e2385
- Mononeuropathies e2723
- Monosaccharides, lysosomal storage diseases and e772t–e773t
- Monosomy 270
- Monroe-Kellie doctrine 813
- Mood disorders  
antiseizure medications 638  
and selective serotonin reuptake inhibitors 491–492
- Mood disturbances, in systemic juvenile idiopathic arthritis e2164
- Mood instability, and ADHD 451
- Mood stabilizers 492–493, e1175–e1181, e1176t  
carbamazepine 493, e1178–e1179  
gabapentin e1180  
lamotrigine 493, e1179–e1180  
lithium 492–493, e1175–e1177
- Mood stabilizers (Continued)  
oxcarbazepine e1180  
topiramate e1180–e1181  
valproic acid 493, e1177–e1178
- Morality, common 1264
- Morbidity  
and febrile seizures 520  
in status epilepticus 548–549
- Morning glory 1196b
- Morning glory, sensorium changes e2682b
- Moro reflex 17, e34–e35
- Morpheme 433b, e1054b
- Morphine  
associated with myoclonus e2685b  
for pain management 1257t  
toxicity 1199b
- Morquio syndrome e772t–e773t, e805
- Mortality  
in children with epilepsy e1482–e1489  
epidemiology of e1482–e1483  
five categories of e1483t  
prevention of  
not related to seizure e1487  
related to seizure e1486–e1487  
sudden unexpected death in e1483, e1483b  
in comatose patients 779  
and febrile seizures 520  
in status epilepticus 548–549  
in West syndrome 567
- Mosaicism 270
- Mossy fiber sprouting 508
- Motor disabilities, arterial ischemic stroke and 856
- Motor dyspraxia, and ASD 465
- Motor-evoked potentials (MEPs)  
impairment of consciousness and e1752  
spinal cord injury and e1879

juvenile 1098  
neonatal transient 1098  
clinical and laboratory tests for 1099–1105  
antibody testing 1100–1105  
edrophonium (Tensilon) test 1099  
electrophysiologic testing 1099–1100  
clinical features of 1098  
drugs to avoid in 1103, 1103*b*

- Myasthenia gravis (MG) (*Continued*)  
 treatment of 1100  
   acetylcholinesterase inhibitors for 1100  
   azathioprine for 1102  
   corticosteroids for 1101–1102  
   cyclophosphamide for 1102  
   cyclosporine for 1102  
   intravenous immunoglobulin for 1103  
   mycophenolate mofetil for 1102  
   plasmapheresis for 1103  
   tacrolimus for 1102  
   thymectomy for 1100–1101
- Myasthenic syndromes 1096  
 congenital 1092–1097
- Mycobacterium leprae* e2024–e2025
- Mycophenolate mofetil  
 for juvenile myasthenia  
   gravis e2463–e2464  
 for myasthenia gravis 1102  
 for neuromyelitis optica 765
- Mycoplasma pneumoniae* 892, e2024
- Mycotoxin, renal toxicity of 1225t, e2765t
- Mydriasis, lightning and 809
- Myelin-associated inhibitors, for spinal cord injury e1887
- Myelin basic protein (MBP) 751
- Myelinated axon, longitudinal anatomy of 1035, 1036f
- Myelination, and nutritional status 385–386
- Myelitis, transverse 759, 761f, 896
- Myelomeningocele (MMC) 186–188, 186f, e432, e433f  
 antenatal diagnosis of 186–187, e432–e433, e433f  
 bladder and bowel dysfunction of 187  
 central nervous system complications of 187  
 Chiari II malformation 187–188  
 clinical features of 187, e434  
 counseling of e437  
 fetal repair of 188, e436–e437, e436f  
 management of 188, e436–e437  
   in newborn period 188, e437  
 orthopedic problems of 187  
 outcome of 188, e437  
 prevention of e433–e434  
 secondary abnormalities of 187–188, e434–e436  
   bladder and bowel dysfunction e434  
   central nervous system complications e434  
   Chiari II malformation e435–e436  
   orthopedic problems e434–e435
- Myelopathy, in polyarticular juvenile idiopathic arthritis e2164–e2165
- MYH7*-related myopathies e2532
- Myoadenylate deaminase deficiency 1139, e2567  
