Myoclonus dystonia syndrome (DYT11) is a disorder with a combination of both symptoms. The major cause for this syndrome is mutation in the epsilon-sarcoglycan gene. Myoclonus involves the neck, trunk, and arms and is often alcohol-responsive. Dystonia occurs in approximately half of patients and may be the only manifestation, usually with torticollis or arm dystonia. Mood disorders and obsessive-compulsive disorder have also been associated with gene mutations. This disorder is autosomal-dominant, although *de novo* mutations may occur. When the epsilon-sarcoglycan gene is inherited from the father, there is approximately 100% symptomatic expression, but when inherited from the mother, there is only 10% symptomatic expression, suggesting an important role of maternal imprinting. The myoclonus responds to ethanol, and alcoholism may be a problem in adults with myoclonus-dystonia syndrome. Treatment is with benzodiazepines, valproate, or trihexyphenidyl. In severe cases, DBS may be effective.

## Dystonias Associated With Neurodegenerative Disorders

### Pantothenate Kinase-Associated Neurodegeneration (PKAN)

PKAN is a member of the group of diseases referred to as neurodegeneration with brain iron accumulation (NBIA). The NBIA's are discussed in the online version of this chapter. Symptoms of PKAN include progressive dystonia, dysarthria, rigidity, ballism, choreoathetosis, spasticity, dementia, and pigmentary retinal degeneration. In its later stages, this disorder has characteristic ballistic flinging movements of arms and legs, as well as involuntary and repetitive tongue protrusion. The limb and tongue movements may lead to injury, requiring restraint of the arms and legs, and dental extraction. There is a gradual progression over years, with loss of ambulation within 5 to 15 years of onset. The initial symptoms usually occur in either the childhood or the juvenile years. Dystonia in PKAN usually starts in the leg, but axial dystonia may be prominent. There is often associated bradykinesia. The rate of progression is more rapid with younger onset. An atypical form of PKAN generally starts later, between 10 and 30 years of age with a mean of 13 years. It has slower progression, and retinopathy is rare. The atypical form presents with dysarthria and psychiatric disturbances, which include emotional lability, depression, and sometimes aggressive or violent behavior. There are also freezing episodes similar to those seen in Parkinson disease.

MRI shows a characteristic "eye of the tiger" sign. This sign consists of a dark globus pallidus internus on T2 imaging, with a bright region in the center of the globus pallidus that is thought to be due to central necrosis. The dark signal is due to iron accumulation, although deposition of iron may be secondary to other metabolic deficits rather than the primary cause of symptoms. When the full eye of the tiger sign is present in childhood, 100% of such cases have the *PANK-2* mutation. Children with clinical features of PKAN but without the eye of the tiger sign only have a 50% chance of being positive for the *PANK-2* mutation.

Treatment is symptomatic. Some children receive benefit from benzodiazepines, anticholinergic medications, botulinum toxin, baclofen, or deep brain stimulation. The prognosis is universally poor, with death from medical complications usually within 10 to 20 years of the onset in the typical form. Deep brain stimulation can be helpful as a palliative treatment in PKAN.

### Lesch-Nyhan Disease

Lesch-Nyhan disease is a progressive neurodegenerative disorder that initially presents with hypotonia and developmental delay in the first year of life. It progresses over several years and can mimic athetotic cerebral palsy with ballism, choreoathetosis, axial dystonia, and spasticity. Dystonia is a prominent neurologic sign in Lesch-Nyhan disease. There is a striking prevalence of self-mutilation behaviors, including tongue-biting, head-banging, biting the fingers and lips, and thrusting of the arms or legs against objects. The behavioral disorder seems to be unique, with adult patients describing compulsions to injure themselves or to behave inappropriately. There is an increase in uric acid in both the blood and the urine, and this leads to symptoms of gout in advanced cases, although gout is less common in children. Both arthritis and renal stones have been reported, but usually in older patients.

Treatment is symptomatic. Allopurinol may alleviate signs of gout and prevent renal calculi. Behavioral programs can be used to reduce self-mutilation. Benzodiazepines, carbamazepine, and possibly selective serotonin reuptake inhibitors can be helpful for the behavior disorder. Tetrabenazine or l-DOPA may be helpful to treat the dystonia. Naltrexone has been used to reduce self-mutilation but with limited success. In some patients, restraint and removal of teeth are required in order to prevent self-mutilation, and patients who can communicate often will request to be placed in restraints in order to reduce self-injury. The prognosis is poor. Most children with the severe childhood-onset form never walk, and there may be progression of symptoms over several years.

## Dystonia Associated With Other Metabolic Disorders

### Organic Acidemias

Organic acidemias, including methylmalonic aciduria, glutaric aciduria types 1 and 2, biotinidase deficiency, disorders of fatty acid oxidation, and mitochondrial respiratory chain disorders, can lead to dystonia. Many of these disorders do not present until a time of metabolic stress, at which time a rapid decompensation with onset of severe generalized dystonia over a period of hours to days is possible. Once dystonia has occurred, symptoms are often irreversible. Specific treatment is usually needed urgently, and in some cases this requires limitation of intake of specific amino acids, whereas, in other cases, specific medications or metabolites are needed.

Many of these disorders can be detected with newborn screening. For children with new onset of symptoms or rapid progression of symptoms, there needs to be a high index of suspicion in order to detect these disorders, as any delay in treatment usually leads to a significantly worse prognosis. Most of these diseases are autosomal-recessive.

A particularly striking presentation that often occurs in infancy, but which can occur later in childhood, has been referred to as infantile bilateral striatal necrosis (IBSN). This can occur with many metabolic disorders but also seems to occur in the context of acute infections, particularly with mycoplasma, and it has been reported in children with *PANK-2* mutations. Most often, the cause is unknown. There

have been some rare familial cases. This disorder is characterized by a rapid onset of dystonia and dyskinesia, sometimes associated with chorea, and the MRI often shows evidence of irreversible striatal and sometimes pallidal injury on diffusion-weighted, T2, or gadolinium-enhanced images. There have been a few reported cases of a biotin-responsive type of striatal necrosis that has been thought to be due to an abnormality of biotin transport, and such cases may have rapid and effective resolution when treated with biotin.

### Non-Dopa-Responsive Disorders of Dopamine Synthesis and Metabolism

Aromatic L-amino acid decarboxylase deficiency (ALAD) leads to dopamine agonist-responsive dystonia. In this disorder, conversion of L-DOPA to dopamine is impaired, and therefore administration of L-DOPA will not be helpful. Although this disorder does respond to dopamine agonists, due to the combination of severe autonomic and sleep disturbances, treatment with serotonergic medication is often required as well. Very few cases have been reported. This disorder is detectable by a characteristic pattern of cerebrospinal fluid neurotransmitter metabolites. Symptoms include dysautonomia, sleep disturbances, eye movement disturbances, and severe generalized dystonia, usually with onset in the first year of life. It appears to be autosomal-recessive.

Dopamine-transporter deficiency is a newly reported disorder in which the presynaptic reuptake of dopamine in the striatum is impaired (Kurian et al., 2011). The disorder is due to mutations in the dopamine transporter (*DAT*) gene, and symptoms include severe dystonia, hypotonia, bradykinesia, and developmental delay, with onset in the first year of life. Some children exhibit spontaneous hyperthermic spells associated with rigidity and rhabdomyolysis. Cerebrospinal fluid shows dramatic elevation of homovanillic acid, and serum prolactin levels may be decreased, particularly during hyperthermic episodes. No specific treatment has been found, although some children have responded to tetrabenazine, L-DOPA, dopamine agonists, or a combination.

## Dystonia Due to Nonprogressive Disorders

### Cerebral Palsy

Cerebral palsy is probably the most common cause of dystonia in childhood. This is due to its relatively high prevalence. Further details about this disorder, including the etiology and details of the symptomatology, can be found in Chapter 97. Dyskinetic cerebral palsy represents between 6% and 15% of all cases of cerebral palsy. In dyskinetic cerebral palsy, dystonia is usually the primary feature. Dystonia occurs frequently as an associated feature in other forms of cerebral palsy, including tetraplegic and hemiplegic cerebral palsy. Although the dystonia in cerebral palsy presumably is due to a static injury, the symptom can worsen over time. In fact, the onset of dystonia may be many years after the initial injury leading to cerebral palsy.

### Kernicterus

Kernicterus occurs due to high bilirubin levels in the perinatal period, but the effects are variable and unpredictable. Injury to the globus pallidus is thought to be the etiology of the movement disorder. Symptoms include choreoathetosis, dystonia (which can be progressive), sensorineural hearing loss, and supranuclear gaze palsy. Symptom type and severity may be quite variable across individuals. In the absence of other associated injury, the intellect is usually normal, and the motor disorder is often the single greatest cause of disability.

The most effective treatment is prevention of neonatal hyperbilirubinemia. Treatment of symptomatic cases is often quite difficult. There is only a slight benefit to anticholinergic medications, valproic acid, benzodiazepines, or botulinum toxin. Some children have benefited from intrathecal baclofen. In general, treatment of this disorder is poorly effective. Life span is shortened in severely affected children due to pulmonary complications.

## Medication-Induced Dystonias

Medication-induced dystonia can occur as a dose-related, idiosyncratic, or tardive phenomenon, so evaluation of a child with dystonia requires a careful history of past and current medication exposure. This is particularly true for acute-onset dystonia. Medication-induced dystonia is discussed in Chapter 96. Treatment of medication-induced dystonia requires elimination of the precipitating agent. Tardive dystonia is rare in children.

## Treatment of Dystonia

Because DRD is highly responsive to treatment with L-DOPA, it is recommended that all children with unexplained dystonia be given a trial of L-DOPA. L-DOPA may also be helpful in other forms of dystonia, but the benefits are usually incomplete. The optimal dose of L-DOPA is very low in DRD (typically 50 to 100 mg per day) but may be much higher in other forms of dystonia. Dosages as high as 10 mg/kg/day divided into three doses are sometimes needed. Common side effects of L-DOPA include nausea, vomiting, diarrhea, and more rarely, somnolence. L-DOPA must be combined with a peripheral decarboxylase inhibitor such as carbidopa in order to increase central uptake and decrease peripheral side effects. Commercial preparations with a ratio of L-DOPA to carbidopa of 4:1 are typically used.

Anticholinergic medications are the mainstay of treatment in many forms of dystonia. It is often necessary to proceed to very high doses to achieve maximum benefit. The effectiveness may be greater in young children, and speech and hand function seems to improve the most. The dose must be increased gradually, and it may often take 3 to 4 months to achieve an appropriate dosage. The initial dosage is 0.05 to 0.1 mg/kg/day or less and is divided into dosing three times per day. Side effects are similar to those of other anticholinergic medications.

Baclofen has been used and may be effective in some patients, and painful dystonia may respond best to baclofen. As with anticholinergic medications, high doses may be required to provide optimal benefit (120 to 180 mg/day in older children). Intrathecal baclofen may be effective in children with mixed dystonia and spasticity, but evidence for efficacy in isolated dystonia is limited.

When dystonia-related disability is limited to a small number of muscles, botulinum toxin may be effective. Diazepam and other benzodiazepines may be helpful in some individuals.

Deep brain stimulation may be highly effective in some forms of isolated dystonia (e.g., DYT1), and it may be variably helpful in patients with dystonia due to progressive or nonprogressive neurologic disorders.

## TREMOR

Tremor has been described as "a rhythmical, involuntary, oscillatory movement of a body part." It can be classified based on the time of greatest severity as rest, postural, action, or intention tremor. Tremor can affect the head, extremities,

trunk, voice, or a combination. Estimation of frequency can be useful in categorizing tremor. Tremor associated with parkinsonism is between 4 and 6 Hz, whereas essential tremor is more likely at 6 to 8 Hz, and physiologic tremor has two components at 8 to 12 Hz and at 20 to 25 Hz. In diagnosing tremor, it is important to distinguish it from myoclonus. Myoclonus can be rhythmic, but the rapid shocklike quality distinguishes it from tremor. Causes of tremor in childhood are summarized in [Box 93-3](#).

## Primary Tremor Disorders

Essential tremor is an autosomal-dominant disorder with variable penetrance and severity. It can present in childhood and often is slowly progressive over many years. It is rarely

disabling in childhood except in extreme cases. Tremor is primarily postural but can also worsen with action. Tremor with holding a cup or handwriting may be some of the earliest complaints, but ultimately the head, trunk, and voice can be affected.

Physiologic tremor is normally present and becomes particularly noticeable when a muscle is exerting high levels of force. The distinguishing characteristic of physiologic tremor is that it occurs or worsens only when the child is carrying a heavy object or otherwise needs to contract the muscle against high resistance. Some children have an enhanced physiologic tremor that can become noticeable but is only rarely bothersome.

## Secondary Tremor Disorders

There are a large number of secondary causes of tremor, and many of these are listed in [Box 93-3](#). Tremor may be a side effect of many medications (Chapter 96). It may also accompany a number of systemic disorders that result in increased sympathetic output. Hyperthyroidism also may cause tremor.

In teenagers with new onset of a course tremor, it is important to exclude Wilson disease. This disorder is characterized by a wing-beating tremor that often involves the adductors of the arm and is shown when the child is asked to abduct the arms with elbows bent. The tremor is primarily postural but may occur at rest (Chapter 159). Other forms of tremor may occur in individuals with Wilson disease.

Holmes (rubral) tremor describes a large amplitude, rhythmic, but partly ballistic movement that often affects the arms and can be unilateral. It is associated with attempts at movement and is therefore an action tremor. It can be distinguished from chorea by the triggering or significant worsening with attempted movement. Holmes tremor is associated with lesions in the thalamus, midbrain, pons, or cerebellar peduncles, and not necessarily the red nucleus, despite its name. Holmes tremor is usually nonprogressive but can be severely disabling.

## Treatment of Tremor

The first goal in treatment of tremor is to exclude other possible causes of rhythmic movement, including myoclonus, dystonia, seizures, or cerebellar dysfunction. Any underlying metabolic or hormonal cause must be corrected. Tremor-causing medications should be eliminated. Essential tremor is treated with propranolol, primidone, benzodiazepines (clonazepam may be particularly effective), or gabapentin. Tremor due to "stage-fright," social phobia, or panic disorder often responds to propranolol. Holmes tremor is refractory to most interventions, although some cases will respond to L-DOPA, clonazepam, or thalamic deep brain stimulation.

## PARKINSONISM

Parkinsonism is defined by the presence of two or more cardinal signs of Parkinson disease. These include tremor at rest, bradykinesia, rigidity, and postural instability. Tremor is much less common in childhood parkinsonism than it is in adult Parkinson disease. Bradykinesia is slowness of movement in the absence of weakness or ataxia. There may also be hypokinesia with paucity of movement, few spontaneous movements, and decreased amplitude of movement. Hypokinesia is often seen as diminished spontaneous facial expression, soft speech (hypophonia), small handwriting (micrographia), and general slowness. Rigidity is increased muscle tone that is equal in all directions of movement and does not have a particular preferred posture. Rigidity may have a "lead-pipe"

### BOX 93-3 Causes of Tremor in Childhood

#### BENIGN DISORDERS

- Enhanced physiologic tremor
- Shaking/shuddering spells

#### STATIC INJURY/STRUCTURAL DISORDERS

- Stroke (particularly in the midbrain or cerebellum)
- Multiple sclerosis

#### HEREDITARY/DEGENERATIVE DISORDERS

- Familial essential tremor
- Juvenile parkinsonism
- Pallidonigral degeneration
- Wilson disease

#### METABOLIC DISORDERS

- Hyperthyroidism
- Hyperadrenergic state (including pheochromocytoma and neuroblastoma)
- Hypomagnesemia
- Hypocalcemia
- Hypoglycemia
- Hepatic encephalopathy
- Vitamin B<sub>12</sub> deficiency

#### DRUGS/TOXINS

- Valproate
- Lithium
- Tricyclic antidepressants
- Stimulants (cocaine, amphetamine, caffeine, thyroxine, bronchodilators)
- Neuroleptics
- Cyclosporine
- Toluene
- Mercury
- Thallium
- Amiodarone
- Nicotine
- Lead
- Manganese
- Arsenic
- Cyanide
- Naphthalene
- Ethanol
- Lindane
- Serotonin reuptake inhibitors

#### OTHER CAUSES OF TREMOR

- Cerebellar disease or malformation
- Anxiety
- Functional tremor

quality in which the limb can be moved with difficulty into arbitrary postures but, once placed in a posture, will remain there against gravity. If there is superimposed tremor, the rigidity can feel ratchety, like a cogwheel. Postural instability manifests as increased likelihood of falling and is due to dysregulation of postural reflexes. Clinically, it is evaluated with the “pull test,” in which the patient stands, facing away from the examiner with feet apart at shoulder width. The examiner gives a gentle pull backward at the shoulders bilaterally (and is prepared to catch the patient to prevent a fall). A normal individual may take a step backward, but an individual with parkinsonian postural instability will take many steps backward (retropulsion) or may fall backward with no attempt to compensate. Etiologies of parkinsonism in children are listed [Box 93-4](#).

### Juvenile Parkinson Disease

Juvenile Parkinson disease is rare. The most common cause is due to mutations in the *Parkin* gene (PARK2). This is an autosomal-recessive disorder that typically begins in the second or third decade of life. Other causes for Juvenile Parkinson disease include mutations in the PINK1 and DJ1 genes. Juvenile Parkinson disease progresses over time. Typically these disorders respond to treatment with L-DOPA and dopamine agonists. However, escalating doses are required, and individuals with Juvenile Parkinson disease may develop DOPA-induced dyskinesia early in the course of treatment.

Other genes causing juvenile parkinsonism have been described recently. These disorders have parkinsonism as a prominent feature but are typically accompanied by other signs and symptoms. These genes include ATP13A2, PLA2G6, FBX07, DNAJC6. Pyramidal signs, eye movement abnormalities, and cognitive symptoms are common in these disorders.

### Secondary Parkinsonism

There are many causes of secondary parkinsonism, as listed in [Box 93-4](#). One of the more important causes to recognize is Huntington disease. When it starts in childhood, Huntington disease commonly present with parkinsonism as the initial manifestation. In those cases, the parkinsonism may respond to L-DOPA, which may be a source of diagnostic confusion. Several medications are known to cause parkinsonism. These are discussed in Chapter 96.

### Treatment of Parkinsonism

Bradykinesia is the primary symptom that is responsive to treatment in childhood parkinsonism. It is usually due to dopamine deficiency and therefore is treated with L-DOPA or dopamine agonists. L-DOPA is combined with a peripheral decarboxylase inhibitor such as carbidopa in order to reduce side effects and increase delivery to the brain. Treatment is often initiated with a single dose of L-DOPA 1 mg/kg (or 50 to 100 mg total) given in the morning to evaluate for potential side effects, including nausea or postural hypotension. If this dose is tolerated for 3 to 4 days, then therapeutic treatment can be initiated three times per day. Dosage can be increased to a maximum of 10 to 15 mg/kg/day (divided into three doses), depending on effectiveness. In addition to nausea, common side effects in patients with parkinsonism can include dystonia, agitation, sleeplessness, and behavior changes. The dosage must be adjusted gradually in order to find the optimal dose, and the optimal dose may change as the child grows. Additional carbidopa may be given to decrease nausea.

#### BOX 93-4 Causes of Parkinsonism

##### STATIC INJURY/STRUCTURAL DISORDERS

- Basal ganglia infarcts
- Brain tumor
- Hydrocephalus

##### HEREDITARY/DEGENERATIVE DISORDERS

- Juvenile Parkinson disease
- Spinocerebellar ataxia
- Huntington disease (Westphal variant)
- Pallidal-pyramidal Disorder
- Neurodegeneration with Brain Iron Accumulation (NBIA)
- Pantothenate kinase-associated neurodegeneration (PKAN)
- Rett syndrome
- Pelizaeus-Merzbacher disease
- Machado-Joseph disease (spinocerebellar ataxia type 3)
- Neuronal ceroid lipofuscinosis
- Neuronal intranuclear inclusion body disease

##### METABOLIC DISORDERS

- Dopa-responsive dystonia
- Tyrosine hydroxylase deficiency and other abnormalities of bioamine metabolism
- Abnormalities of folate metabolism
- Wilson's disease
- Basal ganglia calcification (Fahr syndrome, hypoparathyroidism)

##### INFECTIOUS/PARA-INFECTIOUS DISORDERS

- Encephalitis lethargica (Von Economo disease)
- Autoimmune encephalitides, including anti-NMDA receptor associated encephalitis
- Viral encephalitis
- Acute demyelinating encephalomyelitis

##### DRUGS/TOXINS

- 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) poisoning
- Rotenone
- Tetrabenazine
- Reserpine
- Methylidopa
- Sedatives
- Neuroleptics
- Antiemetics
- Calcium channel blockers
- Isoniazid
- Serotonin reuptake inhibitors (sertraline, fluoxetine)
- Meperidine

##### DISORDERS THAT MIMIC PARKINSONISM

- Catatonia
- Spasticity
- Hypothyroidism
- Depression (with psychomotor retardation)

In Juvenile Parkinson disease, long-term treatment with L-DOPA will eventually lead to dyskinesias and freezing episodes that can limit its use. Some authors have advocated “dopamine-sparing” strategies that involve the early use of dopamine agonists such as pergolide, pramipexole, or ropinirole, or of dopamine breakdown inhibitors such as entacapone or selegiline. This approach has not been studied in children.

## MYOCLONUS

Myoclonus consists of very brief, abrupt, involuntary, nonsuppressible, jerky contractions (or interruption of contraction), involving a single muscle or muscle group. The rapidity of these movements warrants the descriptor “shocklike,” as if an electrical shock had just been applied to the peripheral nerve innervating the muscle. Myoclonus can be rhythmic, in which case it often appears tremor-like. However, in true tremor the movement oscillates with near-equal amplitude around a midpoint, whereas in myoclonus, the movement has more of a “sawtooth” character. It is present in normal (associated with sleep, exercise, or anxiety) and pathologic situations, both epileptic and nonepileptic. Epileptic myoclonus is discussed elsewhere. We limit our focus here to nonepileptic myoclonus.

### Classification of Myoclonus

Several different schemes have been used to classify myoclonus, using clinical, anatomic, or etiologic criteria. Perhaps the simplest classification is based upon when the myoclonus occurs. Thus myoclonus may occur at rest, with action, or in response to a sensory stimulus (reflex myoclonus). In adults, it is helpful to classify based on presumed neuroanatomical location (e.g., cerebral cortex, thalamus, brainstem, or spinal cord). The neurophysiology of myoclonus has been reviewed elsewhere. In children, etiologic classification is the most useful, as summarized in [Box 93-5](#).

## Physiologic and Developmental Myoclonus

Physiologic myoclonus is that which occurs in normal individuals in specific settings. It includes such entities as hiccups, sleep starts, and sleep myoclonus. Sleep starts, also known as hypnic or hypnagogic myoclonus, occur with sleep initiation. They are often accompanied by a sense of falling. Benign myoclonus may occur in association with specific developmental stages. Benign neonatal sleep myoclonus and benign myoclonus of early infancy are discussed in Chapter 95.

### Essential Myoclonus

Essential myoclonus is a relatively mild condition, starting in the first or second decade. It is inherited as an autosomal-dominant trait with incomplete penetrance. It is usually slowly progressive for a few years after onset and then stabilizes. The myoclonus may fluctuate slightly over the years or may show mild spontaneous improvement. Essential myoclonus may be allelic with Myoclonus Dystonia syndrome (DYT11). Essential myoclonus may respond to benzodiazepines, primidone, or propranolol.

### Symptomatic Myoclonus

Myoclonus can be symptomatic of many disorders, as listed in [Box 93-5](#). These are discussed in detail in the online version of this chapter. Opsoclonus-Myoclonus-Ataxia syndrome (OMAS) is discussed in detail in Chapter 120.

#### BOX 93-5 Etiologic Classification of Myoclonus

##### PHYSIOLOGIC

- Hiccups
- Hypnic jerks (sleep starts)
- Nocturnal (sleep) myoclonus

##### DEVELOPMENTAL

- Benign neonatal sleep myoclonus
- Benign myoclonus of early infancy
- Myoclonus with fever

##### ESSENTIAL

- Familial myoclonus dystonia syndrome

##### FUNCTIONAL

###### Symptomatic

###### Storage Diseases

- Juvenile Gaucher disease (type III)
- Sialidosis type 1 (cherry-red spot–myoclonus)
- GM<sub>1</sub> gangliosidosis
- Neuronal ceroid-lipofuscinosis (late infantile)

###### DEGENERATIVE CONDITIONS

- Dentato-rubro-pallido-luysian atrophy (DRPLA)
- Huntington disease
- Progressive myoclonus ataxia
- Ramsay–Hunt syndrome
- Early myoclonic encephalopathy
- Rasmussen encephalitis

###### DEMENTIAS

- Bovine spongiform encephalopathy
- Creutzfeldt–Jakob disease

###### INFECTIOUS AND POSTINFECTIOUS

- Meningitis (viral or bacterial)
- Encephalitis
- Epstein–Barr virus (EBV)

- Coxsackie virus
- Influenza
- Human immunodeficiency virus (HIV)
- Acute disseminated encephalomyelitis (ADEM)

##### METABOLIC

- Uremia
- Hepatic failure
- Electrolyte disturbances
- Hypo- or hyperglycemia
- Aminoacidurias
- Organic acidurias
- Urea cycle disorders
- Myoclonic epilepsy with ragged red fibers (MERRF)
- Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS)
- Biotinidase deficiency (usually epileptic)
- Cobalamin deficiency (infantile)
- Opsoclonus-myoclonus syndrome (myoclonic encephalopathy of infancy)

##### TOXIC

- Psychotropic medications (tricyclic antidepressants, lithium, selective serotonin reuptake inhibitors, monoamine oxidase inhibitors, neuroleptics)
- Antibiotics (penicillin, cephalosporins, quinolones)
- Antiepileptics (phenytoin, carbamazepine, lamotrigine, gabapentin, benzodiazepines [in infants], vigabatrin)
- Opioids
- General anesthetics
- Antineoplastic drugs
- Strychnine, toluene, lead, carbon monoxide, mercury

##### HYPOXIA

- (Lance–Adams syndrome)

## Treatment of Myoclonus

Myoclonus is often refractory to medical treatment. Cortical myoclonus may respond to benzodiazepines and is commonly treated with clonazepam. Valproic acid is sometimes helpful, but it must be used with caution due to the ability to cause tremor as a side effect, with consequent confusion of symptoms. Piracetam has been used for many years in the UK and Europe to treat myoclonus, with good efficacy. Levetiracetam is a piracetam analog but does not seem to have equivalent efficacy to piracetam for treatment of myoclonus. There are reports of efficacy with zonisamide in some forms of myoclonus. Posthypoxic myoclonus seems to be particularly responsive to serotonergic medications, including selective serotonin reuptake inhibitors and oral administration of 5-hydroxytryptophan or 5-hydroxytryptamine. Baclofen has been occasionally used, but the mechanism of action is not clear. Carbamazepine can worsen myoclonus.

## STEREOTYPY

Motor stereotypies are rhythmic, patterned, repetitive, involuntary movements that can occur in association with specific diseases or in otherwise normal children. Stereotypies may be associated with autism, sensory deficits, or intellectual disabilities, but they are also seen in otherwise normal children. Typical movements include repeated, recurrent raising and lowering of the arms, flapping, waving, wrist rotation, and finger wiggling. They are often accompanied by facial movements or grimacing. Other terms have been used to describe stereotypies, including “rhythmic habit patterns,” “gratification phenomena,” “self-stimulation,” and “motor rhythmicias.” Physiologic stereotypies may be present in any setting but are most common when the child is excited, mentally engaged, stressed, or bored. They may increase with fatigue. A hallmark of stereotypies is that they usually cease when the child is distracted or engaged in a new activity. Most children appear to be unaware of the stereotypies.

There is no consistently effective pharmacologic treatment for stereotypies. They typically do not bother the patient but can be distressing to the parents. Stereotypies rarely interfere with task performance by the individual but may cause embarrassment or have some other social influence. Behavior therapy has been effective in some cases.

## OTHER MOVEMENT DISORDERS

### Restless Legs Syndrome and Periodic Leg Movements of Sleep

Restless legs syndrome (RLS) manifests as an uncomfortable sensation in the legs that is typically relieved by movement. The sensation is poorly described by most children, but adults often use the descriptors “crawling,” “pulling,” or “creeping” in connection with the sensation under the skin. The sensation and movements occur most often at night and usually peak within the first 20 minutes of lying down. Relief is obtained by moving the legs when lying down or by walking. RLS responds to treatment with dopaminergic medication, and dopamine agonists are most often used for adults with this condition. If serum ferritin is low, then iron supplementation may be considered. RLS is associated with Periodic Leg Movements of Sleep (PLMS), usually diagnosed on polysomnography. Treatment for PLMS, when needed, is the same as for RLS. Treatment is not needed in most children unless PLMS interferes with sleep or RLS prevents classroom participation. These disorders are discussed in Chapter 89.

## Hyperekplexia

Hyperekplexia, otherwise known as familial startle disease, is an autosomal-dominant disorder characterized by an exaggerated startle reaction in response to sudden, unexpected auditory or tactile stimuli. Symptoms may begin in the neonatal period with profound and potentially fatal paroxysmal hypertonia and opisthotonic extensor posturing. Such episodes often resolve if the examiner flexes the neck, back, and knees of the child. Older children and adults may display nonadapting head retraction in response to nose tapping. The disorder is associated with several different gene mutations, but the classic form is due to mutation in the alpha-1 subunit of the glycine receptor. Symptoms respond well to treatment with clonazepam.

## Bobble-Head Doll Syndrome

The bobble-head doll syndrome is a condition in which an infant or child has jerky head movements similar to certain types of toy doll. The movement is a continuous or episodic, involuntary, forward-and-backward or side-to-side movement of the head at the frequency of 2 to 3 Hz. The condition is usually associated with structural abnormalities leading to third ventricular dilatation, including third ventricular cyst, aqueductal stenosis, or tumor. Brain imaging virtually always confirms the presence of a structural abnormality. Surgical treatment is usually beneficial.

## INTRODUCTION

Paroxysmal dyskinesias are a relatively rare subset of hyperkinetic movement disorders that are defined by their episodic nature. Patients present with repeated episodes of dyskinesia (dystonia, chorea, or both) that have sudden onset and, after a duration that ranges from seconds to days, remit entirely and subsequently recur in a stereotyped fashion. They may be primary or secondary, and when primary they are often associated with genetic causes.

The clinical syndromes of paroxysmal dyskinesia were characterized throughout the 20th century according to their clinical features, including triggers, duration, and frequency of the episodes. These syndromes were named based on the main triggering factor that promotes the dyskinesia attacks. Paroxysmal kinesigenic dyskinesia (PKD) is triggered by sudden movements, paroxysmal exercise-induced dyskinesia (PED) is triggered by sustained physical effort, and paroxysmal nonkinesigenic dyskinesia (PNKD) is not triggered by movement, but sometimes is provoked by consumption of coffee or alcohol or by stress.

Although classic descriptions delineated clear motor phenotypes, it is now clear that paroxysmal dyskinesias form part of a spectrum of clinical manifestations. These manifestations include movement disorders, other paroxysmal phenomena like epilepsy, ataxia and migraine, and in addition some patients may present cognitive difficulties. Overlapping phenotypes as well as underreported associated features are now being integrated into the decision-making process for treating these conditions.

In the previous decades enormous progress was achieved in discovering gene mutations that underlie these very characteristic phenotypes, and previously overlooked clinical features (like the association with epilepsy, migraine, or other motor phenomena) gained renewed interest. The pathophysiology of these conditions is not entirely clear but some experimental evidence demonstrates increased activity in the basal ganglia corresponding to the dyskinesias. A link with epilepsy was proposed in the past and largely ignored until recently when it became clear that mutations in two of the genes associated with paroxysmal dyskinesias (namely, *PRRT2* and *SLC2A1*) could cause both paroxysmal dyskinesia and epilepsy.

Paroxysmal dyskinesias can also be secondary to varied causes, including structural, metabolic, infectious, and inflammatory damage to the basal ganglia. These include head trauma, cerebral palsy, stroke, multiple sclerosis, moyamoya disease, infection, hypoglycemia, hyperglycemia, thyrotoxicosis, hypoparathyroidism, pseudohypoparathyroidism, maple syrup urine disease, bipterin synthesis defects, and methylphenidate therapy. For a review of secondary causes of paroxysmal dyskinesia (Roze et al., 2015). Management of secondary paroxysmal dyskinesias varies widely and includes the management of the etiologic factors as well as symptomatic treatment. Currently there are no guidelines as to how symptomatic treatment of secondary and primary paroxysmal dyskinesias differs, and so it is reasonable to adopt the more structured

approach to treat primary dyskinesias, which are mainly classified by their phenomenology. Therefore a patient with a secondary PKD can be treated like one with primary PKD if the baseline condition does not contraindicate this approach. For instance, for a patient with Wilson disease that presents with PKDs, a trial of carbamazepine is warranted, except if contraindicated. For example, clinical or laboratorial alterations in liver function might preclude the use of carbamazepine. If this is the case, another strategy can be tried.

Paroxysmal dyskinesia may occasionally appear as a secondary phenomenon in various genetic conditions, but the classic idiopathic phenotypes are largely associated with mutations in specific genes reviewed in this chapter. The prevalence of idiopathic paroxysmal dyskinesias is not known, but they are assumed to be rare. Their iconic phenotypes, the possibility of genetic diagnosis, and the often positive response to treatment warrant recognition by any practicing clinician. In this chapter we describe in detail the clinical features of the classic idiopathic paroxysmal dyskinesias and the current management strategies. The online expanded version also includes a review of the historical context and often confusing terminology used to describe paroxysmal dyskinesias over the years, under a section named "Historical context and terminology." An expanded section, "Other phenotypes", elaborates further on the clinical description of rarer atypical forms of genetic paroxysmal dyskinesias as well as the expanded phenotypic spectrum of manifestations of the paroxysmal dyskinesia genes, including episodic ataxias, benign paroxysmal torticollis of childhood, paroxysmal tonic upward gaze and recurring hemiplegia (e.g., hemiplegic migraine and alternating hemiplegia of childhood).

## HISTORICAL CONTEXT AND TERMINOLOGY

The variations in terminology used for these basic three forms have been a cause for confusion and are reviewed in the expanded online edition under this section. The current classification is largely based on the one proposed by Demirkiran and Jankovic in 1995. This classification is based primarily on the precipitating triggers, and divides the paroxysmal dyskinesias into kinesigenic, nonkinesigenic, exertion-induced, or hypnogenic (also known as paroxysmal nocturnal dystonia of sleep). After this initial categorization, they proposed a secondary categorization based on duration of the episodes into short (<5 minutes) or long (>5 minutes) and a tertiary classification based on etiology: idiopathic (familial vs. sporadic) and secondary.

## CLASSIC PHENOTYPES OF PAROXYSMAL DYSKINESIA

Table 94-1 summarizes the main clinical features that characterize the classic phenotypes of PKD, PNKD, and PED. We now describe in detail the clinical and genetic features of these conditions, along with management strategies, including diagnosis and treatment. A review of more than 500 cases of

**TABLE 94-1** Clinical Features of Paroxysmal Dyskinesias

Features	Paroxysmal Nonkinesigenic Dyskinesia (PNKD)	Paroxysmal Exercise-induced Dyskinesia (PED)	Paroxysmal Kinesigenic Dyskinesia (PKD)
Age of onset*	Variable, up to teenage onset	Variable, up to young adult onset	Usually in the first decade of life
Disease course	Improvement in adulthood and with ageing	Variable	Improvement or remission by 4th decade of life
Attacks duration	Minutes to hours	Minutes to hours	Seconds to minutes
Attacks frequency	Multiple attacks per month	Variable	Multiple daily attacks
Triggers	Alcohol, caffeine, emotional stress or excitement, fatigue, sleep deprivation	Prolonged exercise, fasting, emotional stress	Sudden voluntary movements (sprinting, standing up, etc.)
Main gene associated	<i>PNKD</i>	<i>SLC2A1</i> , <i>Parkin</i> , <i>GCH1</i>	<i>PRRT2</i>

*GCH1*, GTP cyclohydrolase 1; *SLC2A1*, solute carrier family 2 member 1 (also known as GLUT1).  
\*For most cases of primary paroxysmal dyskinesia, onset is in childhood.

genetically proven paroxysmal dyskinesia has been recently published (Erro et al., 2014).

## Paroxysmal Kinesigenic Dyskinesia

### Clinical Features

PKD is often inherited as an autosomal-dominant trait, but one quarter of the cases are sporadic. It is the most common form of primary paroxysmal dyskinesia, and most neurologists are likely to come across a couple of patients throughout their practicing years. Males are affected more often than females. The age of onset is 5 to 15 years in familial cases but may be variable in sporadic cases. The attacks are typically precipitated by startle or making a sudden movement after a period of rest. There is often a refractory period after an episode, during which a sudden movement will not provoke an attack. The attacks may occur up to 100 times per day, but most patients will report a few per day. The duration is typically a few seconds to a few minutes, usually less than a minute, but longer-lasting attacks may occur. The movements may be preceded by an abnormal sensation in the affected limbs, and some patients may only have an abnormal sensation without developing involuntary movements. Most patients have dystonia combined with choreiform movements, but some have a combination of chorea, dystonia, and, rarely, ballism. The attacks may be limited to one side of the body or even one limb. The attacks decrease in frequency during adulthood and usually subside or become very mild by the fourth decade of life. For a series of videos of attacks, see [Silveira-Moriyama et al. \(2013\)](#). The classic trigger is sudden voluntary movement after a period of rest or being still. Examples include quickly standing up from a chair, or quickly running after standing for a period of time. The well-known maneuver of asking the patient to quickly stand up after sitting down for a few minutes might elicit attacks during a clinic visit and is often found to be useful, although not very sensitive. The majority of patients will also report spontaneous nonkinesigenic attacks in association, and so their presence should not discourage the diagnosis of PKD.

### Genetics

After the initial clinical descriptions mentioned in the historical background section, it became evident that PKD often had a hereditary nature. In addition, in some of the families with PKD a number of patients presented with infantile seizures similar to benign familial infantile convulsions (also called benign familial infantile seizures, BFIS; OMIM No. 605751), and this association was called infantile convulsions and paroxysmal choreoathetosis (ICCA; OMIM No. 602066). In 1997

ICCA was linked to the pericentromeric region of chromosome 16, and it was observed that individuals homozygous for the disease haplotype in the pericentromeric region of chromosome 16 had earlier age of onset and higher frequency of attacks than heterozygous family members. Later on, PKD without infantile convulsions was also linked to the pericentromeric region of chromosome 16, except for one single family with PKD linked to 16q in another region. It became clear that the ICCA locus was linked to other families with PKD, ICCA, or both. In 2011 mutations in the proline-rich transmembrane protein 2 gene (*PRRT2*) were identified as the cause of ICCA, BFIS and also PKD linked to chromosome 16. Soon after, the same *PRRT2* mutations were found to be associated with hemiplegic migraine, and also one case of benign paroxysmal torticollis and a few of episodic ataxia.

Numerous different pathogenic mutations have been reported in *PRRT2*, most of which are deletions, nonsense and occasionally missense, suggesting haploinsufficiency. The most commonly reported is an insertion (c.649dupC) that leads to a premature stop codon and a consequently truncated protein. This mutation has been associated with various different phenotypes within the spectrum, posing a challenge to clear-cut genotype–phenotype correlations, except for more severe homozygous cases. The few families in which *PRRT2* mutations have been found in homozygosity show a more severe phenotype often involving earlier onset of attacks, coexistence of paroxysmal dyskinesia and episodic ataxia, and cognitive changes, including intellectual disability. Interestingly, a previous study using next-generation sequencing and homozygosity mapping in familial intellectual disability had associated *PRRT2* with nonsyndromic intellectual disability in one family. *PRRT2* codes for a transmembrane protein that is highly expressed during developmental stages of the animal brain, and although its specific function is not known, protein network studies suggest it is associated with synaptic transmission. The homozygous phenotype emphasizes the role of *PRRT2* in brain development. In addition, PKD has also been associated with microdeletions encompassing *PRRT2* in a few cases. In these cases, associated features such as speech delay, intellectual disability, and mild dysmorphic features were described and are likely to be related to neighboring genes.

### Diagnosis

[Bruno et al. \(2004\)](#) proposed a set of clinical criteria for the diagnosis of PKD, which is often useful in clinical practice and is summarized below:

1. Identified kinesigenic trigger of the attacks
2. Short duration of attacks (<1 minute)
3. No loss of consciousness or pain during attacks

4. Exclusion of other organic diseases and normal neurologic examination
5. Control of attacks with phenytoin or carbamazepine, if tried
6. Age at onset between 1 and 20 years, if no family history of PKD

It is important to note that although PNKD and PED are unlikely to have classic kinesiogenic attacks, the opposite is not true: PKD often presents with spontaneous nonkinesiogenic attacks, and attacks might be caused by stress or exercise. In a minority of PKD patients, attacks might be elicited during the clinical visit when patients present sudden movements.

The diagnosis of PKD is made on clinical grounds, but investigation is often warranted to exclude other conditions. In cases with recent onset without a clear family history, brain imaging might be needed to investigate structural brain damage associated with secondary paroxysmal dyskinesias. In most cases EEG can be performed either to rule out epilepsy, or to investigate the coexistence of epilepsy.

In classic cases of PKD, genetic testing can confirm the presence of a *PRRT2* mutation in order to provide the appropriate genetic counseling. Because of the expanding phenotypic spectrum, atypical cases might also be tested for *PRRT2* mutations. In many centers worldwide, panels of genes associated with paroxysmal motor phenomena will include *PRRT2* along with other genes described later in this chapter. Microarray analyses to screen for microdeletions encompassing 16p11.2 might be indicated when additional features suggest microdeletions.

## Treatment

PKD responds well to anticonvulsants, including phenytoin, carbamazepine, phenobarbital, and levetiracetam. The dose required is usually less than the standard anticonvulsant dosage and familial PKD is exquisitely responsive to carbamazepine. It is possible that *PRRT2*-related PKD (as opposed to cases in which gene testing is negative) might indicate a better response to low doses of carbamazepine, but gene testing is not needed for therapeutic management. Carbamazepine is usually well tolerated in low doses, but in Asian populations human leukocyte antigen (HLA) testing for haplotypes associated with carbamazepine-induced pharmacodermia may be useful to guide anticonvulsant therapy. With or without treatment, the attacks tend to diminish during adulthood and individuals with the classic phenotype do not have progressive neurologic deficits.

## Paroxysmal Nonkinesiogenic Dyskinesia

### Clinical Features

PNKD is usually inherited as an autosomal-dominant trait. Males are affected more often than females, by a ratio of 2:1. The age of onset is usually in early childhood, but attacks may start in the first months of life, or as late as young adulthood. The frequency varies from three per day to two or fewer per year. Typical precipitating factors are alcohol, caffeine, fatigue, and emotional excitement. Alcohol and caffeine are the most consistently reported. Attacks might be preceded by sensory aura (in about half the patients), and an episode usually starts with involuntary movements of a single limb or hemibody, but tends to spread to involve all extremities and the face. The usual duration is minutes to 3 to 4 hours, but shorter and longer episodes have been reported. Attacks may be relieved by sleep. During the attack, the patient may be unable to communicate, but remains conscious and continues to breathe normally. Some individuals have mostly dystonia, whereas others have predominantly chorea but most have a combination of both.

For detailed and systematized clinical information of more than 40 cases of PNKD, see [Bruno et al. \(2007\)](#).

## Genetics

In 1997 PNKD was linked to chromosome 2q and in 2004 mutations of the myofibrillogenesis regulator 1 gene (then called the *MR1* gene, and now called the *PNKD* gene) were found to cause the majority of PKND cases. [Bruno et al. \(2007\)](#) compared 8 kindreds with detailed clinical information on 49 subjects harboring PNKD mutations to 6 kindreds without the mutations and found the following criteria to be predictive of positive testing for PNKD mutations:

1. Hyperkinetic involuntary movement attacks, with dystonia, chorea, or combination of these, typically lasting 10 minutes to 1 hour, but up to 4 hours
2. Normal neurologic examination results between attacks, and exclusion of secondary causes
3. Onset of attacks in infancy or early childhood
4. Precipitation of attacks by caffeine and alcohol consumption
5. Family history of movement disorder meeting criteria 1 through 4

*PNKD* mutation carriers studied by [Bruno and colleagues \(2007\)](#) presented the classic features described by Mount and Reback, had onset in childhood (average 4 years  $\pm$  4.6 years), reported frequency up to once a week at least at some point in life, and were likely to respond to benzodiazepines and improve with ageing. Migraine was a frequent comorbidity, but none of 49 patients had epilepsy.

The function of the PNKD protein is not well known. PNKD is expressed in the brain, and pathogenic mutations lead to abnormalities of postprocessing (cleavage and stability) of the PNKD protein affecting the cell glutathione antioxidant system in animal models. In addition, PNKD might be linked with an enzyme that metabolizes methylglyoxal, which is found in coffee and alcoholic beverages, possibly explaining why they act as triggers in PKND.

In addition to PNKD, another gene has been associated with PNKD in a single family that had PNKD and generalized epilepsy. The locus was therefore named *generalized epilepsy and paroxysmal dyskinesia* (GEPD), and a mutation was found in the gene *KCNMA1* segregating with the phenotype. This gene codes for the pore-forming alpha subunit of a specific potassium channel activated both by intracellular Ca(2+) ions and by membrane. Although this remains a possibility in cases of PED with concomitant generalized epilepsy, there has been only a single description of pathogenic mutation, and therefore screening for *PRRT2* mutations, which can also cause nonkinesiogenic episodes as well as epilepsy, might be warranted in most patients.

## Diagnosis

The clinical criteria proposed by [Bruno et al. \(2007\)](#) help to make the diagnosis, in particular when associated with video-recordings of attacks, either in telemetry or homemade. PNKD is less prevalent than PKD, and the attacks are very unlikely to be witnessed by the physician. Except for the positive diagnosis of *PNKD* mutations, PNKD is a clinical diagnosis. EEG may be warranted to exclude epileptic seizures. Imaging may be warranted to rule out structural damage to the basal ganglia causing secondary paroxysmal dyskinesia. Metabolic testing might be indicated based on the age and associated features. In older children and teenagers, psychogenic movement disorder is an important differential. Because various genetic causes of paroxysmal dyskinesia can cause nonkinesiogenic attacks, in atypical cases genetic testing by a panel can be indicated, although empirical management should be performed regardless.

## Treatment

Management of PNKD relies on avoidance of precipitating factors, such as alcohol, caffeine, and stress. Several medications have been used, including clonazepam, haloperidol, oxazepam, acetazolamide, and anticholinergics. Anticonvulsants are ineffective in most cases of PNKD, including those that are mutation negative and positive. In PNKD mutation-positive cases, clonazepam is likely to be helpful, taken as both prophylactic and abortive agent. In Bruno et al (2007) 97% (34/35) of patients who tried benzodiazepines responded. Other medications tried included a variety of anticonvulsants (including carbamazepine and phenytoin) and haloperidol, all without a consistent response. Deep-brain stimulation surgery might be considered in selected cases with significant impairment of quality of life, given that two reports exist of successful treatment of PNKD with this technique.

Prognosis is variable and depends on the underlying cause, but in familial cases, neurologic function between the attacks is normal, even after repeated attacks, and the frequency of attacks decreases with age.

## Paroxysmal Exertion-Induced Dyskinesia

### Clinical Features

PED is usually inherited in an autosomal-dominant fashion, although sporadic cases have been described. The characteristic feature of PED is the triggering of attacks by sustained exercise (minutes to hours of exercise, as opposed to the sudden movements in PKD). Stress and fasting have also been described as additional triggers in these patients, although their presence as triggers alone does not characterize PED, remitting more to PNKD. The frequency varies from one per day to two per month. The usual duration is 5 to 30 minutes and therefore an intermediate duration between what is expected of PKD (seconds to minutes) and PNKD (minutes to hours). Unlike PKD and PNKD, which are more clinically homogeneous and in which a significant proportion of the cases (more than half) have genetic cause, PED is more likely to be an umbrella phenotype encompassing manifestations of different conditions.

### Genetics

Many cases of PED remain idiopathic, although cases of the classic form of PED have been linked to mutations in the *SLC2A1* gene. *SLC2A1* codes for a transmembrane protein that facilitates glucose transport, known as GLUT1, and its mutations cause a range of neurologic manifestations, including a well-recognizable form of neonatal epileptic encephalopathy, and various other pleomorphic manifestations, including epilepsy and movement disorders. For a review of *SLC2A1* manifestations, see Pearson et al. (2013). De Giorgis and colleagues (2015) observed that in a cohort of 22 patients with GLUT1 deficiency syndrome and confirmed *SLC2A1* mutations, at least half presented with PED, making it a common feature for *SLC2A1*. GLUT1 facilitates transport of glucose across the blood-brain barrier, and mutations usually lead to loss of function causing low glucose levels in the CNS, which can be detected in many patients with GLUT1 deficiency syndrome as hypoglycorrhachia providing a useful diagnostic clue.

In addition to classic PED linked to GLUT1 deficiency syndrome, cases of exercise-induced paroxysmal dyskinesia have also been described in dopamine deficiency syndromes, more specifically in dopa-responsive dystonia caused by mutations in *GCH1* and levodopa-responsive young-onset parkinsonism caused by *PARKIN* mutations. It is likely that the paroxysmal episodes have a different pathophysiology to classic PED and are phenocopies. In favor of this is the fact that the episodes are usually dystonic and localized (although this is also seen

in PED), and they are often associated with fatigue, instead of being truly exercise induced. Nevertheless, there is definitely an overlap with classic PED features, and two cases of response to levodopa in PED caused by *SLC2A1* mutations have been described, pointing out a possible pathophysiological overlap between the functions of these three genes.

### Diagnosis

Like other paroxysmal dyskinesias, PED must be differentiated from secondary forms of paroxysmal dyskinesia, and brain imaging, EEG, and biochemical studies are often needed. Most cases of PED are still idiopathic, but the positive diagnosis can be made by finding hypoglycorrhachia (which is not sensitive but is specific for *SLC2A1* mutations) and by encountering mutations in *SLC2A1*, *GCH1*, or *PARKIN* on genetic testing. Given that the coexistence of seizures in individuals suffering from *SLC2A1*-related PED is high, they can also be considered a diagnostic clue. Given the growing availability of diagnostic gene panels and the genetic heterogeneity that marks paroxysmal movement disorders, testing by a gene panel including genes associated with episodic motor phenomena might be warranted.

### Treatment

Avoidance of prolonged exercise may help diminish the frequency of attacks and might be recommended given that drug therapy is often ineffective in PED. There are isolated and conflicting reports of response to different strategies, including carbamazepine, acetazolamide, gabapentin and levodopa. In the patients from Di Giorgi and colleagues who were put on a classical 3:1 ketogenic ratio diet (i.e., 3 g lipids:1 g carbohydrates + proteins), later reduced to 1.8:1 ratio, there was a noticeable response of PED episodes, which disappeared in a few weeks, compatible with previous reports of response of PED to the ketogenic diet found in the literature. Nevertheless, the practical challenges in effectively implementing this diet make it a second-line option in isolated PED. One recent report of four patients with GLUT1 deficiency syndrome suggested the use of a modified Atkins diet, which is more tolerated, as an alternative to ketogenic diet, but further studies are needed. For a review of GLUT1 deficiency syndrome and its phenotypic spectrum, please see Chapter 76.

## OTHER PHENOTYPES

### Paroxysmal Hypnogenic Dyskinesia

For a review of the current knowledge about paroxysmal hypnogenic dyskinesia, please refer to the online material. This condition, previously thought to be a movement disorder and now mostly believed to be a form of epilepsy, is discussed in detail in the online expanded edition under this same section.

For a brief review of nocturnal frontal lobe epilepsy (NFLE), see Nobili (2007).

### Genotype–Phenotype Association in Paroxysmal Dyskinesia

In addition to abnormalities in *PRRT2*, *PNKD*, *SLC2A1*, *GCH1*, and *PARKIN*, a series of other genetic disorders can cause paroxysmal episodes of dyskinesia. Usually in these conditions, there are also other features, which can point toward the genetic diagnosis. Alternating hemiplegia of childhood, which is caused by mutations in the *ATP1A3* gene, often presents with associated episodes of paroxysmal dyskinesia. This gene also causes rapid-onset dystonia parkinsonism (RDP), a juvenile condition in which dystonia and/or parkinsonism develops acutely over the course of hours or days, and

remains stable thereafter. Patients with alternating hemiplegia or childhood or RDP can present with paroxysmal dyskinesia, although these are thought to be rare in RDP. Attacks can be nonkinesigenic or exercise-induced, and although mainly dyskinesia can also present with choreiform movements.

*SLC2A1* mutations can manifest with a wide range of clinical phenotypes, both chronic and paroxysmal, of which PED is a common (and relatively mild) feature. Some patients present with more chronic pyramidal and extrapyramidal disorders (such as spasticity, dystonia, or ataxia) or cognitive decline (a spectrum from clear-cut encephalopathy to varying degrees of cognitive difficulties) in addition to epilepsy, whereas others can have milder phenotypes with isolated PED, or with PED and combined epilepsy. The locus originally reserved for *DYT9*, called paroxysmal choreoathetosis/spasticity, was later found out to correspond to *SLC2A1*, and it is now clear that these manifestations fall within the spectrum of *SLC2A1* disease.

In addition to genetic heterogeneity and variable expressivity, there is ample phenotypic pleiotropy in the paroxysmal dyskinesia genes. Phenotypic pleiotropy is the name given to the fact that one single gene, or even a single gene mutation, can influence various different phenotypic traits. *PRRT2*, for instance, is a gene with a very wide phenotypic pleiotropy, and can cause isolated PKD, isolated BFIS, combined ICCA, various forms of epilepsy of varied age of onset, hemiplegic migraine, episodic ataxia, benign paroxysmal torticollis, progressive ataxia, and intellectual disability. This particular spectrum of manifestations overlaps largely with that of *CACNA1A*, the gene that is associated with episodic ataxia type 2.

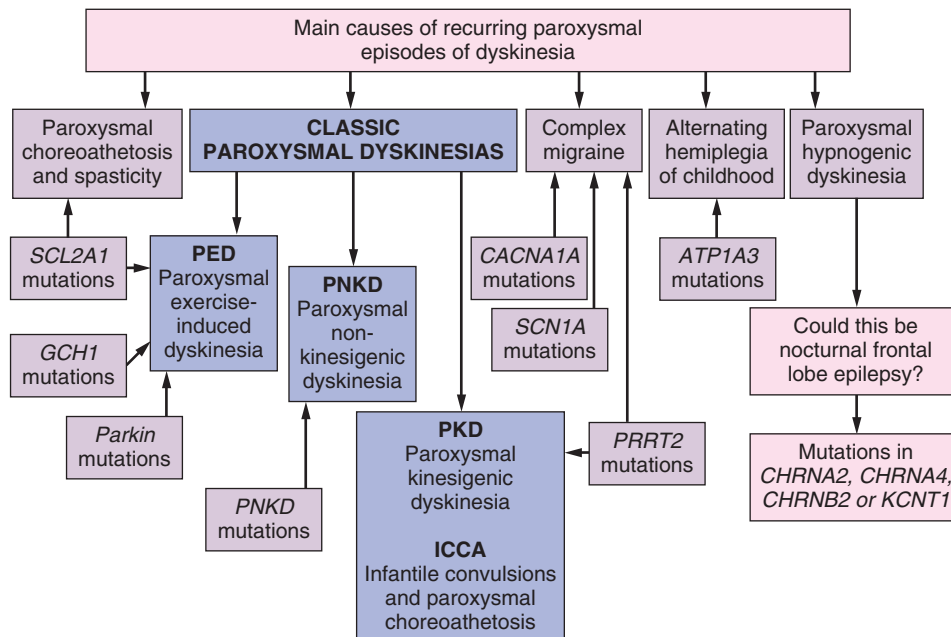

Figure 94-1 shows how various genes can cause paroxysmal episodes of dyskinesia. The overlap in clinical presentations and expression mean that it is reasonable that genetic testing with gene panels with all these genes will be suitable for the investigation of paroxysmal dyskinesia patients.

These overlapping phenotypes between the genes for paroxysmal dyskinesias, episodic ataxias, and some other

paroxysmal conditions (such as alternating hemiplegia) have been used as a rationale to justify empirical treatment of paroxysmal dyskinesias with some of the drugs used to treat these other conditions, and reports of successful treatment with rescue therapies are progressively appearing in the literature. It is possible that, in the future, treatment will be guided by the underlying genetic basis of the condition, but for the moment there is not enough evidence to support this as first line. Table 94-2 summarizes the current main treatment strategies used for paroxysmal dyskinesias.

**TABLE 94-2** Treatment Strategies for Paroxysmal Dyskinesias

Features	Main Treatment Strategies
Paroxysmal nonkinesigenic dyskinesia (PNKD)	Variable response to treatment. Benzodiazepines can be tried and many report benefit from clonazepam. Unlikely to respond to antiseizure medications. Anecdotal reports of other treatments being successful. Usually improves or disappears with age.
Paroxysmal exercise-induced dyskinesia (PED)	Variable response to pharmacologic treatment, which can include benzodiazepines, acetazolamide, ketogenic diet, antiseizure medications, and levodopa. Variable course can persist into adulthood. When caused by <i>GCH1</i> and <i>Parkin</i> can evolve into dystonia or parkinsonism, which is responsive to levodopa.
Paroxysmal kinesigenic dyskinesia (PKD)	Reassurance. Pharmacotherapy with antiseizure medications. Carbamazepine is the most widely used, and many report successful use of phenytoin. Other antiepileptic drugs can be tried. Usually subsides by 4th decade of life.

**Figure 94-1.** Main genetic causes of recurring paroxysmal episodes of dyskinesia. *ATP1A3*, ATPase, Na<sup>+</sup>/K<sup>+</sup> transporting, alpha-3 polypeptide; *CACNA1A*, calcium channel, voltage-dependent, p/q type, alpha-1a subunit; *CHRNA2*, A4 and B2, cholinergic receptor, neuronal nicotinic, polypeptide alpha 2, alpha 4, beta 2; *GCH1*, GTP cyclohydrolase 1; *KCNT1*, potassium channel, subfamily t, member 1; *PRRT2*, proline-rich transmembrane protein 2; *SCN1A*, sodium channel, neuronal type I, alpha subunit; *SLC2A1*, solute carrier family 2 member 1 (also known as *GLUT1*).

The presence of a movement disorder in an infant usually raises concerns about an underlying serious, progressive, degenerative, or metabolic disease. However, many movement disorders are benign and related to normal stages of development. In fact, it may be difficult to justify the term “disorder” in describing many of these movements. The developing nervous system may produce a variety of motor patterns that would be pathologic in older children and adults, but are simply a manifestation of central nervous system immaturity. Like many of the neonatal reflexes (e.g., grasping, rooting, placing, tonic neck reflexes), these motor patterns disappear as neuron connectivity and myelination mature. Examples include the minimal chorea of infants, the mild action dystonia commonly seen in toddlers, and the overflow movements that are seen in young children. Other transient or developmental movement disorders of infancy may be manifestations of abnormal neural function, but do not correlate with serious underlying pathology. These are typically associated with complete resolution of the abnormal movements and, ultimately, normal development and neurologic function. It is important to recognize these transient developmental movement disorders of infancy to distinguish them from more serious disorders, and to be able to provide reassurance when possible. Correct identification of this group of disorders may decrease the need for additional diagnostic testing. Often these disorders can be distinguished from a pathologic movement disorder on the clinical basis alone. The phenomenologies of movement disorders of infancy include myoclonus, stereotypic movements, tremors, and dystonia or posturing (Table 95-1).

### Benign Neonatal Sleep Myoclonus

Benign neonatal sleep myoclonus was first described in 1982 and is characterized by repetitive myoclonic jerks occurring during sleep (Maurer, Rizzi, Bianchetti, and Ramelli, 2010). The myoclonic jerks are typically in the distal more than proximal limbs, and more prominent in the upper than the lower extremities. In some cases, jerks of axial or facial muscles can be seen, but involvement of the facial muscles is more rare. The myoclonus can be focal, multifocal, unilateral, or bilateral. The movements can be rhythmic or nonrhythmic. Typically, the movements occur in clusters of jerks at 1 to 5 Hz over a period of several seconds.

The prevalence of benign neonatal sleep myoclonus is 0.8 to 3 cases per 1000 births (Maurer et al., 2010). Benign neonatal sleep myoclonus begins during the first week of life, diminishes in the second month, and is usually gone before 6 months of age, but has been reported to persist as long as 3 years in one patient and 4 years in another patient. The movements are most likely to occur during quiet (non-REM) sleep but have been described in all sleep stages. Waking the baby causes the movements to abruptly cease. The differential diagnosis of benign neonatal sleep myoclonus includes benign neonatal seizures, neonatal status epilepticus, typical hypnic jerks, and jitteriness. Episodes of myoclonus are not associated

with eye deviation, oral movements, apnea, color changes, or crying, which can distinguish them from seizures (Maurer et al., 2010). Neurologic examination is normal. Ictal and interictal EEG are typically normal. Episodes of myoclonus can be exacerbated by treatment with benzodiazepines. Episodes of myoclonus have been described to be triggered by rocking motion, tactile stimulation (Maurer et al., 2010), and riding in a car. Benign neonatal sleep myoclonus has been described to occur at a higher incidence in opioid-dependent mothers. Treatment is not required, and neurologic outcome is normal.

Familial cases of benign neonatal sleep myoclonus have been described, with some pedigrees showing an autosomal-dominant inheritance pattern. It was found to be nonallelic to KCNQ2 and KCNQ3, the most common causes of benign familial neonatal seizures, which present at the same age as benign neonatal sleep myoclonus.

### Benign Myoclonus of Early Infancy

Benign myoclonus of early infancy was first described in 1977 as a syndrome that was clinically indistinguishable from West syndrome, but these children had normal EEGs and a good prognosis. Benign myoclonus of early infancy is characterized by episodes of myoclonic spasms involving flexion of the trunk, neck, and extremities in a manner resembling the infantile spasms of West syndrome. The myoclonic spasms typically occur in clusters. In some cases, they involve a shuddering movement of the head and shoulders; in others, the movements of the trunk and limbs are extensor. The clinical spectrum of movements has been expanded to include myoclonic jerks, nonepileptic spasms, brief tonic contractions, shuddering or shivering, and nonepileptic atonic events or negative myoclonus, or a combination of these motor phenomena (Caraballo et al., 2009). There is no change in consciousness during the spells.

The onset of these spells is usually between ages 3 and 9 months, but they may begin in the first month of life. The spells usually cease within 2 weeks to 8 months of onset, but may persist for 1 to 2 years. In most cases, the episodes cease during the second year of life (Caraballo et al., 2009). Both ictal and interictal EEGs are normal. The movements occur only in the awake state. There is no known genetic cause, and cases are sporadic.

The differential diagnosis of benign myoclonus of infancy includes West syndrome, myoclonic epilepsy syndromes, shuddering attacks, benign neonatal sleep myoclonus, and hypnic jerks. Unlike benign neonatal sleep myoclonus, the movements in benign myoclonus of early infancy only occur in the waking state. Both ictal and interictal EEGs are normal, distinguishing this entity from infantile spasms and myoclonic epilepsy syndromes. An EEG is usually needed to exclude infantile spasms or infantile myoclonic epilepsy syndromes. Differentiating benign myoclonus of early infancy from epileptic syndromes of infancy is essential to avoid unnecessary extensive diagnostic workup and treatment with

**TABLE 95-1** Movement Disorders of Infancy

Disorder	Age at Onset	Age at Resolution	Key Features
Benign neonatal sleep myoclonus	<1 month	6 months	Occurs exclusively in sleep
Benign myoclonus of early infancy	3–9 months	<2 years	Normal ictal and interictal EEG
Jitteriness	<1 week	<6 months	Stimulus sensitive Suppressible
Shuddering	Infancy to early childhood	Variable	Predictable triggers Preserved consciousness
Paroxysmal tonic upgaze	<1 year	1–4 years	Sustained upward or, less often, downward gaze
Spasmus nutans	3–8 months	Within a few months	Triad of head tremor, nystagmus, and torticollis
Head nodding	<3 years	Variable	Occurs while sitting or standing, suppressible
Benign paroxysmal torticollis	<1 year	<5 years	Family history of migraines
Benign idiopathic dystonia of infancy	<5 months	<1 year	Segmental dystonia
Infantile masturbation	<3 years	Variable	Characteristic position, distractible

unneded, potentially harmful medications, and to provide an accurate prognosis. Treatment of benign myoclonus of early infancy is not needed, and movements are self-limited. Development and neurologic outcomes are normal.

## Jitteriness

Jitteriness is the most common movement disorder observed in the neonatal period. Jitteriness manifests as generalized, symmetric, rhythmic oscillatory movements that resemble tremor or clonus. Jitteriness can involve the chin and/or extremities. Jitteriness is highly stimulus sensitive. It can be precipitated by startle and suppressed by gentle passive flexion of the limb. Unlike seizures, there are no associated abnormal eye movements or autonomic changes, and the EEG is normal.

Jitteriness is divided into four categories: no jitteriness if observed in sleep only, mild if only when irritable or crying, moderate if when in the awake state, and extreme if during several behavioral states. Up to 50% of term infants exhibit jitteriness during the first few days of life, especially when stimulated or crying. Jittery movements have been noted to occur in sleep (Shuper et al., 1991). Jitteriness usually disappears shortly after birth, but can persist for months or recur after being gone for several weeks (Shuper et al., 1991). Jitteriness usually resolves by a year of age but may persist until 2 years of age. Those with mild jitteriness outgrow their symptoms earlier than those with more severe jitteriness. Jitteriness has been associated with mildly increased muscle tone, hyperactive deep tendon reflexes, and a low threshold to startle (Shuper et al., 1991). Jitteriness has also been associated with infants who are more difficult to console and who are less visually alert. Persistent jitteriness has been associated with hypoxic-ischemic injury, intracerebral hemorrhage, hypocalcemia, hypoglycemia, hypomagnesaemia, and drug withdrawal, which may produce neuronal hyperirritability. Jitteriness has been described to co-occur with spasmus nutans.

Idiopathic jitteriness may be related to a maturational phenomenon rather than cerebral irritability. Peripheral and central mechanisms may contribute to jitteriness in infancy. There may be an increased sensitivity of the muscle spindle afferent endings that causes a response to a tiny stretch of the muscle, leading to jitteriness. With maturation of the inhibitory tracts in the central nervous system, the jitteriness disappears (Shuper et al., 1991). It has also been suggested that temporarily elevated levels of circulating catecholamines may contribute to jitteriness. Idiopathic jitteriness is usually associated with normal development and neurologic outcome. The

outcome of infants with symptomatic jitteriness depends on the underlying cause. There is no treatment needed.

## Shuddering

Shuddering episodes are characterized by periods of rapid tremor of the head, shoulders, and arms that resemble shivering (Kanazawa, 2000). Shuddering is often accompanied by facial grimacing. During a spell, there is no change in consciousness or color change. The episodes last several seconds and can occur up to 100 times a day, with high interindividual and intraindividual variability. Spells are often triggered by excitement, frustration, embarrassment, or surprise. They usually occur in the sitting or standing position. Onset is in infancy or early childhood, but can occur as late as 10 years of age. Ictal and interictal EEGs are normal. Shuddering episodes typically abate as the child grows older. The differential diagnosis of shuddering attacks includes benign neonatal sleep myoclonus, jitteriness, epilepsy, benign myoclonus of infancy, and tremor. The preservation of consciousness, predictable triggers, ability to abort an episode when distracted by a parent, and normal EEG distinguish this entity from seizures. However, frontal lobe epilepsy secondary to focal cortical dysplasia has been described to have a similar semiology to shuddering attacks, but onset of spells was at age 6. Similarity to benign myoclonus of early infancy has been suggested (Kanazawa, 2000), but shuddering differs in the phenomenology of the movement and is better classified as tremor than myoclonus. There may be similarity or overlap between shuddering episodes and stereotypies. Stereotypies are rhythmic, patterned, and repetitive involuntary movements. Similar features include the age of onset in infancy and early childhood, rhythmicity, presence of facial grimacing, and precipitating factors. Stereotypies differ in that they tend to last longer (minutes rather than seconds) and persist into later childhood and adulthood. An association with essential tremor has been described, but further studies have not supported this association. The pathophysiology of shuddering attacks is unknown. The prognosis for development and neurologic function is uniformly good. Treatment with propranolol has been described to be effective in a single patient, but treatment is generally not needed.

## Paroxysmal Tonic Upgaze of Infancy

Paroxysmal tonic upgaze of infancy is a disorder characterized by repeated episodes of upward gaze deviation first described

in 1988 (Ouvrier and Billson, 1988). The gaze deviation can be sustained or intermittent during an episode, sometimes associated with flexion of the neck apparently compensating for abnormal eye position. The typical episode lasts for a few hours but can persist for days. Attempts to look downward are accompanied by down-beating nystagmus. Horizontal eye movements are normal during an episode. Spells may resolve with sleep and be aggravated by fatigue or infection. There is a suggestion that cases with a later onset have a better prognosis. Two infants with paroxysmal down gaze have been described.

In follow up of children with paroxysmal tonic upgaze of infancy, neurologic and ophthalmologic abnormalities have been described. Ocular abnormalities include persistent gaze-evoked nystagmus, hypometric saccades, and strabismus. Neurologic abnormalities include cognitive disorders, structural lesions, epilepsy and ataxia although some infants may only have ataxia during the episodes (Ouvrier and Billson, 1988). Cognitive disorders have been noted in about 50% of children, with the majority having mild deficits. Structural MRI abnormalities include periventricular leukomalacia (Ouvrier and Billson, 1988), hypomyelinating leukoencephalopathy, vein of Galen malformation, and pinealoma. Paroxysmal tonic upgaze of infancy has been described to coexist with absence epilepsy, worsening with valproate treatment in one instance and improving in another, and with febrile seizures. This suggests the possibility that it can be the marker of an underlying neurologic or developmental abnormality and may not always have a positive outcome.

The pathophysiology may be related to immaturity of the cortico-mesencephalic control of vertical gaze or from a lesion of the mesencephalic region. Familial cases have been described with both autosomal-dominant and autosomal-recessive inheritance. Associations with *de novo* mutation in *CACNA1A* and partial tetrasomy of chromosome 15 have been described in case reports. Additional laboratory evaluation is usually unrevealing. There is no specific treatment, but there have been a few reports of improvement with L-DOPA treatment (Ouvrier and Billson, 1988).

## Spasmus Nutans

Spasmus nutans is a condition beginning in late infancy (3–8 months) that is characterized by a slow head tremor (approximately 2 Hz) that can be horizontal (“no-no”) or vertical (“yes-yes”). The head movements are accompanied by a small-amplitude nystagmus that can be dysconjugate, conjugate, or uniocular. The nystagmus is typically pendular, with high frequencies (up to 15 Hz) and low amplitudes (0.5–3 degrees). When the child is looking at an object, the nodding or nystagmus may increase; if the head is held, the nystagmus typically increases. These observations have led to the suggestion that the head nodding is compensatory for the nystagmus. Torticollis by clinical observation and electrooculography has been shown to dampen the nystagmus, suggesting that this also is compensatory. Spasmus nutans generally resolves within several months, but the majority of patients continue to have a fine subclinical nystagmus until at least 5 to 12 years of age (Gottlob, Wizov, and Reincecke, 1995). Long-term outcome for visual acuity is good.

The differential diagnosis of nystagmus in infancy includes congenital nystagmus, retinal abnormalities, and nystagmus in association with an optic glioma. Spasmus nutans most commonly must be distinguished from congenital nystagmus. Congenital nystagmus usually begins earlier than spasmus nutans, starting in newborn period or before 6 months of age. Congenital nystagmus is usually bilaterally symmetric, whereas spasmus nutans is often asymmetric. Congenital nystagmus

persists beyond a few months. Visual acuity is abnormal in about 90% of children with congenital nystagmus. Although these features are useful in distinguishing congenital nystagmus from spasmus nutans, some children who clinically appear to have spasmus nutans at the time of presentation have been found to have retinal abnormalities on electroretinography (ERG).

Neuroimaging abnormalities, including tumor and aplasia of the cerebellar vermis, have been described in patients with spasmus nutans, but this is a rare association. Children found to have optic nerve gliomas or suprasellar tumors often have additional findings on examination, including a relative afferent pupillary defect, optic atrophy or optic nerve swelling, macrocephaly, café au lait spots, coexistent neurologic dysfunction or emaciation. It has been noted that spasmus nutans resolved spontaneously in a child with a chiasmal glioma. The patient with cerebellar vermis hypoplasia also had oculomotor apraxia. Routine neuroimaging in the absence of other evidence for intracranial pathology has limited yield, but the possibility of a mass lesion or destructive process in the posterior fossa must be considered.

## Head Nodding

Head nodding without accompanying nystagmus can occur as paroxysmal events in older infants and toddlers. These head movements can be lateral (“no-no”), vertical (“yes-yes”), or oblique. The episodes may occur several times per day. The frequency (1–2 Hz) is slower than that of shuddering. The movements do not occur when the child is lying down, but can occur in the sitting or standing position. Older children describe an inability to suppress the movement (DiMario, 2000). The movements typically resolve within months, but can persist longer. Some children with head nodding have a prior history of shuddering spells; a few have been noted to have dystonic posturing of the legs when concentrating; others may have a family history of essential tremor (DiMario, 2000). A case of head nodding has been described in an 8-month-old with Down syndrome. Typically, development and neurologic outcomes are unaffected by this condition. Remission is spontaneous and treatment is not needed. The differential diagnosis of head nodding includes spasmus nutans (discussed earlier), stereotypies, and bobble-head syndrome. Stereotypies can persist through adolescence. Bobble-head syndrome is characterized by a forward-backward head nodding in children younger than 5 and is most often caused by a tumor or lesion of the third ventricle, suprasellar arachnoid cyst, or aqueductal stenosis.

## Benign Paroxysmal Torticollis

Benign paroxysmal torticollis is an episodic disorder starting in the first year of life. It typically manifests as a head tilt to one side for a few hours or days. Spells can last as little as 10 minutes or as long as 2 months, but this is uncommon. The torticollis may occur without any associated symptoms, or may be accompanied by pallor, vomiting, irritability, or ataxia. Additional findings may include tortipelvis, persistence in sleep, and upper limb dystonia (Rosman, Douglass, Sharif, and Paolini, 2009). Often there is no trigger for the events. Episodes typically recur with some regularity, initially up to twice a month then become less frequent as the child grows older. The spells abate spontaneously, usually by 2 to 3 years of age, but always by age 5. The child is normal between spells. However, gross motor delay and fine motor delay have been noted in these children, which in some cases did resolve (Rosman et al., 2009). Interictal and ictal EEGs are normal. No treatment has been shown to be effective.

It has been suggested that benign paroxysmal torticollis is a migraine variant. There is often a family history of migraine. Some older children complain of headache during a spell, and many children go on to develop typical migraine after they have “outgrown” the paroxysmal torticollis. Children may develop other migraine variants, such as benign paroxysmal vertigo and cyclic vomiting.

Benign paroxysmal torticollis is idiopathic in most cases. It has been described in association with two genetic mutations. Two patients with benign paroxysmal torticollis have been reported from a kindred with familial hemiplegic migraine with ataxia linked to a CACNA1A mutation; an additional CACNA1A mutation was described in another family without a family history of hemiplegic migraine. More recently, mutations in PRRT2 have been associated with benign paroxysmal torticollis. PRRT2 mutations have been associated with other paroxysmal disorders, including paroxysmal dyskinesias, hemiplegic migraine, benign infantile epilepsy, and episodic ataxia. Family members with the same mutation may develop different clinical phenotypes.

The differential diagnosis is broad, and diagnosis of benign paroxysmal torticollis is one of exclusion. Torticollis can be seen as an acute dystonic reaction to medication, as a symptom of a posterior fossa or cervical cord lesion, or as a symptom of cervical vertebral abnormalities, including Klippel–Feil syndrome. It is important to exclude posterior fossa abnormalities, including Chiari syndrome or a mass. In the case of structural lesions, the torticollis tends to be persistent and not paroxysmal. Torticollis can also be a sign of sixth-nerve palsy. Congenital muscular torticollis is another possibility; it is present from birth, is nonparoxysmal, and is associated with palpable tightness or fibrosis of the sternocleidomastoid muscle unilaterally.

## Benign Idiopathic Dystonia of Infancy

Benign idiopathic dystonia of infancy is a rare disorder characterized by a segmental dystonia, usually of one upper extremity, that can be intermittent or persistent. The syndrome usually appears before 5 months of age and disappears by 1 year of age. The characteristic posture is of shoulder abduction, pronation of the forearm, and flexion of the wrist. The posture occurs when the infant is at rest and goes away completely with volitional movement. Occasionally, both arms, an arm and leg on one side of the body, or the trunk can be involved. In some infants, the posture is only apparent with relaxation or in certain positions. In others, it may be present during all waking hours. The rest of the neurologic examination is normal, as are the developmental and neurologic outcomes. Exclusion of progressive dystonia, brachial plexus injury, infantile hemiplegia, and orthopedic abnormalities is important.

## Posturing during Masturbation

Masturbation is a normal behavior that occurs in the majority of children. Although masturbation occurs at all ages and has even been observed in utero, it is most common at about 4 years of age and during adolescence; it occurs in 90% to 94% of males and 50% to 60% of females at some point in their lives (Yang, Fullwood, Goldstein, and Mink, 2005). Frequency and duration are variable. Masturbation in young children may involve unusual postures or movements (Yang et al,

2005), which may be mistaken for abdominal pain or seizures. Masturbatory movements in boys are usually obvious to the observer because of direct genital manipulation. In girls, they are more subtle. Stereotypic motor manifestations include adduction and rubbing together of the thighs, sitting on a hand or foot and rocking, rocking the body against an object asymmetrically, and stereotyped posture or lower limb scissoring. When the movements are accompanied by posturing of the limbs, they are often mistaken for paroxysmal dystonia. Several characteristic features of masturbating girls who present for diagnosis have been identified: (1) onset after 2 months of age and before 3 years of age; (2) stereotyped posturing with pressure applied to the pubic area; (3) quiet grunting, diaphoresis, or facial flushing; (4) episode duration of less than a minute to several hours; (5) no alteration of consciousness; (6) normal findings on examination; (7) cessation with distraction or engagement of the child in another activity.

Multiple diagnostic tests are often performed before the true nature of the behavior is recognized. No imaging or laboratory evaluation is required if the movements abate when the child is distracted, the movements involve irregular rocking, the child remains interactive, there is some degree of volitional control, direct genital stimulation is involved, and the neurologic and physical examinations are normal. There appears to be no association with sexual thoughts in the child. Instead, it is probably better to view these movements on the spectrum of other self-comforting behaviors, such as thumb sucking or rocking, which have no worrying connotations for the parents. Masturbation is a normal human behavior, so there is no expectation that this behavior will cease as the child grows older. However, the frequency of the behavior usually decreases as the child gets older, and the behavior is less likely to occur under the observation of the parents. Neurologic and developmental outcomes are normal. There is no need for treatment, but parent education and reassurance are important.

## INTRODUCTION AND OVERVIEW

The problem of pediatric drug-induced movement disorders (DIMDs) has received increased attention as the number of children treated with psychotropic medications has increased. Clinical trials and systematic reviews such as those from the Cochrane Collaboration have analyzed recent pediatric data. Naturalistic studies of polypharmacy and epidemiologic studies, particularly those involving children with autism (Spencer et al., 2013) can provide additional insights.

Following most texts and reviews, this chapter is organized by drug class rather than by movement disorder phenomenology. Because dopamine receptor blocking agents, also termed *antipsychotics* or *neuroleptics*, can cause tardive dyskinesia and are widely used in children, these agents require comprehensive discussion.

In recent years, the U.S. Food and Drug Administration (FDA) has approved antipsychotics for several pediatric indications. These include psychiatric symptoms that can be difficult to consistently define, recognize, and diagnose: irritability in autism, schizophrenia in adolescents, manic or mixed episodes of bipolar disorder. It is important to understand that although the newer agents, sometimes referred to as the *atypicals*, were designed to confer lower risks of dopaminergic side effects, this does not indicate the absence of risk.

Fortunately, in the short term, it appears that most DIMDs are reversible in children. It is important to be vigilant for these, however, and to recognize them early.

## DEFINITION OF DRUG-INDUCED MOVEMENT DISORDERS

**Iatrogenic movement disorders, or drug-induced movement disorders (DIMDs)**, are conditions in which the abnormal movements are related to the use of medication. Several time courses may occur (Singer, Mink, Gilbert, and Jankovic, 2016), as detailed in Table 96-1.

## CLINICAL CHARACTERISTICS—PHENOMENOLOGY OF DRUG-INDUCED MOVEMENT DISORDERS IN CHILDREN

The phenomenologies of DIMDs span the spectrum of movement disorders: tremor, hypokinetic/rigid syndrome (parkinsonism), ballism, athetosis, chorea, dystonia, ataxia, tics, stereotypies, and poorly specified dyskinesias. Tremor is one of the most common DIMDs. The case report literature supports clinical experience in that almost any movement disorder may be linked to almost any medication. However, there are certain patterns. Table 96-2 is not exhaustive but presents the more common types of movement disorders seen with the five broad classes of medications emphasized in this chapter. Akathisia may be included in discussions of DIMDs because of the motor phenomenology of restlessness. Akathisia primarily involves uncomfortable sensations of inner restlessness, with compulsion to move secondarily (Table 96-2).

## DRUG-INDUCED MOVEMENT DISORDERS

In general, for each drug class, epidemiology, clinical features, pathophysiology, diagnostic approach, treatment, and outcome are discussed.

### Drug-Induced Movement Disorders Associated with Dopamine Receptor Blockade: Typical Antipsychotics, Atypical Antipsychotics

#### Epidemiology

For decades, conventional low- and high-potency neuroleptics have been prescribed in children as antiemetics and for behavioral indications, particularly in children with intellectual impairment and autism. High-potency dopamine receptor blockers, effective for tic suppression in Tourette syndrome, are known to have both high risks of side effects and high discontinuation rates. In addition, the dopamine receptor blockers, such as metoclopramide, have been used in children as antiemetics and for migraine-associated nausea for many years, despite descriptions of DIMDs.

Pharmaco-epidemiologic studies show dramatic increases in the use of antipsychotics for behavior problems in children of all ages (Olson, Blanco, Liu, Moreno, and Laje, 2006). Conventional neuroleptics are still prescribed because of their effectiveness, relatively lower cost, and concerns about metabolic consequences of the atypical antipsychotics, including weight gain and increased risk of type 2 diabetes.

It is important for neurologists to be aware of situations and groups of patients at risk for DIMDs. Table 96-3 is meant to aid in this process. Because dopamine receptor blocking agents have many short- and long-term uses outside of neurology and psychiatry, Table 96-3 shows the FDA-labeled and non-FDA-labeled indications and specifically pediatric indications. It is important to note that there are other uses besides those listed. Further, although pediatric indications (underlined in Table 96-3) form only a subset of the total uses, it is common for pediatric use to follow adult approval. It is important to consult an updated reference when prescribing any of these medications and particularly to adhere to recommendations regarding electrocardiogram (ECG) monitoring. Dizziness and chest pain are common, and a possible serious side effect of many neuroleptics is a prolonged QT interval. Prescribers need to be aware of the range of complications of these medications (Table 96-3).

With regard to the prevalence of DIMDs, three recent systematic studies with different methods have generated estimates worth considering. The rates reported in two of the studies are remarkably close. Taking the estimates in the context of the study methodologies is informative.

**Study 1: Systematic review of clinical trials** A recent systematic review identified and analyzed 10 open-label and controlled studies of atypical antipsychotics with duration of 12 months or more, involving 783 children and adolescents. The authors reported an overall prevalence of DIMDs of 16%, with tardive dyskinesia in three patients (two prescribed

risperidone and one prescribed olanzapine), or 0.4% of the children in the study (Correll and Kane, 2007).

**Study 2: Large, single site cohort** In a more naturalistic setting, researchers at the Maryland Psychiatric Research Center studied a cohort of 424 pediatric psychiatry patients over a 3-year period. They reported that 9.3% of children ages 5 to 18 treated for 6 or more months with typical or atypical antipsychotics developed tardive dyskinesia (Wonodi et al., 2007). With regard to generalizability, here are some key points:

- The cohort was ethnically diverse.
- The study had a 90% capture rate of the children in the psychiatric facilities involved.
- Polypharmacy, including exposure to multiple antipsychotics, and multiple concurrent diagnoses were common, as is true in the clinical setting of psychiatry patients referred to child neurologists.
- Although there was no placebo control, the authors did identify two comparator groups: (1) 80 neuroleptic-naïve, age- and gender-matched youths with psychiatric disorders and (2) 35 healthy children with no psychiatric disorders.

**TABLE 96-1** Temporal Classification of Drug-Induced Movement Disorders

Temporal Category	Time Course of Appearance and Duration of Movement Disorder
Acute	Onset at treatment onset, within a short time interval of treatment onset, or at the time of a dose increase. Usually reversible/transient.
Chronic	Onset early or insidiously during treatment, persistence for weeks or longer while treatment is ongoing. Reversible.
Tardive	Emergence gradually, after prolonged treatment with the medication. Can be permanent.
Withdrawal	Onset subacutely after dose decreases or discontinuations. May persist for days or weeks. Usually resolves if medication reinitiated.

(Modified from Singer HS, Mink JW, Gilbert DL, Jankovic J. Movement Disorders in Childhood. 2nd ed. Philadelphia, PA: Elsevier, Inc.; 2016.)

- The authors used a structured and validated assessment, the Involuntary Movement Scale.
- The authors trained raters to a high interrater reliability (intraclass correlation coefficient) level of 0.80.
- Raters were blinded to treatment group and diagnosis.

Key findings from this study should inform clinical practice. First, the cohort did not have psychosis. Rather, 80% of the prescriptions of antipsychotics were for youths with mood and other problems, not psychosis. Second, attention deficit hyperactivity disorder (ADHD) was highly comorbid. Third, a total of 9.3% (11 of 118) of the children treated for greater than 6 months with antipsychotics showed tardive DIMDs. This is compared with none in the antipsychotic-naïve group. This tardive dyskinesia risk is much higher than the 0.4% risk estimate from the systematic review of clinical trials (Correll and Kane, 2007) and higher than the 0% incidence reported in a 48-week, open-label extension of risperidone (Findling et al., 2004). Finally, the tardive dyskinesia appeared to be reversible, not permanent. The size of this study allowed for statistical exploration of potential risk factors. Possibly important factors included longer duration, race, medication class, and the effects of polypharmacy.

**Study 3: Systematic review of published literature** The methodology of the third study involved counting patients in the medical literature from 1953 to 2009 to estimate risks for tardive syndromes in children (Mejia and Jankovic, 2010). After removing the case reports and the Maryland study (so as not to double count), this analysis was able to identify 50 affected children out of 540 exposed to neuroleptics, for a rate of 9.3% for tardive dyskinesia, essentially identical to the rate identified in the Maryland study.

Taken together, these studies should promote clinical caution and vigilance, whether atypical or typicals are prescribed.

### Clinical Features of Drug-Induced Movement Disorders Induced by Dopamine Receptor Blocking Agents

Dopamine receptor blocking agents are known to induce parkinsonism, dystonia, tics, tremor, oculogyric movements, orolingual and other dyskinesias, and akathisia from infancy through the teenage years. Symptoms may occur at any time

**TABLE 96-2** Common Drug-Induced Movement Disorders and Classes of Medications

\*Underlining indicates there is an FDA indication for children. Specifics about age approval may vary (e.g., for risperidone approval the lower age limit for ASD is 5 years, for bipolar is 10 years, and for schizophrenia is 13 years). Consult Micromedex®, DrugPoint®, or other sources for details.

(Modified from Singer HS, Mink JW, Gilbert DL, Jankovic J. *Movement Disorders in Childhood*. 2nd ed. Philadelphia, PA: Elsevier, Inc.; 2016.)

after treatment onset. Acute DIMDs, especially dystonia, oculogyric crises, and akathisia, are common and present dramatically, often to the emergency department. Chronic DIMDs occur after 3 or more months of treatment and may take the form of more subtle dystonia, tremor, and rigidity. Tardive DIMD phenomenologies include dyskinesias, stereotypies, tics, dystonia, and oculogyric crises. These symptoms may also develop when dopamine receptor blocking agents are withdrawn, tapered down rapidly, or discontinued because of carelessness or neglect (nonadherence). When dyskinesic movements occur in this setting, it is termed the **withdrawal emergent syndrome** (WES).

### Pathophysiology

The pathophysiology of DIMDs associated with dopamine receptor blocker use may involve effects on the striatal dopamine receptor blockade and imbalance in the striatum of dopamine and acetylcholine levels. Much remains unknown, however, regarding an individual's vulnerability or susceptibility to DIMDs, so this remains an area of active research.

Clinical experience suggests that the occurrence of DIMDs in childhood is not completely random. It may relate in some basic way to the perturbed circuits underlying the neurodevelopmental or psychiatric symptoms treated with these agents. It is intriguing that tardive DIMDs seem to be so much more common in neuroleptic-treated schizophrenia than in, say, neuroleptic-treated Tourette syndrome. Yet tics, stereotypies, and other movement disorders are more common in children with autistic spectrum disorder (ASD) (Canitano and Vivanti, 2007), and clinically children with ASD seem to be particularly susceptible to DIMDs.

With regard to specific genetic risk factors, much research has been done, but few findings have been replicated. On a cellular basis, mechanisms may include the long-term effects of neuroleptics on dopamine receptor density and function, or damage to striatal GABAergic or cholinergic neurons. Genome-wide association studies may support previously unsuspected pathways as well. Evidence related to dopamine receptor polymorphisms has been mixed. GABAergic pathway genes have also been implicated. Within serotonergic systems, polymorphisms in genes encoding receptors 2A or 2C but not

3A may increase risk. Genetic variation in enzymes handling oxidative stress, such as glutathione-S-transferase, glutathione peroxidase, catalase, and tumor necrosis factor alpha polymorphisms, have not been linked to risk for DIMDs.

### Diagnosis of Acute, Chronic, Tardive, and Withdrawal Emergent Syndromes

The acute onset of an involuntary movement disorder in a toddler should raise the diagnostic possibility of ingestion of a dopamine receptor blocking agent. Sources of possible exposure should be sought. Acute onset of dystonia, akathisia, parkinsonism, or other dyskinesias after initiating or raising the dose of a dopamine blocker is also straightforward.

Diagnosis of a chronic or tardive DIMD in children should often be considered when a movement disorder is unusual. For example, unilateral resting tremor, rigidity, and orolingual dyskinesias are all uncommon as idiopathic or genetic presentations but common as drug-induced presentations. Stereotypies and especially tics are less straightforward because they are common, and a tendency to tics may have preceded drug treatment. Thus the emergence of these symptoms later in childhood may be unrelated to medication.

When a new movement disorder occurs at the time of medication tapering or discontinuation, a WES disorder should be considered as a possibility. This is often missed or not considered in the emergency department and even on the inpatient psychiatry service. This phenomenology can also be severe choreic or ballistic movements, among the most severe presentations within the realm of DIMDs. However, if dyskinesic symptoms that have emerged are mild, then the differential diagnosis includes preexisting hyperkinetic movements, emerging after symptoms had been masked by treatment.

### Treatment of Drug-Induced Movement Disorders Related to Use of Dopamine Receptor Blocking Agents

**Acute Drug-Induced Movement Disorders.** For acute DIMDs caused by dopamine receptor blockade, antihistamines and anticholinergic agents, such as diphenhydramine

and benztropine, remain the mainstay of treatment. For akathisia, other options include the alpha-2 adrenergic agonist clonidine and beta blockers such as propranolol.

**Chronic Drug-Induced Movement Disorders.** For chronic DIMDs caused by dopamine receptor blockade, anticholinergics are also used. In chronic and tardive DIMDs, when dyskinesias are mild, withdrawing the offending agent may be sufficient. For functionally impairing tremor or rigidity in situations where withdrawing the dopamine receptor blocking agent is not safe because of aggression or severe mental illness, long-term anticholinergic treatment is reasonable. As an alternative for mood stabilization and aggression, substitution of anticonvulsants as mood stabilizers could be considered.

**Tardive Movement Disorders.** Vigilance for emergence of DIMDs is critical because of the possibility of permanent tardive dyskinesia. Although the risk is highest in adults with schizophrenia, the risk is nonzero in other groups. It is important not to give the impression that dopamine receptor blockers should be avoided at all costs. Rather, when possible, the treatment duration and dose of these dopamine receptor blocking agents should be limited and alternatives considered. In cases where tardive dyskinesia is diagnosed or strongly suspected, removal of the dopamine receptor blocking drug is recommended whenever possible, via slow taper.

For pharmacologic treatment of tardive dyskinesia or tardive dystonia, there are several options. Alpha-methyl-para-tyrosine (AMPT), reserpine, and tetrabenazine have been recommended. Depression is sometimes noted as a side effect of dopamine depletion. Extensive studies of vitamin E, based on the rationale that oxidative stress may be involved, have yielded negative results. Calcium channel blockers are not currently considered effective.

### Neuroleptic Malignant Syndrome

**Neuroleptic malignant syndrome (NMS)** is rare in children. This most commonly occurs after initiation or dose increases and mainly has been described as occurring after taking antipsychotics (including the atypicals), but occasionally has been reported as occurring after the use of other psychiatric medications. NMS can also occur as a withdrawal phenomenon after chronic dopaminergic therapy. The main manifestations are autonomic (fever, tachycardia/tachypnea, diaphoresis), motoric (rigidity/bradykinesia with elevated rhabdomyolysis and creatine kinase), and cognitive (confusion). This is a life-threatening presentation. Treatment may include withdrawing the offending medication, administration of the dopamine agonist bromocriptine, and administration of the skeletal muscle relaxant dantrolene, in addition to general supportive care (hydration, fever reduction).

The differential diagnosis includes several other serious reactions, including malignant hyperthermia (hyperpyrexia, muscle contractions attributable to general anesthesia) and anticholinergic or sympathomimetic poisoning. In addition, **serotonin syndrome** may occasionally be confused with NMS. In serotonin syndrome, hyperreflexia, clonus, tremor, myoclonus, and shivering occur, but rigidity should be less severe.