 biochemistry and molecular genetics in 1139  
 clinical presentation in 1139  
 laboratory tests in 1139  
 pathology of 1139
- Myoclonic absences, epilepsy with 570, e1252
- Myoclonic-astatic epilepsy of Doose 538, e1274  
 EEG for 539  
 etiology of 538  
 outcome for 539  
 semiology of 538–539  
 treatment for 539
- Myoclonic encephalopathies in nonprogressive disorders 557–563, e1317–e1325  
 differential diagnosis of 563, e1324  
 EEG for 557–563, e1317–e1318, e1324f  
 etiology of 557, e1317, e1319t–e1321t  
 laboratory studies for 563, e1318–e1324, e1319t–e1323t  
 neuroimaging for 563, e1318  
 neurologic findings in 563, e1318  
 outcome of 563, e1325  
 seizures in 557–563, e1317–e1318  
 treatment of 563, e1324
- Myoclonic epilepsy  
 in infancy e1198t  
 juvenile 408, e1198t
- Myoclonic epilepsy in infancy 557  
 differential diagnosis 557  
 EEG findings in 557  
 etiology of 557  
 laboratory studies in 557  
 outcome for 557  
 seizures in 557  
 treatment for 557
- Myoclonic epilepsy in infancy, in electroclinical syndrome, infantile onset e1316–e1317  
 differential diagnosis of e1316, e1324f  
 EEG findings of e1316, e1317f–e1318f  
 etiology of e1316  
 laboratory studies for e1316, e1319t–e1323t  
 neuroimaging of e1316  
 neurologic findings in e1316  
 outcome of e1317  
 seizures in e1316  
 treatment of e1316–e1317
- Myoclonic epilepsy with ragged red fibers (MERRF) 335, 345, 579, 596, e1277, e1355, e1384
- Myoclonic jerks 528
- Myoclonic seizures 528, e1256  
 clinical features of 528  
 delayed postanoxic 810  
 electroencephalographic findings in 528  
 epilepsy syndromes with 538  
 epileptic spasms and 538–542, e1273–e1291  
 and Lennox-Gastaut syndrome 571, e1340  
 lysosomal storage diseases and e782
- Myoclonus 707, 707t, 715–716, e1599, e1615–e1617  
 benign, of early infancy e1636  
 benign neonatal sleep e1636–e1639  
 classification of 715, 715b, e1616, e1616b  
 essential 715  
 focal 533  
 physiologic and developmental 715, e1616  
 symptomatic 715, e1616–e1617  
 treatment of 716, e1617
- Myoclonus-dystonia syndrome 711, e1606–e1607
- Myoclonus epilepsy, progressive, infantile 403
- Myocyte enhancer factor 2 (*MEF2C*) gene, mutation in 515
- Myoglobinuria 1132, 1132b, e2538  
 phosphofructokinase deficiency 314
- Myokymia 409
- Myopathies e2723  
 congenital 1123–1130  
   cardiac management of 1130  
   centronuclear 1127–1128  
   classification of, by genes 1123, 1124t–1125t  
   congenital fiber-type disproportion 1129  
   core 1128–1129  
   diagnostic testing in 1123–1127  
   diagnostics in 1123, 1126f  
   gastrointestinal management of 1129–1130  
   general management of 1129–1130  
   genetics in 1127  
   multimini-core disease 1128  
   muscle biopsy for 1123–1127  
   muscle imaging in 1127  
   nemaline 1123–1127  
   nutrition in 1129–1130  
   oromotor management of 1129–1130  
   orthopedic management of 1130  
   peripheral hypotonia and 1055t–1056t  
   physical therapy/exercise for 1130  
   prevalence of 1123  
   respiratory management of 1129  
   RYR1-related 1128–1129  
   SEPN1-related 1129  
   subtypes of 1127–1129  
   SLE-associated 950  
   in systemic lupus erythematosus e2170  
   uremic 1219
- Myophosphorylase deficiency e728t, e737–e739, e737f
- Myosin 1031–1032
- Myosin ATPase 1131
- Myositis  
 eosinophilic 1145  
 focal nodular 1145  
 infectious 1044, 1045t–1046t  
 influenza 1145  
 in systemic juvenile idiopathic arthritis e2164
- Myotilinopathy 1115–1116, e2494
- Myotonia congenita 1150–1151, 1151t  
 autosomal-dominant (Thomsen's disease) 1150–1151, 1151t, e2603–e2605, e2603t  