### Drug-Induced Movement Disorders Associated with Treatment of Attention Deficit Hyperactivity Disorder

#### Epidemiology of Psychostimulant Use in Children

The prevalence of the ADHD diagnosis and the use of pharmacologic treatment have increased markedly in the last 20

years in the United States. This includes primarily stimulants in an ever-increasing variety of preparations, but also includes atomoxetine, a selective norepinephrine reuptake inhibitor marketed for ADHD treatment, and the alpha-2 adrenergic agonists guanfacine and clonidine.

#### Clinical Features

Stimulants have been prescribed for decades. When dosed at less than 1.0 mg/kg/day, they only rarely induce clinically significant movement disorders. These medications and, to a less acute degree, the nonstimulants affect dopamine and norepinephrine levels. Therefore the most common DIMDs are hyperkinetic disorders such as tics, stereotypies, chorea, or other dyskinesias. The risk of DIMDs is higher in children who manifest clinical or subthreshold diagnostic features of obsessive-compulsive disorder (OCD) or ASD. Such children may experience new or increased repetitive behaviors, including tics, compulsions, or repetitive picking behaviors. They may also become hyper-focused or have personality changes parents describe as a "zombie" or "robot" effect, in part resulting from increased attention to internal stimuli or thoughts.

A longstanding concern is the clinical observation that stimulants seem in some cases to induce, unmask, or exacerbate tics. Fortunately, rigorous randomized controlled trials support that stimulants reduce ADHD symptoms for most children, irrespective of the presence of a tic disorder, and that should worsening of tics occur, it is usually transient, usually mild, and always reversible. Prospective studies suggest that in most cases tics would have occurred eventually, even in the absence of any exposure to stimulants. The most rigorous clinical assessment of the relationship between stimulants and tics is the Treatment of ADHD in Children with Tics (TACT) study (Group, 2002). In that study, children with comorbid tics and ADHD were randomized to treatment with methylphenidate, clonidine, both, or double placebo. Tics improved by the study's end in all treated groups, even the group treated with methylphenidate alone, compared with the placebo. Even in cases where tics consistently worsen on stimulant medication, some individuals and families choose to continue stimulant medication if the benefits warrant.

Atomoxetine has been reported in a few cases to induce tics and dyskinesias in the context of rapid dose change and polypharmacy. However, in a randomized, placebo-controlled trial of atomoxetine treatment for ADHD in 148 children with tics, atomoxetine tended to reduce tic severity (Allen et al., 2005).

#### Pathophysiology

The pathophysiology of this susceptibility is unknown. Induced stereotypies and tics, as with idiopathic ones, may be more general markers of perturbed neurodevelopment. A genetic influence on the risk of DIMDs has been suggested through genotyping data from the Preschool ADHD Treatment Study (PATS). In that study, 183 preschoolers were treated with methylphenidate at several doses or placebo. Several modestly statistically significant associations were identified, including polymorphisms in synaptosomal-associated protein 25 (SNAP25) associated with tics, buccal-lingual movements, and irritability and variants of dopamine receptor 4 (DRD4) associated with picking (McGough et al., 2006).

#### Diagnosis

The diagnosis of a DIMD in a child treated for ADHD should be suspected if the movements have the typical hyperkinetic phenomenology and the onset is within a week or two of treatment onset or a dose increase. Stimulants are short acting

and readily discontinued or restarted, allowing for a plan of stopping and restarting medications to clarify cause and effect.

## Treatment

It is most often not necessary to discontinue stimulants when mild tics or tremor emerge. If the stimulant dose exceeds 1 mg/kg/day, it is generally beneficial to reduce the dose.

## Drug-Induced Movement Disorders Associated with Other Medications

### Serotonin Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) are widely prescribed in children with mood disorders and OCD and tend to work better in combination with cognitive behavioral therapy. The emergence of movement disorders related to use of SSRIs is well known. Phenomenology can include akathisia most commonly, with parkinsonism, dystonia, acute dystonic reactions, and dyskinesias also described. The most serious complication, rare in childhood, is serotonin syndrome as a result of excess SSRI exposure. This involves neuromuscular excitation (manifest by clonus, hyperreflexia, myoclonus, tremor, shivering), autonomic stimulation (hyperthermia, diarrhea, tachycardia, diaphoresis, tremor, flushing), and changed mental state (anxiety, agitation, confusion). More commonly, treatment with an SSRI results in a mild degree of hyperreflexia and tremor. The emergence of hyperreflexia in a child prescribed an SSRI is an indication that toxicity is more likely if the dose is increased or if other psychiatric agents are prescribed. Lack of awareness of SSRI-induced tremor and hyperreflexia may result in unnecessary medical diagnostic tests such as brain magnetic resonance imaging (MRI). Similarly, failure to observe and document SSRI-induced neurologic symptoms may place patients at risk of developing more severe symptoms with future dose increases. Myoclonus, in distinction to tics, is involuntary, not urge driven.

The identification of SSRI-induced movement disorders in children supports the importance of clinician and patient education. Treatment is dose reduction, elimination of the medication, or selection of alternative interventions or cognitive behavioral therapies.

### Antiseizure Medications

Physicians prescribe antiseizure medications for diverse indications, including prevention of seizures and migraines, and sometimes stabilization of mood. Numerous case reports describe acute and chronic DIMDs in children caused by antiseizure medications. The most common acute clinical presentations are acute ataxia and nystagmus. Phenytoin and carbamazepine are most commonly identified. These medications are also prone to cause problems resulting from pharmacokinetics and drug-drug interactions.

Less commonly, antiseizure drugs may produce other hyperkinetic movement disorders. Phenytoin, carbamazepine, and even valproic acid have been reported to produce acute chorea, orofacial dyskinesias, and Tourettism. Lamotrigine has been reported to induce tics. Tremor is also common.

Generally, the treatment plan involves clinical watch and wait, weighing the impairment related to the movement disorder against the benefits of the seizure control, with thoughtful consideration of reduction of dose or changing of medication or formulation if the movement disorder causes much impairment.

## Drug-Induced Movement Disorders Associated with Chemotherapeutic, Immunomodulatory, and Anti-infectious Medications

Neurology consult teams seeing oncology patients may encounter DIMDs. Chemotherapeutic agents such as vincristine may cause sensory ataxia, along with dysarthria and tremor. Seizures, stroke-like episodes, and ataxia can occur with intrathecal methotrexate. Acute neurologic symptoms such as headaches, confusion, and seizures, but also associated with tremor, ataxia, dysarthria, and parkinsonism, may occur during bone marrow transplantation.

Seizures, tremor, and acute dystonic reactions have been observed after organ transplantation, sometimes with a leukoencephalopathy syndrome involving headache, confusion, and myoclonus. Metronidazole may rarely cause cerebellar dysfunction.

## CONCLUSION

Neurologists should be aware of the wide spectrum of phenomenologies of drug-induced movement disorders that may present acutely or chronically in childhood. Treatment strategies may involve specific antidotes, such as anticholinergics for acute dystonic reactions, or longer-term changes in medical regimens.

- IX. CONCLUSION

### I. INTRODUCTION

Cerebral palsy (CP) is a chronic neurodevelopmental disorder that is heterogeneous in all of its aspects: etiology, presentation, functional severity, comorbidities, treatment options, individual trajectories, and outcomes. It is never the same disease twice. CP is frequently accompanied by a range of conditions that implicate the child neurologist in medical management and in the utilization of an interdisciplinary team for comprehensive management. The chronicity of CP enables the neurologist to form close and enduring bonds with the affected child and family that facilitates the practice of family-centered care that addresses changing challenges as the child matures and that prioritizes these challenges according to the individual and family context. Some children with CP graduate from universities and become health professionals. Other children with CP may be unable to roll or feed and may be entirely dependent for all activities of daily living with a lifespan shortened by decades compared with their chronological peers. The challenge for healthcare practitioners is to comprehensively and holistically address this entire spectrum of individual care needs.

### II. CURRENT DEFINITION

The current definition of CP is the product of an international effort of consensus drawing upon the experience of a diverse interdisciplinary group of recognized experts. The value of CP as a diagnostic entity was affirmed as a clinical descriptor of a group of individuals with a neurodevelopmental disability of diverse etiologies featuring varying presentations, functional limitations and individual life trajectories.

*Cerebral palsy (CP) describes a group of permanent disorders of movement and posture, causing activity limitation, that are attributed to nonprogressive disturbances that occurred in the developing fetal or immature brain. The motor disorders of CP are often*

*accompanied by disturbances of sensation, perception, cognition, communication, and behavior, by epilepsy, and by secondary musculoskeletal problems.*

The definition fits well into the World Health Organization's International Classification of Functioning, Health, and Disability (ICF) framework by providing as necessary and sufficient conditions for CP both bodily impairment ("disorders of movement and posture") and "activity limitation." Neuromotor impairment, reflecting an alteration in motor control, is the invariable sine qua non of CP, as is the latter's explicit recognition that all individuals with CP have difficulties in executing a motor-dependent task or action. The heterogeneity of CP is captured by the term "group" and the avoidance in the definition of any specification by etiology, presentation, or severity. Transitory processes are eliminated from consideration by the word "permanent," which also emphasizes CP's chronicity over the lifespan and the recognition of its clinical evolution as the individual ages and matures. CP is fundamentally a disruption in the orderly sequential processes of early child development, and this is captured by the words "disorders," "disturbances," and "developing."

Although the clinical manifestations of CP will change over time in a particular individual, the underlying pathology is "nonprogressive." This lesion is the result of either a single event or a discrete series of events that has "run its course" by the time the clinical features of CP are apparent and diagnosable. Pathologic processes that are progressive are excluded from CP. However, the brain injury that underlies CP may occur in the immature brain; it alters the developmental trajectory of the brain and, consequently, produces a clinical picture that changes over time.

A further aspect of the current consensus definition is its specification of CP as an attributable neurobiologic disorder rooted in an abnormality occurring at an early phase in the not-yet-mature brain. Specifically excluded from being considered as CP are early-onset neuromotor disorders with activity limitations that are the result of spinal disorders or neuromuscular processes. A final important and unique aspect of this most recent definition is the notation that CP is "often accompanied" by a range of "comorbid" conditions that include: convulsive disorders, abnormalities in the primary senses, perceptual integrative disorders, intellectual disability, speech-language limitations, behavioral disorders, and orthopedic deformities. Some of these comorbidities may be attributed to the underlying pathologic lesion that does not uniquely respect motor control pathways but may also represent the influence of these motor dysfunctions on complex processes or on skeletal structures.

Although the current definition has been widely accepted, limitations have been recognized. A lack of clarity with regards to the meaning of "nonprogressive" has been highlighted. Syndromes traditionally excluded from categorization as CP are not enumerated as they have been elsewhere in the literature. Similarly, the lower threshold for severity for inclusion as CP is left open, as is an upper age limit for both an acquired pathology and clinical diagnosis. These aspects of imprecision

will influence on the operationalization of CP for such traditional epidemiologic processes as determining prevalence and incidence. For most CP registries currently in existence, a pathologic onset and a clinical diagnosis before the age of 2 years have been implemented.

### III. PRESENTATION AND DIAGNOSTIC ASSESSMENT

Two distinct cohorts of children present with CP. The first and largest consists of children considered at high risk for CP as an eventual outcome due to evident perinatal adversity. This group includes infants born preterm. The second group includes those born at term experiencing a neonatal encephalopathy, which includes as a subset those with documented intrapartum asphyxia. These “at-risk” newborns are carefully monitored in regional neonatal follow-up programs with rigorous developmental surveillance and screening. The appearance of motor delay and findings on neurologic examination would prompt consideration of a diagnosis of CP. These infants typically have an earlier age of diagnosis and onset of rehabilitation interventions with more severe functional impairments and worse outcomes compared with the second cohort of infants with CP.

The second cohort typically has experienced no evident perinatal adversity. Developmental surveillance provided through a community-based provider may alert to the possibility of motor delay in gross and fine motor domains, prompting referral to a pediatric specialist for evaluation. Some children without prior perinatal adversity may present in a symptomatic manner, either acutely or in a chronic fashion. The former typically involves urgent in-hospital evaluation for a paroxysmal event highly suspicious of a seizure of any type. The chronic mode of presentation may be suggested by the early preferential hand use or the parental observation of “stiffness” or gait disturbances. The diagnosis of this second cohort of children with CP and the implementation of interventions may be delayed beyond the child’s second birthday.

In both cohorts, the diagnosis of CP is made on clinical grounds. Documentation on neurologic examination of neuromotor impairment and either observation or report of activity limitation in the affected child are required and sufficient conditions. The neuromotor impairment is grounded in either motor delay or abnormalities in strength, tone, reflexes, or gait. The activity limitation may be readily evident in the office in the execution of a motor-based task or by historical report by parents. An underlying etiology does not need to be identified to satisfy a diagnosis of CP. Spinal dysraphisms, neuromuscular disorders, progressive pathology, and specific syndromic diagnoses need to be excluded to merit a diagnostic assignment of CP. Due to the known occurrence of transitory neuromotor deficits in infancy, there is some reluctance to diagnose CP formally in infants younger than 1 year, unless severely affected. Thus some practitioners speak of “probable” CP before the age of 2 years, and “definite” CP after the age of five.

An evidence-based consensus guideline on the diagnostic assessment of the child with CP was developed by the American Academy of Neurology and Child Neurology Society (Fig. 97-1). CP is a clinical diagnosis, and all children should undergo a detailed history and physical examination that excludes a neurodegenerative disorder and that also classifies the neurologic subtype of CP. Among children with hemiplegic CP and a history of perinatal stroke (Chapter 20), diagnostic testing for a coagulation disorder should be considered (level B). Screening for associated comorbidities (such as epilepsy, cognitive or visual impairments, speech, language or

hearing deficits, and oromotor dysfunction) is also recommended (level A). An EEG is recommended only if paroxysmal events suggestive of seizures are present (level A). Neuroimaging is also recommended in all children with CP to establish an etiology, with MRI as the preferred modality done either in the perinatal period or at the time of presentation (level A). Metabolic and genetic studies are not routinely recommended (level B) unless there are atypical features such as normal neuroimaging, episodic decompensation, or the presence of a family history of CP (level C).

### IV. EPIDEMIOLOGY

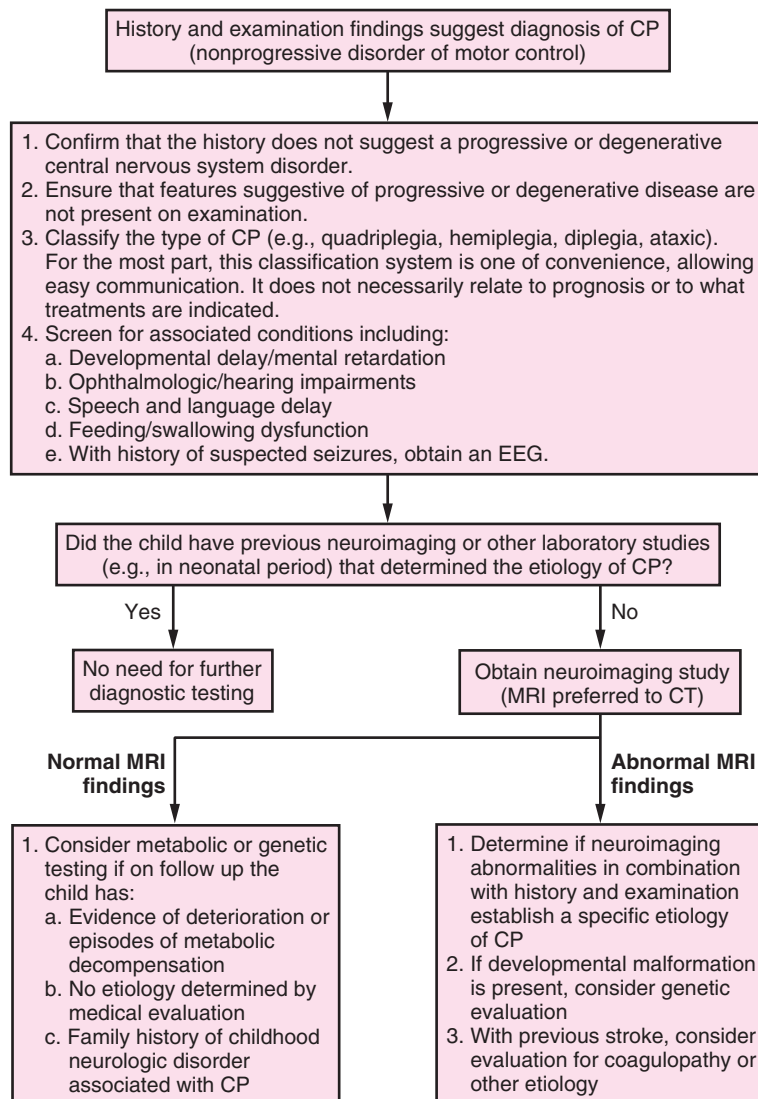

Cerebral palsy is the most common cause of motor disability in childhood, affecting about 2 per 1000 live births in high resource settings. Over the past few decades, there have been major changes and advances in obstetric and neonatal care, with a decline in neonatal mortality. The prevalence of CP has been shown to be constant over time by several studies; however, the at-risk population and subtypes observed appear to have changed. The pooled prevalence of CP across studies from North America, Europe, and Australia is 2.11 per 100 live births (95% CI 1.98–2.25).

Prematurity is one of the largest risk factors for CP, with a well-established inverse relationship between CP prevalence and gestational age. The pooled birth prevalence of CP is highest in children born earlier than 28 weeks’ gestation (82.25 per 1000 live births) and lowest in children born at term (1.35 per 1000 live births). Intrauterine growth restriction and low birth weight are also strongly associated with a risk of CP. The pooled prevalence of CP shows a similar inverse relationship to birth weight, affecting 56.64 per 1000 live births in children with a birth weight lower than 1000 grams and 1.33 per 1000 live births in children with a birth weight of 2500 grams or greater.

### V. ETIOLOGIC SPECTRUM

Our understanding of the etiologic spectrum of CP has advanced, over the past few decades, yet much of the underlying pathophysiology continues to remain poorly understood. Individual risk factors have been identified across numerous population-based studies, broadly classified as antenatal, perinatal, and postnatal risk factors, which differ among term and preterm born children. However, in each individually affected child, multiple risk factors can be involved and their contribution along causal pathways and timing of injury is complex. Two recent systematic reviews have explored the risk factors for CP in term-born children. Although birth asphyxia was historically considered as a major causal factor in term CP, improved understanding has shown this to be a factor in only a minority of children. Preconceptional antenatal risk factors identified in these systematic reviews include social deprivation (both individual and area-based indicators), prior maternal disease such as epilepsy, thyroid disease, and intellectual disability, and both early and late maternal age (younger than 20 and older than 40 years). Among antenatal risk factors in term-born children, major and minor birth defects and aberrant intrauterine growth both hold a strong association with CP. Other antenatal factors include polyhydramnios or oligohydramnios, multiple gestation, documented genetic abnormalities, second or third trimester bleeding, intrauterine infection, chorioamnionitis, and placental abnormalities. Intrapartum events found to increase the risk of CP across population-based studies include meconium aspiration, breech or nonvertex presentation, and instrumental deliveries. Birth asphyxia associated with a sentinel event (uterine rupture, major placental abruption, or cord prolapse)

**Figure 97-1.** Diagnostic assessment of a child with CP. (With permission from Ashwal, S., Russman, B.S., Blasco, P.A., et al., 2004. Practice parameter: diagnostic assessment of the child with cerebral palsy: report of the Quality Standards Subcommittee of the American Academy of Neurology and the Practice Committee of the Child Neurology Society. *Neurology* 62, 851–863.)

was consistently established as a risk factor. Birth asphyxia is variably defined across studies, often in the absence of a true sentinel event. Birth asphyxia, however, cannot be reliably solely defined by clinical indicators such as Apgar scores, cord pH, or presence of a neonatal encephalopathy, all of which are multifactorial. During the neonatal period, presence of seizures is a strong predictor of CP. Neonatal infection, hypoglycemia, hyperbilirubinemia, and respiratory distress syndrome also have been reported as risk factors. Improved management of neonatal hyperbilirubinemia has resulted in a decreased number of affected children who develop CP (typically the athetoid or dystonic subtypes) from kernicterus in developed countries.

Among very preterm infants, the EPIPAGE (étude EPIdemiologique sur les Petits Âges GEstationnels) population-based cohort study in France identified several risk factors for CP in an unadjusted model, including cystic periventricular leukomalacia, intraparenchymal hemorrhage, earlier gestational age, male gender, preterm rupture of membranes, respiratory distress syndrome, maternal-fetal infection, acute anemia, and postnatal corticosteroid use. In multiple adjusted models,

male gender and cerebral lesions documented with neuroimaging were the strongest predictors of CP.

Multiple risk factors are often identified in children with CP, especially in children born preterm, suggesting a sequence of events along a causal pathway. In children with CP born at term, an antenatal or a single risk factor suggests an existing vulnerability, with no specific risk factor identified in up to 30% of individual cases. These risk factors are also believed to have a differential effect across gestational ages. For example, in a population-based study in Norway, preeclampsia was found to increase the risk of CP in offspring, mediated by either preterm birth or being born small for gestational age only in term infants. Among preterm infants, there is emerging robust evidence for a cerebral dysmaturation process. In response to an initial ischemic insult, there is both an expansion of the preoligodendrocyte pool that is blocked from maturation and survival of immature neurons. This leads to dysmaturation of both gray and white matter during a critical period of rapid brain growth and connectivity in which postnatal environmental factors can further enhance or impair brain health. Slower postnatal growth (related to nutrition or

other factors) has been associated with delayed cerebral cortical maturation. Brain growth and maturation in preterm infants is also influenced by systemic illness such as postnatal infections, which have been linked to altered development of white matter pathways and impaired neurodevelopmental outcome. Procedural pain and stress exposure in premature newborns in the neonatal intensive care unit have also been linked to altered brain maturation and impaired postnatal growth. Although the consensus definition of CP describes a static injury, this injury occurs in an immature brain thereby altering the course of its developmental maturation. This shift from static to dynamic injury broadens the potential targets for both preventive and disease-modifying interventions.

## VI. CLASSIFICATION

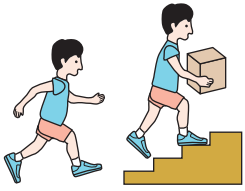

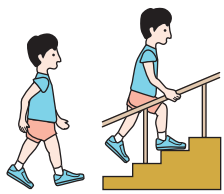

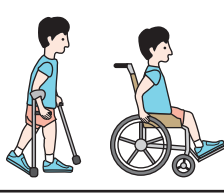

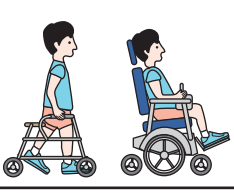

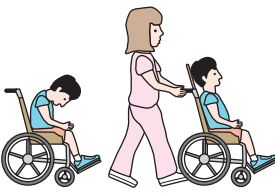

### A. Common Cerebral Palsy Syndromes

The standardized neurologic examination forms the basis of the classification approach to CP most familiar to child neurologists. This approach utilizes both the topographic distribution of affected limbs and the predominant quality of the observed motor impairment to stratify CP into mutually exclusive subtypes. The quality of the motor impairment has its basis in neuropathology, specifically whether cortical and/or subcortical structures are affected (i.e., basal ganglia, cerebellum) and is divided broadly into pyramidal (i.e., spastic) and

extrapyramidal (i.e., dyskinetic [choreoathetotic, dystonic], ataxic-hypotonic, or mixed [dyskinetic and spastic elements both present]) categories. Further stratification within the spastic (pyramidal) category is based on the observed distribution of affected limbs: a) quadriplegic—all four limbs affected, with an asymmetry between the left and right side permitted (i.e., double hemiplegia); b) hemiplegic—hemibody involvement with asymmetry permitted between the affected upper and lower limb; c) diplegic—involvement of both lower extremities without appreciable upper limb involvement noted; and d) other monoplegic or triplegic limb distribution.

### B. Functional Classification

As neuromotor impairment is a core feature of CP, it is not surprising that a functional classification focused on gross motor skills, particular ambulation, was initially formulated (Rosenbaum et al., 2008). The Gross Motor Function Classification System (GMFCS) stratifies individuals with CP into five nonoverlapping categories ranging from most able (level I) to least able (level V). The distinctions between successive levels are clinically and functionally meaningful and are captured quite succinctly in Figure 97-2. Individuals at level I and II can ambulate independently without assistance, varying in terms of their capacity to run, jump, and climb stairs; individuals in level III ambulate independently with assistance

	<p><b>GMFCS Level I</b></p> <p>Children walk indoors and outdoors and climb stairs without limitation. Children perform gross motor skills including running and jumping, but speed, balance and coordination are impaired.</p>
	<p><b>GMFCS Level II</b></p> <p>Children walk indoors and outdoors and climb stairs holding onto a railing but experience limitations walking on uneven surfaces and inclines and walking in crowds or confined spaces.</p>
	<p><b>GMFCS Level III</b></p> <p>Children walk indoors and outdoors on a level surface with an assistive mobility device. Children may climb stairs holding onto a railing. Children may propel a wheelchair manually or are transported when traveling for long distances or outdoors on uneven terrain.</p>
	<p><b>GMFCS Level IV</b></p> <p>Children may continue to walk for short distances on a walker or rely more on wheeled mobility at home and school and in the community.</p>
	<p><b>GMFCS Level V</b></p> <p>Physical impairment restricts voluntary control of movement and the ability to maintain antigravity head and trunk postures. All areas of motor function are limited. Children have no means of independent mobility and are transported.</p>

**Figure 97-2.** GMFCS. (With permission from GMFCS descriptors: Palisano et al. (1997) *Dev Med Child Neurol* 39:214–23 *CanChild*: [www.canchild.ca](http://www.canchild.ca). (i.e., walker, crutches, leg braces), whereas those at levels IV and V are wheelchair bound, differing in their ability to control the wheelchair themselves. The GMFCS has been extensively validated and shown to be reliable, psychometrically robust, and sensitive to the effects of therapeutic intervention. Introduced in the late 1990s, it is now a standard part of international care provision, rehabilitation, registry inscription, and research in CP.

About three quarters of individuals with CP will have appreciable involvement of an upper extremity. Half of such individuals will have bilateral involvement of the upper limbs. These individuals are thus at risk for functional impairment in bimanual ability (i.e., fine motor skills). Upper limb function is influenced by contextual factors such as physical capability, the immediate environment, social advantage, and personal motivation. Contextual factors may act to produce different function in bimanual ability despite the same objective degree of physical motor impairment. Bimanual ability can be defined as “the capacity to manage daily activities that require the use of the upper limb, with whatever strategies involved, which can be observed from activity or performance in the person’s everyday context.” The fine motor limitations evident in a subset of children with CP prompted the development of the Manual Ability Classification System (MACS) subsequent to the GMFCS. In a manner analogous to the GMFCS, the MACS stratify individuals with CP into five nonoverlapping categories ranging from most able (level I) to least able (level V). The distinction between the levels is based on the quality and quantity of bimanual performance in “everyday” life and whether there is any requisite need for assistance or adaptation to carry out these tasks (Fig. 97-3). The MACS is also noted to be psychometrically robust with its validity and reliability well-established. It is, however, generally applied consistently to individuals older than the age of 4.

Communication through oral language is dependent on cognitive processes and the complex interplay of oral, pharyngeal, laryngeal, lingual, and diaphragmatic musculature. Communication may also be nonverbal, and this is also dependent on cognitive and voluntary motor control. The underlying lesion responsible for an individual’s CP may subtly or dramatically affect each of these components. Within the past decade, the Communication Function Classification System (CFCFS) has been developed to stratify everyday communication. All methods of communication are considered for the affected individual’s performance as both a sender and receiver of varied communication, including the pace and the effectiveness of communication in the context of either a familiar or unfamiliar conversational partner. Five nonoverlapping categories are utilized ranging from most able (level I) to least able (level V) (Fig. 97-4).

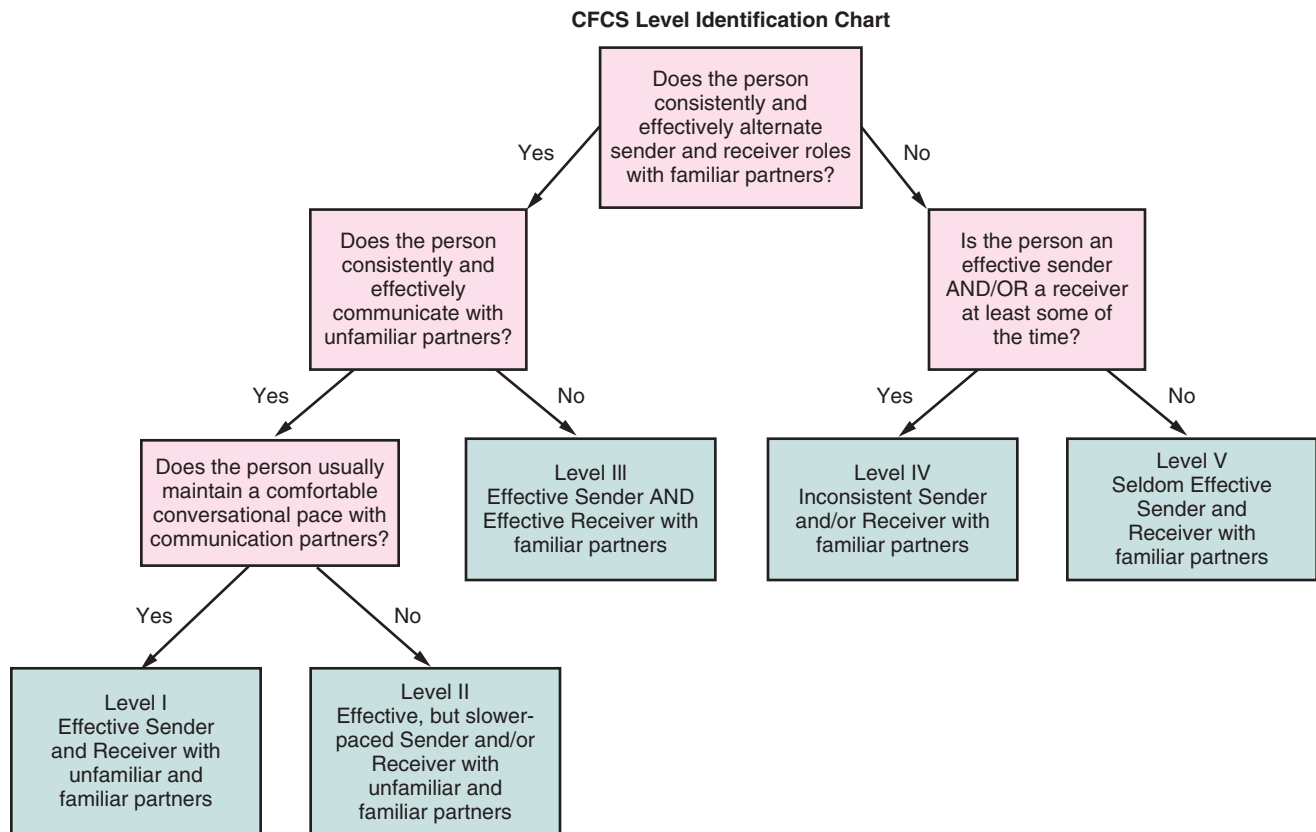

The eventual capacity to ambulate (“Will my child walk?”) represents a major concern for parents upon being told the diagnosis of CP if the affected child is not yet ambulatory. Stratification through the GMFCS objectively responds to this explicit concern. Two thirds of individuals with CP will be assigned to GMFCS levels I through III, indicating ambulation with (level III) or without (levels I and II) assistance. Slightly more than half (55%) will be in level I (45%) and level II (10%), and 12% will be in level III. The one third that will be wheelchair bound (levels IV and V) will be equally split between these two assignments. There is a dichotomous correlation observed between neurologic subtype and GMFCS levels. For children with either a diplegic or hemiplegic neurologic variant, more than 95% will be GMFCS levels I through III, whereas for those with a quadriplegic or dyskinetic variant only 25% will be ambulatory with or without assistance (levels I through III).

With respect to bimanual function, roughly 60% of children stratify to MACS levels I (35%) and II (25%), indicating

Field trial version

**Figure 97-3.** MACS Level Identification Chart. (With permission from Manual Ability Classification System, 2016. [www.macs.nu](http://www.macs.nu))

**Figure 97-4.** CFCS. (With permission from *The Communication Function Classification System*, 2016. [www.cfcs.us](http://www.cfcs.us))

an ability to do bimanual tasks at an age-appropriate level without the need for adaptation or external assistance. For a third of children with CP, no limitations aside from that related to speed and accuracy of handling was noted (level I). One in seven children with CP will have no discernible functional hand use (level V), leading to major task limitations that effectively preclude the eventual attainment of individual autonomy.

The GMFCS and MACS levels are positively correlated, varying by neurologic subtype and cognitive level. The agreement between GMFCS and MACS levels is moderate in quadriplegic or dyskinetic youth, fair in diplegic youth, and poor in hemiplegic youth. Quadriplegic youth tend to have worse ambulatory skills, hemiplegic youth worse bimanual ability, and diplegic youth equivalent skills in both functional domains. The presence of concurrent intellectual disability was noted to strengthen the correlation in gross and fine motor skills.

A similar distribution across levels has been reported for the CFCS measure. Half of children with CP were noted at school entry to be effective communicators as senders and receivers with both familiar and unfamiliar partners (level I: 32%; level II: 22%). One in seven were at level V, indicating a noncommunicative status in both verbal and nonverbal capacities, with one in six at level IV, indicating inconsistent communication skills restricted to familiar communication partners only. Level V status strongly correlated with documentation of greatest impairment (i.e., level V) on the GMFCS and MACS.

## VII. COMORBIDITY SPECTRUM

The current consensus definition of CP explicitly recognizes associated conditions in addition to the core neuromotor

impairment. Half of children with CP will experience a comorbid condition with many of these experiencing more than one. Comorbidities occur disproportionately among those with a spastic quadriplegic or dyskinetic variant or those individuals who are nonambulatory. These comorbidities may be the major health burdens that effectively limit activity, participation, and health-related quality of life.

A recent systematic review on co-occurring conditions in CP provides clinical prognostic information. Among children with CP, 3 in 4 were in pain; 1 in 2 had an intellectual disability (IQ lower than 70), and 1 in 3 had a severe intellectual disability (IQ lower than 50); 1 in 3 could not walk, 1 in 6 walked with assistance and 1 in 2 walked independently; 1 in 3 had a hip displacement (migration greater than 30%); 1 in 4 could not talk; 1 in 4 had active epilepsy, and 1 in 3 had epilepsy at some point; 1 in 4 had a behavior disorder; 1 in 4 had bladder-control problems; 1 in 4 had a sleep disorder; 1 in 5 had excessive drooling; 1 in 10 were blind; 1 in 15 were tube-fed; and 1 in 25 were deaf. The highest reported comorbidity in this review was pain, and it affected children and adults with CP regardless of levels of physical disability. In ambulatory patients, pain was reported in the neck, back, and feet, and individuals with contractures were also at increased risk of pain, which appeared to increase in prevalence with age.

In a population-based study in Europe, the prevalence of CP with epilepsy was 0.69 (99% CI, 0.66 to 0.72) per 1000 live births. Of their cohort of children with CP, 35% had a history of epilepsy, which was seen more often in children with a bilateral spastic subtype and associated other comorbidities. Neonatal characteristics independently associated with epilepsy in this cohort were the presence of a brain malformation or a syndrome, a term or moderately preterm birth compared with a very premature birth, and signs of

perinatal distress including neonatal seizures, need for neonatal ventilation, and an admission to a neonatal care unit. In a surveillance study of 8-year-old children in the United States, 35% of children with CP had concurrent epilepsy. Among children with CP who were nonambulatory, 70% had a concurrent diagnosis of epilepsy. The proportion of children with CP who have epilepsy has been consistent across several studies, ranging between 30% and 35%.

Receptive and expressive language impairment is one of the most common comorbidities in children with CP. In a longitudinal study, development of an expressive language impairment was most closely related to motor function, with the best developmental trajectory seen in children with unilateral spastic CP. Receptive language development, however, was most closely related to intellectual disability.

Excessive drooling is a common comorbidity in CP, affecting up to 40% of children aged 7 to 14 years. Predictors of drooling include nonspastic (dyskinetic) or spastic quadriplegic subtypes, feeding difficulties, anterior open bite, intellectual disability, poor gross motor function, and the lack of speech. Saliva control improves in some children over time, with benefit from oromotor therapy, botulism toxin injection, or salivary gland duct surgery. In children with dyskinetic CP, poor oromotor coordination and an excessive salivary production from hyperkinetic oral motor activity are believed to cause drooling.

Associated psychiatric comorbidities and behavioral disorders in CP contribute to family stress and quality of life. A behavioral disorder was found in a quarter of children with CP in the previously mentioned systematic review and seen equally across functional severity. Similarly, in a cross-sectional study in school-age children with CP, 39.4% scored in the borderline to clinically abnormal range in the total difficulties score of the Strength and Difficulties questionnaire. These difficulties did not appear to be associated with sociodemographic variables and physical and cognitive characteristics. In a population-based study in Norway, 57% of children with CP had a psychiatric comorbidity, the most common being ADHD/ADD seen in 50% of the children. Communication impairment was the best predictor of psychiatric comorbidity, with no association detected with intellectual disability, clinical subtype, and motor function. In a surveillance study among 8-year-old children in the United States, an autism spectrum disorder was seen in 8% of children with CP.

Limited studies have looked at sleep disorders in CP. In a single European study, 23% of school-aged children with CP had a sleep disorder, including difficulty in initiating and maintaining sleep, sleep-wake transition, and sleep breathing disorders. Active epilepsy was 17 times more likely to be associated with the presence of a sleep disorder, as was being the child of a single-parent family (4 times more likely), sleeping with parents (6 times more likely), having a spastic quadriplegia subtype (13 times more likely) or dyskinetic CP (21 times more likely), and having a severe visual impairment (13 times more likely).

## IX. CONCLUSION

Challenges remain in understanding the causal spectrum and mechanisms of CP and providing comprehensive care for

these individuals. At present, a subset remains without an apparent underlying etiology and normal neuroimaging despite objective findings of substantive neuroimpairment on examination. Genetic and epigenetic factors are clearly at play, affecting both the predisposition to either congenital or acquired etiologies and modifying interindividual differences in resiliency and the response to acquired injury. These factors remain to be elucidated. Early diagnosis, in both at-risk and community-derived populations, should be a goal as early interventions are thought to improve later functional outcomes. Increasing emphasis on the functional categorization of severity, together with sensitivity to the contextual influences on individual participation and quality of life, should prompt a widening of the lens of care provision and foster partnerships across healthcare professions to optimize individual potential. Policy changes at a health service delivery and societal level, at least in high resource settings, can effectively enable this alteration in approach and improve outcomes. In contrast, low resource settings will need to address fundamental issues of prevention, through improved maternal and obstetric care, and a fairer population-wide distribution of access to healthcare. Through these efforts in a variety of domains, we can foresee a lessening of the incidence of CP and improvements in the quality of life of those affected and their primary caregivers.

Tourette syndrome is a disorder characterized by chronic motor and vocal tics. It is one of several disorders that have tics as a cardinal feature, and many other psychopathologies can coexist with tic disorders. There is now strong evidence for involvement of genetics and environmental influences in underlying etiology. Cortico-striatal-thalamo-cortical pathways have been implicated, but a precise pathophysiological location remains under investigation. There is no cure for tics, but various behavioral and pharmacologic therapies are currently used for symptom control.

### TIC PHENOMENOLOGY

Tics are involuntary, sudden, rapid, abrupt, repetitive, recurrent, and nonrhythmic movements or vocalizations. They have differing degrees of intensity and frequency and have unpredictable durations (Cohen, Leckman, and Bloch, 2013). Because some vocal (phonic) tics are the result of muscle contractions of the diaphragm or oropharynx forcing air across the vocal cords or through the nose and mouth, the formal separation of tics into motor and vocal components has been questioned. Both motor and phonic tics are subdivided into simple and complex categories. Simple motor tics are brief, rapid movements that involve only a single muscle or localized group. Examples include eye blinking, head jerking, nose wrinkling, shoulder shrugging, and abdominal tensing. In contrast, complex motor tics involve either a cluster of simple actions or a more coordinated sequence of movements. Complex motor tics can be nonpurposeful, such as facial or body contortions, have a more prolonged maintenance of a position or dystonic character, or appear purposeful but actually serve no purpose, such as touching, hitting, smelling, jumping, repeating observed movements (echopraxia), or making obscene gestures (copropraxia). Some have subdivided tic movements into additional categories such as clonic (eye blinking, head jerking), tonic (muscle tensing), dystonic (sustained posture), and blocking (prolonged tonic or dystonic tics that interrupt ongoing motor activity). Simple phonations include various sounds and noises, such as grunts, barks, yelps, sniffs, screeches, and throat clearing. Complex vocalizations involve the repetition of words, syllables, phrases, echolalia (repeating other people's words), palilalia (repeating one's own words), or coprolalia (repeating obscene words).

Several common characteristics of tics include their presence in typical locations, a waxing and waning course, the presence of particular factors that exacerbate or reduce tics, a suggestible nature, the report of a premonitory sensation, and suppressibility. Although tics may involve almost any external body part, nearly all TS patients at some time have tics involving the face and head regions. Tics can be exacerbated by periods of anticipation, emotional upset (e.g., stress, anxiety, excitement, anger), or fatigue. Tic reduction often occurs when the affected individual is concentrating, focused, engaged in an activity, emotionally pleased, or during sleep. Patients with tics may occasionally attempt to disguise a tic as a seemingly purposeful behavior.

Premonitory urges are sensory phenomena and can consist of a feeling, urge, impulse, tension, pressure, itch, burning, or tingle that occurs before a motor or phonic tic. These sensations occur in more than 90% of adults with TS but less frequently in young children. The "urge" often immediately disappears following performance of the tic, but recurs. Severity of premonitory sensations has been correlated with tic severity. The ability to briefly suppress tics is relatively common. This active suppression of tics, however, is often associated with an exacerbation of premonitory sensations.

Misdiagnoses are common because, for example, eye-blinking tics may be thought to stem from ophthalmologic problems, ocular tics can be confused with opsoclonus, throat-clearing tics can be thought to result from sinusitis or allergic conditions, involuntary sniffing frequently results in referral to an allergist, and a chronic and persistent cough-like bark could be mistaken for asthma. Nontic movements that should be distinguished from tics include motor stereotypies, drug-induced akathisia, dystonia, and parkinsonism, and those associated with common comorbidities such as obsessive-compulsive disorder (OCD), attention deficit hyperactivity disorder (ADHD), and impulsive and antisocial behaviors.

Tics can be assessed clinically with the use of several scales. The most widely used is the Yale Global Tic Severity Scale (YGTSS), which consists of (1) a total tic score based on number, frequency, intensity, complexity, and interference of tics, and (2) a tic impairment score based on the effects on self-esteem, family life, and social acceptance (Cohen et al., 2013).

### TIC DISORDERS

The diagnosis of a tic disorder is based solely on historical features and a clinical examination that confirms their presence and eliminates other conditions. There is no biomarker for the disorder, and thus no blood test, brain scan, or genetic screen is available for diagnostic confirmation. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-V) lists six different tic disorders, as shown in Box 98-1.

*Provisional tic disorder* is the new recommended term established to designate an individual with ongoing fluctuating motor and/or vocal tics that began before age 18 years and have been present for less than 1 year.

*Chronic motor or vocal tic disorder* requires that fluctuating tics start before age 18, be present for more than 1 year, and individuals have either solely motor or, less commonly, solely vocal tics, but not both.

*Tourette syndrome (TS)* formal criteria based on the definition provided by the Tourette Syndrome Classification Study Group are very similar to those for Tourette disorder (TD) in the DSM-V. Diagnoses require multiple motor and at least one vocal tic to have been present at some time during the illness, although not necessarily concurrently. Criteria from the TS classification group retain an age of onset before 21 years, rather than the DSM-V's age-of-onset limitation to less than

**BOX 98-1** Tic Classifications**DSM-V CLASSIFICATION**

Provisional Tic Disorder  
 Chronic Motor or Vocal Tic Disorder  
 Tourette Disorder (Tourette Syndrome)  
 Substance-Induced Tic Disorder  
 Tic Disorder Due to a General Medical Condition  
 Tic Disorder, Not Otherwise Specified

18 years. Tics should occur many times a day, nearly every day or intermittently, throughout a period of 1 year.

**Substance-induced tic disorder** requires evidence that motor and/or vocal tics developed during or within 1 month of substance intoxication or withdrawal, or that substance use is etiologically related to the disturbance. Examples include cocaine-induced tics and tics that developed following the use of neuroleptics. Stimulants used to treat ADHD are not included, because evidence indicates that treatment with stimulants does not exacerbate tics.

**Tic disorder due to a generalized medical condition** can involve many diagnoses, because tics have been reported in many sporadic, genetic, and neurodegenerative disorders. For example, tics have been associated with neuroacanthocytosis, Huntington disease, neurodegeneration with brain iron accumulation, encephalitis, infection, stroke, and head trauma.

**Tic disorder not otherwise specified** refers to disorders that do not meet criteria for a specific tic disorder because the movements or vocalizations are atypical in age of onset (i.e., adult onset) or clinical presentation. Tic disorders in adults usually have their onset in childhood, although some have had their onset beyond the age of 21 years. Symptoms with origination in adulthood are often associated with potential environmental triggers, are typically more severe, have a greater social morbidity, and show a poorer response to medications.

**COURSE**

Motor tics typically begin between the ages of 4 to 8 years with a mean of about 6 to 7 years. The average age of diagnosis is just over 8 years of age. Coprolalia, when present, has a mean age of onset of 14 years. Tics have a waxing and waning course, and fluctuation of symptoms is expected. Fluctuations occur within the course of a day and throughout periods of months or longer. The course of TS can be quite variable, with most patients having a decline in symptoms during the teenage and early adulthood years. Maximum tic severity tends to be between the ages of 10 to 12 years. Long term, most studies support a broad “rule of thirds”—one third of cases disappear, one third are better, and about one third continue—as a reasonable estimate of outcome. Predictors of outcome are controversial, with severity, motor control, and imaging findings having been investigated (Singer, Gilbert, Wolf, Mink, and Kurlan, 2012).

**EPIDEMIOLOGY**

Epidemiologic studies have shown that about 20% to 27% of children in a regular classroom setting will exhibit tics. Tourette syndrome occurs worldwide, with evidence of common features in all cultures and races. Prevalence is estimated at 0.52%. The disorder is more common in males than in females, with a ratio of about 3 to 4 boys to 1 girl. TS is more common in those with autism spectrum disorders or fragile X syndrome.

**COMORBID DISORDERS**

Comorbid diagnoses are common in TS, specifically psychiatric diagnoses. Approximately 85% of TS patients qualify for at least one psychiatric diagnosis, most commonly ADHD or OCD (Hirschtritt et al., 2015).

**ADHD** is characterized by impulsivity, hyperactivity, and a decreased ability to maintain attention. Symptoms begin in early childhood and typically precede the onset of tics. ADHD is reported to affect approximately 50% of patients with TS. ADHD symptoms in TS correlate with increased psychosocial difficulties, disruptive behavior, peer rejection, emotional problems, functional impairment, family conflict, learning disabilities, and school problems. Those with comorbid ADHD may have poorer overall functioning and worse scores on quality-of-life assessments.