 autosomal-recessive (Becker's disease) 1150–1151, 1151t, e2603–e2605, e2603t  
 clinical features of 1150–1151, e2603  
 clinical laboratory tests for e2604–e2605, e2604f  
 genetics of 1151, e2603  
 laboratory tests for 1151  
 pathophysiology of 1151, e2603–e2604  
 treatment of 1151, e2605
- Myotonia fluctuans 1151–1152, 1152t, e2605–e2606, e2606t
- Myotonic dystrophies 1148–1149, e2495, e2595–e2599, e2596t, e2726  
 acetazolamide-responsive sodium channel myotonia. *see* Acetazolamide-responsive sodium channel myotonia  
 animal models for e2599  
 congenital, peripheral hypotonia and 1055t–1056t  
 current human research for e2599  
 diagnostic approach for e2599–e2600, e2599f–e2600f, e2601t  
 disease mechanisms for e2597–e2599  
 experimental therapeutics in e2602–e2603  
 genotype-phenotype correlations e2596–e2597

- Myotonic dystrophies (*Continued*)  
 human studies supporting RNA-mediated pathomechanism for *e2598–e2599*  
 laboratory testing for *e2602*  
 management of *e2621*  
 mode of inheritance of 1148, *e2595, e2597f*  
 myotonia congenita. *see* Myotonia congenita  
 in peripheral hypotonia *e2348*  
 RNA-mediated diseases *e2597–e2598, e2598f*  
 treatment of *e2602–e2603*  
 type 1 1148, 1149*t*, *e2595–e2596, e2726*  
 clinical features of 1148  
 diagnostic approach in 1149–1150  
 in disorders of excessive sleepiness *e1535*  
 genotype-phenotype correlations in 1149  
 laboratory testing for 1150  
 serum CK levels found in 1039*t*  
 treatment of 1150  
 type 2 1148–1149, 1149*t*, *e2596, e2726*  
 clinical features of 1148–1149  
 diagnostic approach in 1149–1150  
 genotype-phenotype correlations in 1149  
 laboratory testing for 1150  
 treatment of 1150
- Myotonic-like disorders, stiff-person syndrome *926t*
- Myotubular myopathy *e2525–e2526, e2527f*  
 serum CK levels found in 1039*t*
- Myotubularin (*MTM1*) 1124*t*–1125*t*, 1127

- Renal diseases  
 affecting kidney, and nervous system *e2756–e2763*  
 amyloidosis *e2759–e2761, e2759b, e2760t*  
 hepatorenal syndrome *e2758–e2759*  
 metabolic diseases, producing renal and neurologic dysfunction *e2761*  
 nephropathic cystinosis *e2762–e2763*  
 proximal renal tubular acidosis *e2761–e2762, e2763b*  
 selective tubular dysfunction *e2761, e2762b*  
 thrombotic thrombocytopenic purpura *e2756–e2757*  
 vasculitic diseases, with neurologic-renal presentations *e2758*  
 affecting nervous system *e2738–e2756*  
 acute kidney injury *e2738–e2742*  
 chronic kidney disease *e2742–e2746, e2742t*  
 dialysis-associated  
   complications *e2746–e2751*  
   hypertension *e2753–e2756*  
   renal transplantation, complications associated with *e2751–e2752*  
 drug-induced encephalopathy in *e2766, e2766b*  
 drug therapy for *1224–1226, e2765–e2768*  
 kidney stones in *e2768*  
 nervous system, affecting *1215–1221*  
 acute kidney injury *1215–1216*  
 amyloidosis *1222*  
 chronic kidney disease *1216–1218*  
 dialysis-associated complications in *1218–1219*  
 hemolytic-uremic syndrome (HUS) *1222*  
 hepatorenal syndrome (HRS) *1222*  
 hypertension and *1220*  
 kidney and *1221–1223*  
 metabolic diseases and *1223*  
 nephropathic cystinosis *1223*  
 proximal renal tubular acidosis *1223*  
 renal transplantation, complications associated with *1219–1220*  
 selective tubular dysfunction *1223*  
 thrombotic thrombocytopenic purpura (TTP) *1221–1222*  
 neurologic disorders with *1215–1227, e2738–e2774*  
 neurologic drugs *e2763–e2765, e2763b, e2765t, e2768*
- Renal diseases (*Continued*)  