**OCD** is characterized by persistent obsessions (persistent recurrent intrusive, thoughts, images, or impulses that are unwelcome and intrude upon conscious thought) or compulsions (repetitive seemingly purposeful behaviors usually performed in response to an obsession, in accord with certain rules, or in a stereotyped fashion). Obsessive-compulsive behaviors (OCBs) become a disorder (OCD) when activities are sufficiently severe to cause marked distress, take up more than 1 hour of the day, or have a significant negative effect on normal routine, function, social activities, or relationships. In patients with TS, behaviors usually include a need for order or routine and a requirement for things to be symmetric, involving behaviors such as arranging, ordering, hoarding, touching, tapping, rubbing, counting, checking for errors, or evening up. In contrast, OCD subjects without tics typically have compulsions related to fear of contamination and cleaning. Differentiating OCB from tics may be difficult; however, suggestive features for OCD include a cognitive-based drive and need to perform the action in a particular fashion (e.g., a certain number of times, until it feels “just right,” or equally on both sides of the body). OCBs occur in from 20% to 89% of patients with TS, generally emerge several years after the onset of tics, typically become more severe at a later age, and are more likely to persist than tic symptoms.

**Anxiety and depression** are also commonly diagnosed in TS patients. The high-risk period for development of an anxiety disorder begins around age 4, and for mood disorder around age 7. Children with chronic tic disorders are more likely to have suicidal thoughts or behaviors. Additional non-OCD-related anxiety disorders include separation anxiety, agoraphobia, and panic disorder.

**Disruptive behaviors** have been noted in some individuals with TS, including significant problems with labile emotion, anger control, and aggression. Episodic outbursts may include screaming, threatening behaviors, stomping, kicking, destroying objects, punching holes in walls, and so forth. Self-inflicted, nonaccidental behaviors (head banging, body punching or slapping, banging oneself against a hard object, poking sharp objects into the body, scratching body parts) also occur in TS. Explosive outbursts are more common in patients with younger age of tic onset, greater tic severity, and ADHD. Conduct disorder and oppositional defiant disorder are also seen in TS, although no evidence exists to suggest that patients with TS are more likely to engage in criminal activities. Other psychopathologies such as personality disorders may also be more frequent in TS.

Despite typically having normal intellectual functioning, poor school performance is common in children with tics. This effect may extend into adulthood; adults with tics can have impairments within the workplace. Potential etiologies for academic problems are multiple and include tic severity,

psychosocial problems, ADHD, OCD, learning disabilities, executive dysfunction, and prescribed medication.

Problems associated with sleep have been reported in about 20% to 65% of children and young adults with TS and include difficulties with insomnia, bedtime rituals, dreams, and parasomnias. Restless leg syndrome (RLS) has been reported in up to 10% of patients with TS.

## ETIOLOGY

**Genetic** A genetic or epigenetic basis for TS has long been hypothesized, but despite extensive subsequent investigations, the precise pattern of transmission and the identification of the gene remain elusive. Family studies show a 10- to 100-fold increase in incidence of TS in first-degree relatives. The strongest support for a genetic disorder is based on studies of monozygotic and dizygotic twins; there is 77% to 94% concordance for tic disorders in monozygotic twins versus 23% in dizygotic twins (Paschou, 2013). Linkage analyses identified strong evidence for linkage to markers on chromosome 2p23.2, with suggestive evidence for linkage on chromosomes 5p and 6p. Candidate gene studies, focusing primarily on genes involved in neurotransmitter systems, have found a significant association between TS and a dopamine transporter polymorphism and a serotonin receptor polymorphism. A heterozygous loss-of-function mutation in L-histidine decarboxylase has been identified (Paschou, 2013). A genome-wide association study (GWAS) in TS failed to find any significant loci, but several strong signals were identified, including COL27A1, POLR3B, and the intergenic region between SLITRK1 and SLITRK6. It is possible that no causative gene has been identified as a result of the phenotypic heterogeneity of the disorder. Epigenetic factors and in utero exposures have also been suggested to have a role.

If a mother or father has TS, the likelihood that a son will develop a condition on the TS spectrum is estimated to be about 40% to 45%: the approximate risk for TS is 10% to 15%; for chronic tics 15% to 20%; and for OCB without tics approximately 5% to 10%. The overall risks for a daughter are about 25% to 35%: 3% to 5% for TS; 10% to 15% for chronic tics; and 10% to 20% for OCB without tics. If both parents have TS and/or OCD, based on studies of only small numbers of bilineal families, the offspring's risk for a TS-spectrum problem may be as high as 70% to 90%: for TS 25% to 50%, and for chronic tics 40% to 65%. It is emphasized, however, that although susceptibility risks may be high, most affected individuals have very mild conditions.

**Autoimmune** Several investigators have proposed that, in a subset of children, tic symptoms are caused by a preceding  $\beta$ -hemolytic streptococcal infection (GABHS). Labeled as pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection (PANDAS), proposed criteria include the presence of OCD and/or tic disorder; prepubertal age at onset; sudden, "explosive" onset of symptoms and/or a course of sudden exacerbations and remissions; a temporal relationship between symptom exacerbations and GABHS; and the presence of neurologic abnormalities, including hyperactivity and choreiform movements. The existence of PANDAS as an etiologic entity remains controversial based on both epidemiologic and autoimmune studies (Elamin et al., 2013). Concerns about individual criterion proposed for the diagnosis include the following: the age of onset does little to separate tic disorders from the PANDAS subgroup; neuropsychological and family genetic studies of PANDAS cases show few differences from what is typically seen in early-onset OCD or TS; the sudden, explosive onset or worsening of tic symptoms occurs frequently in unselected children with tic disorders; studies do not consistently support an epidemiologic

link to GABHS; and clinical findings have shown that exacerbations in PANDAS cases are usually not temporally related to a streptococcal infection. Results of serum antineuronal antibodies and other immune factors in PANDAS have been inconclusive via multiple methodologies. Although the PANDAS diagnosis is controversial, there still remains the clinical entity of an acute or fulminant onset of neuropsychiatric symptoms, which can include tics in some individuals. Updated diagnoses with broader criteria have been proposed: childhood acute-onset neuropsychiatric symptoms (CANS) and pediatric acute-onset neuropsychiatric syndrome (PANS). Diagnostic criteria for PANS include lack of other known medical diagnosis to account for symptoms, abrupt onset of OC symptoms or restrictive food intake, and at least two of the following: anxiety, emotional lability/depression, aggression, developmental regression, school performance deterioration, motor or sensory abnormalities, somatic symptoms. Presence of tics has been deemphasized in newer PANS criteria. The diagnosis of CANS requires the acute onset of symptoms. These diagnoses do not suggest a definite relationship with a specific infectious etiology, such as streptococcal infection, and such dramatic symptom onset should prompt a thorough evaluation for multiple possible underlying causes, such as infectious, metabolic, toxic, and autoimmune etiologies (Singer et al., 2012).

## NEUROBIOLOGY OF TIC DISORDERS

### Anatomic Abnormalities

A series of parallel cortico-striatal-thalamo-cortical (CSTC) circuits provides a framework for understanding the neurobiological relationships that exist between tic disorders and associated comorbidities. The motor circuit, proposed to be abnormal in the production of tic symptoms, originates primarily from the supplementary motor cortex and projects to the putamen in a somatotopic distribution. The oculomotor circuit, possibly influencing ocular tics, begins principally in the frontal eye fields and connects to the central region of the caudate. The dorsolateral prefrontal circuit links Brodmann's area 9 and 10 with the dorsolateral head of the caudate and appears to be involved with executive functions (flexibility, organization, constructional strategy, verbal and design fluency) and motor planning (sequential and alternating reciprocal motor tasks). The lateral orbitofrontal circuit originates in the inferior lateral prefrontal cortex (area 11 and 12) and projects to the ventral medial caudate. This circuit is associated with obsessive-compulsive behaviors, personality changes, mania, disinhibition, and irritability. Finally, the limbic circuit arises in the cingulate gyrus and projects to the ventral striatum, which also receives input from the amygdala, hippocampus, medial orbitofrontal cortex, and entorhinal and perirhinal cortex. A variety of behavioral problems may be linked with this circuit. Although direct and indirect evidence suggest that components of CSTC circuits are involved in the expression of tic disorders, identification of the primary abnormality (i.e., cortical or striatal) remains an area of active research (Singer, 2005).

The striatum is often implicated in anatomic investigations of TS. Postmortem studies showed a reduction in GABAergic interneurons in the striatum. Multiple volumetric magnetic resonance imaging (MRI) studies have shown abnormalities in the shape or volume of the caudate or lenticular nuclei. One hypothesis suggests a striatal compartment abnormality at the level of striosome-matrix organization based on anatomic, physiologic, and lesion studies (Ganos, Roessler, and Munchau, 2013). The ventral striatum, with its role in sequential learning and habit formation, has also been a

focus, and positron emission tomography (PET) studies with  $^{11}\text{C}$ -raclopride and amphetamine have also shown robust increases in DA release in the ventral striatum of TS subjects compared with controls. Functional MRI has shown decreased putamen and globus pallidus activity and increased caudate activity during tic suppression, and activation of the putamen before tic onset, and single-photon emission computed tomography (SPECT) imaging demonstrated decreased glucose utilization in the basal ganglia.

Although there is support for striatal involvement, there is also persuasive evidence supportive of primary cortical dysfunction in TS. Children with TS have executive dysfunction, cognitive inhibitory deficits, larger dorsolateral prefrontal regions on volumetric MRI, larger hippocampal regions, increased cortical white matter in the right frontal lobe, and alterations in size of the corpus callosum. Diffusion-tensor MRI studies of the corpus callosum in TS have shown lower fractional anisotropy, suggesting reduced white-matter connectivity in this interhemispheric pathway and in tracts of the CSTC pathway. Imaging has identified frontal and parietal cortical thinning, most prominent in ventral portions of the sensory and motor homunculi. Event-related  $^{15}\text{O}$ - $\text{H}_2\text{O}$  PET techniques showed that tics activated sensorimotor, language, executive, and paralimbic regions, and functional MRI studies have shown cortical activation before tic onset.

## Neurotransmitter Abnormalities

**Dopamine** Evidence supporting a dopaminergic abnormality in TS is derived from therapeutic responses to neuroleptics, data from postmortem studies, and a variety of nuclear imaging protocols. An increased release of dopamine has been demonstrated in both striatal and extra-striatal regions following amphetamine stimulation. With some variability, imaging studies of the striatum have shown a slight increase in the binding potential of dopamine receptors. A potentially unifying hypothesis has been proposed involving an abnormality of the phasic release of dopamine. The phasic DA hypothesis is further supported by clinical findings, including (1) the exacerbation of tics by stimulant medications, likely secondary to enhanced dopamine release from the axon terminal; (2) tic exacerbation by environmental stimuli, such as stress, anxiety, and medications, events shown to increase phasic bursts of dopamine; and (3) tic suppression with very low doses of DA agonists, likely attributable to presynaptic reduction of phasic DA release. Although this hypothesis could refer to either the cortex or striatum, a frontal dopaminergic abnormality is favored (Felling and Singer, 2011). Genetically, an association has been identified between a polymorphism of the dopamine transporter gene, *DAT Ddel*, and TS (Paschou, 2013).

**Serotonin** Serum studies in TS patients have shown decreased levels of serotonin and tryptophan. [ $^{123}\text{I}$ ]βCIT and SPECT studies investigating serotonin transporter binding capacity in TS patients show reduced binding in TS, but these findings are likely associated with the presence of OCD. PET imaging of tryptophan metabolism (alpha-[ $^{11}\text{C}$ ]methyl-L-tryptophan) has demonstrated decreased uptake in the dorsolateral prefrontal cortical regions and increased uptake in the thalamus. Polymorphic variants of tryptophan hydroxylase 2 have been postulated to be associated with TS, as have serotonin transporter gene polymorphisms and receptor gene polymorphisms.

**Glutamate** Reduced levels of the amino acid glutamate have been identified in the globus pallidus interna, globus pallidus externa, and substantia nigra pars reticulata regions of four TS brains (Felling and Singer, 2011). A large multigenerational family genome scan and a genome scan using sibling pairs and multigenerational families have identified evidence for

linkage to 5p13, an area that overlaps with the genomic region for the glial glutamate transporter1 (*SLC1A3* or *EAT1*) gene (Paschou, 2013). Other factors supporting a potential role for glutamate in TS include its essential role in pathways involved with CSTC circuits, the extensive interaction between the glutamate and dopamine neurotransmitter systems, and reports demonstrating that glutamate-altering medications have a beneficial therapeutic effect on obsessive-compulsive symptoms.

**GABA** On pathologic examination, brains of TS patients were found to have a decrease in parvalbumin-positive GABAergic interneurons in the caudate and putamen (Felling and Singer, 2011). PET imaging of GABA binding using  $^{11}\text{C}$ -flumazenil showed reduced GABA receptor binding within the striatum and other areas. Magnetic resonance spectroscopy has shown increased GABA concentrations in cortical supplementary motor areas. GABA-related gene expression has also been shown to correlate with tic severity.

## TREATMENT

Despite advances in understanding TS, there is neither a cure for tics nor an ideal tic-suppressing therapy. It is essential for the treating physician to identify whether tics or associated problems (e.g., ADHD, OCD, school problems, behavioral disorders) represent the greatest handicap. Specific criteria for initiating tic-suppressing therapy include the presence of psychosocial problems (e.g., loss of self-esteem; peer problems; difficulty participating in academic, work, family, social, and after-school activities; disruption of classroom settings) and/or musculoskeletal and physical difficulties. Tics have a natural waxing and waning course, and education is an essential component of the treatment process. The goal of treatment is not complete suppression of tics, but rather their reduction to a level at which they no longer cause significant psychosocial or physical disturbances.

**Nonpharmacologic Treatments** Classroom strategies include educating teachers and fellow students, providing optional study breaks, and eliminating unnecessary stressful situations. Various behavioral approaches (supportive psychotherapy, conditioning techniques, exposure and response prevention, cognitive behavioral therapy, awareness training, habit reversal, and hypnosis) have been tried in the treatment of tics. Comprehensive Behavioral Intervention for Tics (CBIT), a behavioral therapy that incorporates several approaches (psychoeducation, habit reversal therapy, functional intervention, reward system, and relaxation training), has been shown to be effective in randomized controlled trials of children and adults (Roessner et al., 2013). Alternative diets, supplements, and vitamins have not been validated in controlled trials. Acupuncture and repetitive transcranial magnetic stimulation may be helpful.

**Pharmacotherapy** Despite the absence of an ideal tic-suppressing medication, numerous medications have been tried, with varying levels of empirical support (Roessner et al., 2013) (see Table 98-1). A two-tiered approach is recommended based on side-effect profiles. For milder tics, non-neuroleptic medications (tier 1) can be used, and for more severe tics, typical and atypical neuroleptics (tier 2) may be needed (McNaught and Mink, 2011). Medications should be prescribed at the lowest effective dosage. The patient should be periodically reassessed and determinations made about the need for continued therapy. General principles include obtaining a ECG before starting neuroleptics, starting all medications at low doses, gradually increasing the dose if tic-induced psychosocial and/or physical difficulties persist, monitoring efficacy and side effects on an ongoing basis, using monotherapy whenever possible, and considering a

TABLE 98-1 Medications

Tier 1		Tier 2		Tier 3	
Drug	Category	Drug	Category	Drug	Category
Clonidine	A	Pimozide*	A	Dopamine agonists	—
Guanfacine	A	Fluphenazine	B	Pergolide	(B)
Baclofen	C	Risperidone	A	Pramipexole	—

Levetiracetam	C	Olanzapine	C	Delta-9-THC	C
Clonazepam	C	Haloperidol*	A	Donepezil	C
		Ziprasidone	B	Botulinum toxin	B
		Quetiapine	C	Sulpiride and tiapride	—

A, good supportive evidence (two randomized, placebo-controlled studies); B, fair (one positive placebo-controlled study); C, minimal (open-label, case reports)

\*Drug is FDA approved for the treatment of tics.

gradual medication taper during a nonstressful (e.g., summer vacation) period. Only two medications, pimozide and haloperidol, are approved by the U.S. Food and Drug Administration (FDA) for tic suppression.

**Tier 1 Medications.** Tier 1 medications include clonidine and guanfacine, among others. Clonidine and guanfacine are preferred in the treatment of comorbid ADHD as well.

**Tier 2 Medications.** Dopamine receptor antagonists (antipsychotics) are effective tic-suppressing agents, but side effects frequently limit their usefulness. The typical neuroleptics pimozide and fluphenazine are preferred over haloperidol because of fewer side effects. Long-term follow up of patients taking fluphenazine showed tolerability and no incidences of tardive dyskinesia. Atypical neuroleptics (risperidone, aripiprazole, olanzapine, ziprasidone, quetiapine) are characterized by a relatively greater affinity for serotonin receptors than for D2 receptors and a reduced potential for extrapyramidal side effects.

**Surgery** Deep-brain stimulation (DBS) has had preliminary success in treating tics. Target sites for high-frequency stimulation have included the centromedian-parafascicular complex of the thalamus, the globus pallidus interna, and the anterior limb of the internal capsule, although the ideal target site remains to be determined. DBS can be considered in refractory cases in which therapies such as alpha-adrenergic agents, neuroleptics, behavioral therapy, and additional agents such as tetrabenazine or clonazepam have failed (McNaught and Mink, 2011). The approach should involve a multidisciplinary team, and additional ethical review is recommended for patients under age 18. Comorbidities need to be adequately addressed and managed.

## Genetic and Metabolic Disorders of the White Matter

*Adeline Vanderver and Nicole I. Wolf*

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

**INTRODUCTION**

Over the past several decades, an increasing number of novel heritable disorders affecting the white matter of the brain, or leukodystrophies, have been described, often with identification of a causative gene (Table 99-1). Pathognomonic MRI patterns (Fig. 99-1) or clinical characteristics permitted identification in a number of these disorders, and should guide the clinician's molecular diagnosis for many conditions (see Fig. 99-3 and 99-5 for MRI features). In addition, the recent advent of next generation sequencing approaches has permitted rapid increase in the number of novel diseases identified, as well as improved diagnosis for individual patients.

It remains challenging to distinguish inherited disorders from acquired white matter pathologies such as periventricular leukomalacia, immunologic disorders, toxic or infectious processes. This distinction is critical to patient management and genetic counseling, and acquired etiologies should be excluded by clinical history, examination, and laboratory testing before pursuing differential diagnosis of the heritable white matter disorders. Special consideration should be given to endocrine dysfunction, as both congenital and acquired thyroid and adrenal dysfunction have been associated with white matter abnormalities, as have nutritional factors such as vitamin B12 deficiency.

Although history and clinical examination are critical to excluding acquired leukoencephalopathies or disorders with secondary white matter manifestations, many classic leukodystrophies share clinical manifestations with these other disorders. The hallmarks of CNS white matter disorders are progressive spasticity (often associated with rigidity or ataxia), bulbar symptoms, and relatively preserved cognitive function. Cranial nerve abnormalities such as optic nerve atrophy, strabismus, or nystagmus and hearing loss can be seen. Peripheral nerve function may be impaired depending on the disorder. Seizures are less commonly seen and should alert the clinician to the possibility of an underlying neuronal disorder, as should prominent dementia.

Given the heterogeneity and limited specificity in clinical findings, MRI pattern recognition is the most useful tool for evaluating suspected leukodystrophy patients (Schiffmann and van der Knaap, 2009) (Fig. 99-1). Imaging should be reviewed comprehensively, with attention to changes over time, expected myelin development for the patient's age, and characteristics of T1-weighted and T2-weighted signal abnormalities. Broadly, there are two groups of leukodystrophies. Hypomyelinating leukodystrophies show increased white matter signal on T2 relative to age and often isointense or hyperintense white matter signal on T1. Conversely, demyelinating leukodystrophies show increased white matter signal on T2 relative to

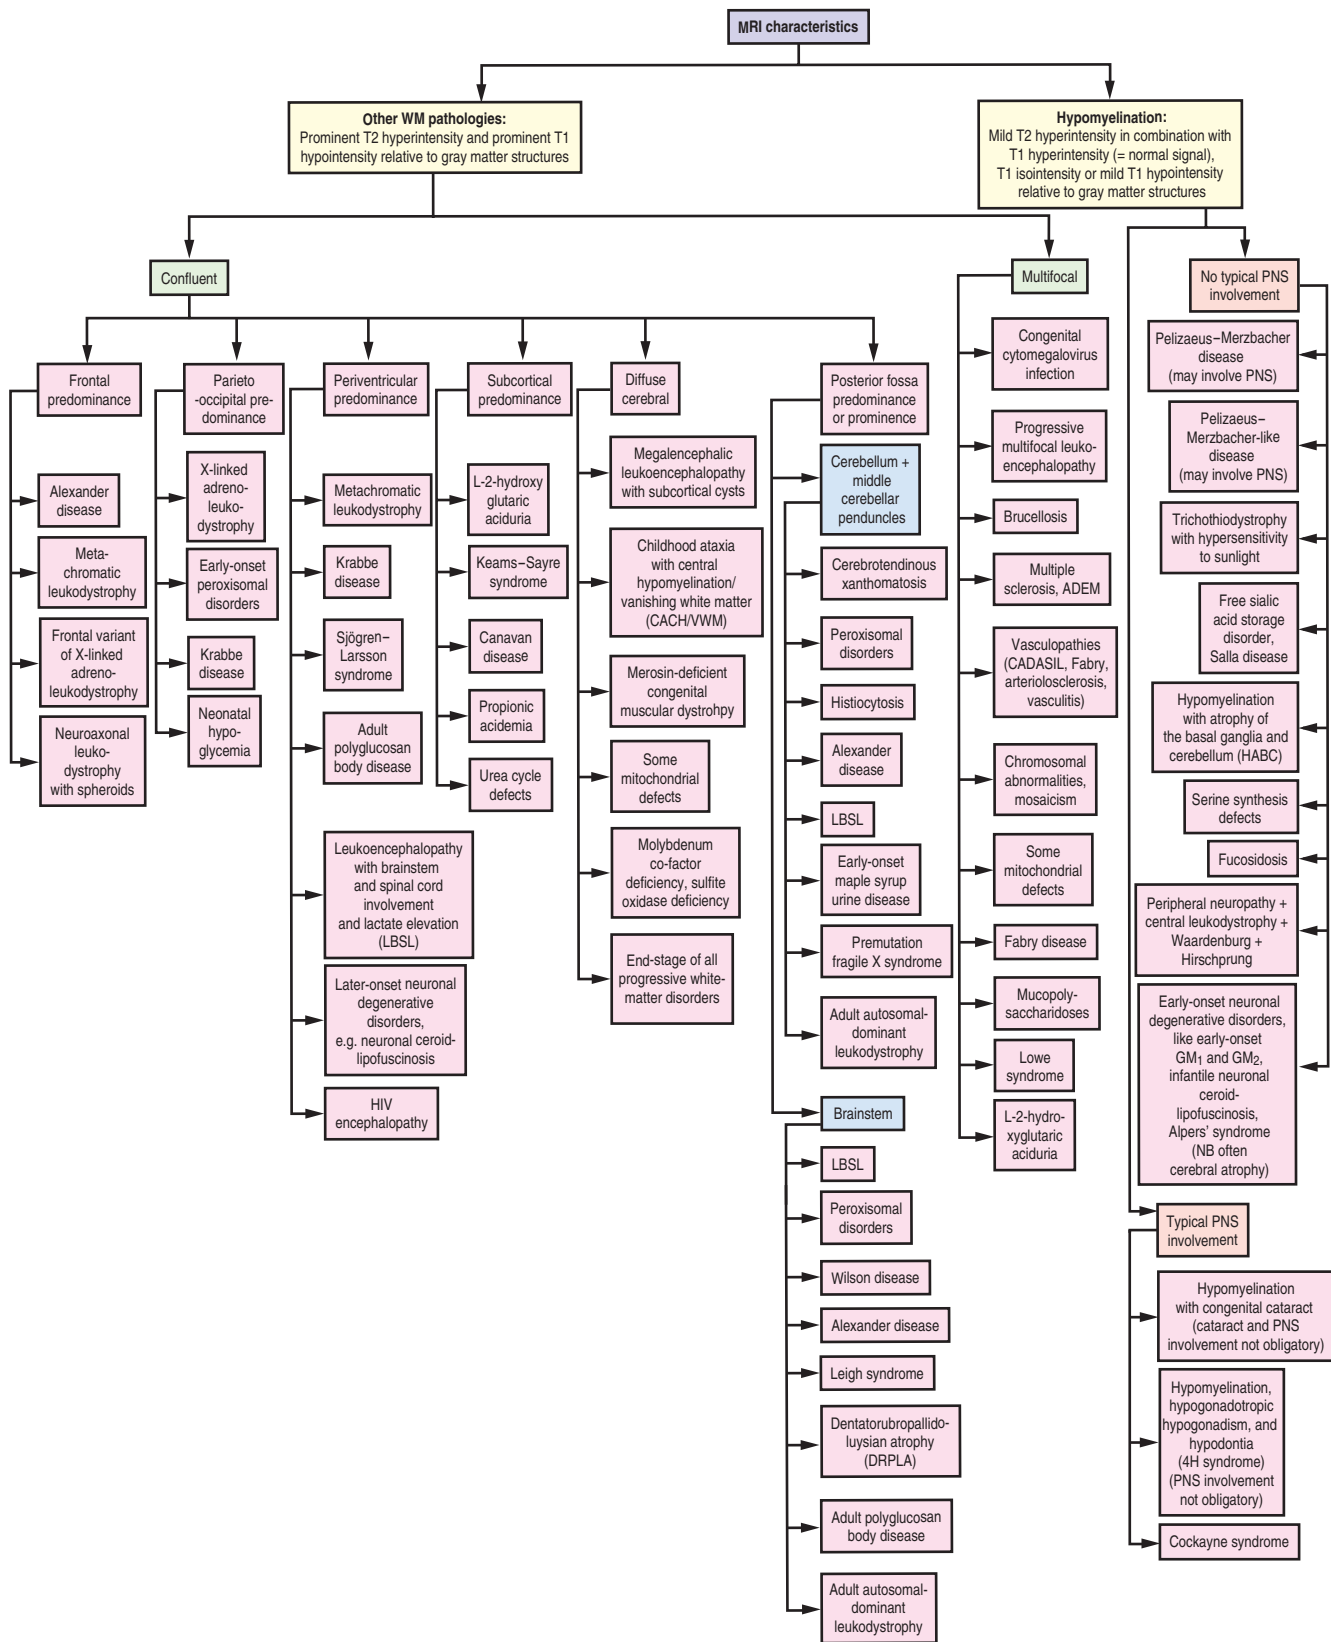

age and hypointense white matter signal on T1. Additional radiologic features should be assessed, such as white matter vacuolization or cysts, best seen on FLAIR or similar imaging paradigms; involvement of the basal ganglia, brainstem, cerebellum, or spinal cord; and abnormalities of cortical gray matter. Finally, findings consistent with calcifications should be noted, and a CT scan or calcium-sensitive MRI sequences should be acquired to exclude the presence of calcifications that might be missed on standard MR imaging. An overview of those features and the disorders exemplifying them can be found at GeneReviews (<http://www.ncbi.nlm.nih.gov/books/NBK184570/>).

**PART I. HYPOMYELINATING WHITE MATTER DISORDERS**

White matter disorders with hypomyelination are relatively frequent; hypomyelinating leukodystrophies comprise 20% of leukodystrophies. They are characterized by a significant and permanent deficit of myelin (Pouwels et al., 2014; Schiffmann and van der Knaap, 2009). Even with thorough genetic investigation, at least half of these hypomyelinating disorders lack definitive diagnosis, prognostic information, and potential for prenatal diagnosis. Although most of these disorders show autosomal recessive inheritance, both X-linked inheritance and de novo mutations are possible. Clinical manifestations common to hypomyelinating disorders are ataxia, spasticity, and nystagmus. Other nonneurologic features such as hypodontia in 4H syndrome or cataracts in hypomyelination with congenital cataracts can be valuable in diagnosis.

The diagnosis of hypomyelination may be made if two MRIs at least 6 months apart after the age of 12 months show little or no myelin development. Images in hypomyelinating leukodystrophies demonstrate a diffusely hyperintense signal of the supratentorial white matter in T2-weighted images and an isointense or hyperintense white matter signal on T1-weighted images. Certain areas such as the posterior internal capsule may have more normal-appearing myelin signal. Myelin deposition in infratentorial structures is usually less affected. A definitive diagnosis of hypomyelination is not possible in young infants, as myelination is incomplete. If no myelin deposition is visible on the first MRI of a child older than 24 months, however, hypomyelination is highly probable (Schiffmann and van der Knaap, 2009).

Delayed myelination is sometimes misdiagnosed as hypomyelination. In contrast to hypomyelination, myelination progresses on serial MRI images to near normal myelin development (Fig. 99-2). A typical example of a disease with severely delayed but progressing myelination is the X-linked recessive condition thyroid hormone transporter (MCT8)

**Figure 99-1.** Diagnostic algorithm for use in patients with abnormal myelination by MRI. (With permission from Schiffmann, R., van der Knaap, M.S., 2009. Invited article: an MRI-based approach to the diagnosis of white matter disorders. *Neurology* 72, 750–759).

**Figure 99-3. Hypomyelinating leukodystrophies and their differential diagnosis.** **A**, MRI of a 23-month-old child with Pelizaeus-Merzbacher disease and a duplication of PLP1. The supratentorial axial T2-weighted images show homogeneous hyperintense white matter signal, indicating profound hypomyelination. There is also lack of myelin in the cerebellum. **B**, MRI of a 5-year-old child with Pelizaeus-Merzbacher-like disease due to a missense mutation in GJC2. The brainstem is less well myelinated, and the signal of the pyramidal tracts is slightly elevated. In the supratentorial structures, signal of the white matter is too high in the T2-weighted image. The sagittal T1-weighted image shows a normal cerebellar volume but a thin corpus callosum. **C**, MRI of a 3-year-old child with 4H syndrome. White matter shows diffusely elevated signal with sparing only of a part of the posterior limb of the internal capsule and of the optic radiation. The coronal and sagittal images demonstrate the cerebellar atrophy. **D**, MRI of an 8-year-old child with Salla disease. Note diffuse increased signal of the supratentorial white matter, with relatively better myelination of the corpus callosum and posterior limb of the internal capsule. **E**, MRI of a child with hypomyelination with congenital cataracts. The white matter signal in the T2-weighted image is slightly higher than in other hypomyelinating disorders. In the corresponding T1-weighted image, there are hypointense areas. Both indicate elevated water content. **F**, MRI of a 20-month-old child with GM1 disease. Note the delayed myelination, accompanied by globus pallidus signal abnormality. **G**, MRI of a 15-month-old child with POLG1 deficiency. Note the delayed myelination and atrophy in this child with a gray matter disorder. **H**, Axial T2-weighted image of a 12-month-old child with infantile neuronal ceroid lipofuscinosis; the signal of the white matter is also elevated compared with healthy children. Note the severe atrophy in the child with this gray matter disease.

deficiency, and thyroid function should be tested in boys with severe myelination delay on MRI, severe cognitive delay, and a pyramidal syndrome. Appropriate testing includes free T3 (which is elevated) and reverse T3 (which is decreased) in the context of either normal or reduced T4 and normal or slightly elevated TSH. Gray matter disorders with early onset often show hypomyelination, presumably a result of defective axonal function. Features such as early atrophy and signal changes of cortex and basal ganglia may help distinguish between primary hypomyelination and hypomyelination secondary to neuronal dysfunction (Fig. 99-3F, G, and H).

### 1. Pelizaeus-Merzbacher Disease

Pelizaeus-Merzbacher disease (PMD, OMIM 312080) is the prototypic hypomyelinating disorder and is caused by alterations in the proteolipid 1 (PLP1) gene. Located on Xq22.2, this gene encodes the PLP1 protein, which constitutes roughly half of all myelin protein. The most common abnormality is a duplication of the entire gene, found in 60% to 70% of PMD cases and associated with the classic form of the disease. Missense mutations account for 10% to 15% of cases. Deletions are also seen in a smaller number of cases. Triplications or even higher copy numbers are present in 1% to 2% of cases. More complex chromosomal rearrangements involving PLP1 or its promoter region have been described in individual cases. Deletions or null mutations are rare.

### 2. Pelizaeus–Merzbacher-Like Disease

Pelizaeus–Merzbacher-like disease (PMLD, OMIM 608804) is phenotypically similar to PMD, although its inheritance is autosomal-recessive instead of X-linked. Children with hypomyelination on MRI but without the PMD phenotype are often mischaracterized as PMLD. The primary clinical features include early nystagmus, ataxia, and spasticity. PMLD is a genetically heterogeneous disease. In most cases, no gene has been identified. In a small subset of clinically identified PMLD patients (fewer than 10%), mutations in GJC2 (also called GJA12), coding for Connexin 46.6 (Cx47), have been found (OMIM 608804), and the term PMLD is now mostly used for patients with GJC2 mutations.

### 3. 4H Syndrome

This recently described leukoencephalopathy (OMIM 607694, 614381) is also characterized by hypomyelination. Its name is derived from its three main clinical findings: hypomyelination, hypodontia, and hypogonadotropic hypogonadism. About 90% of cases are caused by recessive mutations in either POLR3A or POLR3B, encoding the two largest subunits of RNA polymerase III. 4H syndrome is the second most frequent hypomyelinating white matter disorder after PMD.

### 4. Hypomyelination Related to Cytoplasmic tRNA Synthetase Defects

Recently two hypomyelinating disorders were described due to mutations in DARS or RARS—coding for the cytoplasmic tRNA synthetases for aspartate (OMIM 615281) and arginine (OMIM 616140), respectively. Clinically, both entities are remarkably similar with onset in infancy in most cases, a fine, rapid nystagmus, early severe spasticity, and ataxia. Again, cognition is much less affected than motor abilities, with normal cognitive abilities in a part of the patients with DARS mutations. Two patients with subacute onset in late

adolescence and DARS mutations have been reported, mimicking multiple sclerosis, including presumed response to steroids.

### 5. Oculodentodigital Dysplasia

Oculodentodigital dysplasia is another hypomyelinating disorder characterized by dental abnormalities (ODDD, OMIM 164200). Its inheritance is autosomal dominant. Dominant mutations in another connexin gene on chromosome 6q21-23.2, GJA1 coding for connexin 43 (Cx43), cause ODDD. There is one family described with autosomal recessive mutations leading to the same phenotype. Cx43 is expressed in the developing brain and teeth, as well as in hands and feet.

### 6. Hypomyelination With Congenital Cataract

Hypomyelination with congenital cataract (HCC, OMIM 610532) is a recently described disorder with CNS hypomyelination reported in five families. The genetic locus of HCC is FAM126A, earlier called DRCTNNB1A, on chromosome 7p15.3. It encodes the hyccin membrane protein. Missense mutations, mutations affecting splice sites, and a deletion of the entire gene have been identified, but its role in myelination remains obscure.

### 7. Hypomyelination With Atrophy of the Basal Ganglia and Cerebellum

Hypomyelination with atrophy of the basal ganglia and cerebellum (H-ABC, OMIM 612438) is a rare disorder caused by dominant de novo mutations in the gene coding for one of the beta-tubulins, TUBB4A. MRI shows hypomyelination, cerebellar atrophy, and atrophy or absence (in later stages) of the putamen apparent within the first year of life. The caudate is reduced and disappears entirely in some patients. Over time, white matter loss leads to supratentorial atrophy. These MRI features are considered diagnostic. Recently it became obvious that basal ganglia may be normal in this disorder. TUBB4A is therefore an important gene to consider in the differential diagnosis of hypomyelination.

### 8. Sialic Acid Storage Disorders

Salla disease (OMIM 604369) and infantile sialic acid storage disease (ISSD, OMIM 269920) are both caused by autosomal recessive mutations in SLC17A5 coding for sialin, a lysosomal membrane protein transporting sialic acid from lysosomes. The gene is located on chromosome 6q14/15.

### 9. Fucosidosis

Fucosidosis is another lysosomal storage disorder characterized by hypomyelination (OMIM 612280). MRI shows hypomyelination. A characteristic imaging feature of fucosidosis is high T1-signal and low T2-signal in globus pallidus, thalamus, and substantia nigra. Cerebral and cerebellar atrophy may be prominent in older patients.

### 10. Serine Synthesis Defects

Serine is synthesized by a three-step biochemical pathway, and defects in any of the three enzymes in this pathway have been shown to cause serine biosynthesis defects: 3-phosphoglycerate dehydrogenase (OMIM 601815),

phosphoserine phosphatase (OMIM 172480), and phosphoserine aminotransferase (OMIM 610992). The biochemical hallmark of these disorders is low serine and glycine concentration in CSF. Supplementation with serine and glycine is effective in seizure management. If treatment is commenced prenatally, head circumference at birth and development are normal. In untreated children, MRI shows hypomyelination and white matter volume loss.

## 11. Cockayne Syndrome and Trichothiodystrophy

Cockayne syndrome (CS) is a rare disease combining neurologic and nonneurologic features. This disorder and related disorders of DNA repair such as cerebro-oculo-facial syndrome (COFS) and trichothiodystrophy (TTD) are genetically heterogeneous. The classic form, Cockayne syndrome type I, presents in the first year of life with failure to thrive; weight is more affected than length (“cachectic dwarfism”), and there is loss of subcutaneous fat, leading to a “wizened,” bird-like, progeroid face. Microcephaly also develops, usually by the end of the second year. Children develop contractures of the large joints, giving them a typical posture. Hands and feet are disproportionately large. Dental caries are prominent. Psychomotor development is also delayed resulting in mild to severe cognitive disability. In Cockayne syndrome type II, the clinical picture is much more severe with growth failure already evident at birth. Loss or even absence of subcutaneous fat is striking. Joint contractures and kyphosis develop rapidly. Hypotonia is prominent initially, followed by development of spastic tetraparesis. MRI of patients with Cockayne syndrome shows hypomyelination. In severe cases with Cockayne syndrome type II, hypoplasia of cerebellum and brainstem are possible. Basal ganglia calcifications are common. Similar features are seen in trichothiodystrophy, although calcifications are less common than in Cockayne syndrome.

## 12. 18q Minus Syndrome

In this disorder (OMIM 601808), the distal region of the long arm of chromosome 18 is deleted. It occurs de novo most commonly. The contiguous gene deletion usually involves the bands 18q22.3→qter. The gene for myelin basic protein (MBP), a component of healthy myelin, is located within this region. It has been postulated that haploinsufficiency for MBP leads to the myelin abnormalities observed in 18q minus syndrome. Heterogeneity in severity of clinical symptoms and hypomyelination between patients, despite consistent loss MBP, is a focus of ongoing inquiry.

## 13. SOX10-Associated Disorders

These rare syndromes are caused by mutations in SOX10 on chromosome 22q13, which encodes a transcription factor for various genes, some such as GJB1 (connexin 32) involved in myelin formation and metabolism. They are characterized by a white hair lock and hypomelanotic spots, sensorineural deafness, and Hirschsprung disease. Patients are affected with varying severity, ranging from antenatal onset with congenital arthrogryposis multiplex and severe neurologic abnormalities to more mildly affected patients, lacking neurologic manifestations (Waardenburg-Shah syndrome, WS4, OMIM 277580). Consistent with a neurocristopathy, many features of this disease can be explained by defective differentiation or migration of neural crest cells. In the severe cases, MRI reveals hypomyelination.

## PART II. WHITE MATTER DISORDERS WITH DEMYELINATION

If MRI is not consistent with hypomyelination, if there is white matter hypointensity on T1 instead of isointensity or hyperintensity, and if there is hyperintensity on T2, then the imaging pattern fits the demyelinating leukodystrophies. They comprise the leukodystrophies with primary demyelination, leukodystrophies with white matter vacuolization and intramyelinic edema, calcifying leukoencephalopathies, cystic leukoencephalopathies, leukoencephalopathies with brainstem involvement, and most adult-onset leukoencephalopathies. In assessing patients with these leukodystrophies, careful attention should be paid to specific neuroimaging features, including basal ganglia or brainstem signal abnormalities, contrast enhancement, cysts, calcifications, contrast enhancement, or specific FLAIR imaging abnormalities (Figs 99-3 and 99-5) to assist in the differential diagnosis.

### A. Primary Demyelinating Leukodystrophies

These conditions comprise several of the “classic” leukodystrophies and include Alexander disease, X-linked adrenoleukodystrophy, metachromatic leukodystrophy, and Krabbe disease, as well as other less common disorders.

#### 1. Alexander Disease

Alexander disease (AxD, OMIM 203450) is associated with mutations in the gene encoding the glial fibrillary acidic protein (GFAP). GFAP mutations are thought to confer gain of function mutations, and a mutation on a single allele is sufficient to cause disease. In most cases, mutations are sporadic, although familial cases are described in adult or juvenile onset cases.

Type I AxD typically presents before the fourth year of life and with typical MRI features (van der Knaap et al., 2001). In very rare cases, patients present in the neonatal period with macrocephaly and delay in milestones, with both cognitive and motor deficits. Patients may present with seizures. Pyramidal and sometimes extrapyramidal features develop and children often lose motor skills in the first decade of life. Bulbar features such as intractable vomiting, swallowing difficulties, and respiratory compromise can be present early on or only develop over time. Hydrocephalus can become a significant clinical issue. Type II AxD (older than 4 years at onset) typically is associated with atypical MRI abnormalities, often sparing the supratentorial white matter and affecting predominantly the brainstem. These patients present with predominant motor dysfunction, often with progressive gait disturbance or fine motor difficulties and clinically evident spasticity. Bulbar symptoms, in particular palatal myoclonus, can be very suggestive of the diagnosis. Over time, dysphonia and dysphagia can become increasingly debilitating. Dysautonomia is frequent. Sleep apnea is a commonly reported problem.

#### 2. X-Linked Adrenoleukodystrophy

X-linked adrenoleukodystrophy (XALD, OMIM 300100) is associated with mutations in the ABCD1 gene encoding a peroxisomal membrane transporter. This disorder follows X-linked inheritance. Differences in disease manifestations are known to occur with identical genotype and even within a sibship, underscoring the likely effect of other genetic factors on clinical presentation.

XALD is characterized by three predominant phenotypes. The best known is the childhood-onset cerebral form (35%

**Figure 99-5. Dysmyelinating/Demyelinating leukodystrophies and pathognomonic MRI features, part I.** **A**, MRI of a child with juvenile-onset Alexander disease shows frontal predominance of white matter abnormalities on FLAIR imaging. Other features not demonstrated here include brainstem and basal ganglia abnormalities, contrast enhancement of various intracranial structures, T1 high and T2 low periventricular rim, ventricular garlands, and characteristic capping of the frontal horns of the lateral ventricles. **B**, MRI of a 20-month-old male with metachromatic leukodystrophy shows the butterfly pattern of involvement in the cerebral white matter, sparing the U-fibers. Note the prominent involvement of the corpus callosum. Within the affected white matter the presence of radiating stripes can be seen that are low signal on T2 and high signal on T1. **C**, MRI of a child with eIF2B4 mutations and vanishing white matter, demonstrating (image to the left) rarefaction of affected white matter on FLAIR images, and typical appearance of radiating strips on sagittal T1 images (image to the right). **D**, MRI images of a 10-year-old male with X-linked adrenoleukodystrophy, demonstrating (top image) posterior predominance of white matter involvement and involvement of the corpus callosum on FLAIR images, as well as the pathognomonic contrast enhancement of the border of the demyelinating lesion on post contrast images (lower image). **E**, Neuroimaging from a child with TREX1 mutations resulting in Aicardi-Goutières syndrome. MRI at 2 and 4 months (left and middle images) show the swollen appearance of subcortical white matter, in particular in the temporal lobes, and the rapid atrophy that occurred over a period of weeks. CT imaging of the head shows the sometimes limited calcifications in periventricular white matter, not visualized on standard MR imaging. **F**, MRI of a 3-year-old child with megalencephalic leukoencephalopathy with subcortical cysts. Sagittal T1 weighted images demonstrate subcortical swelling and cystic degeneration of the white matter, in particular in the temporal lobes (image to the left). FLAIR imaging clearly demonstrates cystic degeneration of affected white matter (image to the right). **G**, MRI of a 9-month-old female with Krabbe disease, demonstrating increased signal in the hilus of the dentate. This infant also had thickening of the optic chiasm, and diffuse white matter involvement.

of affected individuals), in which male children of school age (usually 4 to 8 years) present with a prior history of behavioral or cognitive changes. These are often initially misdiagnosed as attention deficit disorder, or hyperactivity. The progressive nature of the symptoms, overlaid with progressive motor difficulties, deteriorating school function and handwriting, altered perception of speech, and worsening behavior problems, usually brings the child to medical attention, and neuroimaging frequently is highly suggestive of the diagnosis. Disease course is variable, but complete symptom development occurs over a range of 6 months to 2 years. Over time, significant motor involvement develops with a spastic quadriplegia. In addition, bulbar dysfunction becomes problematic and often necessitates gastrostomy tube feeding. Adrenal insufficiency is a life-threatening complication of XALD, and studies suggest that a large number of subjects with the childhood-onset cerebral form have adrenal insufficiency at time of diagnosis. Adrenal function should be tested at diagnosis and monitored thereafter to permit symptomatic management.

A second frequent type of presentation is adrenomyeloneuropathy (AMN; 40% to 45% of affected individuals), characterized by onset in young adult males (20s to middle age) of progressive gait abnormalities, sexual dysfunction, and abnormalities of sphincter control. A third type is isolated adrenal insufficiency. On occasion, patients with adrenoleukodystrophy may first present with an Addisonian crisis and no neurologic features or abnormalities on neuroimaging. XALD should be on the differential diagnosis of isolated adrenal insufficiency in a male subject. Female carriers were long thought to be asymptomatic, but recent research demonstrated that the vast majority does develop symptoms and signs by the age of 60 years, especially progressive spastic paraparesis and urinary incontinence.

Diagnosis is based on characteristic clinical presentation and suggestive MRI features. MRI shows a predominance of occipital findings (Fig. 99-5C), although frontal and corpus callosum variants are recognized. The affected white matter appears hyperintense on T2 and hypointense on T1. Characteristically, there is a rim of enhancement around the abnormal tissue that can be very helpful in establishing the diagnosis, as few other leukodystrophies, with the exception of Alexander disease, show significant contrast enhancement. Treatment is possible in early stages of the childhood cerebral form and consists of hematopoietic stem cell transplantation (HSCT). Several children have been successfully treated with gene therapy.

### 3. Peroxisome Biogenesis Disorders

Peroxisome biogenesis disorders (PBD) are abnormalities of peroxisome biosynthesis caused by mutations in a series of PEX genes (at least 15 in humans) encoding various peroxins. A variety of clinical presentations exist. Rhizomelic chondrodysplasia punctata, characterized by skeletal deformities, facial dysmorphisms, and developmental abnormalities, is associated with hypomyelination or focal white matter signal abnormalities. A second clinical phenotype is characterized by the Zellweger spectrum, in which patients can present at variable ages with facial dysmorphisms, hypotonia, seizures, liver dysfunction, and developmental delay. Neuroimaging can show polymicrogyria and both hypomyelination and demyelination in cerebral and cerebellar white matter (Fig. 99-5F). Single enzyme deficiencies of peroxisomal fatty-acid  $\beta$ -oxidation (acyl-CoA oxidase deficiency (OMIM 264470), D-bifunctional protein deficiency (OMIM 261515), and peroxisomal thiolase deficiency) are clinically and radiologically similar to the peroxisomal biogenesis disorders.

### 4. Metachromatic Leukodystrophy

Metachromatic leukodystrophy (MLD, OMIM 250100) is caused by recessive mutations in the ARSA gene encoding Arylsulfatase A on chr. 22q13.31 and is inherited in an autosomal recessive manner. It is one of the most prevalent inherited white matter disorders. Homozygous or compound heterozygous ARSA mutations impair arylsulfatase A degradation of sulfatides, causing sulfatide accumulation within the brain and peripheral nervous system. Complete loss of arylsulfatase A activity ("I" or "O" alleles) is typically associated with early infantile MLD. Partial loss of arylsulfatase A activity ("R" or "A" alleles) is typically associated with juvenile or adult-onset MLD. Compound heterozygosity with an I and A allele usually results in juvenile onset MLD.

Additionally, there are common polymorphisms of ARSA (referred to as "PD" alleles), which result in sufficient residual activity to avoid sulfatide accumulation (pseudodeficiency). Enzymatic evidence of low arylsulfatase activity must be accompanied by abnormal urine sulfatides or demonstration of pathogenic ARSA mutations before establishing a diagnosis of MLD.

MLD is characterized by three clinical subtypes, defined primarily by age at presentation. Late-infantile MLD patients usually present by age 30 months, after a period of apparently normal development. Initial clinical manifestations include gait disturbance, ataxia, dysarthria. Initially symptoms may be slowly progressive or plateau, sometimes followed by a rapid loss of motor skills over a few weeks, during which time the diagnosis is commonly made. In the beginning, demyelinating peripheral neuropathy may be prominent, causing misdiagnosis as chronic inflammatory demyelinating polyneuropathy. Tonic spasms with pyramidal and extrapyramidal dysfunction and loss of peripheral reflexes are striking. Eventually, the disease progresses to severe motor impairment with loss of volitional movements, bulbar dysfunction, loss of vision and hearing, and seizures. The time course of deterioration is highly variable, and, with maximal supportive care, death often occurs much later than reported in older texts. The disease, however, is relentlessly progressive after the initial period.

Juvenile MLD patients present between age 30 months and 16 years (12 to 14 years). Patients presenting after this age are classified as having adult-onset MLD. Patients often present with cognitive and behavior difficulties. Younger juvenile-onset patients often show early motor involvement and may also show rapid decline. Clumsiness, gait problems, dysarthria, incontinence, and worsening behavioral problems occur later in the course and often prompt etiologic evaluation and diagnosis. Patients may have seizures, most often complex partial seizures. Progression is similar in juvenile MLD as described in infantile MLD, with a slower course.

Adult-onset MLD patients may present with motor symptoms common to earlier presentation. More commonly, they develop severe neuropsychiatric symptoms, often leading to misdiagnosis until motor features evolve. Patients may initially present with predominant peripheral neuropathy, or with seizures.

MLD diagnosis is often suspected based on clinical manifestations of central motor impairment with a peripheral neuropathy. Typical MRI features include sparing of arcuate fibers and a rim of subcortical white matter with involvement of periventricular and deep white matter in the supratentorial CNS (Fig. 99-5B). Involved white matter takes on the appearance of radiating stripes that can be highly suggestive of the disorder and reflects accumulation of sulfatides in perivascular macrophages. These radiating stripes are also present in other disorders, however, including Krabbe disease.

MLD is the focus of intensive research exploring approaches to restore partial enzymatic activity. HSCT has been performed in patients with MLD, but its success is dependent on the age and stage of disease progression and does not appear to completely halt disease progression. Gene therapy may be an emerging treatment option.

### 5. Metachromatic Leukodystrophy-Like Variants

In some cases, there is strong clinical suspicion of MLD, including presence of urinary sulfatides, but ARSA sequencing is normal. Two disorders should be considered in this clinical situation: deficiency of arylsulfatase activator protein (Saposin B) (OMIM 249400) and multiple sulfatase deficiency (MSD) (OMIM 272200).

### 6. Krabbe Disease or Globoid Cell Leukodystrophy

Krabbe disease (OMIM 245200) is caused by autosomal recessive mutations in the gene encoding galactosylceramidase (GALC) on chromosome 14q31(83-87). Two recurring mutations are associated with specific phenotypes. One common 30-kb deletion results in the classic infantile form in the homozygous state or when compound heterozygous with another mutation associated with severe disease. The 809G>A mutation is associated with the late-onset form of Krabbe disease, even when associated with mutations associated with severe disease.

Krabbe disease has two main forms. In the classic infantile form, onset is within the first 6 months, typically after a few months of apparently normal development. Patients present with irritability, hypertonia, and peripheral nerve involvement (stage I). CSF protein is elevated. This stage is followed by rapid deterioration leading to decerebrate posturing and almost opisthotonic positioning of the head and neck (stage II). Optic atrophy develops and pupillary light reflexes are abnormal. Seizures often occur at this stage. This period is often followed by a longer period of slow deterioration in infants in a near vegetative state (stage III). Infants often succumb to respiratory infections in the first years of life, although supportive care has been known to extend life. Late-infantile-onset forms (after 6 months of age) present with symptoms of vision loss, developmental regression, and spasticity. Juvenile (after 4 years of age) and adult-onset cases present with variable symptoms, including gait dysfunction, loss of vision, seizures, or cognitive-behavioral changes. The rapidity of decline appears to correlate with age at onset, with younger patients (late infantile and juvenile) progressing more rapidly than the adult-onset cases.

Diagnosis is suspected based on combined motor and peripheral nerve involvement. Neuroimaging can also guide diagnosis, with CT demonstrating highly suggestive hyperdensity of the thalami, caudate, corona radiata, and, in some cases, cerebellum, and brainstem. MRI is less pathognomonic than in other disorders; however, early involvement of the brainstem and cerebellar white matter, in particular the hilus of the dentate nucleus, can be helpful in establishing the diagnosis (Fig. 99-5G). If diagnosed early enough, cases with later onset may be treated with HSCT.

### 7. Saposin A Deficiency

An infant with abnormal myelination resembling Krabbe disease was found to have a mutation in the saposin A region of the prosaposin (PSAP) gene (OMIM 611722). Prosaposin is one of several known sphingolipid activator proteins and interacts with the enzyme GALC to catalyze the hydrolysis of lipids.

### 8. Sjögren-Larsson Syndrome

Sjögren-Larsson syndrome (OMIM 270200) is an autosomal recessive disorder characterized by ichthyosis, spastic diplegia or tetraplegia, and cognitive disability. The disorder is caused by mutations in the fatty aldehyde dehydrogenase (FALDH) gene, which result in impaired oxidation of long-chain aliphatic aldehydes derived from fatty alcohol metabolism. Neuroimaging reveals white matter disease in most patients with mild periventricular signal abnormalities on T2-weighted images.

## B. White Matter Disorders With White Matter Vacuolization and Intramyelinic Edema

Among the specific radiologic features associated with white matter disease, white matter vacuolization is very helpful in the differential diagnosis of leukodystrophies. The disorders most likely to present with white matter vacuolization are Canavan disease and eIF2B-related disorders, also known as vanishing white matter (VWM) and CACH (childhood-onset ataxia and central nervous system hypomyelination), although these disorders are clinically and radiologically distinct. One other disorder, not considered a leukoencephalopathy or leukodystrophy but which may have vacuolization on MRI is Lowe disorder. The oculocerebrorenal syndrome of Lowe (OCRL) is a multisystem disorder with major ocular, cerebral and renal abnormalities. OCRL is an X-linked disorder caused by mutations in OCRL1, encoding a phosphatidylinositol -4,5- bisphosphate 5-phosphatase.

In addition to disorders with white matter vacuolization, a new category of disorders is emerging, related to intramyelogenic edema. These include megalencephalic leukoencephalopathy with subcortical cysts (MLC), which is detailed in the section on cystic leukodystrophies, as well as the mechanistically related CIC-2 chloride channel-related leukoencephalopathy.

#### 1. Canavan Disease

Canavan disease (CD; OMIM 271900) is caused by a deficiency of aspartoacylase, encoded by ASPA. This disorder has been documented since at least the 1950s, but a biochemical marker was not identified until nearly 30 years later. Inheritance is autosomal recessive. Incidence is increased in patients of Ashkenazi Jewish descent, with two common mutations, p.Glu285Ala and p.Tyr231X, responsible for 98% of disease alleles, facilitating carrier screening in this population. In addition, p.Ala305Glu is responsible for 40% to 60% for the disease-causing alleles in non-Jewish populations and is responsible for 1% of disease-causing alleles in the Ashkenazi Jewish population.

Most patients with CD present with the infantile form. These children appear normal until approximately 3 to 6 months of life, when hypotonia with loss of head control, irritability, loss of milestones, and head circumference growth become notable. Over time, spasticity replaces hypotonia, optic atrophy, extrapyramidal movement disorders, seizures, and autonomic disturbances develop. In time, a more chronic vegetative state develops that can evolve over years. Tonic extensor spasms are often described. More rarely, a congenital variant is seen in which poor feeding, irritability, and hypotonia become evident within days after birth, followed by rapid deterioration and death.

Aspartoacylase deficiency results in accumulation of N-acetylaspatic acid (NAA) in the brain, which can be ascertained by proton MR spectroscopy and its excretion in the urine. The synthesis and role of NAA, and the related

compound N-acetylaspartylglutamate (NAAG) within the brain remains poorly understood and the subject of active research.

## 2. eIF2B-Related Disorder (Vanishing White Matter)

The eIF2B-related disorder and its various allelic clinical subtypes (VWM, OMIM 603896 or CACH [Schiffmann et al., 1994], ovarioleukodystrophy, and Cree leukoencephalopathy) are caused by mutations in one of the five genes (EIF2B1-5) encoding a complex, eIF2B (Leegwater et al., 2001). The eIF2B disorder, or eukaryotic translation initiation protein 2B, is the guanine nucleotide exchange factor for eIF2, another critical protein in initiation of translation. The eIF2B-related disorders are inherited in an autosomal recessive manner, with 65% of mutations found on the gene EIF2B5. There is known genotype-phenotype correlation for certain more common genotypes, including homozygous R113H mutation positive subjects, who have an adult onset with milder phenotype, and the homozygous R195H mutation positive subjects, who have a more severe early-onset presentation.

Patients with eIF2B mutations may present with a variety of clinical syndromes. The best-known presentation is the infantile or early childhood presentation with VWM. These children, previously healthy, present with acute neurologic decompensation after events of physiologic stress, including fever, falls, or fright. The precipitating event is usually followed after several hours by acute motor dysfunction, typically hypotonia or ataxia, and even coma. The child may die during the acute event or survive with neurologic sequelae and be vulnerable to future events of decompensation. On occasion, no acute event is noted, but loss of skills is gradual and relentlessly progressive. At opposite ends of the phenotypic spectrum, eIF2B mutations can also present in a congenital form, where neurologic disability is evident from birth (with additional findings such as ovarian dysgenesis, cataract or hepatomegaly) or present in an adult form with progressive spastic paraparesis.

Diagnosis of eIF2B-related disorder is based on appropriate clinical history, neuroimaging and molecular genetics. Common MRI features include diffuse signal abnormality of the supratentorial white matter, with less constant signal abnormalities in the cerebellar white matter, brainstem, thalamus, and globus pallidus. In supratentorial white matter, FLAIR images show low signal intensity, isointense with CSF, and suggestive of white matter rarefaction and cystic degeneration. On sagittal T1-weighted images, a pattern of radiating tissue strands may be seen, compatible on pathology with preserved tissue (Fig. 99-5C). MRI findings of eIF2B-related disorder are nearly pathognomonic, except in very early-onset or late-onset cases.

## 3. Megalencephalic Leukoencephalopathy With Subcortical Cysts

Megalencephalic leukoencephalopathy with subcortical cysts (MLC, OMIM 604004) is an autosomal recessive disease associated with mutations in the gene encoding MLC1 protein, HEPACAM, encoding GlialCAM. These proteins contribute to water homeostasis in myelin sheath (van der Knaap et al., 2012).

Synonyms for MLC include leukoencephalopathy with swelling and discrepantly mild course, cysts, infantile leukoencephalopathy and megalencephaly, van der Knaap disease, and vacuolating leukoencephalopathy. There is a founder effect in the Agarwal community in India, with a common genotype in MLC1 (p.Cys46LeufsX34), as well as some more common mutations in individual populations, including

persons of Libyan and Turkish Jewish descent and Japanese descent.

Postnatal macrocephaly is the predominant presenting symptom, developing in the first year. This is of diagnostic importance because a number of other disorders can present with temporal lobe subcortical cysts, including AGS, CMV infection, and RNaseT2-deficient leukoencephalopathy, among others. Stabilization of head growth rate often occurs after age 1, up to four to six standard deviations higher than normal. Patients may have normal early development or mild delays in motor and cognitive milestones. Later in life, patients develop a spastic ataxia of variable severity. Epilepsy, often easily controlled, is common. Cognitive deterioration is usually late and mild. Dysarthric speech can be particularly debilitating in MLC. In the dominant forms of HEPACAM mutations, there is a discrepantly mild course, with improvement over time of both the clinical and radiologic manifestations.

## 4. CIC-2-Related Leukoencephalopathy

CIC-2 chloride channel deficiency results in a leukoencephalopathy (OMIM 615651) associated with cerebellar ataxia, spasticity, chorioretinopathy with visual field defects, optic neuropathy, cognitive defects, and headaches. Patients may present in childhood or adolescence/adulthood. This disorder is characterized by T2-weighted MRI signal abnormalities in the posterior limbs of the internal capsules, midbrain cerebral peduncles, and middle cerebellar peduncles. MRI also shows restricted diffusion, suggesting myelin vacuolation confined to the specified white matter structures in adult patients, and more diffusely involved the brain white matter in children (Depienne et al., 2013).

## C. Calcifying Leukoencephalopathies

A series of leukoencephalopathies is distinguished by calcifications on neuroimaging. Although not all of these disorders qualify as classic leukodystrophies, significant white matter abnormalities on MRI may cause confusion unless the calcifications are recognized. Although in some cases the calcifications are large and unlikely to be missed on standard MR images, in other cases the white matter abnormalities may precede or so overshadow visible calcifications that these patients are initially thought to have an unsolved leukodystrophy. Therefore imaging modalities that will detect calcium, CT or MR based, should be considered in patients with unsolved leukoencephalopathies and should be performed serially for patients without specific diagnoses whose status continues to deteriorate. Several heritable disorders that might be confused with leukodystrophies are described here, although a comprehensive list of calcifying brain disorders exceeds the scope of this chapter and includes multiple infectious, immune, and vascular disorders such as congenital CMV, toxoplasmosis or rubella infections, HIV, systemic lupus erythematosus, and radiotherapy or methotrexate leukoencephalopathy. In addition to the classically calcifying leukoencephalopathies, certain leukoencephalopathies mentioned in other sections that may also develop calcifications include Krabbe, Alexander disease, RNase T2-deficient leukoencephalopathy, and mitochondrial cytopathies.

### 1. Aicardi-Goutières Syndrome

Aicardi Goutières syndrome (AGS; OMIM number[s] 225750 [AGS1], 610181 [AGS2], 610329 [AGS3], and 610333 [AGS4]) is a genetically heterogeneous disorder associated with mutations in a series of genes encoding nucleases or putative nucleases, or resulting in interferon activation. These include TREX1, SAMHD1, RNaseH2 A, B, and C, ADAR1, and IFIH1.

In most cases, AGS appears to be autosomal recessive, although rare cases of heterozygotes with AGS phenotypes are reported. The disorder presents in a fairly homogenous fashion, with a subacute encephalopathy associated with dystonia, spasticity, progressive microcephaly, leukoencephalopathy, and intracranial calcifications. Additionally, rare patients with clinical diagnoses of systemic lupus erythematosus have been found to harbor heterozygous mutations in *TREX1*. In addition, a disorder now referred to as autosomal dominant retinal vasculopathy with cerebral leukodystrophy (RVCL) is allelic with AGS. This disorder has previously been described as cerebretinal vasculopathy (CRV)/hereditary retinal vasculopathy (HRV)/hereditary endotheliopathy with retinopathy, nephropathy, and stroke (HERNS), associated with linkage to 3p21, and with heterozygous mutations in *TREX1*. RVCL is a rare disorder with retinal vasculopathy, migraine, Raynaud phenomenon, stroke, and dementia with onset in middle age. Allelic disorders with AGS with an autosomal recessive inheritance include familial chilblain lupus, Cree leukoencephalitis, and TORCH-like disorders.

AGS is characterized by leukoencephalopathy, basal ganglia or white matter calcifications, and elevated CSF alpha interferon, with no detectable infectious etiology. Patients present most often in the neonatal period or in infancy. Early-onset patients may present in the neonatal period with a syndrome that mimics in utero viral infections, including Coombs positive hemolytic anemia and autoimmune thrombocytopenia, elevated transaminases, microcephaly, seizures, vasculitic skin lesions, and cerebral calcifications. This condition may also present in older infants with progressive microcephaly, dystonia, seizures, and developmental delay, as well as sterile pyrexias, lupus-like skin and joint manifestations, progressive intracranial calcifications, chronically elevated CSF lymphocytes, autoantibodies, and elevated CSF pterins. Less common presentations include peripheral neuropathy, striatal necrosis, intracranial large vessel vasculopathy, and spastic paraplegia (Crow et al., 2015).

## 2. Cerebretinal Microangiopathy With Calcifications and Cysts

Cerebretinal microangiopathy with calcifications and cysts (CRMCC, OMIM 612199) is caused by mutations in *CTC1*, which encodes the CTS telomere maintenance complex component 1. CRMCC is a spectrum of affected patients with presumed microvascular disorders affecting the brain, eyes, liver, intestines, and bones. Prenatal and postnatal growth retardation is common. The patient may develop visual symptoms leading to an ophthalmologic examination before or after the onset of neurologic symptoms. Ophthalmologic evaluation identifies bilateral retinal telangiectasias and retinal exudates. Patients may develop spontaneous fractures of the long bones or skull and have documented osteopenia. Life-threatening intestinal bleeding may occur, and many patients are found to have cirrhosis or portal hypertension. Less often, patients may have dystrophic nails, hyperpigmented skin lesions, and sparse hair with premature graying. Neuroimaging suggests the diagnosis.

## 3. Leukoencephalopathy With Calcifications and Cysts

Leukoencephalopathy with calcifications and cysts (LCC) is thought to be on a continuum with CRMCC and Coats plus syndrome. An underlying genetic etiology has not been identified, although reports of affected siblings, male and female probands, and children born to consanguineous families suggest an autosomal recessive inheritance pattern. LCC is similar in MRI pattern to CRMCC but the disorder lacks the systemic manifestations of CRMCC and Coats plus.

## 4. Bandlike Intracranial Calcification With Simplified Gyration and Polymicrogyria

Bandlike intracranial calcification with simplified gyration and polymicrogyria has been found to be caused by mutations in the *OCN* gene, encoding occludin, an integral component of tight junctions. Neuropathologic analysis demonstrates calcification predominantly associated with blood vessels. Two series of patients have been characterized by severe post-natal microcephaly, dysmorphic facial features, developmental arrest, and seizures. Neuroimaging demonstrates simplified sulcation, and a large calcified band most often in the frontal white matter and basal ganglia, as well as large central brainstem calcifications.

## 5. Cockayne Syndrome

Cockayne syndrome, as discussed previously, is a disorder characterized by cachectic dwarfism, neurologic disability, cutaneous photosensitivity, pigmentary retinopathy, leukodystrophy, and, occasionally, intracranial calcifications. Disorders allelic with Cockayne, including COFS and TTD, are less likely to have significant intracranial calcifications, although these have been described in a restricted number of cases.

## 6. Spondyloenchondrodysplasia

Spondyloenchondrodysplasia (SPENCD, OMIM 271550) is a disorder with generalized enchondromatosis and platyspondyly that may also develop progressive intracranial calcifications. Its molecular cause is not known, and its inheritance pattern is unclear. The bone abnormalities in these subjects should suggest this diagnosis when cerebral calcifications are present.

## 7. Cytomegalovirus

Although a number of prenatal and perinatal infections can result in significant brain disorders, cytomegalovirus (CMV) deserves a special mention in this chapter because of its significant white matter injury, leading to frequent concerns of an underlying inherited leukoencephalopathy. In addition, CMV frequently, but not always, results in intracranial calcification. This phenomenon is discussed in the section on cystic leukoencephalopathies. Other infections can cause significant white matter changes and intracranial calcification, including HIV, tuberculosis, and toxoplasmosis, but clinical features should indicate that these are unlikely to be consistent with an inherited leukoencephalopathy.

## 8. Cerebral Autosomal Dominant Arteriopathy With Subcortical Infarcts and Leukoencephalopathy

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL, OMIM 125310) is a primarily cerebral microangiopathy, presenting in adults with a history of migraine headaches, progressive early-onset cerebrovascular disease, and early-onset dementia, with leukoencephalopathy and subcortical infarcts on neuroimaging. Over 90% of individuals have dominant mutations in *NOTCH3*.

## 9. Intracranial Calcification Associated With Leukoencephalopathy

Intracranial calcification associated with leukoencephalopathy is also seen in mitochondrial disease, sporadically reported for various disorders, including MELAS.

## 10. Dihydropterine Reductase Deficiency

Dihydropterine reductase deficiency can be associated with leukoencephalopathy and calcifications.

### 11. 27-Hydroxylase Deficiency or CTX

CTX or 27-hydroxylase deficiency (OMIM 213700) is an inherited disorder of sterol storage, with accumulation of cholestanol and cholesterol in xanthomas, gall bladder, and brain. Affected patients have encephalopathy, myelopathy, cerebellar ataxia, early atherosclerosis, tendon xanthomas, and cataracts. Diagnosis is based on clinical manifestations and elevations in cholestanol in the serum. Neuroimaging is remarkable for deep white matter changes, and hyperintense lesions seen on T2-weighted images in the dentate nucleus, globus pallidus, substantia nigra, and inferior olive. Affected white matter may become calcified. Patients may be treated successfully using chenodeoxycholic acid.

### 12. Bilateral Occipital Calcifications With Leukoencephalopathy, Seizures, and Clinical or Subclinical Celiac Disease

This has also been reported as a distinct entity.

### 13. Familial Hemophagocytic Lymphohistiocytosis

Familial hemophagocytic lymphohistiocytosis (FHLH) is characterized by proliferation and infiltration of hyperactivated macrophages and T-lymphocytes. It can be caused by autosomal recessive mutations in a number of genes, including *PRF1* (FHL2, OMIM 603553), *UNC13D* (FHL3, OMIM 608898), *STX11* (FHL4, OMIM 603552), and *Munc-18-2* (FHL5, OMIM 613101), although a number of patients have no identified mutation. FHLH is characterized by acute illness with prolonged fever (longer than 7 days), and features associated with macrophage activating syndrome, including hepatosplenomegaly, cytopenias (anemia, thrombocytopenia, and neutropenia), hypertriglyceridemia and/or hypofibrinogenemia, and bone marrow hemophagocytosis. Neurologic symptoms are highly variable and may include motor deficits and seizures. Onset is usually within the first few months of life. MRI may show hypomyelination or demyelination and also multifocal abnormalities at the gray white matter junction, hemorrhage, atrophy, focal necrosis, and edema. Calcifications can be seen in areas of abnormal brain tissue. Allogeneic HSCT is the only curative therapy.

## D. Cystic Leukoencephalopathies

In addition to demyelination, several leukodystrophies and leukoencephalopathies present with cystic lesions. Megalencephalic leukoencephalopathy with subcortical cysts (MLC), caused by mutations in *MLC1*, is one of several other disorders characterized by cystic changes in abnormal white matter exist. Others include RNase T2 deficiency, congenital CMV infection, and cerebrotendinous microangiopathy with calcifications and cysts, also known as Coats plus syndrome. Cystic changes can less commonly be seen in an array of other leukodystrophies, including Aicardi-Goutières syndrome and Alexander disease. Other disorders beyond the classically defined leukodystrophies include mitochondrial leukoencephalopathies, which can present with cystic leukoencephalopathies in a number of molecularly defined mitochondrial disorders, or COL4A1/2 associated disorder. Mutations in the gene encoding type IV collagen  $\alpha$ -chain 1 or 2, *COL4A1* and *COL4A2*, are thought to disrupt the vascular basement membrane. In patients with a history of familial intracranial hemorrhage and stroke, as well as familial intraventricular hemorrhage and porencephalic cysts in neonates, this disorder should be considered as a possible cause of cystic leukoencephalopathy (Gould et al., 2005).

## E. Leukoencephalopathies With Brainstem, Cerebellum, and Spinal Cord Involvement

Certain leukoencephalopathies present with significant brainstem, cerebellum, and spinal cord involvement. This MRI feature should always be carefully noted and is often useful in differential diagnosis. In addition to the disorders discussed in detail later in this chapter, other disorders, including Alexander disease, peroxisomal disorders, mitochondrial cytopathies, Krabbe, cerebrotendinous xanthomatosis, and familial histiocytosis, may have brainstem or cerebellar involvement. In addition, X-linked Charcot-Marie-Tooth, fragile-X premutation, and dentatorubral-pallidoluysian atrophy (DRPLA), although not considered leukoencephalopathies, may have significant brainstem and cerebellar involvement, occasionally mischaracterized as primary leukoencephalopathies.

### 1. Leukoencephalopathy With Brainstem and Spinal Cord Involvement and Lactate Elevation

Leukoencephalopathy with brainstem and spinal cord involvement and lactate elevation (LBSL, OMIM 611105) is caused by autosomal recessive mutations in *DARS2*, encoding mitochondrial aspartyl-tRNA synthetase. Patients, with single exceptions, are compound heterozygous for pathogenic mutations, one of which usually affects splicing in intron 2.

LBSL is characterized by slowly progressive cerebellar and sensory ataxia, spasticity and dorsal column dysfunction. Onset ranges from infancy to adulthood, with childhood onset as most typical variant. Severe infantile presentation is rare. In some patients, gait is never normal, but most patients have initial normal milestones. The predominant presenting feature is spastic ataxia accompanied by distal abnormalities in vibration and proprioceptive sensation. Loss of motor function is slowly progressive and may result in loss of independent ambulation in adulthood. There may be mild cognitive difficulties. A few patients have a paroxysmal and partially reversible neurologic decline associated with physiologic stressors, including febrile infection or minor head trauma (van der Knaap and Valk, 2005).

Classic MRI features include patchy cortical and cerebellar white matter abnormalities with striking tract involvement over the entire length of the central nervous system, including the spinal cord. Initial reports note involvement of the pyramidal tracts from the internal capsule to the spinal cord corticospinal tracts; the sensory tracts including the dorsal column, medial lemniscus, thalamus, and corona radiata; cerebellar peduncles; and the trigeminal nerve and mesenchymal trigeminal tracts. The corpus callosum is involved. Elevated lactate in affected white matter on MRS is often seen, but not always.

### 2. Alexander Disease (AxD)

As described previously, AxD patients may have significant and sometimes isolated brainstem signal abnormalities, particularly in late-onset cases, in which clinical and radiologic features are primarily related to brainstem structures. Of note, posterior fossa abnormalities are sometimes misdiagnosed as gliomas, only correctly identified by histopathologic evidence of excessive Rosenthal fiber aggregation.

### 3. Polyglucosan Body Disease (PGBD, OMIM 263570)

PGBD is an adult-onset leukoencephalopathy with upper and lower neuron motor impairment, distal sensory neuropathy, and neurogenic bladder, characterized by polyglucosan body accumulation in nervous structures. *GBE1*, encoding 1,4-alpha-glucan-branching enzyme, is the only gene known to be associated with APBD.

#### 4. Autosomal Dominant Leukodystrophy With Autonomic Disease (LaminB1)

Autosomal dominant leukodystrophy with autonomic disease (ADLD, OMIM 169500) is an adult-onset leukoencephalopathy caused by duplications in LMNB1, encoding lamin B1. The first neurologic sign is often autonomic dysfunction such as urgency in urination, impotence, constipation, anhidrosis, and postural hypotension. Disease onset is typically in the fourth to sixth decade. These symptoms are followed by pyramidal tract dysfunction and ataxia with slow progression, sometimes over decades. No peripheral neuropathy is reported. Mild cognitive decline may be seen. Notable radiologic features include confluent white matter changes in supratentorial regions, predominantly affecting the deep white matter, with relative sparing of the periventricular white matter and the subcortical fibers. In some cases, predominance in the rolandic regions and pyramidal tracts is seen at onset, evolving over time into diffuse white matter abnormalities. The corpus callosum is relatively spared but can show posterior abnormalities. The posterior limb of the internal capsule is often involved. Abnormal signal is seen in brainstem tracts, and the upper and middle cerebellar peduncles are often involved.

#### F. Adult-Onset Leukoencephalopathies

A number of leukoencephalopathies that may present in adults have already been discussed previously, including ADLD, PGBD, CTX, adult-onset Krabbe, adult-onset MLD, adult-onset AxD, adult-onset eIF2B-related disorder, ovarioleukodystrophy, and adrenomyeloneuropathy, as well as theoretically almost any of the childhood-onset leukoencephalopathies. Several inborn errors of metabolism can also present in adulthood with leukoencephalopathy, such as Sjögren-Larson disease, Fabry disease, disorders of transsulfuration such as cobalamin disorders, and PKU, to name a few. Additionally, many adult-onset leukoencephalopathies remain unsolved, and the study of these patients is likely to produce new nosologic entities. Neuroaxonal leukodystrophy with spheroids is an important leukoencephalopathy with primarily adult presentation. Leukoencephalopathy due to mutations in AARS2 has recently been identified with nonspecific, mild developmental delay in some patients and rapid deterioration in adolescence or adulthood with cerebellar ataxia, spasticity, and prominent cognitive decline. MRI shows involvement of left-right connections also affecting the corpus callosum and also longitudinal tracts.

### PART III. SECONDARY LEUKOENCEPHALOPATHIES TO INBORN ERRORS OF METABOLISM, EXCLUDING THE CLASSICAL LYSOSOMAL AND PEROXISOMAL DISORDERS

Inborn errors of metabolism result in significant disturbances of cellular function, and the resultant disruption in energy metabolism or accumulation of toxic metabolites interferes with a normal function of a number of organs. The brain, specifically glial cells, is sensitive to such disturbances and, as such, secondary abnormalities of cerebral white matter can be seen in a broad range of inborn errors of metabolism. In some cases, such as metachromatic leukodystrophies and Krabbe disease, the phenotype nearly exclusively affects the white matter of the brain, and these disorders have long been classified as leukodystrophies. In a number of other disorders, however, multisystem abnormalities are seen, and white

matter involvement is one of many disease symptoms (Table 99-3). In the majority of cases, straightforward biochemical testing will exclude these disorders, and comprehensive testing should be considered in unsolved leukodystrophies because many of these disorders show nonspecific white matter abnormalities (Table 99-2).

#### Acknowledgments

Special thanks is given to the patients who provided images for this review and to Marjo van der Knaap and Raphael Schiffmann who have provided mentorship and education to the authors. We also thank Marjo van der Knaap for providing some of the MRIs used in this chapter.

# 100 Acquired Disorders Affecting the White Matter

Naila Makhani, J. Nicholas Brenton, and Brenda Banwell

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Demyelination of the central nervous system (CNS) may occur as a monophasic illness or may represent the first attack of chronic inflammatory diseases such as multiple sclerosis (MS) and neuromyelitis optica (NMO). Herein, we review the clinical and neuroimaging features of childhood acquired CNS demyelinating disorders.

## ACUTE CENTRAL NERVOUS SYSTEM DEMYELINATION

Children with an acquired demyelinating syndrome (ADS) may present either with neurologic signs and symptoms attributable to a single CNS location (monofocal ADS) or with signs attributable to multiple CNS sites (polyfocal ADS), with or without encephalopathy (Krupp et al., 2013).

## OPTIC NEURITIS

Optic neuritis (ON) should be considered in any child presenting with acute or subacute visual loss (Fig. 100-1). Demyelinating ON is typically clinically characterized by reduced visual acuity, a central visual field deficit, pain with eye movements, and red color desaturation. Optic disc edema is sometimes seen, but may be absent in retrobulbar ON.

Although some studies suggest that childhood ON is more commonly bilateral, others have reported that ON is more commonly unilateral. In one study of 36 children with ON, neuroimaging studies of the optic nerve were abnormal in 55%, and 88% had abnormal visual-evoked potentials (typically a P100 latency delay).

Optical coherence tomography (OCT) utilizes near-infrared light to measure the thickness of the retinal nerve fiber layer (RNFL) and ganglion cell layer (GCL), yielding a quantitative measure of axonal and neuronal loss. RNFL and GCL thinning have been demonstrated in children with isolated ON and MS and may provide quantifiable information about retinal integrity.

Following ON, 80% to 85% of children achieve full visual recovery. Children with ON have a 30% risk of a subsequent MS diagnosis. Magnetic resonance imaging (MRI) evidence of one or more T2-weighted lesions apart from the optic nerve is strongly predictive of MS, with up to 68% of such patients being diagnosed with MS within 2 years. Concurrent or rapidly sequential transverse myelitis, MRI features of brainstem or diencephalic involvement in a pattern atypical for MS, and serum antibodies against aquaporin-4 suggest a diagnosis of NMO.

## Transverse Myelitis

Demyelination of the spinal cord is termed transverse myelitis (TM). Typical features of TM include subacute bilateral lower extremity weakness, a spinal sensory level, and impaired bowel/bladder control. L'Hermitte's symptom (pain with

forward neck flexion) suggests a cervical cord lesion. Paresis is often initially flaccid with hyporeflexia, and later hyperreflexia develops below the lesion level. These features help distinguish TM from other spinal cord pathologies (Fig. 100-2).

A review of 47 pediatric TM patients reported that, at the time of maximal deficit, 89% either were unable to walk and/or required ventilator assistance. After 3 years, 43% were unable to ambulate more than 30 feet, and 21% required an ambulatory aid; in addition, 68% had residual bladder symptoms. Younger age at TM, complete paraplegia, sphincter dysfunction, and less than 24 hours to maximal deficit are associated with poorer functional outcomes. MS risk following TM is 2% to 8%. Less than 24 hours to symptom nadir and abnormal baseline brain MRI were strong predictors of relapse in one study.

Longitudinally extensive TM (LETM) ( $\geq 3$  spinal segments), recurrent TM, and TM with ON should prompt consideration of NMO.

## Polyfocal Demyelination

Neurologic symptoms suggesting multiple CNS areas of involvement may occur +/-encephalopathy (Fig. 100-3). When encephalopathy (behavioral change or alteration in level of consciousness) is present, the clinical syndrome is acute disseminated encephalomyelitis (ADEM). ADEM occurs in younger patients (especially < 10 years). Fever and a recent history of infection are often present.

ADEM generally carries a favorable prognosis, but 11% to 17% of children experience residual motor deficits. Cognitive deficits may also persist.

ADEM is typically monophasic. However, approximately 5% to 29% of children will go on to have additional demyelinating attacks characteristic of MS. Rarely, ADEM represents the first attack of NMO. ADEM may also precede or follow a diagnosis of anti-NMDA receptor encephalitis.

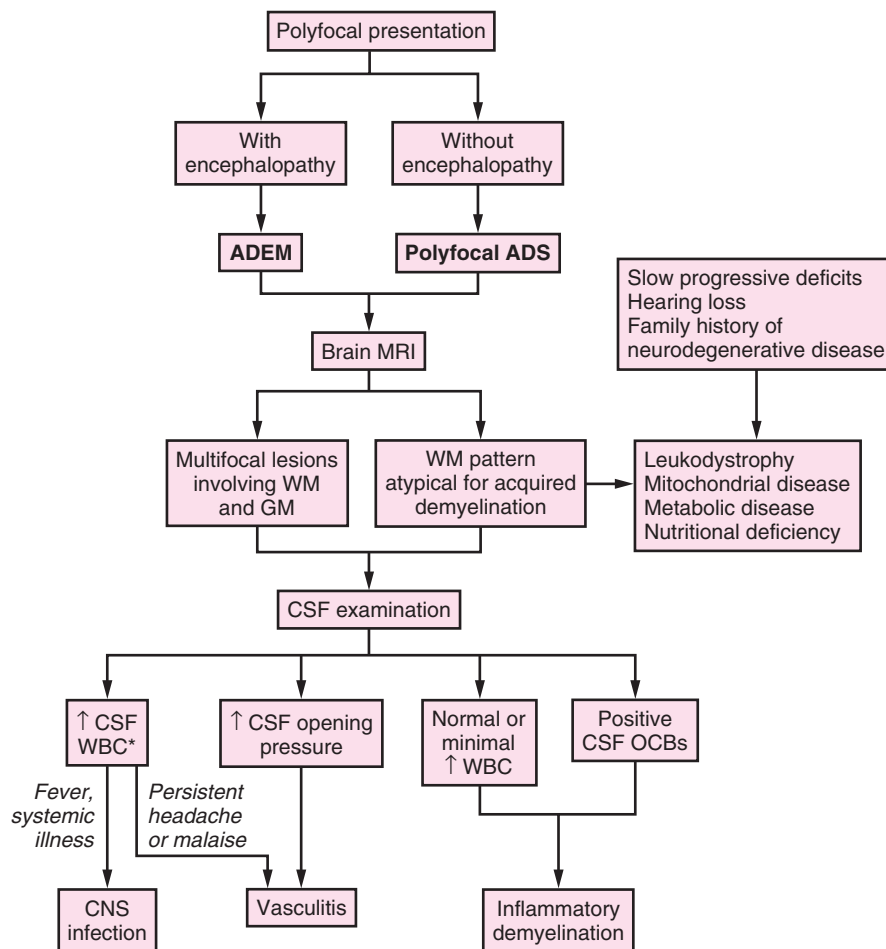

## Other Clinical Presentations

Children with ADS may also present with intranuclear ophthalmoplegia (INO), focal motor deficits, sensory loss/paresthesias, or isolated cerebellar deficits.

## Investigation of a Child with Acute Demyelination

### Laboratory Investigations

Cerebrospinal fluid (CSF) analysis is important for excluding other diseases, including infection and malignancy. CSF leukocyte counts in children with MS are elevated ( $>4$  cells/ $\mu$ L) in 66% (typically  $< 30$  cells/ $\mu$ L). Higher leukocyte counts are more consistent with infection, vasculitis, or NMO. A study of 107 children with MS reported that those younger than 11 years of age had a higher percentage of CSF neutrophils and

**Figure 100-3. Approach to polyfocal neurologic symptoms.** ADEM, acute disseminated encephalomyelitis; ADS, acquired demyelinating syndrome; CNS, central nervous system; CSF, cerebrospinal fluid; GM, gray matter; MRI, magnetic resonance imaging; OCBs, oligoclonal bands; WBC, white blood cell count; WM, white matter.

a lower percentage of monocytes and were less likely to have an elevated IgG index than children older than 11 years of age. Elevated protein (typically 100–720 mg/L) may be seen, indicating disruption of the blood–CSF barrier. CSF oligoclonal bands (OCBs) are detected at diagnosis of ADS in up to 90% of children subsequently diagnosed with MS, which is lower than the reported rate of 98% in adult MS. Isoelectric focusing methods have the highest yield for OCB detection. CSF OCBs are detected in less than 10% of children with either ADEM or NMO. CSF immunoglobulin G synthesis can occur later in the disease course, and OCBs may therefore only be detected over time.

Evoked potential testing in the visual-evoked potential, brainstem auditory-evoked potential, and somatosensory-evoked potential pathways is useful for confirming the presence of demyelination and for detecting clinically silent disease. In one study, almost 50% of 85 children with MS demonstrated clinically silent abnormalities in at least one of the evoked potential pathways, most commonly the visual pathway.

### Magnetic Resonance Imaging

MRI is a valuable tool to illustrate inflammatory demyelination and to exclude other diagnoses. The MRI appearance of MS in children younger than 10 years of age is similar to that of adults (Figure 100-4). MS lesions are typically ovoid and

are often seen in the periventricular or juxtacortical region, brainstem, and/or spinal cord. Periventricular lesions are often oriented 90 degrees perpendicular to the long axis of the corpus callosum. Infratentorial lesions and large, ill-defined lesions are more common in children than in adults. The presence of one periventricular lesion and one “black hole” (a T1 iso- or hypo-intense lesion relative to cortical gray matter) on imaging obtained at ADS identifies children with MS with 84% sensitivity and 93% specificity.

Large lesions, ill-defined lesions, and lesions in gray and white matter commonly occur in younger children, especially those with ADEM. Lesions located predominantly in the diencephalon or periaqueductal gray matter, longitudinally extensive spinal cord lesions, and bilateral or extensive optic nerve lesions characterize NMO.

### Management of Acute Demyelination

Acute demyelination is generally treated with corticosteroids if symptoms are severe enough to interfere with daily functioning (Fig. 100-5). Typically 20 to 30 mg/kg/day of intravenous methylprednisolone (maximum 1 g) is given as a single daily dose for 3 to 5 days. If there is a significant improvement in symptoms, no further treatment is required. If there is an incomplete response to treatment but residual symptoms are relatively mild, a tapering course of oral steroids (starting at

**Figure 100-4. MRI in childhood ADS and MS.** **A**, Axial T1-weighted image with gadolinium of a child with optic neuritis shows optic nerve thickening and enhancement (*arrow*). **B**, T2-weighted hyperintense spinal lesion (*arrow*) in a child with transverse myelitis. **C**, Axial fluid-attenuated inversion-recovery (FLAIR) image demonstrates diffuse bilateral deep gray- and white-matter lesions in a child with acute disseminated encephalomyelitis. **D**, Axial FLAIR image demonstrates multiple lesions in a child with multiple sclerosis. **E**, Several of the lesions observed in panel D enhance following gadolinium administration. **F**, Multiple nonenhancing T1 “black holes” are present in the same child, suggesting chronic disease.

1 mg/kg/day and tapering over 14–21 days) is often considered. If children have significant residual symptoms after intravenous steroid treatment, a second 3- to 5-day course may be given. Alternatively, treatment with intravenous immunoglobulin (IVIg; 2 g/kg over 2–5 days) may be of benefit (class IV evidence).

Profound encephalopathy and respiratory depression may occur with brainstem/upper cervical spinal cord involvement and may be a life-threatening condition. Plasma exchange may be useful in this situation (class I evidence in adult-onset MS). A typical regimen of plasma exchange treatment is 5 to 8 exchanges in 10 days.

## RELAPSING DEMYELINATING DISORDERS

### Multiple Sclerosis

MS, a chronic inflammatory and degenerative disorder of the CNS, is being increasingly diagnosed in children.

### Epidemiology of Pediatric Multiple Sclerosis

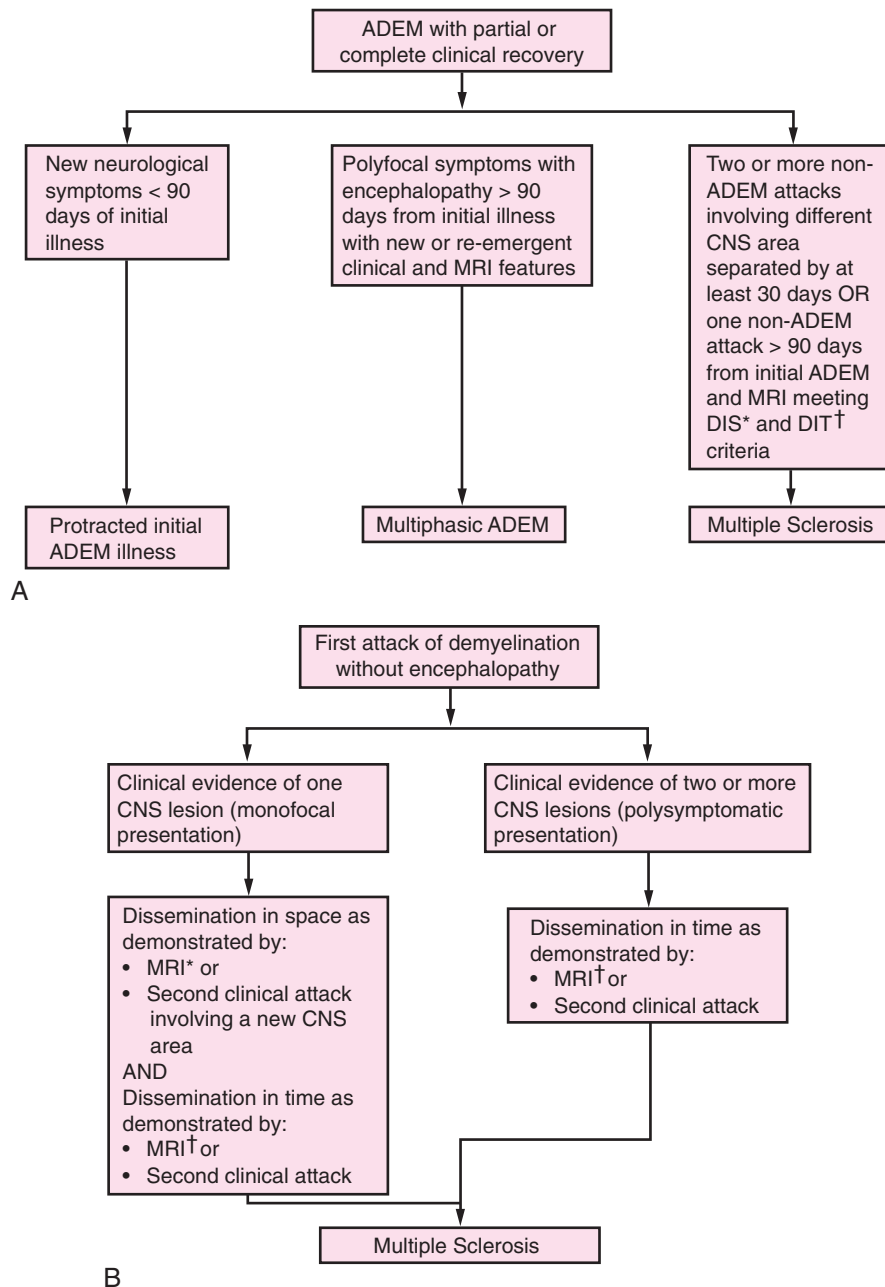

Childhood-onset MS has been reported in many countries. Although the exact incidence remains unknown, 3% to 10% of MS patients experience their first symptoms at younger than 18 years of age.

Gender differences in pediatric MS are related to age. In children younger than 10 years of age, the female-to-male ratio is approximately 1:1. After age 10, this ratio increases to 3:1.

A family history of MS is reported in 5% to 15% of children, slightly lower than the 20% to 30% of adult MS patients who report MS in at least one first-degree relative.

### Diagnostic Criteria for Pediatric Multiple Sclerosis

MS diagnosis requires demonstration of CNS demyelination separated in both space and in time (Fig. 100-6). A child with two separate characteristic attacks meets the clinical criteria for dissemination in space (DIS) and time (DIT). MRI may

**Figure 100-6. Classification of further attacks of demyelination. A,** Approach to further attacks of demyelination in the child initially presenting with acute disseminated encephalomyelitis (ADEM). **B,** Approach to further attacks of demyelination in the child presenting with a monofocal or polyfocal neurologic syndrome without encephalopathy. \*MRI criteria for dissemination in space require the presence of at least one lesion in the following locations: periventricular, juxtacortical, infratentorial, and spinal cord. †MRI criteria for dissemination in time require either new T2 lesions on serial scans or the simultaneous presence of a clinically silent gadolinium-enhancing and nonenhancing lesion on a single baseline scan (Polman, Reingold et al., 2011).

also be used to demonstrate DIS or DIT (Polman et al. 2011). Specifically, MRI evidence of DIS requires at least one T2-hyperintense lesion in two of four CNS areas: periventricular, juxtacortical, infratentorial, and/or spinal cord. MRI DIT criteria require new T2 or gadolinium-enhancing lesions over time ( $\geq 30$  days from a baseline scan) or at the time of initial presentation, provided the baseline scan shows the simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions.