 neurologic drugs for, affecting nervous system and kidney *1223–1224, 1226*  
 seizures with, treatment of *1225–1226, e2766–e2768*  
 vasculitic diseases and *1222*
- Renal stones, ketogenic diets and *628*
- Renal transplantation, complications associated with *1219–1220, e2751–e2752*
- Renal tubular acidosis *e2550*
- Reoviruses *896b, e2049–e2050*
- Repetitive nerve stimulation (RNS)  
 in autoimmune myasthenia gravis *e2457, e2457f–e2458f*  
 for myasthenia gravis *1099, 1100f–1101f*
- Repetitive speech, in ASD *459*
- Repetitive transcranial magnetic stimulation *e1438*  
 for seizure suppression *621*
- Replicative segregation *335*
- Resective surgery, for refractory status epilepticus *549t*
- Reserpine, associated with Parkinsonism *e2684b*
- Reserpine toxicity *1198b*
- Residual language function *e1733*  
 disorders of consciousness and *768*
- Respiratory acidosis, in drowning *808–809*
- Respiratory chain  
 defects of *1132b, e2564*  
 coenzyme Q deficiency *1132b*  
 complex I deficiency *1132b*  
 complex II deficiency *1132b*  
 complex III deficiency *1132b*  
 complex IV deficiency *1132b*  
 “direct hits” *338–340*  
 function, enhancement of *345–346*  
 “indirect hits” *340*  
 Mendelian defects of *337–345*
- Respiratory chain, Mendelian defects of *e845–e851*  
 “direct hits” *e845–e846*  
 complex I *e846*  
 complex II *e846*  
 complex III *e846*  
 complex IV *e846*  
 complex V *e846*  
 “indirect hits” *e846–e847*  
 coenzyme Q10 defects *e846*  
 complex I *e846*  
 complex III *e846*  
 complex IV *e846–e847*  
 complex V *e847*
- Respiratory distress, neonatal *1160*
- Respiratory dysfunction, management of, in congenital myopathies *e2532*
- Respiratory failure, spinal muscular atrophy and *1063, e2369–e2370*
- Respiratory mechanism, in proposed mechanisms for sudden unexpected death in epilepsy *e1484–e1486*
- Respiratory sinus arrhythmia (RSA) *e2647–e2648*
- Responsive neurostimulation *620–621, e1437–e1438*
- Resting ankle foot orthoses (AFOs) *1157*
- Resting state and connectivity studies, disorders of consciousness and *767*
- Resting state functional MRI (rs-fMRI) *97–98*
- Restless legs syndrome (RLS) *678–682, 716, e1539–e1544, e1617*  
 coexistent conditions in *680–681, e1541–e1542, e1542b*  
 diagnosis of *678–681, 679b, e1539–e1543, e1540b*  
 differential diagnosis of *680b, e1541b*  
 exacerbating factors of *681b*  
 family history in *680, e1541*  
 genetics of *680, e1541*  
 iron and neuroimaging *680*  
 iron deficiency in *680, e1541*  
 presentation of *678, e1539*  
 prevalence of *678, e1539*  
 symptoms of *678, e1539*  
 treatment of *681–682, e1542–e1543, e1542b*
- Resuscitation  
 hypoxic-ischemic encephalopathy and *811–812*  
 metabolism after *808*  
 neonatal, to prevent brain injury *124*  
 and supportive care to prevent brain injury *e302*
- Resveratrol, for fatty acid oxidation disorders *e2563*
- RET gene, mutations in *1182*
- Retigabine *511, e1477*
- Retina, anomalies of *38, 38t, e78–e79, e79f, e79t*
- Retinal dysplasia *36, e74–e75*
- Retinal hemorrhages  
 abusive head trauma and *e1822–e1823, e1822f–e1823f, e1822t, e1825*  
 posttraumatic *797*  
 differential diagnosis of *798–799*  
 terminology for *797t*
- Retinal nerve, fiber layer integrity of, assessment of *34, e70, e72f*
- Retinitis pigmentosa *38, e79*  
 lysosomal storage diseases and *e782*
- Retinocephalic angiomatosis *371, e906*
- Retinoic acid *388, e431*
- Retinoids, neuroteratology *1203t*
- Retinol *e917–e921*
- Retinopathies *926t*  
 cancer-associated *930, e2137*  
 of prematurity *35, e73*
- Retinoschisis *797*
- Retroauricular ecchymosis *782, 787*
- Retroviruses *896b, 904–905, e2055–e2057*
- Rett, Andreas *244*
- Rett syndrome (RTT) *121, 242–244, 478–479, 479t, 1182, e589, e2656*  
 history of *244*  
 and infantile onset epilepsies *558t–560t*  
 treatment of *e1138–e1139, e1138t, e1141f*  
 variant *e1228–e1229*
- Revascularization, for moyamoya arteriopathy *873, e1989*
- Reversible posterior leukoencephalopathy syndrome (RPLS). *see* Posterior reversible leukoencephalopathy syndrome (PRES)
- Revised Conners parent rating scale *4, e5*
- Rey-Osterreith Complex Figure *68t–69t, e143t–e146t*
- Reye-like syndrome *278, 950*  
 in systemic lupus erythematosus *e2170*
- Reye syndrome *856, 904, 1235, e2797*  
 EEG and *e239*
- RFT1-CDG (In) *e761*
- Rhabdoid cells *996, 996f, 999*

- Rhabdomyolysis, recurrent 283  
 metabolic disorders and *e666*
- Rhabdomyosarcoma 1020, *e2285*
- Rhabdoviruses 896*b*, 903–904, *e2052–e2053*
- RHADS (repetitive high amplitude delta waves with spikes or polyspikes) 595*f*
- Rhagades 890–891
- Rheumatic disorders  
 autoantibodies 946*t*  
 classification of 946*b*  
 laboratory findings in 947*t*  
 neurologic manifestations of 945–956, *e2162–e2191*  
 arthritis associated with infectious agents *e2166–e2168*  
 autoantibodies in *e2163t*  
 classification of *e2163b*  
 connective tissue disorders and *e2168–e2176*  
 juvenile idiopathic arthritis in *e2162–e2165, e2164t*  
 periodic fever syndromes in *e2165–e2166*  
 primary vasculitic diseases and *e2176–e2184*
- Rheumatic fever *e2166–e2167, e2166b*  
 acute 947*t*, 948–949  
 Jones criteria for diagnosis of 948*b*  
 neurologic manifestations of 948  
 neuropathology of 948  
 other central nervous system manifestations 949  
 postinfectious Tourette syndrome and PANDAS 949  
 treatment of 948–949  
 neurologic manifestations of *e2166–e2167*  
 neuropathology of *e2167*  
 other central nervous system manifestations in *e2167*  
 postinfectious Tourette syndrome and PANDAS in *e2167*  
 treatment of *e2167*
- Rheumatologic drugs, in myasthenia gravis 1103*b*
- Rhinorrhea 787
- Rhizomelic chondrodysplasia punctata 347, *e865–e866, e865t, e866f*
- Rho pathway antagonists, for spinal cord injury *e1888–e1889*
- Rhombencephalosynapsis (RES) 204, *e477–e478, e477f*  
 prenatal diagnosis of 254, *e609*
- Riboflavin 374, *e918t–e919t, e921*  
 deficiency 374, *e921*  
 for fatty acid oxidation disorders 1136, *e2561*  
 for headache prevention *e1501*  
 transport, disorders of 374, *e921–e924*
- Riboflavin-dependent enzymatic reactions 374, *e921, e921t*
- Riboflavin transporter deficiency neuropathy 374, *e922*
- Rich club (RC) organization 99, *e259*
- Rickettsia* spp.  
*R. felis* *e2076*  
*R. prowazekii* *e2073t–e2074t*  
*R. rickettsii* 909, *e2072, e2073t–e2074t*  
*R. typhi* *e2073t–e2074t, e2076*
- Rickettsial diseases 907–916, *e2072–e2078, e2073t–e2074t*  
 ehrlichiosis *e2077–e2078*  
 Rocky Mountain spotted fever 909–910, *e2072–e2076, e2075f*  
 typhus fever group *e2076–e2077*
- “Rieger’s syndrome” *e73–e74*
- Rifampicin, for tuberculous meningitis 890
- “Right to left shunts” 1205
- Rigid spine syndrome (RSS) 1121  
 congenital muscular dystrophy with *e2508*
- Rigidity 27, 713–714, *e54, e1599*
- Riley Ray syndrome *e2349*
- Riluzole 1063, *e2368*  
 for spinal cord injury *e1886*
- Ring chromosomes 270–271, *e630f, e638*
- Risk assessment 1246
- Risperidone 494, *e1184t, e1185–e1186*  
 for ASD 466, 467*t–468t*  
 for tic disorders 745*t*
- Rituximab  