McDonald 2010 MS criteria have a positive predictive value of 76% and a negative predictive value of 100% when applied to children with ADS; however, these criteria are less

predictive in younger children and cannot be reliably applied in ADEM.

### Clinical Course of Pediatric Multiple Sclerosis

MS is relapsing-remitting in more than 95% of children. A study of 21 pediatric and 110 adult patients demonstrated that, compared with adults, children with MS experience more frequent relapses in the first few years following diagnosis (annualized relapse rate of 1.13 versus 0.4,  $p < 0.01$ ). A German study showed that relapse rates decreased between year 1 and year 5 following diagnosis in both patients younger than 11

years of age (relapse rate of 2.1 versus 0.79) and patients between 14 and 16 years of age (1.8 versus 0.42). Secondary disease progression, when accrual of disability occurs in the absence of discrete relapses, typically begins after 15 years of age. Because of their younger age at onset, pediatric MS patients accrue disability approximately 10 years earlier than do adult patients.

### Magnetic Resonance Imaging Features of Pediatric Multiple Sclerosis

Imaging studies have shown that pediatric-onset MS is associated with a global reduction in brain volume, especially in the thalami, and a reduction in age-expected head size. Both T1- and T2-weighted lesion volume is higher in pediatric-onset MS patients compared with adults, with a greater lesion burden located infratentorially in children. The long-term effects of this extensive pathology on cognitive, physical, psychiatric, and socioeconomic functioning have yet to be defined.

Complex imaging modalities, including diffusion-tensor imaging (DTI), magnetization transfer ratio (MTR) imaging, and functional MRI (fMRI), hold great promise as tools to link structural and functional parameters.

### Pathobiological Insights Into Pediatric Multiple Sclerosis

The greatest genetic contributor to MS risk in children and adults is associated with the HLA DRB1\*1501 haplotype. Over 100 non-HLA risk SNPs have been identified as contributors to adult-onset MS risk. Early studies indicate that similar non-HLA risk SNPs also contribute to pediatric-onset MS risk.

Several environmental risk factors have been shown to contribute to pediatric MS risk (reviewed in [Waldman et al., 2014](#)), including:

1. Low serum 25-hydroxyvitamin D levels
2. Remote Epstein–Barr virus (EBV) infection
3. Earlier age at menarche
4. Secondhand smoke exposure
5. Increased body mass index (BMI)

Case-control studies suggest that cytomegalovirus infection may be associated with reduced pediatric MS risk.

A Canadian study of children with ADS found a higher risk of later MS diagnosis in children who had (a) low serum 25-hydroxyvitamin D level (<75 nmol/L), (b) evidence of remote EBV infection, and (c) at least one HLA DRB1\*1501 allele compared with those children who had none of these risk factors at presentation (hazard ratio [HR] = 5.27, 95% confidence interval [CI] = 1.23–22.6) ([Banwell et al., 2011](#)).

Children with demyelination may display antibodies against MOG, aquaporin-4, NMDA receptors, voltage-gated potassium channels, and glycine receptors. Defining the range of autoantibodies present in children with demyelination and their associated clinical phenotypes will be of considerable future interest.

The cerebrospinal fluid (CSF) of children with ADS appears to be enriched in components of the axoglial apparatus, including neurofascin, contactins, and contactin-associated proteins, suggesting that axoglial apparatus disruption may be involved in MS pathobiology.

Altered cellular immune responses are associated with pediatric-onset MS. Both T-cell repertoire (proportions of naïve versus memory T-cells) and functional T-cell responses to myelin and nonmyelin antigens appear to be disrupted in children with MS.

### Immunomodulatory Therapy in Pediatric Multiple Sclerosis

**Principles of Immunomodulatory Therapy.** There are now 12 MS therapies approved by the U.S. Food and Drug Administration (FDA) available in the United States. In children, first-line treatment is usually with interferons (beta 1a or 1b), or glatiramer acetate (GA) ([Table 100-1](#)). These agents reduce relapse rates by approximately one third in adult MS patients and also reduce the number of T2 brain MRI lesions. Interferons and GA are generally considered safe and well tolerated in children with MS. Transaminitis is the most frequent laboratory abnormality in children treated with interferons and is possibly reduced by a gradual dose titration starting at one fourth of the usual adult dose. GA is utilized at full dose.

**TABLE 100-1** Immunomodulatory Therapies for Pediatric Multiple Sclerosis

Drug	Dosing Regimen	Common Side Effects	Potential Laboratory Abnormalities
Interferon beta 1a (Avonex <sup>®</sup> )	30 µg IM weekly	Flu-like myalgia and headache Depression	Transaminitis (typically 2- to 3-fold elevation of transaminases) Rarely, fulminant liver failure
Interferon beta 1a (Rebif <sup>®</sup> )	22–44 µg SC weekly	Flu-like myalgia and headache Injection-site reaction (redness, pain, and induration) Depression	Transaminitis (typically 2- to 3-fold elevation of transaminases) Rarely, fulminant liver failure
Pegylated Interferon beta 1a (Plegridy <sup>®</sup> )	125 µg SC every 14 days	Flu-like myalgia and headache Injection-site reaction (redness, pain, and induration) Depression	Transaminitis (typically 2- to 3-fold elevation of transaminases) Rarely, fulminant liver failure
Interferon beta 1b (Betaseron <sup>®</sup> )	0.25 mg SC every 2 days	Flu-like myalgia and headache Injection-site reaction (redness, pain, and induration) Depression	Transaminitis (typically 2- to 3-fold elevation of transaminases) Rarely, fulminant liver failure
Glatiramer acetate (Copaxone <sup>®</sup> )	20 mg SC daily or 40 mg SC 3 times a week	Injection-site reaction (redness, pain, and induration) Immediate postinjection reaction (flushing, tachycardia, and chest pain)	No significant effect on liver or hematological function

IM, intramuscular; SC, subcutaneous.

White blood cell counts and liver function tests should be monitored monthly for 6 months and then every 3 months thereafter during interferon treatment. Thyroid function should be monitored yearly. Sexually active patients should receive counseling regarding contraceptive use.

**Second-Line Therapies.** Immunosuppressive therapy is offered when frequent relapses occur despite compliance with interferon or GA. Proposed definitions for inadequate treatment response require full compliance for at least 6 months and at least one of the following: (a) increased or stable relapse rate or new T2- or contrast-enhancing lesions compared with pretreatment baseline or (b) at least two clinical or MRI attacks within 12 months (Chitnis et al., 2012). Therapeutic options for children experiencing an inadequate treatment response include switching between first-line therapies or escalating to a second-line agent. Children with frequent relapses on interferon therapy should be checked for neutralizing antibodies.

Cyclophosphamide, azathioprine, methotrexate, mitoxantrone, and rituximab have all been utilized in isolated cases or small case series of pediatric MS patients. There are increasing numbers of reports of natalizumab use in pediatric-onset MS. A study of 55 children with MS treated with natalizumab reported that the annualized relapse rate (ARR) decreased from 2.4 +/- 1.6 to 0.1 +/- 0.2 ( $p < 0.001$ ). Mild transient hematological abnormalities were observed in 7 out of 55 patients, and no serious adverse events were reported. Natalizumab is associated with increased risk of progressive multifocal leukoencephalopathy, especially in patients seropositive for JC virus (particularly with an index value  $> 1.5$ ), patients previously treated with other immunosuppressive agents, and those treated for more than 24 months.

Several oral agents (e.g., dimethyl fumarate, fingolimod, and teriflunomide) and infusion-based therapies (e.g., alemtuzumab) are now approved for use in adult-onset MS. Clinical trials for some of these agents are ongoing in pediatric MS, and future trials are expected.

### General Care Issues

The care of children with MS requires a multidisciplinary team that often includes a neurologist, nurse, occupational therapist, physiotherapist, psychologist, dietician, and social worker. An MS diagnosis has important implications for social functioning, family functioning, and overall psychosocial well-being.

### Multiphasic Acute Disseminated Encephalomyelitis

MS diagnosis in a child with initial ADEM requires either two subsequent non-ADEM attacks or one subsequent clinical attack not accompanied by encephalopathy at least 3 months from the initial ADEM associated with MRI findings meeting current definitions for DIS and DIT (Krupp, Tardieu et al., 2013). Recurrence of ADEM more than 3 months after an initial ADEM episode is termed multiphasic ADEM (Krupp et al., 2013), which is treated in the same manner as an acute demyelinating attack.

### Neuromyelitis Optica

NMO is a severe, inflammatory CNS demyelinating disorder with unique clinical, laboratory, and MRI features. The identification of a biomarker for NMO (NMO-IgG) has resulted in improved diagnostic accuracy (Lennon et al., 2004).

### Epidemiology of Pediatric Neuromyelitis Optica

The exact incidence of NMO in childhood is unknown. In children and adults, NMO has a marked female predominance, with some studies reporting a female-to-male ratio as high as 9:1. There is an overrepresentation of children reporting non-Caucasian ethnicity compared with other demyelinating diseases. In one U.S. study, 42 out of 58 NMO-IgG-seropositive children (73%) with available ethnicity data were non-Caucasian.

### Clinical Features of Pediatric Neuromyelitis Optica

NMO is characterized by severe ON (visual acuity typically 20/200 or worse) and TM, occurring either simultaneously or sequentially. When sequential, ON and TM may be separated by months or even years.

Approximately 53% to 100% of pediatric NMO patients experience a relapsing (as opposed to monophasic) course. Predictors of a relapsing course in one study of adult NMO patients included female gender, older age at onset, and evidence of systemic autoimmunity. NMO-IgG-seropositive patients appear more likely to experience a relapsing course compared with seronegative individuals. In a retrospective analysis of 20 children with NMO, mean time to relapse was shorter in seropositive patients compared with seronegative patients (0.76 versus 2.4 years,  $p = 0.03$ ). Serum NMO-IgG titers correlated with disease severity in one study.

NMO is typically characterized by severe attacks with poor recovery, leading to rapid disability accrual. In a study of adults with NMO, 31 out of 66 (47%) were functionally blind (visual acuity of 20/200 or worse) in at least one eye, and 32 out of 71 (45%) exhibited permanent monoplegia or paraplegia, after a mean follow up of 16.9 years in relapsing patients and 7.7 years in monophasic patients. Respiratory failure was observed in one third of relapsing patients. One pediatric study reported that after a median of 12 months of follow up, 54% of NMO patients had permanent visual impairment, and 44% had limb weakness severe enough to affect mobility.

### Symptomatic Brain Involvement in Neuromyelitis Optica

Brain MRI lesions in NMO typically follow the distribution of aquaporin-4 water channel expression, including the diencephalon and brainstem periaqueductal gray matter. Brain lesions are symptomatic in 35% to 45% of children. Brainstem involvement may present as hiccups, nausea/vomiting, ophthalmoplegia, and, in severe cases, respiratory failure or death. Symptoms of diencephalic involvement may include hypersomnolence, narcolepsy, inappropriate antidiuretic hormone secretion, or menstrual irregularities. Large multifocal lesions have been associated with encephalopathy and an ADEM-like phenotype.

### Diagnostic Criteria for Pediatric Neuromyelitis Optica

Revised pediatric consensus criteria for NMO require the presence of ON and TM with at least two of the following supportive features (Krupp et al., 2013):

1. MRI evidence of a contiguous spinal lesion at least three spinal segments in length
2. Brain MRI not meeting diagnostic criteria for MS
3. NMO-IgG seropositivity

The presence of two of the three supportive criteria has 99% sensitivity and 90% specificity in distinguishing adults with NMO from those with MS (Wingerchuk, Lennon, Pittock,

Lucchinetti, and Weinshenker, 2006). Children may present with recurrent ON or TM associated with serum NMO-IgG; such cases are considered NMO spectrum disorders (Krupp et al., 2013).

### Systemic Autoimmunity in Neuromyelitis Optica

There is a high frequency of coexisting systemic autoimmunity in NMO. In one pediatric cohort, 16 out of 38 patients (42%) met the criteria for clinical diagnosis of another autoimmune condition, including systemic lupus erythematosus, type 1 diabetes, juvenile rheumatoid arthritis, and Graves disease. Some children with NMO harbor other autoantibodies without meeting formal diagnostic criteria for another autoimmune disorder. Some children with anti-NMDA receptor encephalitis display NMO-IgG in the absence of clinical NMO symptoms. The relevance of incidentally detected NMO-IgG in children with other CNS autoimmune conditions is unclear.

### Laboratory Features of Neuromyelitis Optica

The CSF in NMO patients typically demonstrates a marked pleocytosis (>50 leukocytes/ $\mu$ L), with a neutrophilic or lymphocytic predominance. This is in contrast to the moderate lymphocytic pleocytosis (<25 leukocytes/ $\mu$ L) typical of pediatric MS. One study of lumbar punctures in 89 pediatric and adult NMO patients found that pleocytosis (>5 leukocytes/ $\mu$ L) occurred in 50% of samples, with a median white blood cell count of 15 leukocytes/ $\mu$ L (range = 6–380). The median number of white blood cells and percentage of samples containing neutrophils were higher during relapses compared with periods of clinical quiescence. CSF OCBs are detected in less than 10% of children with NMO. In one pediatric study, OCBs were more commonly detected in seropositive (2/10) compared with seronegative (0/7) NMO patients.

Visual-evoked potentials are frequently abnormal in NMO patients and typically display a prolongation or absence of the P100 response. In adults with NMO, markedly abnormal or absent visual-evoked potential responses at baseline are associated with worse long-term visual outcomes. Delayed P100 responses have been observed in the absence of a clear history of ON, suggesting that optic nerve involvement may be subclinical.

OCT-based studies have demonstrated that RNFL thinning is frequently seen in NMO patients, and that RNFL thinning after an episode of ON is more severe in patients with NMO compared with those with MS.

NMO-IgG is directed against the aquaporin-4 water channel located on astrocytic end feet. This serum biomarker has a sensitivity of 73% and a specificity of 91% in differentiating NMO from other demyelinating disorders, including MS, in adult patients (Lennon et al., 2004) and is detected in up to 78% of children with relapsing NMO. NMO-IgG has also been detected in children with NMO spectrum disorders.

A proportion of individuals with clinical NMO will repeatedly test negative for NMO-IgG, even when sensitive cell-based assays are employed. A subset of these NMO-IgG-seronegative patients displays serum anti-MOG antibodies. Studies suggest that NMO patients with anti-MOG antibodies (without NMO-IgG) have an increased likelihood of being male, are slightly younger, have better recovery from attacks, are less likely to experience a relapsing course, and, in one study, were more likely to present with simultaneous/sequential ON and TM. In three reported children with clinical NMO and anti-MOG antibodies, there was an initial relapsing course, with a beneficial response to longer-term immunotherapy (azathioprine or monthly IVIg). Two children displayed deep gray-matter involvement on MRI.

## Magnetic Resonance Imaging in Neuromyelitis Optica

As in MS, MRI during an acute ON attack in NMO typically reveals optic nerve thickening and an increased signal on fat-suppressed T2-weighted images. Fat-suppressed postcontrast T1-weighted images show optic nerve enhancement in 94% of patients. To date, there are no MRI features that reliably distinguish ON in NMO from that in MS, although a trend toward more extensive and greater posterior optic nerve involvement in NMO has been noted.

Brain MRI lesions are common in children with NMO, with 53% to 100% of children demonstrating brain abnormalities distinct from the optic nerves at presentation. In NMO, brain MRI lesions typically occur in areas of aquaporin-4 water channel expression, including (a) lesions surrounding the ventricular system (e.g., diencephalic lesions around the third ventricle, dorsal brainstem lesions adjacent to the fourth ventricle, and peri-ependymal lesions surrounding the lateral ventricles); (b) hemispheric lesions that may be large (>3 cm diameter); (c) lesions involving the corticospinal tracts; and (d) small, nonspecific, deep white-matter lesions (most common lesion type) (Fig. 100-7) (Kim et al., 2015). Enhancing lesions may demonstrate a patchy, diffuse, “cloud-like” enhancement pattern. As discussed earlier, brain lesions may be symptomatic. Lesions that are perpendicular to ventricles, S-shaped U-fiber lesions, lesions along the inferior aspect of the lateral ventricles, temporal lobe lesions, and lesions that have an ovoid or open-ring enhancement pattern are more characteristic of MS (Kim et al., 2015).

Acute spinal MRI in NMO typically reveals lesions spanning at least three contiguous spinal segments that are hyperintense on T2-weighted images (Fig. 100-7A) and hypointense on T1-weighted images. It is important to note, however, that LETM is frequently seen in children with idiopathic TM, in TM with ADEM, and in up to 25% of TM cases associated with an MS attack. NMO patients occasionally present with short-segment spinal lesions. Partial cord lesions in NMO often localize to the cervical and upper thoracic cord. Acutely, lesions typically affect central cord gray and white matter, with diffuse gadolinium uptake within the lesion core. Bilateral and symmetric anterior horn cell signal abnormalities resembling anterior cord infarction have been described. Over time, the development of spinal cord atrophy is associated with an increased likelihood of persistent neurologic deficits.

### Treatment of Pediatric Neuromyelitis Optica

Acute attacks are usually treated with intravenous corticosteroids. If symptoms progress despite steroid therapy, IVIg and/or plasmapheresis is usually administered.

Longer-term immunosuppression is generally used to prevent relapses and disability accrual given the aggressive nature of this disease. Azathioprine (+/- oral prednisone), repeated IVIg or plasmapheresis, rituximab, cyclophosphamide, mycophenolate mofetil, and ofatumumab have all been used in children with NMO.

## CONCLUSIONS

Acquired demyelination of the CNS, including transient forms and pediatric-onset MS and NMO, is being increasingly recognized and diagnosed worldwide. This has been aided by the development of consensus diagnostic criteria, evolving MRI criteria, and the discovery of the NMO-IgG biomarker. The current and emerging armamentarium of increasingly powerful medications for adult-onset MS will require vigilant and

**Figure 100-7. MRI in childhood neuromyelitis optica.** **A**, Sagittal T2-weighted MRI image shows a longitudinally extensive intramedullary spinal lesion. **B**, Axial fluid-attenuated inversion-recovery (FLAIR) MRI from a different child shows bilateral hyperintense diencephalic lesions.

thoughtful use in children. Collaboration between clinicians and scientists, such as that fostered by the International Pediatric MS Study Group and other organizations, is essential to optimize care.

## 101 Disorders of Consciousness in Children

Stephen Ashwal

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Disorders of consciousness (DOCs) in children are usually due to serious nervous system injuries as well as infectious, genetic, and metabolic disorders. Assessment of consciousness remains challenging because of the inherent limitations imposed by the structural and functional developmental level of the neonate, infant, and child and how it affects the ability to evaluate language, cognitive, and behavioral functions. This chapter reviews aspects of the diagnosis, management, and prognosis of DOCs in children as well as recent evolving concepts related to the “neural correlates of consciousness.”

**HISTORICAL PERSPECTIVE**

Please see online chapter for a discussion of this topic.

**Neural Correlates of Consciousness**

In the past quarter century, increasing research has focused on the concept of the *neural correlates of consciousness* (NCC), defined “as the minimal neuronal mechanisms jointly sufficient for any one specific conscious percept.” Comprehensively reviewing this topic is beyond the scope of this chapter, and the reader is referred to several reviews for further consideration (Giacino et al., 2014; Gosseries et al., 2014).

Consciousness is defined as having two components: awareness and arousal (Di Perri et al., 2014). Arousal, also called wakefulness, refers to the level of alertness (clinically determined by eye opening), whereas awareness refers to the content of consciousness (clinically determined by the obeying of commands or nonreflex motor behavior such as eye tracking or localized responses to pain). Arousal is related to structures in the brain, specifically to the brainstem and hypothalamus, whereas awareness has been shown to be related to a wide fronto-parietal network encompassing associative cortices and the thalamus (Laureys, 2005).

Assessment of awareness remains subjective. One can only determine whether a patient is conscious if he/she is capable of manifesting behavioral or verbal responses. An “unresponsive” patient may be in a locked-in syndrome or have a disorder of consciousness but with a low-level of conscious awareness and be unable to respond because of coexistent conditions such as motor, sensory, or language impairments, complicating medical conditions, subclinical seizures, etc. About 30% to 40% of individuals diagnosed as being in a VS/UWS do manifest conscious behaviors or have neuroimaging or electrophysiological evidence of limited consciousness. The advent of functional imaging and EEG computational methods have provided significant supportive evidence that conscious behavior may be present even in patients who appear

unconscious. Certainty of diagnosis is necessary as it forms the basis of clinical decision making. However, medical centers may not have the facilities and technical and medical staffing/expertise to acquire and interpret such data.

**Approaches to Studying the NCC**

Several types of experimental paradigms combined with functional neuroimaging and neurophysiological testing are used to explore brain function (Osborne et al., 2015; Di Perri et al., 2014):

*Passive stimulation paradigms.* Subjects are presented with various stimuli and their brain responses are monitored for characteristic patterns indicative of normal cognitive processing. These paradigms do not require intentional interaction and activation will not appear unless the patient intentionally performs the task.

*Active stimulation paradigms.* Specific instructions are given to the subject, with or without accompanying stimulation, and brain activation responses are monitored.

*Resting state and connectivity studies.* Resting state activity using fMRI or EEG to measure regional brain interactions when an individual is not performing specific tasks is based on the concept that even at rest the brain has measurable resting activity. Studies in individuals with disorders of consciousness have identified the default mode network and other NCCs that affect conscious behaviors.

*Transcranial magnetic stimulation (TMS).* TMS directly perturbs underlying neuronal networks, allowing for the study of effective regional connectivity. In DOC patients, TMS paradigms have shown functional connectivity abnormalities that may correlate with behavioral observations.

*Commonly used testing paradigms.* Numerous testing paradigms have been used to assess behavioral, imaging, or neurophysiological responses:

- a. *Oddball paradigm.* Repetitive audiological or visual stimuli are infrequently interrupted by a deviant stimulus and the responses recorded with event-related potentials (ERPs). Typically detected is an abnormal surface positive P300 response best seen in the parietal regions or with fMRI.
- b. *Mismatch negativity.* Similar in concept to the oddball sequence, but the activated response is different. It is a negative frontal response (the N200 response).
- c. *Binocular rivalry and flash suppression.* Binocular rivalry is a visual response in which perceptions alternate between different images (e.g. red versus green) presented to each eye. Flash suppression is a form of visual perception in which an image that is presented to one eye is

- suppressed by a flash of another image to the other eye. Both are used to study visual processing.
- d. *Residual language function.* Many types of language stimuli can be assessed by fMRI or EEG (e.g., the N400 ERP response). Typical stimuli include presentation of narratives that had personally meaningful content and that were read forwards by a familiar voice.
  - e. *Visual imagery.* One of the most dramatic tasks in which the “unconscious” patient is asked to visualize is that they are playing tennis, swimming, or navigating about their house, etc. with activation detected in similar regions as control conscious individuals.
  - f. *Tactile stimulation/motor movement commands.* Multiple forms of touching or asking the patient to move an extremity have been tried with activation on fMRI interpreted as a sign of consciousness.

## Neuroimaging

Positron Emission Tomography (PET) and fMRI studies have been used to study DOC patients (Harrison and Connolly, 2013; Di Perri et al., 2014) and have documented significant (i.e., up to 40%) reductions in cerebral metabolism in patients who were in a VS/UWS. Recovery has been associated with improved connectivity—but not to the degree that PET could be used to differentiate between VS/UWS and MCS. fMRI activation has demonstrated cortical responses in MCS patients resembling those in healthy controls whereas VS/UWS patients showed only low level activation if at all (Fig. 101-1) (Di Perri et al., 2014). Multiple paradigms have been successfully used to detect evidence of brain activation in patients who are deemed unconscious. So far these studies have shown that

only about 20% of unconscious patients will show such activation (Gosseries et al., 2014). Also, almost all studies have been performed in adult patients, and it is uncertain as to whether such studies will be able to be done in pediatric patients. There has been one case report in a pediatric patient who was in a MCS in whom fMRI was acquired.

## Neurophysiology

Several reviews have examined the role of EEGs, evoked potentials (EPs), and event-related potentials (ERPs) in patients with DOCs (Harrison and Connolly, 2013). Conventional EEG has limited value and can determine whether a DOC patient is having seizures or if there is evidence of diffuse slowing or suppression. In some patients, changes in sleep/wake EEG patterns correlate with a patient’s clinical state.

Evoked potentials (EPs) and event-related potentials (ERPs) have been used in DOC patients to assess brainstem and forebrain integrity. EPs generally reflect sensory processing responses, whereas ERPs reflect perceptual and cognitive processing and appear more sensitive in detecting functional abnormalities activity. Chapters 102 to 104 describe the different types of EPs for outcome prediction.

## Neural Correlates of Consciousness in DOC Patients

Abnormalities in several connectivity networks have been associated with DOCs in adults and include:

*Default Mode Network (DMN).* The DMN, considered responsible in part for intrinsic awareness, encompasses the posterior and anterior cortical midline structures, with major hubs being located in the posterior cingulate cortex and precuneus, the medial prefrontal cortex, and the angular

**Figure 101-1.** fMRI and PET in two Vegetative State (VS)/Unresponsive Wakefulness Syndrome (UWS) patients: one Minimally Conscious State (MCS) patient and one healthy control showing possible dissociations between active and passive paradigms and how they complement each other in the evaluation of patients. fMRI mental imagery tasks (motor imagery on the left, navigation imagery on the right) show positive results in the control subject and in the second VS/UWS patient. PET and fMRI resting-state results typically show a strong decrease in brain activity and anatomy [here, diffusion tensor imaging (DTI)] in the first VS/UWS patient and show partially preserved brain activity in the second VS/UWS patient as in the MCS patient. Negative responses to active paradigms in MCS patients frequently occur. (With permission from Gosseries, O., Di, H., Laureys, S., Boly, M., 2014. *Measuring consciousness in severely damaged brains. Annu Rev Neurosci* 37, 457–478.)

gyrus (Andrews-Hanna et al., 2014). The DMN shows greater activity during the resting state when an individual is focused internally rather than on the external world or on attention-demanding tasks. Studies have shown that DMN connectivity is reduced in patients with VS/UWS compared with healthy controls. It has been shown that there is limited evidence of the DMN in infancy but that DMN connectivity can be detected in children 9 to 12 years of age, suggesting that the DMN evolves with maturation.

**Executive Control Network (ECN).** The ECN is considered responsible for extrinsic awareness that regulates executive functions that control and mediate cognitive processes, including working memory, reasoning, flexibility, problem solving, and planning (Qin et al., 2015). Traditionally, ECNs have been considered to be located in prefrontal regions of the frontal lobes (e.g., dorsolateral prefrontal cortex, anterior cingulate cortex, orbitofrontal cortex), but more recent studies suggest that subcortical and brainstem sites participate in network functioning. A previous study has shown altered ECN connectivity in DOC patients compared with controls, but more recent studies have not confirmed such findings (Qin et al., 2015; Demertzi et al., 2014).

**Saliency Network.** The Saliency Network (SN) is a large-scale network anchored in the anterior insula and dorsal anterior cingulate cortex and includes three key subcortical structures: the amygdala, the ventral striatum, and the substantia nigra/ventral tegmental area (Menon, 2015). The SN contributes to communication, social behavior, and self-awareness. SN connectivity studies early after injury may differentiate patients in MCS from patients in VS/UWS.

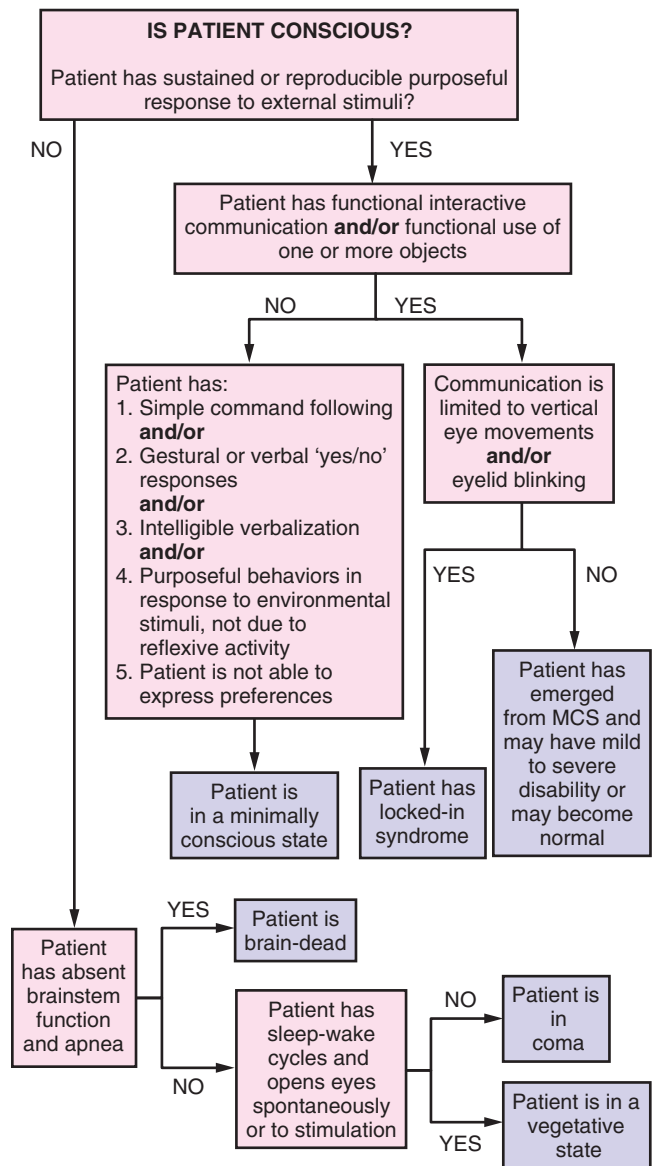

**Frontal Mesocircuit Network (FMN).** The frontal mesocircuit network consists of hubs in the mesencephalon (pedunculo-pontine nucleus, PPN), central thalamus, deep anterior frontal lobes, striatum, globus pallidus interna, and regions in the parietal, occipital, and temporal cortex with the major pathways involving thalamocortical, thalamostriatal, and corticostriatal outflow (Giacino et al., 2014). The mesocircuit serves as the basic underlying tonic driver of the forebrain networks and is necessary for supporting consciousness and governing the quality of consciousness.

Other networks include sensorimotor, auditory, cerebellar, and three visual networks in healthy controls and in patients with varying levels of diminished consciousness. Also, as alluded to previously, there is now extensive research examining the development of many of these networks in the pediatric population, particularly in children with neurodevelopmental disabilities.

## DEFINITIONS

Along the continuum from normal consciousness to coma or unarousable unconsciousness, many terms are used to describe mental state and reactivity. When there is doubt about the appropriate use of one of these terms, it is far better to describe the state and reactivity of the individual rather than label it. See Table 101-1 and Figure 101-2 that describe the major DOCs and associated conditions.

**Clouding of consciousness** is the minimal reduction of wakefulness or awareness wherein the main difficulty is attention or vigilance. Clouding of consciousness is distinguished from daydreaming in that the child cannot be easily stimulated to normal consciousness. **Confusion** is the state of impaired ability to think and reason clearly at a developmentally and intellectually appropriate level. Confused children have persistent difficulty with orientation, simple cognitive processing, and acquisition of new memory. Definitions of impairment of consciousness states may be divided into the categories as listed here:

**Figure 101-2.** An algorithm useful for distinguishing among brain death, vegetative state, locked-in syndrome, and higher-order consciousness. MCS, minimally conscious state. (With permission from Ashwal, S., Cranford, R., 2002. The minimally conscious state in children. *Semin Pediatr Neurol* 9, 19.)

## Impairment of Consciousness With Activated Mental State

**Hallucinations** are perceptions of sensory input that are not present; **illusions** are misinterpretations of actual sensory stimuli. **Delusions** are incorrect thoughts or beliefs that do not change when challenged by contradictory evidence or logical reason. **Delirium** is an activated mental state that may include disorientation, irritability, fearful responses, and sensory misperception. Common causes include intoxication, infection, fever, metabolic disorders, epilepsy, and night terrors.

## Impairment of Consciousness With Reduced Mental State

**Obtundation** is mild to moderate alertness reduction with decreased interest in the environment and slower than normal

**TABLE 101-1** Severe Disorders of Consciousness and Related Conditions

Condition	Self-Awareness	Pain and Suffering	Sleep-Wake Cycles	Motor Function	Respiratory Function	Outcome
Coma	Absent	No	Absent	No purposeful movement	Variably depressed	Evolves to persistent vegetative state, dies, or recovers in 2–4 weeks
Vegetative state	Absent	No	Intact	No purposeful movement	Normal	Depends on etiology
Minimally conscious state	Very limited	Yes	Intact	Severe limitation of movement	Variably depressed	Recovery unknown
Akinetic mutism	Limited	Yes	Intact	Moderate limitation of movement	Normal to variably depressed	Recovery unlikely or limited
Locked-in syndrome	Present	Yes	Intact	Quadriplegia; pseudobulbar palsy; eye movements preserved	Normal to variably depressed	Recovery unlikely; remains quadriplegic
Brain death	Absent	No	Absent	None or only reflex spinal movements	Absent	None

reactivity to stimulation. *Stupor* is a state of unresponsiveness with little or no spontaneous movement, resembling deep sleep from which the patient can only be aroused by vigorous and repeated stimulation.

*Coma* is a state of deep, unarousable, sustained pathologic unconsciousness with the eyes closed and results from dysfunction of the ascending reticular-activating system in the brainstem or in both cerebral hemispheres. Coma usually requires the period of unconsciousness to persist for at least 1 hour to distinguish coma from syncope, concussion, or other states of transient unconsciousness.

### Vegetative State, Minimally Conscious State, and Related Conditions

Table 101-1 lists several of the major neurologic conditions that the clinician must be capable of differentiating from coma. This table was modified from the report issued by the Multi-Society Task Force and more recent work that is defining the concept of the minimally conscious state (see Figure 101-2 algorithm).

#### Vegetative State/Unresponsive Wakefulness Syndrome

The VS/UWS can be described as a condition of complete unawareness of the self and the environment, accompanied by sleep-wake cycles with either complete or partial preservation of hypothalamic and brainstem autonomic (vegetative) functions (Multisociety Task Force Report, 1994). Recently the term “unresponsive wakefulness syndrome” has been suggested as a better descriptive alternative term (Laureys et al., 2010).

Criteria to diagnose the VS/UWS are listed in Box 101-1. Children in a vegetative state lack evidence of self-awareness or recognition of external stimuli. Rather than being in a state of “eyes-closed” coma, they remain unconscious but have irregular periods of wakefulness alternating with periods of sleeping. Vegetative patients demonstrate a variety of sounds, emotional expressions, and body movements, and they may smile or shed tears. They have inconsistent head- and eye-turning movements to sounds and inconsistent, nonpurposeful trunk and limb movements. The most objective sign is lack of sustained visual fixation or visual tracking.

It is estimated that there are about 4000 to 10,000 children in a vegetative state in the United States and about 100,000

#### BOX 101-1 Criteria for the Diagnosis of the Vegetative State

No evidence of awareness of themselves or their environment; they are incapable of interacting with others  
 No evidence of sustained, reproducible, purposeful, or voluntary behavioral responses to visual, auditory, tactile, or noxious stimuli  
 No evidence of language comprehension or expression  
 Intermittent wakefulness manifested by the presence of sleep-wake cycles  
 Sufficiently preserved hypothalamic and brainstem autonomic functions to survive if given medical and nursing care  
 Bowel and bladder incontinence  
 Variably preserved cranial nerve (pupillary, oculocephalic, corneal, oculovestibular, gag) and spinal reflexes

(Based on the Multi-Society Task Force on Persistent Vegetative State, 1994. *Medical aspects of the persistent vegetative state, Part 1. N Engl J Med* 330, 1499–1508.)

worldwide. The etiology of the vegetative state in children can be classified into the following three broad groups of disorders:

1. Acute traumatic and nontraumatic brain injuries
2. Metabolic and degenerative disorders affecting the nervous system
3. Developmental malformations

The most common causes of acute brain injury leading to the vegetative state in children are head trauma and hypoxic-ischemic encephalopathies. The clinical course of evolution to a vegetative state after an acute injury usually begins with eyes-closed coma for several days to weeks, followed by the appearance of sleep-wake cycles.

The progression of many metabolic and degenerative nervous system disorders in children also may result in an irreversible vegetative state and slowly evolves over several months or years. Severe congenital central nervous system (CNS) malformations also can result in a vegetative state. At birth, anencephaly is the only malformation in which an infant can be diagnosed as being in a vegetative state. Other malformations such as hydranencephaly may result in

a vegetative state, but because of the limitations of the neurologic examination, it is recommended that such infants not be diagnosed as being vegetative until there is certainty about the diagnosis.

Recovery from the VS/UWS in children depends on the etiology and is reviewed in more detail in the 1994 Multi-Society Task Force Report. In children with severe closed-head injuries who were vegetative 1 month after injury, follow up at 1 year found that 29% remained in a vegetative state, 9% had died, and 62% recovered consciousness.

In contrast, children in a nontraumatic vegetative state have a much poorer prognosis. At 1 year, most children remained in a vegetative state (65%) or died (22%); only 13% demonstrated recovery, usually to a severe disability. It was based on these data and consensus opinion that the Task Force came to the conclusions that, in children (as well as in adults), the vegetative state could be judged permanent 12 months after traumatic brain injury and 3 months after nontraumatic injury. This perspective has received general acceptance, although concerns have been raised about the certainty of diagnosis and whether there is a greater potential for patients to recover than previously realized. In addition, the number of patients in the Task Force report was small and points to the need to do studies with greater numbers of patients.

Children in a vegetative state have a shorter life expectancy. Those younger than 1 year of age had a median survival of 2.6 years; median survival of children aged 2 to 6 years was 5.2 years; and in children 7 to 18 years, the median survival was 7 years.

## Minimally Conscious State

The minimally conscious state has been defined as a condition of severely altered consciousness in which the person demonstrates minimal but definite behavioral evidence of self- or environmental awareness. The term minimally conscious state may also be used to describe patients with degenerative disorders who are no longer functionally interactive but are not in the vegetative state. Criteria to diagnose the minimally conscious state are summarized in [Box 101-2](#). Patients show wakefulness and are able to do the following:

1. Follow simple commands
2. Gesture or verbally give “yes” or “no” responses (regardless of accuracy)
3. Verbalize intelligibly
4. Perform movements or affective behaviors, which are not attributable to reflexive activity, in contingent relation to relevant environmental stimuli

Recently the MCS was divided into two subcategories depending on the complexity of behavioral responses: (1) MCS (– minus) in which patients have visual pursuit, can reach for objects, have orientation to noxious stimuli, and show contingent behavior; and (2) MCS (+ plus) in which patients can follow commands, have intentional communication, and intelligible verbalization. A third category, *emergent MCS*, has been defined in which the patients had emerged from a MCS—that is, they were functioning at a higher level and had functional communication (e.g., follow instructions) and functional object use (e.g., use a comb) ([Gosseries et al., 2014](#)). It is likely that the terms MCS–, MCS+, and emergent MCS are applicable to children, but there have been no reported studies in children using this terminology.

Based on limited literature on this disorder in adults, it is possible that children in a MCS, depending on the etiology of the insult, may have a better potential for neurologic recovery and a longer life expectancy than children in the vegetative

### BOX 101-2 Diagnostic Criteria for the Minimally Conscious State

#### MCS\*

Simple command obeying  
 Gestural or verbal yes-no responses (regardless of accuracy)  
 Intelligible verbalization

Purposeful behavior, including movements or effective behaviors that occur in contingent relation to relevant environmental stimuli and are not due to reflexive activity. Some behavioral examples of qualifying purposeful behaviors include the following:

- Appropriate smiling or crying in response to the linguistic or visual content of emotional but not to neutral topics or stimuli
- Vocalizations or gestures that occur in direct response to the linguistic content of questions
- Reaching for objects that demonstrates a clear relationship between object location and direction of reach
- Touching or holding objects in a manner that accommodates the size and shape of the object
- Pursuit eye movement or sustained fixation that occurs in direct response to moving or salient stimuli

#### MCS–

- Have visual pursuit
- Can reach for objects
- Have orientation to noxious stimuli
- Show contingent behavior

#### MCS+

In addition to what MCS– patients can do, MCS+ patients can also:

- Follow commands
- Have intentional communication and intelligible verbalization

*\*(Adapted from Giacino, J.T. et al., 2002. The minimally conscious state. Definition and diagnostic criteria. Neurology 58, 349.) Criteria for MCS– and MCS+ are from Bruno, M.A., et al., 2012. Functional neuroanatomy underlying the clinical subcategorization of minimally conscious state patients. J Neurol 259(6), 1087–1098.)*

state. However, studies have shown that mobility may be more important than consciousness in predicting survival.

## Locked-in Syndrome

The locked-in syndrome refers to a condition in which patients retain consciousness and cognition but are unable to move or communicate because of severe paralysis. By definition, patients in coma or a vegetative state are unconscious and differ from patients in a locked-in syndrome, who retain awareness, although this difference may be difficult to determine. The locked-in syndrome is quite rare in children.

## Akinetic Mutism

Akinetic mutism is a rare condition consisting of pathologically slowed or nearly absent bodily movement, accompanied by a similar loss of speech. It has been reported in children with brain tumors, bacterial and viral CNS infections, hydrocephalus, and occasionally as a postoperative phenomenon. Wakefulness and self-awareness are preserved but the level of mental function is reduced. The condition accompanies gradually developing or subacute, bilateral damage to the paramedian mesencephalon, basal diencephalon, or inferior frontal lobes. The long-term outlook for children with akinetic mutism is unknown.

## Brain Death

Please see Chapter 107.

## CONSCIOUSNESS RATING SCALES

The best known and most widely used scale is the Glasgow Coma Scale, which yields a score of 3 to 15, based on best response to stimuli in the these three categories: eye opening, verbal response, and motor response (Table 101-2). In its original form, the Glasgow Coma Scale was not developmentally suitable for assessment of newborns, infants, and younger children, and a variety of alternate scales have been proposed. The Pediatric Coma Scale makes minor changes in the verbal scale of the Glasgow Coma Scale and redefines the “best” score based on developmental and age-appropriate norms (Table 101-3). The Children’s Coma Scale included pupillary reflexes, extraocular movements, and apnea in its categories, and is therefore substantially different from the Glasgow Coma Scale (Table 101-4). The Glasgow Coma Scale—Modified for Children is also a valuable tool (Table 101-2) as is the Full Outline of UnResponsiveness (FOUR) Score Coma Scale (Table 101-5). The FOUR Score is divided into four categories (eye response, motor response, brainstem reflexes, and respiration) and provides a measure of consciousness. The Coma Recovery Scale-revised (CRS-R) is considered the best tool to use to assess adult patients with a DOC, but it has not been validated in children.

**TABLE 101-2** Glasgow Coma Scale and Modification for Children

Glasgow Coma Scale	Score	Glasgow Coma Scale (Infant Modification)	Score
EYE OPENING (E)		EYE OPENING (E)	
Spontaneous	4	Spontaneous	4
To speech (to shout)	3	To speech (to shout)	3
To pain	2	To pain	2
None	1	None	1
VERBAL RESPONSE (V)		VERBAL RESPONSE, MODIFIED FOR INFANTS (V)	
Oriented	5	Babbles, coos appropriately	5
Confused conversation	4	Cries, but consolable	4
Inappropriate words	3	Cries inconsolably	3
Incomprehensible sounds	2	Grunts or moans to pain	2
None	1	None	1
MOTOR RESPONSE (M)		MOTOR RESPONSE (M)	
Obeys commands	6	Purposeful movements	6
Localizes pain	5	Localizes pain	5
Withdraws	4	Withdraws	4
Abnormal flexion	3	Abnormal flexion	3
Extensor response	2	Extensor response	2
None	1	None	1

## PATHOPHYSIOLOGY

See online chapter and also Chapters 102, 103, and 104.

## ETIOLOGIES

A more relevant and practical classification for the etiology of impairment of consciousness and coma in children produces three distinct but overlapping categories (Box 101-3):

1. Infectious or inflammatory
2. Structural
3. Metabolic, toxic, or nutritional

Bacterial, viral, rickettsial, or protozoan infections of the CNS may cause conscious alteration by direct involvement of brain parenchyma, interference with blood flow, production of cerebral edema with resulting increased intracranial pressure, and increasing metabolic activity beyond metabolic substrate availability. Viral infections are more likely to involve brain parenchyma (encephalitis). The meningitis produced by bacterial infections may produce injury as a result of large blood vessel occlusion, microvascular inflammation, or disturbance of cerebral autoregulation. Cerebral edema, focal mass or abscess, and hydrocephalus as a result of intracranial infection

may produce injury by reducing cerebral blood flow or leading to herniation.

Structural causes of consciousness impairment or coma include intracranial neoplasm, infectious space-occupying lesion (abscess, tuberculoma), nonaccidental and accidental trauma, cerebral infarction or hemorrhage, and hydrocephalus. These conditions are described in detail in other chapters.

Metabolic and toxic causes of impaired consciousness or coma include hypoxic-ischemic injury (focal or generalized), electrolyte abnormality, endocrinopathy, hepatic or renal failure, and inherited disorders, including organic and aminoacidurias, urea cycle disorders, mitochondrial disorders, and porphyria. Paroxysmal disorders such as uncontrolled seizures, nonconvulsive status epilepticus, or migraine may produce changes in consciousness that may be episodic. The diagnosis, pathophysiology, and treatment of specific disorders are reviewed elsewhere in this book. Children with psychiatric disorders such as conversion, panic, or anxiety disorders may present with neurologic symptoms including genuine or apparent impairment of consciousness. Nutritional causes of alteration of consciousness or coma are relatively uncommon in and are reviewed in Chapters 46 and 47.

## EVALUATION

Coma is a medical and neurologic emergency requiring immediate consideration of key issues, including immediate life support, identification of the cause of coma, and institution of specific therapy. These critical issues will be reviewed in sequence. As accidental and nonaccidental traumatic brain injury (Chapters 102, 103), global hypoxic-ischemic injury (Chapter 104) and disorders associated with increased intracranial pressure (Chapter 105) are the most common conditions causing coma in children; the reader is referred to these chapters for additional discussion.

## Clinical Evaluation

The ABCs of basic life support (immediate life support—airway, breathing, and circulation) must be evaluated and managed as an emergency (see online chapter).

## Identification of Cause

Accurate and rapid identification of the cause of coma is important to direct specific treatment. The history and physical examination are the basis for identification of the cause of coma.