 for dermatomyositis 1143–1144, 1144*t*  
 for multiple sclerosis 764  
 for neuromyelitis optica 765  
 in OMS 942, 942*t*
- Rizatriptan 650, 650*t*
- Rnase T2-deficient  
 leukoencephalopathy *e1701*
- Robertsonian translocations 270
- Robot-assisted rehabilitation, for arterial ischemic stroke *e1946*
- Robot-assisted therapy, for stroke 1254, *e2839–e2840*
- Rocker-bottom foot 271
- Rocky Mountain spotted fever 909–910, *e2072–e2076, e2075f*  
 clinical characteristics of *e2075–e2076, e2075f*  
 management of *e2076*
- Rodenticides 1196*b*, 1199*b–1200b*  
 associated with tremor *e2685b*  
 in ataxia *e2685b*  
 sensorium changes *e2682b*
- Rogers syndrome 373, *e920*
- Rolandic epilepsy 104, *e268*  
 and developmental language disorders 432
- Romaña sign 912
- Romberg maneuver *e37*
- Rooting reflexes *e50*  
 in preterm infants 24
- Ropinirole, for restless legs syndrome *e1543*
- Rostral verminal lesions 689
- Rotational testing *e119–e120*
- Rotavirus *e2050, e2787*
- Rotavirus vaccines 921, *e2127*
- Roth spots. 852
- RPS6KA3 gene mutation 421*t*
- Rpx/Hesx1* gene mutations 1169, *e2632–e2633*
- RSS. *see* Rigid spine syndrome (RSS)
- RTK1 protein family, in ependymomas *e2220*
- Rubella vaccines 921, *e2126*
- Rubella virus 897, *e2046–e2047, e2046f*
- Rubeola vaccines 920–921
- Rubinstein-Taybi syndrome, with kidney malformation 1224*t, e2764t*
- Rufinamide 511, 601*t–602t*  
 for antiseizure drug therapy in children *e1402*  
 for Lennox-Gastaut syndrome 572  
 pharmacokinetics of 604*t–605t*
- Ryanodine receptor (*RYR1*) 1128
- Ryanodine receptor (*RYR1*)-related myopathies *e2530–e2532, e2531f*
- RYR1*-related myopathies 1128–1129
- S**
- S-100B 800
- S-kit, in germinoma 1001
- Saber shins 890–891
- Sacral agenesis 190, *e443–e444, e444f*
- Saddle nose 890–891
- Saethre-Chatzen syndrome 235
- Salicylates  
 abuse in *e2692–e2693*  
 associated with myopathies *e2683b*  
 and Reye’s syndrome *e2799*  
 sensorium changes *e2682b*  
 toxicity 1196*b–1197b, 1201*
- Saliency Network 769, *e1736*
- Salla disease 749*f, 750*
- Salt and pepper syndrome *e752t–e760t*
- Salt/sodium balance, correctable disturbances of 171, *e402–405*
- Salty taste *e131*
- Salvia 1200
- Sandhoff disease 107, *e277, e772t–e773t, e777f, e780*
- Sandifer syndrome 671, 1229, *e1527*
- Sanfilippo syndrome 482*t–486t, e772t–e773t, e804–e805, e804f*
- Sanger sequencing 260, *e618–e619, e618t, e621–e622*
- Saposin A deficiency 754, *e1695*
- Saposins, lysosomal storage of 393
- Sappinia pedata* *e2085*
- $\alpha$ -sarcoglycan mutation 1113
- $\beta$ -sarcoglycan mutation 1113
- $\delta$ -sarcoglycan mutation 1113

 recommendations for, in preterm neonate and child born preterm 168–169, 168f, e390, e391f  
 ultrasound e388–e389, e388f–e389f  
 neuropathology of 165, e385–e386  
 NICU management of 169  
 nutrition and e387  
 outcome of 169, e390–e392, e390b  
 cognitive 169, e391–e392  
 epilepsy 168f, 169, e392  
 motor 169, e392  
 social/behavioral 169, e392  
 visual 169, e392  
 pathogenesis of 165–166, 166b, e386–e387, e386b  
 hypoxia-ischemia 165–166  
 inflammation/infection 166  
 vulnerability of immature white matter 166  
 postnatal corticosteroid use and e387  
 of premature newborn 165–170, e384–e393  
 prevention and management of 169–170, e392–e393  
 after NICU discharge e393  
 NICU e393  
 risk factors for 166, e387
- White matter vacuolization, white matter disorders with e1696–e1698
- Whole-bowel irrigation 1193
- Whole-cell pertussis vaccines 919
- Whole exome sequencing 420, e1004  
 progressive encephalopathies and 428