## History

Coma may manifest as the progression of a known underlying illness, unpredictable consequence, or complication of a known disease, or it may be the result of a totally unexpected event or illness. Sudden onset of coma suggests convulsions or intracranial hemorrhage. Coma preceded by sleepiness or unsteadiness suggests ingestion of a drug or toxin. Fever is typical when coma is due to an infectious process. A history of headache may suggest elevated intracranial pressure. In patients who were in coma after a traumatic brain injury and in whom CT scanning was normal or could not explain the severity of clinical symptoms, MRI should be performed to evaluate for diffuse axonal injury.

## General Physical Examination

See online chapter and Chapters 102 to 104.

**BOX 101-3** Etiologies of Impaired Consciousness and Coma

## Infectious or Inflammatory

## A. Infectious

- Bacterial meningitis
- Viral encephalitis
- Rickettsial infection
- Protozoan infection
- Helminth infestation

## B. Inflammatory

- Sepsis-associated encephalopathy
- Vasculitis, collagen vascular disorders
- Demyelination
- Acute disseminated encephalomyelitis
- Multiple sclerosis

## Structural

## A. Traumatic

- Concussion
- Cerebral contusion
- Epidural hematoma or effusion
- Intracerebral hematoma
- Diffuse axonal injury
- Abusive head trauma

## B. Neoplasms

## C. Vascular Disease

- Cerebral infarction
  - Thrombosis
  - Embolism
  - Venous sinus thrombosis
- Cerebral hemorrhage
  - Subarachnoid hemorrhage
  - Arteriovenous malformation
  - Aneurysm
- Congenital abnormality or dysplasia of vascular supply
- Trauma to carotid or vertebral arteries in the neck

## D. Focal Infection

- Abscess
- Cerebritis

## E. Hydrocephalus

## Metabolic, Nutritional, or Toxic

## A. Hypoxic-Ischemic Encephalopathy

- Shock
- Cardiac or pulmonary failure

## Near-drowning

- Carbon monoxide poisoning
- Cyanide poisoning
- Strangulation

## B. Metabolic Disorders

- Sarcoidosis
- Hypoglycemia
- Fluid and electrolyte imbalance
- Endocrine disorders
  - With acidosis
    - Diabetic ketoacidosis
    - Aminoacidemias
    - Organic acidemias
  - With hyperammonemia
    - Hepatic encephalopathy
    - Urea cycle disorders
    - Disorders of fatty acid metabolism
    - Reye's syndrome
    - Valproic acid encephalopathy
- Uremia
- Porphyria
- Mitochondrial disorders
- Leigh's syndrome

## C. Nutritional

- Thiamine deficiency
- Niacin or nicotinic acid deficiency
- Pyridoxine dependency
- Folate and B12 deficiency

## D. Exogenous Toxins and Poisons

- Alcohol intoxication
- Over-the-counter medications
- Prescription medications (oral and ophthalmic)
- Herbal treatments
- Heavy-metal poisoning
- Mushroom and plant intoxication
- Illegal drugs
- Industrial agents

## E. Hypertensive Encephalopathy

## F. Burn Encephalopathy

**Neurologic Examination**

The neurologic examination is of paramount importance in assessing the comatose patient. Examination of the fundi, pupillary size and reactivity, eye movement control, corneal reflexes, motor responses, body posture, and the presence or absence of meningeal signs gives important information. Localization may be aided by detailed understanding of brainstem pathways involved in the eye examination. Funduscopic examination offers important clues about the etiology of coma, including papilledema and retinal hemorrhages. See online chapter and Chapters 102 to 104. Passive resistance to neck flexion suggests meningeal irritation, tonsillar herniation, or craniocervical trauma.

Pupillary reactivity can be elicited by shining a light on the eye or by opening and closing the eyelid. An abnormality of the pupillary light reflex suggests midbrain dysfunction. With unilateral loss of visual acuity, the opposite pupil may dilate when the light is moved from the unaffected to the affected side. This reaction results from a defect in the afferent limb of the reflex arc on the affected side. Most metabolic disorders

and drug ingestions produce symmetrically small pupils that retain some reactivity to light. Severe hypoxic-ischemic injury produces symmetric dilated pupils that may not respond to light. Structural or mass lesions of the cerebral hemispheres typically do not produce pupillary abnormalities unless herniation occurs. Midbrain injuries may interrupt both sympathetic and parasympathetic pupillary innervations, producing midposition unresponsive pupils.

Unilateral stimulation of the frontal gaze center produces conjugate eye deviation to the opposite side and can be produced by seizure activity or other unilateral irritating stimuli. Unilateral injury, destruction, or metabolic exhaustion of the frontal gaze center produces conjugate deviation toward the affected side.

The oculocephalic maneuver is performed by moving the head side to side or vertically and should only be performed when there is certainty that there is no cervical spine injury or abnormality. A positive oculocephalic response consists of conjugate deviation of the eyes in the direction opposite head movement. Absence of a positive oculocephalic response may be seen in structural abnormalities of the brainstem, in which

it may be asymmetric, and in metabolic-toxic encephalopathies, in which it is almost always symmetric.

Caloric testing or oculovestibular responses are obtained by irrigating one or both external ear canals with warm and cold water and should only be performed when the external canal is clean and the tympanic membrane intact. The usual protocol for unconscious patients involves cold-water irrigation with the head elevated 30 degrees from the horizontal, which induces convection currents in the endolymphatic fluid of the labyrinth. The resulting vestibular nuclei stimulation affects the ipsilateral paramedian pontine reticular formation-abducens nuclear complex and also the contralateral oculomotor and trochlear nuclei through the medial longitudinal fasciculus. In awake patients, cold-water irrigation produces a lateral nystagmus, with the quick phase away from the stimulated ear. Warm-water stimulation has the opposite effect. This finding gives rise to the mnemonic COWS (cold opposite, warm same). In the unconscious patient, however, the quick phase is lost, and slow tonic deviation is noted toward the irrigated ear. Unilateral or asymmetric caloric responses suggest a brainstem structural abnormality, whereas bilateral absence can be seen in metabolic, as well as structural, abnormalities.

The corneal reflex consists of closure of the eyelid, elicited by gently touching the cornea with a suitable stimulus. An absent response suggests abnormal afferent or trigeminal input or bilateral pontine involvement. A contralateral blink response suggests intact sensory input through the fifth cranial nerve, whereas an abnormal motor limb response on the ipsilateral side is more consistent with an ipsilateral structural abnormality. Metabolic lesions typically produce bilateral loss of the response. Absence of the corneal reflex must be interpreted with caution in the presence of conjunctival edema or injury.

Observation of spontaneous movement and motor responses to stimulation is an important clue in the assessment of coma and localization of the level of injury or lesion. Asymmetric involvement is a hallmark of structural abnormality. Unilateral cortical or subcortical structural lesions may cause contralateral weakness. Bilateral absence of movement or tone (flaccidity) occurs in metabolic-toxic encephalopathies such as drug intoxications and in disruption of brainstem-cortical interconnections higher than the pontomedullary junction. Flaccidity resulting from spinal cord injuries or neuromuscular paralysis is not associated with coma unless other injuries exist.

Posturing may occur spontaneously or in response to stimulation. Decorticate posturing involves flexion of the upper extremities and extension of the lower extremities and usually indicates cortical or subcortical abnormalities with preservation of brainstem function. Decerebrate posturing involves extension of all extremities with internal rotation and may be seen with metabolic-toxic disorders or midbrain compression.

## BRAIN HERNIATION

Within the skull are unique dural reflections that divide the intracranial contents into compartments. The falx cerebri lies between the cerebral hemispheres, and the tentorium cerebelli separates anterior fossa structures (cerebral hemispheres and diencephalon) from posterior structures (brainstem and cerebellum). The opening in the tentorium through which the midbrain passes is called the tentorial notch. Focal or generalized lesions, which produce mass effect or increased intracranial pressure, may produce one of the three brain herniation syndromes based on squeezing of brain structures over or through the tentorium or through the foramen magnum.

## Historical Perspective

See online chapter.

## Herniation Syndromes

Three herniation syndromes are briefly presented and are discussed in detail in Chapter 102.

### Uncal Herniation

Uncal herniation refers to the medial displacement of the uncal gyrus of the temporal lobe over the free lateral edge of the tentorium, associated with an asymmetric supratentorial mass or edema. The uncal gyrus (uncus) comes in direct contact with the oculomotor nerve, producing ipsilateral pupillary dilatation and external ophthalmoplegia. Radiologic studies, however, emphasize horizontal shift of the mesencephalon away from the lesion as the cause of early consciousness alteration because the ambient cistern and prepontine cistern are widened ipsilaterally. The ipsilateral pupillary dilatation is due to stretch of the oculomotor nerve over the clivus.

There is early ipsilateral pupillary dilation with sluggish reactivity to light because of interruption of parasympathetic innervation to the pupil, producing unopposed sympathetic response (dilatation). Further, horizontal displacement of the upper brainstem may cause the contralateral cerebral peduncle to be pressed against the opposite tentorial edge and produce hemiparesis ipsilateral to the lesion (and ipsilateral to the enlarged pupil). False localization may occur if the uncus compresses the ipsilateral cerebral peduncle, producing contralateral hemiparesis, or if the contralateral oculomotor nerve is caught between the mesencephalon and the edge of the tentorium, producing contralateral pupillary dilation and external ophthalmoplegia. Uncal herniation is often associated with the central or transtentorial downward herniation syndrome.

### Central or Transtentorial Downward Herniation

With generalized increases in intracranial pressure, there is gradual downward displacement of the diencephalon (thalamus and hypothalamus) through the tentorium cerebelli, producing progressive compression and ischemia of the brainstem from mesencephalon (rostral brainstem) to medulla (caudal brainstem). In the diencephalic stage, patients do not follow instructions but will localize to noxious stimuli and have small reactive pupils and preserved oculocephalic and oculovestibular reflexes. Respiration may be regular, with yawns or sighs, or Cheyne-Stokes respirations may appear. In the midbrain-upper pons stage, patients have decerebrate rigidity or no movement, midposition pupils that may be irregular in shape and demonstrate no reactivity, and abnormal or absent oculocephalic and oculovestibular reflexes. Patients usually hyperventilate. In the lower pontine-medullary stage, there is no spontaneous motor activity or activity in response to stimuli, midposition fixed pupils, absent oculocephalic and oculovestibular reflexes, and shallow and rapid or slow and irregular (ataxic) respirations. The lower extremities may withdraw to plantar stimulation. Finally, in the medullary stage, there is generalized flaccid tone, absence of pupillary reflexes and ocular movements, further slowing and irregularity of respiration, and ultimately death.

### Infratentorial (Cerebellar) Herniation Syndromes

Space-occupying lesions in the posterior fossa can produce upward herniation of brainstem structures through the tentorial notch and may result in obstructive hydrocephalus,

brainstem ischemia, and death. Progressive alteration of consciousness or coma, associated with miotic pupils, gaze paresis, decerebrate posturing, and asymmetric or absent caloric response with relative preservation of respiration, suggests upward transtentorial herniation.

Downward herniation of the cerebellum and medulla at the foramen magnum may cause apnea and death because of pressure on medullary respiratory centers. The lesions that cause cerebellar herniation in children are often subacute or chronic and are discovered before herniation as a result of widespread use of neuroimaging.

In children with meningitis, the cerebellar pressure cone effect has been implicated as a cause of death after lumbar puncture, even with a normal CT scan of the head. In cases of suspected bacterial meningitis, lumbar puncture should be avoided if there is evidence of increased intracranial pressure or early coning. When lumbar puncture is performed, measurement of opening pressure is essential to allow early treatment if increased intracranial pressure persists.

## DIAGNOSTIC TESTING

All patients with significant impairment of consciousness or coma should have an immediate blood glucose finger stick determination and should have blood drawn for a chemistry profile, complete blood count, and arterial blood gas analysis. The blood chemistry profile should minimally include glucose, sodium, potassium, blood urea nitrogen, calcium, magnesium, and ammonia. When infection is suspected, blood and urine cultures should be obtained.

Lumbar puncture should be performed when there is a suggestion of infection of the CNS, with or without fever. Depending on the clinical findings and evaluation, CT needs to be performed before the lumbar puncture. When medically stable, all patients with impairment of consciousness of undetermined etiology should have a CT performed as rapidly as possible. In children with closed-head injury, CT or preferably MRI may be critical in identifying the specific cause of impaired loss of consciousness.

The EEG is essential to diagnose clinically inapparent status epilepticus. Certain EEG patterns such as periodic lateralized epileptiform discharges may suggest herpes simplex encephalitis. The EEG also is useful in the serial reassessment and evaluation of patients in status epilepticus or persistent coma, as well as in patients requiring pharmacologic paralysis or sedation. See Chapters 102 to 104.

## TREATMENT

Treatment requires scrupulous attention to basic principles while definitive diagnostic tests are obtained and therapy initiated. Specific etiologies of many individual causes of disordered consciousness are listed in [Box 101-3](#) and are reviewed by specific diagnostic category in other sections of this book. The following principles of management are similar in most patients and are described here (see [Box 101-4](#)):

### 1. Maintain Airway, Oxygenation, and Ventilation

Maintenance of an adequate airway remains one of the most important principles in the management of children with altered states of consciousness and coma. It is important to ensure that cervical spine injuries are not worsened in the process of managing a patient's respiratory problems. Monitoring adequacy of oxygenation with pulse oximetry and providing supplemental oxygen as needed are important.

### 2. Maintain Circulation

To maintain cardiovascular function, intravascular access is critical and should be provided. Fluid resuscitation or support with vasoactive drugs may be needed.

### 3. Administer Glucose

Glucose administration is recommended if the glucose levels reveal an abnormally low value. All other therapies are superfluous when oxygen and glucose are not delivered to neurons and toxic metabolites are not removed.

### 4. Correct Acid-Base and Electrolyte Imbalance

Electrolyte imbalance is often mediated by inappropriate antidiuretic hormone secretion. Inappropriate administration of fluids may worsen this situation. More commonly, hyponatremia, hypernatremia, hypocalcemia, or hypomagnesemia occur in conjunction with systemic illness and be the cause of coma.

### 5. Consider Specific Antidotes

Naloxone is available for treatment when an opiate overdose occurs. Physostigmine may reverse CNS and cardiac effects of anticholinergic agents but may cause nonspecific CNS stimulation or seizures. Flumazenil, a benzodiazepine receptor antagonist, may be valuable in such patients.

### 6. Reduce Increased Intracranial Pressure

See Chapter 105.

### 7. Stop Seizures

Treatment of status epilepticus and other seizure emergencies is discussed in Chapter 69. It is always important to consider seizures, even when there are no obvious outward seizure manifestations. Continuous bedside EEG monitoring is now commonly used for this purpose.

### 8. Treat Infection

Underlying infectious processes should be treated if specific treatment is available. When there is concern about focally elevated intracranial pressure, it may be appropriate to start antibiotic therapy for meningitis or antiviral therapy for encephalitis before lumbar puncture.

### 9. Adjust Body Temperature

Usually, normal body temperature is best for recovery and prevention of acidosis. Patients with fever should have appropriate antipyretic agents administered. The use of hypothermia is being reevaluated as a potential treatment for coma. Recent studies have shown that therapeutic hypothermia improves outcomes in neonates with hypoxic ischemic injury (Chapter 19) but not in older children with traumatic (Chapter 102) or hypoxic-ischemic injuries (Chapter 104).

### 10. Manage Agitation

Agitation may increase intracranial pressure and make it difficult to control respiration. The decision to sedate may make serial neurologic examination difficult as a measure of change in a patient's status. In these circumstances, EEG may be valuable.

### 11. Treatment of Chronic Impairments

The previously mentioned management principles relate to the acute care of patients in coma, but many of the principles

also apply to patients who do not fully regain consciousness and have long-term functional disabilities. Other chapters in this book review overall principles of neurorehabilitation (Chapter 162) and more specifically management after accidental (Chapter 102) and nonaccidental (Chapter 103) traumatic brain injury and after global hypoxic-ischemic brain injury (Chapter 104).

There are no pharmacologic agents that have undergone appropriate clinical trials and subsequently been approved for use in children with DOCs. In adults, amantadine and zolpidem have been shown to improve awareness. One small case series involving seven children with DOCs has been reported and demonstrated safety but no efficacy. Neuromodulation is another approach gaining increasing interest.

## MONITORING OF THE COMATOSE PATIENT

After initiation of treatment, it is necessary to reevaluate serially the patient's condition and effectiveness of intervention. The neurologic examination is the gold standard for evaluation and reevaluation, but often is significantly modified by iatrogenic intervention such as mechanical ventilation, sedation, and paralysis. Many clinical neurophysiology monitors are available to improve critical care monitoring; some are in more widespread use than others.

Traditionally, the EEG has been used to identify presence of or risk for seizures and has additive value in that certain patterns may suggest specific pathology such as triphasic waves in metabolic causes of coma and periodic lateralized epileptiform discharges in focal injury and infection. Continuous EEG monitoring may be very helpful in children.

EEG reactivity to sensory stimulation is considered a favorable sign in coma recovery. EEG has the advantage of ready availability in most centers and is usually definitive in the evaluation for ongoing seizures. These and other issues related to the use of EEG for outcome prediction are discussed in other parts of this book and in the online chapter.

Sensory-evoked potentials allow assessment of the integrity of visual, auditory, and somatosensory pathways in the unconscious patient. Somatosensory-evoked potentials are relatively resistant to sedation effect and are useful in predicting outcome in comatose patients. Visual-evoked potentials have not been as valuable. Brainstem auditory-evoked potentials are valuable for monitoring brainstem function but do not predict cortical function. Middle latency auditory-evoked potentials have cortical representation and have been shown to improve coma outcome prediction in adults.

Measurement of cerebral blood flow is a direct way to determine delivery of essential metabolic substrate to the brain but is not useful for continuous monitoring. Brain-tissue PO<sub>2</sub> measurement, however, is suitable for continuous monitoring. Low brain-tissue PO<sub>2</sub>, as a measure of cerebral hypoxia, is predictive of poor neurologic outcome and is an important independent measurement parameter in adults with severe traumatic brain injury. Monitoring of brain tissue PO<sub>2</sub> may also allow early detection of critical and potentially irreversible worsening, and allow measurement of intervention effect on a continuous basis.

Local sampling of energy substrates by microdialysis during ischemia is feasible and allows measurement of glucose, lactate, pyruvate, and glutamate in brain tissue serially over time. Microdialysis measurements have thus far only been applied in children for monitoring of severe traumatic brain injury.

Near-infrared spectroscopy (NIRS) noninvasively monitors brain-tissue oxygenation by measuring the distinct absorption spectra of oxygenated and deoxygenated hemoglobin in the frontal cortex. Cerebral oxygenation measured by NIRS also

has been found to be of some value in pediatric patients being monitored for seizures in the pediatric intensive care unit and in patients being evaluated in the epilepsy monitoring unit, in which it was shown that preictal increases in cerebral oxygenation suggested perfusion-metabolism mismatch during seizure activity. The use of NIRS to monitor brain-tissue oxygenation has not been studied extensively in children, except in surgery for congenital heart defects.

## OUTCOME MEASUREMENT

When consciousness is impaired, outcome is related to the etiology of the insult and rapid identification and treatment of the underlying cause. Outcome studies in childhood coma are available for traumatic and nontraumatic causes, and typically emphasize predictive value of signs and symptoms at the time of initial medical intervention. These studies are described in detail in Chapters 102 to 104.

A commonly used and widely accepted measurement of outcome after severe closed-head injury is the Glasgow Outcome Scale. The Glasgow Outcome Scale has the following five broad outcome categories:

1. Death
2. Persistent vegetative state
3. Severe disability (conscious but disabled)
4. Moderate disability (disabled but independent)
5. Good recovery

The Glasgow Outcome Scale heavily emphasizes functional independence in mobility, transportation, and self-care but is limited in its ability to quantify impairments related to social skills and emotional and cognitive dysfunction.

Early studies using the Glasgow Outcome Scale as an outcome measure after closed-head injury reported that patients advance to the highest functional level by 6 months after injury. Meaningful recovery may occur for months to years after injury.

Another scoring system, the Pediatric Cerebral Performance Category Scale is a modified form of the Glasgow Outcome Scale. This six-point outcome scoring system has been validated in children and also been shown to correlate with neuropsychological test scores. The score has six categories and the numbering system is the reverse of the GOS score—that is, a lower number indicates a better functional outcome:

1. Normal—able to perform all age-appropriate activities
2. Mild disability—conscious, alert, and able to interact at an age-appropriate level, but may have a mild neurologic deficit
3. Moderate disability—conscious, sufficient cerebral function for most age-appropriate independent activities
4. Severe disability—conscious, dependent on others for daily support because of impaired brain function
5. Persistent vegetative state
6. Death

Another scoring system is the King's Outcome Scale for Childhood Head Injury (KOSCHI). The KOSCHI expands the five-category Glasgow Outcome Scale to provide increased sensitivity at the milder end of the disability range (Table 101-6). The scale is easy to use and reliable and is very helpful in differentiating children with milder outcomes into subcategories.

The Disability Rating Scale consists of eight items divided into four categories:

1. Arousability and awareness (best eye-opening, verbal, and motor response)
2. Cognitive ability for self-care activities (feeding, toileting, and grooming)

**TABLE 101-6** King's Outcome Scale for Childhood Head Injury (KOSCHI)

Category	Definition
1	Death
2	Vegetative The child is breathing spontaneously and may have sleep-wake cycles. He may have nonpurposeful or reflex movements of limbs or eyes. There is no evidence of ability to communicate verbally or nonverbally, or to respond to commands
3	Severe disability The child is at least intermittently able to move part of the body/eyes to command or make purposeful spontaneous movements; e.g., confused child pulling at nasogastric tube, lashing out at caregivers, rolling over in bed. May be fully conscious and able to communicate but not yet able to carry out any self-care activities, such as feeding Implies a continuing high level of dependency, but the child can assist in daily activities; e.g., can feed self or walk with assistance or help to place items of clothing. Such a child is fully conscious but may still have a degree of posttraumatic amnesia
4	Moderate disability The child is mostly independent but needs a degree of supervision/actual help for physical or behavioral problems. Such a child has overt problems; e.g., a 12-year-old with moderate hemiplegia and dyspraxia, insecure on stairs or needing help with dressing The child is age-appropriately independent but has residual problems with learning/behavior or neurologic sequelae affecting function. He probably should have special needs assistance but his special needs may not have been recognized/met. Children with symptoms of posttraumatic stress are likely to fall into this category
5	Good recovery This should only be assigned if the head injury has resulted in a new condition that does not interfere with the child's well-being and/or functioning; e.g., Minor headaches not interfering with social or school functioning Abnormalities on brain scan without any detectable new problem Prophylactic anticonvulsants in the absence of clinical seizures Unightly scarring of face/head likely to need cosmetic surgery at some stage Mild neurologic asymmetry but no evidence of effect on function of limb. Includes isolated change in hand dominance in young child Implies that the information available is that the child has made a complete recovery with no detectable sequelae from the head injury.

(With permission from Crouchman, M., et al., 2001. A practical outcome scale for pediatric head injury. *Arch Dis Child* 84, 120-124.)

- Physical dependence on others
- Psychosocial adaptability for work or school

The Functional Independence Measure and its pediatric counterpart, the Wee Functional Independence Measure (WeeFIM), further refine outcome assessment using six items and 18 categories. The WeeFIM items and categories are as follows:

- Self-care (eating, grooming, bathing, dressing—upper body, dressing—lower body, toileting)
- Sphincter control (bladder and bowel)
- Mobility/transfer (chair or wheelchair, toilet, tub, shower)
- Locomotion (walking, wheelchair, crawling, stairs)
- Communication (auditory and visual comprehension, verbal and nonverbal expression)
- Social cognition (social interaction, problem solving, memory)

The Pediatric Evaluation of Disabilities Inventory measures both capability and performance of multiple functional activities in three areas:

- Self-care
- Mobility
- Social function

This score is designed for use from 6 months to 7 years of age but is appropriate for older children whose functional level is within the intended age range.

The WeeFIM and the Pediatric Evaluation of Disabilities Inventory are sensitive measures of functional outcome and are suitable for inpatient rehabilitation monitoring and long-term outpatient follow up. They are two of the most commonly used functional outcome measures in children and are superior to the Glasgow Outcome Scale and its pediatric variants.

The School Functional Assessment was developed to measure performance of functional tasks that are important for participation in an elementary school level program. The School Functional Assessment evaluates:

- Ability to participate in major school activity settings
- Support necessary to participate effectively in an education program
- Performance of specific school-related functional activities

The Barthel Index is commonly used as a prognostic indicator in adult clinical stroke trials. It has functional disability categories (Table 101-7) that lend themselves to use in children who are emerging from coma, but it has not been studied in detail.

Neuropsychological assessment in children with acute brain injuries is discussed in more detail in Chapters 10, 162 and 168.

## PROGNOSIS

### Traumatic Injury

Children who survive traumatic injury have a better prognosis than children who suffer a global hypoxic-ischemic injury. In a study of 127 children said to be in the persistent vegetative state for at least 30 days, 84% of the traumatic brain injury group, but only 55% of the hypoxic-ischemic injury group, improved beyond the vegetative state. Up to 80% to 90% of children with severe traumatic brain injury have good outcomes or recover to a moderate disability, based on studies using the Glasgow Outcome Scale score. See previously mentioned information, the online chapter, and Chapters 102  and 103.

**TABLE 101-7** Barthel Score

Activity	Score
Feeding	
0 = unable; 5 = needs help cutting, spreading butter, etc., or requires modified diet; 10 = independent	0, 5, 10
Bathing	
0 = dependent; 5 = independent (or in shower)	0, 5
Grooming	
0 = needs to help with personal care; 5 = independent face/hair/teeth/shaving (implements provided)	0, 5
Dressing	
0 = dependent; 5 = needs help but can do about half unaided; 10 = independent (including buttons, zippers, laces, etc.)	0, 5, 10
Bowels	
0 = incontinent (or needs to be given enemas); 5 = occasional accident; 10 = continent	0, 5, 10
Bladder	
0 = incontinent, or catheterized and unable to manage alone; 5 = occasional accident; 10 = continent	0, 5, 10
Toilet use	
0 = dependent; 5 = needs some help, but can do something alone; 10 = independent (on and off, dressing, wiping)	0, 5, 10
Transfers (bed to chair and back)	
0 = unable, no sitting balance; 5 = major help (one or two people, physical), can sit; 10 = minor help (verbal or physical); 15 = independent	0, 5, 10, 15
Mobility (on level surfaces)	
0 = immobile or <50 yards; 5 = wheelchair-independent, including corners, >50 yards; 10 = walks with help of one person (verbal or physical) >50 yards; 15 = independent (but may use any aid; e.g., stick) >50 yards	0, 5, 10, 15
Stairs	
0 = unable; 5 = needs help (verbal, physical, carrying aid); 10 = independent	0, 5
Total (0–100)	

(With permission from Jöhnk, K., et al., 1999. *Assessment of sensorimotor functions after traumatic brain injury (TBI) in childhood—methodological aspects. Restor Neurol Neurosci* 14(2–3), 143.)

## Nontraumatic Injury

Outcome after coma resulting from nontraumatic causes is poor but better than that seen in adults. In a cohort of 104 children ranging in age from 1 month to 17 years with nontraumatic coma, 32% died, 50% were normal, and the remaining 18% had mild to severe handicaps. In another retrospective study of nontraumatic coma (278 children aged 1 month to 16 years), 12-month follow up found that the overall mortality rate was 46%, and the etiology-specific mortality rate varied from 3% (intoxication) to 84% (accident). The overall incidence of moderate to severe disability was 70%. See online chapter and Chapter 104.

## Clinical Neurophysiology

In the comatose patient, clinical neurophysiology evaluation (EEG, somatosensory-evoked potential) is the most valuable method for prediction of survival, brain death, and functional recovery. There are, however, a few reports of contrary findings such as normal somatosensory-evoked potentials in a child in a vegetative state after near-drowning. Therefore the neurophysiology assessment is used as an adjunct to the clinical examination and other outcome predictors. Also see Chapters 13 and 102 to 104.

## Neuroimaging

MRI has been explored to help evaluate patients with disorders of consciousness and is reviewed in depth in Chapters 12 and 102 to 104. Several studies also have indicated the prognostic value of proton MR spectroscopy, susceptibility-weighted imaging, and diffusion tensor imaging in children with CNS insult or injury.

## CONCLUSIONS

Altered states of consciousness in pediatric patients are urgent situations, and coma is a medical emergency requiring rapid and organized intervention. Specific diagnoses must be treated appropriately, but there are key general principles to management of impaired consciousness and coma that apply in all situations.

The outcome for children with coma is better than for adults. Even with the best and most appropriate care, some children die, some survive on mechanical ventilation and become brain-dead, and some survive beyond mechanical ventilation and have minimal consciousness, severe disability, or remain in a vegetative state. Decisions concerning basic life sustenance, type and location of care, and need for rehabilitation should take into consideration the type of injury, time from injury, recovery potential, family wishes, and appropriate ethical guidelines and standards. Application of fMRI and neurophysiological testing will help provide a better understanding of the neural correlates of consciousness and hopefully lead to development of novel strategies to improve outcomes in these severely injured children.

## INTRODUCTION AND BACKGROUND

### Epidemiology of Pediatric Traumatic Brain Injury

Traumatic brain injury (TBI) is a major cause of death and disability in the pediatric population and has been identified as a significant public health problem in the United States and worldwide. Age-related incidence rates for TBI in children have been estimated to be as high as 670 per 100,000 when head injuries of all severities are included. In the developing world, TBI as a result of traffic accidents and other causes is predicted to surpass many diseases as a cause of mortality. Overall, TBI is responsible for the majority of trauma-related death and hospitalization. Moderate and severe pediatric TBI has been associated with long-standing impairments, often borne throughout the person's lifetime. Fortunately, the majority of all TBI is considered mild; however, recent studies suggest that even mild pediatric TBI, particularly if repetitive, may have adverse long-term functional consequences. Despite these facts, no specific treatment standards exist for pediatric TBI, either acutely or during recovery. A recent review of guidelines for pediatric TBI management concluded that acute supportive therapies are often administered inconsistently or simply extrapolated from adult TBI protocols, not taking into account the unique physiology of the immature brain (Kochanek et al., 2012).

The peak incidence of pediatric TBI occurs in the adolescent and young adult, with a secondary peak in infancy. The etiology of TBI varies with age (Fig. 102-1). Adolescents sustain most head injuries in motor vehicle accidents, along with sports-related concussions and assaults. Preadolescent children are also frequent victims of motor vehicle accidents, but more often as a pedestrian or while riding a bicycle. Those under the age of 5 years are more prone to falls, whereas infants are particularly vulnerable to repeated severe TBI in the form of abusive head trauma (AHT). TBI is roughly twice as common in boys as in girls, with this gender distinction becoming increasingly evident in the childhood and adolescent years.

Sequelae of TBI include headaches, posttraumatic epilepsy, motor disturbances, learning disabilities, cognitive impairments, and behavioral problems. The vast majority of children suffering TBI, even those surviving moderate or severe injury, fail to receive adequate follow up upon hospital discharge. Given the magnitude of recurrent head trauma as a problem of youth, it is increasingly noted that healthcare providers should take every opportunity to disseminate education to patients and their families, particularly with regard to potential sequelae of repeated injuries and the importance of injury prevention.

### Anatomy

To understand the mechanisms and types of TBI, knowledge of the basic anatomy of the brain and its coverings is essential. From outside in, these layers are the scalp, galea, subgaleal

space (potential), periosteum, skull, epidural space (potential), dura mater, subdural space, arachnoid, subarachnoid space, and pia mater. The different "spaces" (actual and potential) are areas for traumatic hemorrhage to occur, with different characteristics in each location.

### Biomechanics

Trauma is a unique form of brain injury, whereby a biomechanical force (linear or rotational) is imparted to the brain. Because the brain "floats" in the CSF, these forces often result in compression of the brain at the site of contact (termed the "coup" injury). This injury can take the form of local hemorrhage or contusion, accompanied by overlying soft tissue swelling and occasionally skull fracture. As the intracranial contents are shifted toward the point of contact, however, a relatively low-pressure area evolves in a location opposite to the coup injury. Injury in this area is termed "contre-coup," and it can often be larger and more serious than the coup injury.

Because the brain parenchyma is itself soft and deformable, the brain is also prone to injury from rotational forces. The underlying white-matter tracts are subjected to significant shearing forces that can result in stretch injury and microhemorrhages seen clinically and in experimental models, referred to as diffuse axonal injury (DAI). More details about biomechanics are included in the online version of the chapter.

## PATHOPHYSIOLOGY OF TRAUMATIC BRAIN INJURY

Multiple factors affecting TBI are distinct in the developing brain. Some of these include biomechanical factors, cerebral metabolism, neurovascular regulation, neurotransmission, and ongoing cerebral maturation. These are covered in greater detail in the online version of the chapter.

### The Posttraumatic Neurometabolic Cascade

TBI results in an immediate release of glutamate, widespread ionic changes, fluctuating cerebral glucose metabolism (initially elevated, then reduced), and dynamic changes in blood flow. Later, axonal damage and disconnection, reduced responsiveness to physiologic stimuli, impaired neurotransmission, and apoptosis occur. For an overview of posttraumatic pathophysiology at the cellular level, see Figure 102-4. Specific components of the brain's response to traumatic injury are summarized in the online version of the chapter; these include ionic flux, energy crisis, axonal disconnection, cell death, and impaired plasticity.

### PATIENT HISTORY

The clinical approach to pediatric TBI differs based on whether the presentation is acute (emergency) or delayed (clinic). Essential information includes mechanism of injury, protective factors, loss of consciousness, posttraumatic amnesia,

**Figure 102-1.** Etiology of pediatric traumatic brain injury by age group. (With permission from Thurman D, for the Centers for Disease Control and Prevention. *Traumatic brain injury in the U.S.: Assessing outcomes in children*, Appendix B. Available at: <http://www.cdc.gov>.)

seizure activity, current medications, and any persistent neurologic signs. Examination, monitoring for ABCs (airway, breathing, circulation, spine), and initial management are begun simultaneously. Additional relevant history includes premorbid development, prior head injuries, prior neurosurgical procedures, history of epilepsy or other neurologic disorder, and other pertinent medical conditions. In older children or teens, the possibility of drug or alcohol use should be considered. In infants and toddlers, inconsistencies in the history and presence of associated injuries should raise suspicion of child abuse.

For patients presenting in the clinic with persistent neurologic problems after head injury, the same historical information is sought. In addition, the child and parent should be asked about posttraumatic symptoms. The presence of constant symptoms should be ascertained, along with alleviating or exacerbating factors and premorbid conditions such as attention deficit hyperactivity disorder (ADHD), anxiety, and headache. Episodic symptoms should be characterized, including triggers, duration, pattern, and resolution.

## EXAMINATION

For the acutely and severely brain-injured child, the physical and neurologic examination must be done expeditiously, with the aim of identifying immediately life-threatening signs that would direct initial management. Airway and breathing are of paramount importance. Examination of skin color, pulses, blood pressure, capillary refill, and excessive bleeding is essential. In a hypotensive patient, bodily injuries that result in internal bleeding should be identified as soon as possible. In infants, massive scalp hematomas may result in hypotension and shock. Spinal cord or cardiac injury can also result in hypotension.

The Glasgow Coma Scale (GCS) is a quick rating of the severity of the patient's neurologic injury (Table 102-1). There are three components to this score:

1. Eye opening (ranging from 1 to 4)
2. Best verbal response (1 to 5)
3. Best motor response (1 to 6)

Some obvious pediatric limitations to this scale include how to determine verbal score in preverbal children. Several GCS modifications have been proposed for this age group,

**TABLE 102-1** Glasgow Coma Scale and Modification for Children

Glasgow Coma Scale	Score	Glasgow Coma Scale (Infant Modification)	Score
<b>EYE OPENING (E)</b>		<b>EYE OPENING (E)</b>	
Spontaneous	4	Spontaneous	4
To speech (to shout)	3	To speech (to shout)	3
To pain	2	To pain	2
None	1	None	1
<b>VERBAL RESPONSE (V)</b>		<b>VERBAL RESPONSE, MODIFIED FOR INFANTS (V)</b>	
Oriented	5	Babbles, coos appropriately	5
Confused conversation	4	Cries, but consolable	4
Inappropriate words	3	Cries inconsolably	3
Incomprehensible sounds	2	Grunts or moans to pain	2
None	1	None	1
<b>MOTOR RESPONSE (M)</b>		<b>MOTOR RESPONSE (M)</b>	
Obeys commands	6	Purposeful movements	6
Localizes pain	5	Localizes pain	5
Withdraws	4	Withdraws	4
Abnormal flexion	3	Abnormal flexion	3
Extensor response	2	Extensor response	2
None	1	None	1

and one modified scale is shown in Table 102-1. By convention, mild TBI is defined by a GCS score of 13 to 15, moderate by 9 to 12, and severe by 8 or less. A patient with a GCS score of 13 to 15 but having an intracranial lesion may be classified as having a complicated mild TBI or even a moderate TBI.

Assessment of the patient's mental state should be made, including alertness, orientation, confusion, combativeness, or unresponsiveness. Inspection of the head can reveal lacerations, contusions, and hematomas. Careful examination is warranted to identify foreign bodies, fractures, or penetrating injuries that may underlie more superficial damage. In infants, the open fontanel can be assessed quickly. Periorbital ecchymosis ("raccoon eyes") and/or rhinorrhea raise concern for a fracture of the anterior skull base. Retroauricular ecchymosis ("Battle sign"), hemotympanum, and/or otorrhea are signs indicative of a temporal basilar skull fracture. Ophthalmoscopic examination to detect retinal hemorrhage is very important, particularly in cases of suspected nonaccidental trauma.

Patients rendered unconscious, or those who retained consciousness but report posttraumatic neck pain, should have the cervical spine immobilized until cleared of any significant fracture or dislocation.

The posttrauma neurologic examination is, by necessity, short and directed; it should be performed in just a few minutes. Cranial nerve (CN) testing offers rapid, objective evaluation of brainstem functions. The pupillary response tests integrity of CN II and CN III. Fixed midposition pupils suggest symmetric midbrain dysfunction. A unilateral fixed dilated pupil in conjunction with declining mental status is a sign of impending transtentorial herniation and warrants immediate intervention. Bilateral pinpoint pupils raise the possibility of opiate ingestion or severe pontine injury. Bilateral fixed dilated pupils are evidence of widespread injury, but can also result from the systemic effects of resuscitation drugs. A pupil that fails to constrict under direct light (but does so when light is presented to the opposite eye) is indicative of an afferent pupillary defect (APD), a sign of ipsilateral optic nerve injury resulting from fracture of the orbit.

**Figure 102-4. Neurometabolic cascade after traumatic injury.** Cellular events: **1**, Nonspecific depolarization and initiation of action potentials. **2**, Release of excitatory neurotransmitters. **3**, Massive efflux of potassium. **4**, Increased activity of membrane ionic pumps to restore homeostasis. **5**, Hyperglycolysis to generate more adenosine triphosphate (ATP). **6**, Lactate accumulation. **7**, Calcium influx and sequestration in mitochondria, leading to impaired oxidative metabolism. **8**, Decreased energy (ATP) production. **9**, Calpain activation and initiation of apoptosis. Axonal events: **A**, Axolemmal disruption and calcium influx. **B**, Neurofilament compaction via phosphorylation or sidearm cleavage. **C**, Microtubule disassembly and accumulation of axonally transported organelles. **D**, Axonal swelling and eventual axotomy. ADP, adenosine diphosphate; AMPA, alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid; Glut, glutamate; NMDA, *N*-methyl-d-aspartate. (With permission from Giza CC, Hovda DA. *J Athl Train* 2001;36:230.)

Integrity of nerves innervating the extraocular muscles (CN III, CN IV, CN VI) and their brainstem connections can be tested by observation of the eyes for spontaneous conjugate movements, the oculocephalic response (doll's-eye maneuver), or the oculovestibular reflex (caloric reflex test).

An intact corneal response demonstrates function of CN V and CN VII. If, upon corneal stimulation, the globe rotates upward but the eye does not close, this suggests an intact afferent limb but impaired motor output. Other evidence of CN VII palsy involves tickling the inside of the nose with a wisp of cotton or administering a noxious stimulus and observing the facial grimace for symmetry.

Sensorimotor examination starts with the best motor response elicited on GCS testing. Limb posture and muscle tone should be examined, and particular note should be made of any asymmetry. If the patient is unable to follow commands, sensorimotor responses may be assessed by a peripheral noxious stimulus (e.g., nail bed pressure). If no response

occurs, the site of noxious stimuli can be moved centrally (e.g., sternal rub, supraorbital pressure) to distinguish between afferent versus efferent impairment. Look for changes in vital signs and whether the child can localize pain. If the child is awake, coordination should be assessed by observation of posture, spontaneous movements, and directed movements. Deep tendon reflexes should be checked for asymmetry, hyperreflexia/clonus or areflexia. Flaccid paresis with no reflexes should immediately raise suspicion of a spinal injury. An outline of the rapid trauma examination is provided in [Box 102-1](#).

In the mildly injured child who is conscious at the time of initial evaluation, the neurologic examination can be conducted less urgently and more completely. Mental status testing can be more extensive, including attention, orientation, language, memory, and behavior. Cranial nerve, motor, coordination, and sensory examinations can include voluntary responses to the examiner's commands and subjective

**BOX 102-1** Rapid Pediatric Trauma Examination

1. ABCs, brief history—mechanism of injury, loss of consciousness, amnesia, seizure, persistent neurologic symptoms
2. Glasgow Coma Scale score
3. Physical examination, particularly head and neck
  - a. Scalp—depressions, stepoffs, fluid collections, lacerations
  - b. Other signs of skull fracture—otorrhea, hemotympanum, rhinorrhea, raccoon eyes, Battle sign
  - c. Cervical spine—deformity, point tenderness
  - d. Associated severe bodily injuries—thoracic, abdominal, long bone
4. Mental status—describe succinctly, avoid ambiguous terms
5. Cranial nerves
  - a. Pupillary response (cranial nerve II, III)
  - b. Oculocephalic “doll’s-eye” response (cranial nerve III, IV, VI)
  - c. Oculovestibular “caloric” response (cranial nerve III, IV, VI, VIII)
  - d. Corneal response, facial grimacing (cranial nerve V, VII)
  - e. Gag response (cranial nerve IX, X)
6. Sensorimotor—asymmetry, abnormal muscle tone, coordination (if possible), movement (spontaneous, to command), movement to pain (withdrawal, decorticate, decerebrate, no movement)
7. Reflexes—asymmetry, areflexia, hyperreflexia/clonus, upgoing toes

reports of sensory input. Gait should be observed for signs of unsteadiness or ataxia. Deep tendon reflexes and plantar responses should be normal and symmetric.

In either setting, neurologic reassessment is mandated based on the severity of the injury. Deterioration of the neurologic examination may be a sign of progression of the underlying injury or may represent a new complication and should be evaluated immediately so that appropriate treatment may be instituted.

## IMMEDIATE MANAGEMENT

Initial management of the child suffering from moderate or severe TBI centers on implementation of the ABCs and avoidance of secondary insults. Early management will occur concomitantly with initial evaluation and examination. Appropriate noninvasive monitors should be placed. Intubated patients should also have an end tidal CO<sub>2</sub> monitor. Intravenous access must be established immediately and fluid resuscitation begun. Blood should be drawn for serum electrolytes, glucose, renal and hepatic function, complete blood count, prothrombin time (PT)/partial thromboplastin time (PTT), type and cross for blood transfusion, and, if appropriate, alcohol or drug screens.

## ACUTE CLINICAL SYNDROMES

Because TBI is a heterogenous disorder with multiple manifestations, acute syndromes may occur in isolation but are often overlapping. Concussion can occur alone or as a repeated injury and is rarely associated with more significant complications.

## Herniation Syndromes

Herniation is the displacement of brain tissue from one intracranial compartment to another. The Cushing response is a

paradoxical bradycardia with hypertension and slow irregular respiration that can be seen in the setting of elevated intracranial pressure (ICP) and impending herniation. Definitive treatment for herniation requires surgical removal of the offending mass. Nonsurgical measures to control elevated ICP include proper head positioning, sedation, hyperventilation, and hyperosmolar therapy. Ventriculostomy with cerebrospinal fluid (CSF) drainage should be instituted when possible.

In lateral transtentorial (uncal) herniation, a hematoma can displace the medial temporal lobe structures across the tentorial notch and compress the midbrain, resulting in impaired consciousness, ipsilateral pupillary dilation, and contralateral hemiparesis. Occasionally, this type of herniation compresses the posterior cerebral artery, resulting in an ipsilateral occipital lobe cerebral infarction and contralateral homonymous hemianopia.

A unilateral mass can also result in “midline shift,” which can be readily seen on an acute computed tomography (CT) scan. When most severe, the cingulate gyrus will herniate under the falx, compress the anterior cerebral artery (or arteries), and infarct the medial frontal lobe(s).

Diffuse bilateral edema or lesions can cause central transtentorial herniation. Examination findings consistent with this syndrome include impaired mental status, fixed midposition pupils, impaired upward gaze, hyperventilation (central neurogenic hyperventilation), and posturing (decorticate followed by decerebrate). In the later stages of central herniation, pupils may become symmetrically constricted and respirations may become irregular.

Cerebellar tonsillar herniation occurs when the posterior fossa contents are pushed down through the foramen magnum. Because the infratentorial compartment is smaller than the supratentorial compartment, critical pressure effects can occur rapidly and with much smaller lesions. Tonsillar herniation can cause head tilt, neck stiffness, and lower cranial neuropathies, or can present relatively abruptly with cardiorespiratory compromise.

All of these herniation syndromes can lead to ischemic and hemorrhagic complications. The final stages of herniation occur as medullary centers are compressed, resulting in apnea, cardiac collapse, and death.

## Diffuse Cerebral Swelling

Diffuse cerebral swelling is more common in children, whereas focal cerebral damage, such as contusion, is more common in older adolescents and adults. Diffuse edema can occur as a direct response to trauma, but can also be the result of a post-traumatic secondary insult, such as hypotension or hypoxia. At its extreme, diffuse edema can result in central transtentorial herniation and death.

## Diffuse Axonal Injury

Diffuse axonal injury (DAI) is thought to result from shearing and rotational forces on white-matter fiber tracts and is most commonly seen after a high-impact injury.

Clinically, the patient with DAI has a prolonged period of unresponsiveness or coma that is not explained by a mass lesion or diffuse hypoxia. Gradually, the patient recovers some movement and can initially appear to be posturing or restless. Because of brainstem involvement, autonomic symptoms may be prominent.

DAI is rarely seen on CT, and then only if hemorrhage is present. Magnetic resonance imaging (MRI) is much more sensitive in detecting DAI, which can be seen as hypointensity

on T2\*-weighted gradient recall echo (GRE) imaging. MRI using susceptibility-weighted imaging (SWI) has more clearly demonstrated and allowed quantification of hemorrhagic DAI lesions. In general, patients with DAI will have lasting neurologic impairments, with good outcome at 3 months ranging from 65% of mild DAI patients to only 15% of severely injured.

### Paroxysmal Sympathetic Hyperactivity

Autonomic disturbances are well known to accompany CNS injuries, and the term *paroxysmal sympathetic hyperactivity* has been defined as a syndrome after TBI “of simultaneous paroxysmal transient increase in sympathetic and motor activity” (Baguley et al., 2014). Patients with dysautonomia had worse functional outcomes than those without such symptoms, both groups having had comparable injury severities. Interestingly, the average age of patients with dysautonomia tends to be lower in descriptive studies. Treatment to mitigate autonomic disturbances is directed toward minimizing external triggers and pharmacologically reducing hyperactive autonomic neurotransmission.

### Abusive Head Trauma

Many different terms, including *nonaccidental trauma*, *inflicted TBI*, and *shaking impact syndrome*, have been used to describe this clinical entity; however, in 2009 the American Academy of Pediatrics officially adopted the term *abusive head trauma* (AHT).

The clinical presentation is rarely straightforward, and history may be unclear. These infants can present with lethargy, irritability, seizures, or vomiting. Physical signs include a tense or bulging fontanel, split sutures, enlarged head circumference, retinal hemorrhages, and often evidence of other inflicted bodily injuries. CT scanning typically reveals subdural hematomas, contusions, or intracranial hemorrhage. Subdural hematomas of differing ages are particularly suspicious for AHT and are frequently seen over the cerebral convexities or along the falx (Fig. 102-6B). Inconsistencies in the history should lead the physician to suspect child abuse.

Infants with AHT may need vigorous resuscitation, controlled ventilation, anticonvulsant treatment, and intensive care unit (ICU) management. Beyond CT neuroimaging, diagnostic workup may include whole-body x-rays to look for fractures of varying ages, ophthalmoscopic examination to identify retinal hemorrhages, and a careful inspection of the skin for burns or excessive bruising. Laboratory tests should be sent to evaluate for a coagulopathy.

The outcome of infants suffering AHT is exceedingly poor. Mortality rates range from 7% to 30%, and severe neurocognitive sequelae are reported in one-third to one-half. Up to 80% of deaths resulting from trauma in children under the age of 2 years are attributed to nonaccidental injury. Medical care for these children is often delayed, perhaps setting the stage for secondary injuries as a result of hypoperfusion, hypoxia-ischemia, and recurrent seizures.

### Subarachnoid Hemorrhage

Subarachnoid hemorrhage (SAH) occurs commonly after TBI. Blood products are irritating to the brain itself and to the cerebral vasculature, which can result in seizures or vasospasm, usually after several days. Vasospasm can be severe enough to cause cerebral ischemia or infarction. SAH is easily seen on CT. Subarachnoid blood in the ventricular system is associated with an increased risk of posttraumatic hydrocephalus.

### Subdural Hematoma

Subdural hematomas (SDHs) can be seen after significant head trauma. These hemorrhages can present with a sudden or, more often, gradually progressive focal deficit. Mass effect can lead to neurologic symptoms of depressed mental status and, in severe cases, signs of impending herniation.

The appearance of SDH on CT scan is a crescent-shaped hyperdensity along the inner surface of the skull. Large lesions may track across suture lines (Fig. 102-8). SDHs can also occur over the cerebral convexities, along the falx or tentorium, or, more rarely, in the posterior fossa.

Definitive treatment of an acute symptomatic SDH involves neurosurgical consultation and probable surgical evacuation. If edema is extensive, placement of a ventriculostomy is helpful to monitor ICP and for CSF drainage. Other interventions to control elevated ICP should be instituted if needed. Outcome after SDH is good, with up to 75% of infants developing normally.

Subacute and chronic subdurals will appear as crescent-shaped subdural fluid collections that can be isodense and hypodense, respectively. In infants, a bulging fontanel and an enlarging head size may suggest AHT in an otherwise nonspecific clinical picture of irritability, poor feeding, lethargy, and vomiting. Seizures are frequently seen.

Chronic SDH needs to be distinguished from benign extracerebral collections of childhood (BECCs), which appear hypodense on CT and occur without a history of head trauma. These collections are associated with normal development and spontaneously resolve.

### Epidural Hematoma

Epidural hematomas (EDHs) are often the result of temporal skull fracture with tearing of the middle meningeal artery. On CT, an EDH classically appears as a convex lens-shaped hyperdensity adjacent to the skull (Fig. 102-9). EDHs generally are constrained by dural attachment to the skull and do not cross suture lines.

EDHs occur less frequently in children than in adults. In children, EDH from bridging veins or dural sinuses is more likely, and EDHs are thus less commonly associated with skull fracture. Although the majority of EDHs in adults or children are supratentorial, the percentage of posterior fossa EDHs is higher in the pediatric population. Because of the risk of compression of critical brainstem structures and potential cardiorespiratory collapse, surgical removal is preferred.

Mortality as a result of EDHs ranges from 7% to 15%. Prognosis is less certain with infants, whose nonspecific presenting symptoms increase the likelihood of diagnostic delays. If EDHs are recognized and evacuated promptly, recovery is generally good in up to 90% of children.

### Cerebral Contusion and Laceration

Cerebral contusion and laceration represent types of direct, focal damage to the brain. These injuries are less common in children than in adults. Contusions tend to be frontal or temporal and appear as a subtle hypodensity on CT. Some contusions evolve into hemorrhagic lesions.

Lacerations are also fairly rare and can be associated with a depressed fracture or penetrating injury. Dura and vascular structures can be similarly torn.

### Traumatic Arterial Dissection and Traumatic Aneurysms

There is increasing awareness that traumatic arterial dissection may be a more common cause of acute ischemic stroke in

children than previously thought, occurring in approximately 5% of cases, more frequently in boys. There are no evidence-based guidelines for treatment of pediatric craniocerebral dissections. Onset of focal symptoms in the first week after TBI or unexplained subarachnoid hemorrhage later after TBI should prompt additional diagnostic testing. Magnetic resonance (MR) angiography may be the preferred initial diagnostic modality because of its noninvasive nature.

## Concussion

Concussion has been defined as any traumatically induced disturbance of neurologic function and mental state, occurring with or without actual loss of consciousness. Concussion is often referred to as mild TBI, and is the most common form of TBI in all age groups, accounting for over 75% to 85% of all head injuries.

Acute symptoms include headache, transient confusion or amnesia, dizziness, unsteadiness, nausea, or vomiting. Signs of concussion include vacant staring, observable confusion, disorientation, memory disturbance, ataxia, incoordination, slurred speech, behavioral disturbances, and any witnessed unconsciousness (less than 10%). The hallmark of concussion is that the acute symptoms are self-limited and occur in the absence of demonstrable structural brain injury (with conventional CT imaging). Because of this, concussive symptoms are often ascribed to neural dysfunction that recovers over time.

Several points regarding concussion are particularly relevant in children. First, there is much concern about the proper evaluation of concussion/mild TBI so as not to miss any associated intracranial injury. Second, a child returning to normal activity before complete physiologic recovery may have subtle deficits that need to be considered to integrate the child into his or her preinjury educational settings. Premature return to physical activity, such as contact sports, may place the individual at greater risk for a second injury. Third, studies of a single mild TBI in children showed results different from those of adults with regard to the significance of long-term sequelae. Finally, there is increasing evidence that repeated mild TBI may result in a chronic accumulation of subtle deficits or even an early onset of memory disturbances later in life.

## Sports Concussion/Repeated Concussion

Sports concussion is an increasingly common problem in childhood, occurring during team play in contact sports and accidents involving bicycles, rollerblades, skateboards, and scooters. An important opportunity is the possibility of more effective prevention strategies, by using approved protective gear when engaging in these activities, modifying rules to improve safety, and avoiding return to at-risk sports activity until recovery from injury is complete. There are increasing laws and policies that govern sports concussions in youth athletes, and practitioners are advised to be aware of their local regulations.

## Epidemiology

It is estimated that over 1.6 to 3.8 million sports-related traumatic brain injuries occur annually in the United States, the majority of them mild. For those who have sustained a concussion, there is a three-fold risk of a subsequent concussion during the same sports season. There is a common mentality among players and coaches that one can “shake it off,” which sets the stage for recurrent injuries.

## Symptomatology

One consideration with subjective reporting of symptoms in a sports setting is that the player, being motivated to return to play, may attempt to minimize symptoms. Many athletic teams and physicians are utilizing a concussion checklist or computerized neuropsychological test that can be administered by a certified athletic trainer shortly after injury and again during recovery. Interestingly, there is some evidence that recovery from sports concussion is prolonged in high school students compared with college athletes (Williams, Puetz, Giza, and Broglio, 2015). Other studies of pediatric mild TBI showed lower rates of subacute postconcussive headaches or symptoms in younger ages compared with teens (McCroly et al., 2013).

## Sequelae

Although the long-term significance of a single mild TBI is uncertain, individuals with multiple previous concussions have shown a significantly longer duration of symptoms and length of recovery.

There are no studies that specifically address long-term cognitive consequences of repeat pediatric concussions; however, evidence-based reviews have demonstrated multiple neurocognitive deficits in professional contact athletes. In amateur athletes, some studies have found impairments and others not, although studies below the high school level are few. A recent study of retired NFL players reported an association between an age at first exposure to tackle football of younger than 12 years and late-life cognitive impairment, but group size was small ( $n = 21$ ), the cutoff age (12 years) was arbitrary, and the age at first exposure could not be separated from a longer duration of exposure. There also are case series of postmortem tau protein deposition in the brains of ex-athletes who had neurobehavioral problems preceding death. This condition has been termed chronic traumatic encephalopathy (CTE), but risk or incidence cannot be calculated from these types of studies. Clearly, further work is needed to delineate the risk of chronic cognitive impairment and its relation to timing, number, and age at injury.

## Second-Impact Syndrome

Some controversy surrounds the existence of the so-called “second-impact syndrome” described in circumstances where a mild TBI, usually in a child or adolescent, resulted in catastrophic brain swelling and often death. On some occasions, an earlier head injury was reported, but a careful review of the literature raised concerns regarding poor documentation of a “first impact” in many cases, and the terminology *malignant brain swelling* was proposed.

## Skull Fractures

Skull fractures are relatively common in the pediatric TBI population, particularly in the youngest age groups. The main concern about skull fractures is their association with underlying intracranial injury, such as hematomas.

Linear fractures account for 66% to 75% of all pediatric skull fractures. These are most commonly temporoparietal in location, and can be associated with an overlying scalp injury. Although the fractures themselves rarely require intervention, CT scanning should always be performed to determine whether there is underlying pathology.

Depressed skull fractures involve displacement of the bony skull and increase the risk of underlying cerebral contusion or laceration. Indications for surgical repair of depressed

### **BOX 102-2** Pediatric Traumatic Brain Injury in a Child Greater Than 2 Years Old: Indications for CT Scanning

#### **DEFINITE INDICATIONS**

- Glasgow Coma Scale score less than 15 in emergency department
- Altered mental status
- Skull fracture (on x-ray or clinically)
- Focal neurologic signs
- Deteriorating neurologic condition
- Suspected nonaccidental trauma

#### **RELATIVE INDICATIONS**

- Loss of consciousness or posttraumatic amnesia
- Seizure
- Known coagulopathy
- Need for anesthesia or prolonged sedation
- Persistent or worsening headache, nausea, or vomiting

fractures vary, but treatment is certainly indicated in patients with bony fragments displaced into brain parenchyma, dural tear, an underlying large hematoma, associated focal neurologic deficits or seizures, and overt wound contamination.

Basal skull fractures tend to occur frontally or in the area of the petrous bone. Periorbital or retroauricular ecchymosis (raccoon eyes or Battle sign), rhinorrhea, otorrhea, and hemotympanum all point to a fracture of the skull base. CSF leaks, when present, tend to resolve spontaneously. Persistent leaks may require CSF diversion or surgical repair. Traumatic cranial neuropathies are also associated with these fractures.

Compound or open skull fractures represent a significant risk of infection, and surgical debridement, removal of foreign bodies, repair of any existing dural defects, and prophylactic antibiotics are indicated.

## **Scalp Lacerations and Hematomas**

Scalp injuries are one of the most common types of accidental injury in childhood, and because of their propensity to bleed profusely, they also tend to generate significant parental concern. Most scalp injuries resolve without significant complication.

## **DIAGNOSTIC EVALUATION**

### **Skull X-Rays**

Skull x-rays may be warranted in TBI settings where there is a suspicion of nonaccidental trauma, in infants younger than 1 to 2 years of age with scalp swelling or hematoma, or as a screening tool in older children only if CT scanning is not readily available.

### **Computed Tomography**

Noncontrast CT scanning is the neurodiagnostic test of choice in the evaluation of acute head trauma. Given the high frequency of intracranial lesions in children with moderate or severe TBI, cranial CT is warranted in patients with a GCS score of less than 13. Imaging recommendations are summarized in [Box 102-2](#) and [Box 102-3](#).

The indication for CT is more controversial when only mild-TBI pediatric patients are considered. A recently developed and validated clinical prediction rule is valuable in identifying the subset of children with mild TBI who do not require

### **BOX 102-3** Pediatric Traumatic Brain Injury in a Child Younger Than 2 Years Old: Indications for CT Scanning

#### **DEFINITE INDICATIONS (HIGH-RISK PATIENT)**

- Altered mental status, irritability
- Focal neurologic signs
- Skull fracture (on x-ray or clinically)
- Seizure
- Bulging fontanel
- Vomiting at least 5 times or for more than 6 hours
- Loss of consciousness for at least 1 minute
- Deteriorating neurologic condition
- Suspected nonaccidental trauma

#### **RELATIVE INDICATIONS (INTERMEDIATE-RISK PATIENT)**

- Vomiting 3 to 4 times
- Loss of consciousness for less than 1 minute
- Previous irritability or lethargy, now resolved
- Caregivers concerned about patient's current behavior
- High-energy mechanism of injury
- Scalp hematoma, especially if large or nonfrontal
- Known coagulopathy
- Need for anesthesia or prolonged sedation

CT scanning ([Kuppermann et al., 2009](#)); the specifics of this rule are discussed later in the chapter ([Fig. 102-14](#)).

Recommendations for CT scanning are even broader when children under the age of 2 years are concerned. In this age group, skull fractures are more common, and neurologic examination is more limited. A well-validated CT rule for children younger than 2 years of age shows very good negative predictive value for clinically significant TBI ([Fig. 102-14](#)).

## **Magnetic Resonance Imaging and Angiography**

Although MRI is not currently indicated as the standard of care for evaluation of acute pediatric TBI, it is being used more frequently to identify lesions poorly seen on CT, such as microhemorrhages, isodense hematomas, and posterior fossa lesions. MR spectroscopy performed subacutely (within the first week) in patients with persistent coma has been valuable in predicting outcome and is discussed in the online version of this chapter. 

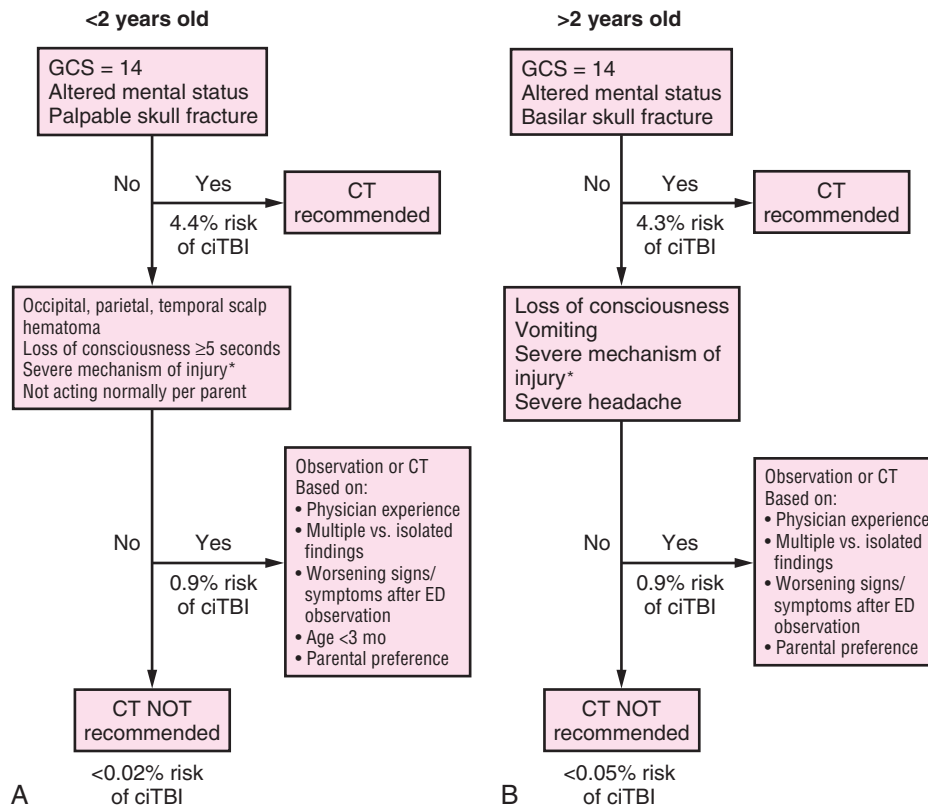

Angiography is useful for diagnosing traumatic vascular lesions, particularly dissections of the great cervical arteries, traumatic intracranial aneurysms, and cavernous carotid fistulas. In some cases, MR angiography is being recommended as a screening test.

## **Neurophysiological Testing**

Electroencephalogram (EEG) is increasingly utilized in the evaluation of patients with TBI. EEG may be very useful in persistently comatose patients whose mental status is altered disproportionately to the documented injury or to monitor patients with more severe injury who are being sedated. In some cases, subclinical seizures may underlie prolonged unresponsiveness after TBI. Continuous EEG (cEEG) monitoring is one method of measuring cerebral function that may play a particularly important role in patients with TBI.

Continuous EEG monitoring may be particularly important in children. It is often quite challenging to assess the mental status in young children, and it is often difficult to determine the cause of paroxysmal events in children. In a recent prospective study of consecutive pediatric admissions

## CLINICAL PREDICTION RULE FOR MINOR PEDIATRIC HEAD INJURY

**Figure 102-14.** Clinical algorithm for CT scanning in children with minor head injury (Glasgow Coma Scale [GCS] score of 14 to 15). **A**, Algorithm for children less than 2 years old. **B**, Algorithm for children over 2 years old. \*Includes motor vehicle crash with ejection, death of another passenger, or rollover; pedestrian or bicyclist without helmet struck by motor vehicle; fall greater than 0.9 m (3 ft) for **A**, greater than 1.5 m (5 ft) for **B**; head struck by high-impact object. A clinically important TBI (ciTBI) is one that results in death, neurosurgery, intubation for more than 24 hours for TBI, hospitalization for more than 48 hours for TBI. ED, emergency department. (With permission from Kuppermann N et al., *Lancet* 2009; 374: 1160–1170.)

for TBI monitored with cEEG, 43% had seizures, 16% had subclinical seizures, 18% had status epilepticus, and 13% had subclinical status epilepticus (Arndt et al., 2013).

## GENERAL MANAGEMENT PRINCIPLES FOR SEVERE PEDIATRIC TBI

An expert review, updated in 2012, summarizes the existing published literature regarding medical management of severe pediatric TBI. The literature did not support any level I recommendations. Four items were listed as level II treatment recommendations:

1. Hypertonic saline should be considered for treatment of intracranial hypertension after severe pediatric TBI.
2. Avoid moderate hypothermia (32 to 33° C) for only 24 hrs duration; consider moderate hypothermia for up to 48 hrs duration. Use slow rewarming (<0.5° C/hr).
3. Use of corticosteroids for severe pediatric TBI is not recommended.
4. The use of an immune-modulating diet to improve outcome is not supported.

Multiple level III treatment options and their rationales were provided, and the following sections summarize these findings and synthesize them with traditional management strategies.

Interestingly, studies have shown that adherence to published guidelines and establishment of neurocritical care

management teams are associated with improved outcomes. One study of five regional pediatric trauma centers demonstrated that guideline adherence was associated with improved survival. The same study found favorable outcomes associated with all operating room and ICU cerebral perfusion pressures greater than 40 mm Hg or no surgery. A retrospective study showed that implementation of a pediatric neurocritical care program (PNCP) improved favorable disposition at hospital discharge (from 48% preprogram to 67% postprogram) (Pineda et al., 2012).

## Stabilization and Prevention of Secondary Injury

After initial assessment and resuscitation, acute management is aimed primarily at avoiding or preventing secondary injuries until more definitive therapy can be instituted. Airway maintenance and supplemental oxygen are crucial, and intubation and ventilation are often necessary for the more severely injured child. Fluid resuscitation to avoid hypotension is also essential.

## Intracranial Pressure Management

The second edition pediatric severe TBI guidelines no longer separate ICP management into “first-tier” and “second-tier” interventions. Previous “first-tier” interventions included

sedation/neuromuscular blockade, controlled hyperventilation, hyperosmolar therapy, ICP monitoring and drainage and cerebral perfusion pressure management. Some of the previous “second-tier” strategies involve methods to reduce brain metabolism and activity (barbiturates, hypothermia) or physical opening of the intracranial space to relieve pressure (craniectomy). Furthermore, corticosteroids are associated with increased mortality and not recommended.

### Sedation and Neuromuscular Blockade

Sedatives and analgesics may be useful to reduce struggling and exacerbation of elevated ICP, promote optimal ventilation, alleviate pain, and allow for adequate nursing care. Sedation may reduce cerebral metabolic activity and prevent seizures. Potential adverse effects of sedation are hypotension, which can exacerbate poor cerebral perfusion, and obscuration of the neurologic examination.

Neuromuscular blockade may aid in the management of TBI patients by promoting ease of ventilation, reducing ICP, and stopping metabolic demands from skeletal muscle. Complications of neuromuscular blockade include an increased risk of pneumonia, cardiovascular depression, immobilization stress (if used with inadequate sedation), unnoticed seizure activity, and prolonged paralysis/myopathy.

### Hyperventilation

Hyperventilation reduces blood and tissue  $PCO_2$  levels, resulting in vasoconstriction, decreased cerebral blood volume, and reduced ICP, often within minutes, making hyperventilation an important tool in managing acute neurologic deterioration. However, the routine use of prophylactic hyperventilation ( $PCO_2 < 35$  mm Hg) in severe pediatric TBI is no longer recommended because of the potential for ischemic complications. Controlled hyperventilation ( $PCO_2$  30 to 35 mm Hg) is sometimes useful to control refractory elevated ICP.

### Hyperosmolar Therapy

Two agents have been recommended for hyperosmolar therapy in pediatric TBI: 3% saline and mannitol; neither has proven superior to the other in a direct comparative study. Mannitol is administered with a bolus infusion, at 0.25 to 1.5 g/kg up to every 4 hours. Overall, mannitol begins to exert its ICP-reducing effects within 10 to 20 minutes, and these may last for several hours. Dosing of hypertonic (3%) saline was on a sliding scale titrated to ICP and serum sodium, but the infusion rates ranged from 0.1 to 1.0 ml/kg/hr. Potential adverse effects include osmotic rebound and, with 3% saline, central pontine myelinolysis.

### Intracranial Pressure Monitoring—Indications and Treatment Threshold

ICP monitoring is recommended in children with a GCS score of 8 or less. In addition, ICP monitoring may be reasonable in selected patients with moderate TBI, particularly those whose clinical examination may be clouded. ICP monitoring may be beneficial in infants, particularly those with severe injuries as a result of abusive head trauma. In general, it is recommended to institute ICP-lowering therapy in pediatric patients whose ICP exceeds 20 mm Hg.

Cerebral perfusion pressure (CPP) is defined as the difference between the mean arterial pressure (MAP) and ICP. Based on the available evidence, maintaining CPP above 40 mm Hg at all times in pediatric TBI patients is recommended, and the range of CPP from 40 to 65 mm Hg most likely represents a spectrum of optimal CPP across the pediatric age range

(Chambers et al., 2006). Use of vasopressor agents may be associated with an increased risk of pulmonary complications.

### Cerebrospinal Fluid Drainage

Physical drainage of CSF is the most direct means of reducing ICP and has been done via intraventricular catheters in patients with severe TBI. CSF drainage can be considered a reasonable treatment option to reduce elevated ICP in children.

### Barbiturates

The use of barbiturates is an option in patients with intractable elevation of ICP. Proper EEG and cardiovascular monitoring should be used at all times. The use of barbiturate coma in traumatically injured neonates and infants should be approached with caution.

### Temperature Control and Hypothermia

Temperature control can be used either to avoid hyperthermia or to institute hypothermia. There is substantial experimental and adult clinical literature suggesting that hyperthermia can exacerbate brain injury. It is recommended that fever/hyperthermia be avoided in brain-injured children. Induced hypothermia for pediatric moderately severe TBI has shown mixed results—for a more thorough discussion, please see the online version of the chapter.

### Surgical Management of ICP

Decompressive craniectomy has been used to alleviate intractable intracranial hypertension and malignant cerebral edema. Expert review of the literature suggested that severely injured children with intractably elevated ICP who are more likely to benefit from decompressive craniectomy could be selected on the basis of meeting at least some of the following criteria: (1) diffuse cerebral swelling on CT, (2) less than 48 hours postinjury, (3) no episodes of sustained ICP greater than 40mm Hg, (4) GCS greater than 3 at some point postinjury, (5) secondary clinical deterioration, or (6) evolving herniation syndrome.

### Early Posttraumatic Seizures and Seizure Prophylaxis

Posttraumatic seizures are divided into early and late. Early posttraumatic seizures (EPTS) occur within the first week after injury. EPTS are generally reactive seizures in response to an acute or subacute insult but may also act as a secondary injury. The incidence of EPTS is higher in children than in adults, and, following severe pediatric TBI, early seizure rates of 20% to 39% have been reported. This risk is increased with lower GCS and younger age. Most EPTS in children occur within the first 24 hours. Prophylaxis for posttraumatic seizure activity in children should be considered for use in the first week after injury. Fosphenytoin can be administered intravenously more rapidly and has fewer infusion-related side effects than phenytoin. Loading doses of either drug range from 10 to 20 mg/kg, and maintenance doses are typically 5 to 7 mg/kg/day, divided at least into two doses per day. Intravenous lorazepam (0.05 to 1.0 mg/kg/dose) may be administered until fosphenytoin levels become therapeutic. Levetiracetam may also be considered, although a pediatric-specific trial remains to be carried out. An alternative strategy is to monitor for seizures with EEG and only treat when needed.

Despite the effectiveness of early prevention, prospective adult studies have revealed the inability of anticonvulsant prophylaxis to prevent subsequent development of late posttraumatic epilepsy. In addition, there are also substantial animal data demonstrating that the immature brain is

particularly vulnerable to apoptosis induced by anticonvulsants and anesthetics. Thus anticonvulsants cannot be recommended routinely for long-term prophylaxis after pediatric TBI. After the acute period, anticonvulsants can be gradually weaned.

## Supportive Care

Management of severe TBI includes general supportive measures to prevent complications of ICU hospitalization and potentially prolonged immobilization. This includes aspiration precautions, nutritional support, skin care, deep venous thrombosis prophylaxis, autonomic monitoring, sedation and analgesia (with periodic “wake-ups” to assess neurologic status), and psychosocial support.

## GENERAL MANAGEMENT OF MILD TRAUMATIC BRAIN INJURY/CONCUSSION

There are multiple guidelines for management of pediatric mild TBI and concussion; currently the Centers for Disease Control are assembling a formal evidence-based guideline for mild pediatric TBI. There are three major guidelines presented in greater detail in the online chapter and summarized here: (1) American Academy of Pediatrics consensus guidelines for the evaluation and management of the mildly head-injured child, with some added clinical prediction rules for CT scanning; (2) the Concussion in Sport Group guidelines, with ongoing updates; and (3) the American Academy of Neurology strict evidence-based guidelines for sports concussion that incorporate some pediatric/youth recommendations.

Neuroimaging (acute CT) is not generally recommended for concussion, but may be helpful in a setting of persistent alteration of mental status or suspected intracranial hemorrhage or skull fracture. Clinical observation and symptom monitoring may be helpful in most other cases.

When the CT scan and examination are normal, the likelihood of clinically significant late deterioration is very low, so children in this category can be discharged home under parental observation. Preverbal children and infants should be managed more conservatively.

## Guidelines for Return to Play Following Sports Concussion

Current sports concussion guidelines have moved away from grading concussion severity and return to activity based on

early symptoms. All recent guidelines and updates recognize that acute concussion management, return to school activity, and return to play need to be individualized to the particular patient, and usually proceed in a stepwise fashion (Table 102-3). Optimal management, particularly for chronically symptomatic patients, is best handled in a multidisciplinary clinic.

## PROGNOSIS AND OUTCOME

Determining the degree of recovery in children is difficult in the early days following a severe head injury. Despite the overall better prognosis seen in children compared with adults, there are certain characteristics worth considering when discussing outcome with the child’s parents. Younger age, particularly infants, greater severity of acute injury, and occurrence of secondary insults (e.g., hypoxia or ischemia) are risk factors for worse long-term outcomes.

Elevations of ICP greater than 20–30 mm Hg have been associated with worse outcomes in children, as have age-specific reductions in cerebral perfusion pressure. Impaired autoregulation (in addition to significant hypotension) was an independent risk factor for a poor 6-month global outcome. For more in-depth discussion of clinical prognostic factors for pediatric TBI outcome, including imaging and electrophysiological measures as well as prognosis after mild TBI, please refer to the online version of the chapter (Ashwal, Tong, Ghosh, Bartnik-Olson, Holshouser, 2014).

## LATE CLINICAL SYNDROMES

### Vegetative and Minimally Conscious States

Following severe TBI, children can emerge from coma into a vegetative state (VS) (Chapter 101). This condition is characterized by the eyes being open and the presence of intact sleep-wake cycles, but with no self-awareness nor any purposeful movement. At the time of discharge, approximately 12% to 15% of severe-TBI patients were in VS across all age ranges. Two studies found that in post-TBI adolescents still in VS after 3 months, 33% to 43% remained in VS at 1 year.

More recently, a distinct state of consciousness termed the *minimally conscious state* (MCS) has been described and is distinguished from the vegetative state by the presence of self-awareness and some limited purposeful movements, in addition to the potential to experience pain and suffering. Children may enter into an MCS as they emerge from a VS.

**TABLE 102-3** Graded Return-to-Play Protocol After Concussion

Rehabilitation Stage	Functional Exercise	Objective
1. No activity	Physical and cognitive rest	Recovery
2. Light aerobic exercise	Moderate-intensity walking, swimming, stationary cycling; no resistance training	Increase heart rate
3. Sport-specific exercise	Skating drills in hockey, running drills in soccer; no head-impact activities	Add sport-specific movement
4. Noncontact training drills	Progression to more complex training drills (passing drills in football and hockey, etc.); start resistance training	Exercise, coordination, and cognitive load
5. Full-contact practice	Following medical clearance, participate in normal training activities	Restore confidence and assess functional skills by coaching staff
6. Return to play	Normal competitive game play	

(With permission from McCrory P et al. Clin J Sport Med 2009;19:185.)

## Cognitive Impairment and Behavioral Disorders

Deficits in many cognitive domains have been demonstrated following moderate to severe TBI in children, including impaired executive function, language, memory, visual-motor integration, attention, and speed of thinking. A meta-analysis of recovery from pediatric TBI suggests that injury severity affects the magnitude of deficits and the trajectory of recovery, with more severely injured children unable to “close the gap” with their uninjured peers over time. Factors associated with a positive outcome included preinjury adaptive ability. Lower socioeconomic status has also been associated with poorer outcomes from pediatric TBI in multiple studies. There is growing evidence that younger children are more likely to develop later impairments that become evident when they fail to acquire higher-level functions normally (Anderson et al., 2005; Babikian and Asarnow, 2009).

The presence of lasting cognitive and academic impairments after mild pediatric brain injury is controversial. Several large studies have failed to detect significant neurocognitive impairment in mildly head-injured children. However, subtle overall impairments have been reported that may indicate weak injury effects across a large spectrum of measures, rather than a major effect in a single cognitive domain.

There is also considerable evidence that pediatric TBI is associated with later behavioral disturbances, including problems with impulse control, attention, and social cognition, including recognition of emotions and social problem solving. Some of this may be attributable to premorbid problems, but there is also evidence for new-onset behavioral disturbances after TBI.

## Sleep Disorders

A variety of sleep problems have been reported after all severities of TBI, particularly sleep-wake cycle disorders. As in most sleep disorders, behavioral changes and sleep hygiene tend to be the first line of therapy. Polysomnography and evaluation by a sleep specialist may be necessary in some cases.

## Spasticity and Motor Impairment

Focal or diffuse injury may injure corticospinal tract pathways, resulting in spasticity, weakness, and loss of dexterity. As a general rule, focal deficits recover better than diffuse ones, and younger age appears to predict better recovery in these circumstances (except perhaps in the earliest age groups). Spasticity can lead to pain and discomfort, contractures, and scoliosis, and it may interfere with bladder and bowel function. Management includes physical and occupational therapy, splints and orthotic devices, assistive devices, and pharmacotherapy (Chapter 162).

## Posttraumatic Hydrocephalus

Posttraumatic hydrocephalus can be seen following intraventricular or subarachnoid hemorrhage and may manifest with chronic headache, sometimes with nausea, vomiting, impaired vertical eye movements, and diminished level of consciousness. Shunting may be necessary to alleviate pressure. Ventriculomegaly ex vacuo is perhaps more common but does not warrant shunting.

## Posttraumatic Epilepsy

Epilepsy is defined as a disorder of recurrent seizures that are not attributable to an underlying metabolic derangement or other provocation. TBI is responsible for about 5% of all new

epilepsy cases annually in the United States. One study showed the risk of developing posttraumatic epilepsy (PTE) across all ages after severe TBI was 7% at 1 year and 11% at 5 years; and after moderate TBI, it was less than 1% at 1 year and 1.6% at 5 years. Strong predictors of posttraumatic seizures/epilepsy include severity of TBI, age, and type of TBI, in particular penetrating head wounds. Other potential risk factors for the development of posttraumatic epilepsy include the presence of early seizures, longer period of unconsciousness, prolonged amnesia, skull fracture, and the presence of intracranial blood on neuroimaging.

Although children are more likely than adults to experience an early posttraumatic seizure, the relation between early and late posttraumatic seizures/PTE in children is unclear.

Posttraumatic epilepsy includes late, recurrent, unprovoked seizures with a significant antecedent history of TBI. When these patients present with their first seizure, they should undergo a thorough history, examination, and EEG. Focal findings on examination or EEG should prompt neuroimaging, with MRI being the modality of choice.

Because the specific type of posttraumatic seizure is usually one of partial onset, medication choice is generally directed toward agents with effectiveness for localization-related epilepsy. Carbamazepine, lamotrigine, valproate, topiramate, oxcarbazepine, gabapentin, and levetiracetam may be useful. Tailoring the choice of agent to take advantage of potentially beneficial side effects (mood stabilization, migraine prevention) is often worthwhile. Surgical resection may be an option in a patient with a focal lesion and seizures refractory to medication. For a more complete discussion of the early and late seizure manifestations after TBI, please see the online version of the chapter.

## Subacute and Chronic Subdural Hematoma

Subacute and chronic SDHs may manifest with signs of gradually increasing ICP—recurrent vomiting, macrocrania, papilledema, seizures, slowly progressive motor deficits, and spasticity, and occasionally systemic signs, such as anemia, poor appetite, or fever. Treatment of these hematomas may require drainage. In cases where abusive head trauma is suspected, a careful search for other bodily injuries is warranted, including a whole-body x-ray series (to look for multiple fractures) and skin examination (to look for bruising, burns, or other injuries).

## Posttraumatic Headache

Acute posttraumatic headache is usually self-limited. Trauma may also appear to precipitate migraines acutely or chronically. Worsening or progressive headache, particularly associated with nausea and vomiting, should warrant performing a careful history and examination to determine whether there is a delayed progressive intracranial complication (chronic subdural, hydrocephalus). If necessary, a cranial CT may be obtained for further evaluation.

Chronic posttraumatic headaches in children may be of new onset or an exacerbation of a preexisting headache disorder (Choe and Blume, 2015). Management of chronic posttraumatic headaches is directed at the etiology. Chronic daily headaches may be treated with analgesics, nonsteroidal anti-inflammatory agents, or antidepressant (amitriptyline) or anticonvulsant (gabapentin) medication. Narcotics should be avoided.

Migraine, tension headaches, and neuralgias should be treated similarly to nontraumatic headaches. These may best

be addressed in a multidisciplinary pediatric concussion or pain clinic and include medications, education, and nonpharmacologic interventions.

### Postconcussive Syndrome

The constellation of symptoms seen in postconcussion syndrome (PCS) in children is similar to that in adults, with chronic headache, dizziness, irritability, behavior change, inattention, sleep disturbance, fatigue, and concentration problems being prominent. The causes of PCSs are unknown, and the exact relation between physiologic abnormalities and the patient's symptomatology remains unknown. Other nonphysiologic factors have been implicated in the development of PCSs, including premorbid personality traits, socioeconomic status, educational level, medicolegal compensation, and family dynamics.

Management of PCS in children should focus on a return to normalcy as quickly as possible. Balance is required because prolonged absence from school may take on a life of its own and become clouded with issues of secondary gain and avoidance.

Medical management should be aimed at identifying treatable problems and initiating appropriate interventions. Postconcussive behavior disturbances should be evaluated by a child psychiatrist or psychologist. Although it is uncertain whether mild TBI results in an increased risk of new-onset behavioral problems, it is clear that children with particular behavioral tendencies (ADHD, oppositional behavior) are more prone to mild TBI, and treatment of these underlying problems is often beneficial. Cognitive problems identified after mild TBI may be best addressed by school assessment or neuropsychological testing. Children with pre-existing learning disabilities may have disproportionate cognitive problems after mild TBI.

### Late Complications of Skull Fracture

The majority of nondisplaced skull fractures will heal without aggressive management. However, "growing skull fracture," or leptomeningeal cyst, complicates less than 1% of cases, usually after cranial vault fractures in infants. In these circumstances there can be outward herniation of dura and underlying brain matter that require carefully planned surgical correction.

Traumatic cranial neuropathies can also occur following fractures of the skull base, most commonly affecting olfactory, optic, facial, and vestibulocochlear nerves. In cases of basilar skull fracture, particularly with persistent CSF leakage, there is an increased risk of central nervous system infection. Patients with known basilar skull fractures who present with fever, meningismus, seizures, or focal neurologic findings should be evaluated promptly for brain abscess, empyema, or meningitis.

### CONCLUSIONS

TBI is a major public health problem in children and is the number one cause of death and acquired disability. No brain-specific therapies exist, and follow up for affected children is limited and often nonexistent. Recently published recommendations for management of severe and mild pediatric TBI provide some direction for practitioners but also point out the

lack of firm guidelines available for the effective management of this common clinical problem. Although the majority of children with mild injury make a good recovery, controversy remains as to whether subsequent learning and behavioral complications are more common in these children than in uninjured controls. Severely injured children generally will have partial recovery and persistent deficits. Persistent subjective symptoms can also occur after all levels of severity of pediatric head injury. In addition, posttraumatic medical complications, such as hydrocephalus, epilepsy, infection, CSF leak, spasticity, and growing skull fracture, must be monitored for and treated promptly. The pediatric physician must not lose the opportunity to educate the child and parents about the significance of head injury, particularly with regard to appropriate measures for injury prevention, such as motor vehicle restraints and helmet use during recreational activities at risk for TBI. A balanced discussion of the risks for repeat concussion and the benefits of sports participation is also an important aspect of patient and parent education.

# 103 Abusive Head Trauma

Elizabeth E. Gilles and Cindy W. Christian

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Abusive head trauma (AHT) is a form of traumatic brain injury (TBI) resulting from assault of typically, but not exclusively, infants and young children less than 3 years of age. It remains a major cause of morbidity and mortality among young children. Infants with abusive head injuries have the most severe illness, the highest mortality risk, and the worst outcome in comparison with other forms of childhood trauma. Of the 1760 child fatalities reported in 2012 by The National Child Abuse and Neglect Data System (20 deaths/100,000), 45% were the result of physical abuse or multiple forms of maltreatment and 44% of victims were infants.

## HISTORICAL PERSPECTIVE

In the past 60 years, much has been learned about the differences between TBI from assault sustained by infants and young children and traumatic brain injuries from other etiologies at other ages. Recognizing that the caregiver history was incompatible biomechanically with the range and extent of injuries involving the craniospinal axis led to acknowledging these as caused by physical abuse. (An extensive review of the history of AHT is found online.)

## TERMINOLOGY

*Abusive head trauma* is the preferred term to use when referring to neurotrauma from assault in children (Christian et al., 2009). *Inflicted head injury* or *nonaccidental head injury* are other terms that also have been used. These are inclusive terms encompassing the range of craniospinal injuries sustained by infants and young children as a consequence of violent assault by parents or other caretakers. Unintentional, or accidental, head injury refers to injury sustained by chance and is unrelated to specific deliberate actions of caretakers.

## DEVELOPMENTAL DIFFERENCES PREDISPOSING THE IMMATURE NEURAXIS TO INJURY

Structural and functional changes of central and peripheral nervous system organization and function are greatest during the first 2 years of life, when AHT occurs most frequently. The infant's unique biochemical and physiologic makeup renders the immature nervous system more vulnerable (Hagberg et al., 2014). Mitochondria, for instance, are important to far more than cellular energetics. They affect brain susceptibility to injury, alter postinjury cascades, and play a role in recovery as well as in apoptosis (Hagberg et al., 2014). A number of biologic and mechanical factors predispose the infant and young child to injury of the craniospinal axis (Box 103-1).

## Mechanical Factors

Important differences from adults biomechanically are that infants and young children have a larger head-to-body ratio,

less muscle development, and thinner, more flexible skull bones that are not yet fused and incomplete myelination.

## Biologic Factors

There are many age-related biochemical, microscopic, and macroscopic differences with infants having greater neuronal excitability and synaptic density, and differences in receptor number, structure, and function.

## RESPONSES TO INJURY

Injury and repair after a CNS insult are quite different in the immature versus the mature CNS. The infant's unique biochemical and physiologic makeup renders the immature nervous system more vulnerable to injury. Many of the postinjury cascades are affected, including mitochondrial function, inflammatory and excitotoxic mechanisms, impaired autoregulation, oxidative stress, apoptosis, and decreased ischemic and seizure thresholds. The immature gyrencephalic brain (having convolutions) is more resistant to direct cortical deformation and isolated subdural hematoma than the mature brain, but is more sensitive to white-matter strains. These mechanisms are discussed in detail in Part IV of this book as well as in Chapters 102 and 104.

## MECHANISMS OF INJURY

Mechanisms of head injury are similar across the age spectrum and are reviewed in Chapter 102. Briefly, injuries occur when applied forces strain the tissue beyond its structural or functional tolerance. Specific patterns of response vary at different ages. The exact type and the magnitude of applied forces determine the severity of injury, with greater applied forces resulting in more severe injuries, regardless of whether the injury was abusive. Primary mechanisms of injury include impact and inertial forces, with impact forces occurring at the surface of the scalp, skull, and brain as a result of contact and inertial forces arising from head deceleration. Most severe primary brain injuries in the clinical world result from head contact. Rotational movement of the head on the neck may be caused by a number of mechanisms, including, but not limited to, shaking. Lateral (side to side) rotational movement is associated with greater brain damage than equivalent anterior-posterior head movements. Primary injury mechanisms are frequently mixed. There are numerous factors affecting severity of injury (Box 103-2).

## Contribution of Hypoxia-Ischemia

Infant animals and human children less than 24 months of age are particularly prone to secondary injury from hypoxia-ischemia after severe TBI, the most significant variable contributing to the evolution of parenchymal injury and deleterious outcome. Most infants with severe head injury, abusive or not, experience apnea or altered respiration during or just after injury (Piteau et al., 2012). Apnea and hypotension can also

**BOX 103-1** Biologic and Mechanical Features Predisposing the Infant to Head Injury**BIOMECHANICAL FACTORS**

- Large head-to-body ratio
- Proportionally heavy head in relation to body mass and neck strength
- Greater skull compliance
- Anatomy of inner skull table (smoother in younger infants)
- More firmly attached dura

**NEUROANATOMIC FACTORS**

- Immature brain (incomplete myelination)
- Increased brain water content
- Increased excitotoxicity
- Increased synaptic density
- Increased excitatory amino acid receptors
- Decreased inhibitory networks

**BOX 103-2** Factors Affecting Severity of Injury

- Types of injury events
  - Biomechanical
  - Deceleration
  - Translational
  - Strangulation
  - Smothering
- Sequence of events
- Single or multiple events
- Other factors
  - Duration of apnea, hypotension
  - Delay in seeking medical care
  - Level of consciousness at the time of the event or events
  - Neuromuscular maturity of the child
  - Antecedent dehydration and/or malnutrition
  - Premorbid brain injury

be a response to smothering or to direct vessel compromise caused by strangulation.

**CLINICAL FEATURES****Acute Presentation**

The brain's response to mechanical trauma, whether blunt force or angular deceleration, or both, is predictable. Symptoms of brain injury are nonspecific and vary by the severity of injury. Mildly injured infants may exhibit a depressed level of consciousness, irritability, altered behavior, seizures, decreased visual alertness, decreased babbling, feeding difficulties, vomiting, fever, or altered respiration. Acutely, they may not appear ill enough for the perpetrator to seek medical attention and the accompanying caregiver may be unaware that an injury has occurred. Children with moderate injuries may have waxing and waning mental status and variable neurologic findings, and usually have preservation of primitive reflexes such as sucking. Severely injured infants may have varying degrees of altered consciousness and respiratory function and often have lost most the ability to perform coordinated actions such as sucking, eating, sitting, or walking.

Sudden neurologic decompensation of a previously healthy infant, accompanied by severe respiratory distress and flaccidity, with or without seizures or posturing, in the absence of

any trauma history is consistent with a major intracranial event (e.g., trauma, herniation, subarachnoid or intraparenchymal bleeding, stroke, uncompensated hydrocephalus).

**Early Posttraumatic Seizures**

Early posttraumatic seizures (those occurring in the first 72 to 96 hours after trauma) occur in 30% to 80% of infants and young children after AHT and vary in severity and type of seizure depending on the age of the infants (more likely if less than a year of age), severity of injury, and the degree of hypoxia-ischemia.

**Subacute and Chronic Presentation**

Infants who have sustained less severe brain injury and lack external findings of trauma manifest nonspecific symptoms, not easily ascribed to trauma. Signs and symptoms attributable to hydrocephalus or an accumulating extraaxial fluid collection include progressive macrocephaly, vomiting, seizures, irritability, high-pitched cry, increasing spasticity, regression of motor skills, and loss of upward gaze, when intracranial pressure is increased.

**Predictors of Outcome**

Clinical predictors of poor outcome after abusive TBI are similar to older children and include the presence of a low Glasgow Coma Scale score, severe brainstem dysfunction, and coma duration of longer than 7 days (Robertson et al., 2002). Other variables helpful in determining that the outcome will be poor include younger age, greater severity of parenchymal injury, early and difficult-to-treat posttraumatic seizures, and the presence of severe retinal hemorrhages.

Laboratory predictors of poor outcome include initial mixed metabolic acidosis plus respiratory acidosis, hematocrit less than 30%, coagulopathy, early and sustained hyperglycemia, hypocortisolemia, and central diabetes insipidus.

Imaging findings on computed tomography (CT) scan associated with worse outcome and greater mortality include the presence of a midline shift of greater than 1 cm, diffuse hypodensities, evidence of herniation, presence of shear injuries, and larger volume of ischemic infarction. The presence of certain magnetic resonance imaging (MRI) abnormalities also correlate with poor outcome. Conventional sequences may demonstrate restricted diffusion and abnormal apparent diffusion coefficient values. Susceptibility-weighted imaging may demonstrate multiple microhemorrhages, and on MR spectroscopy, the presence of reduced N-acetylaspartate levels and increased lactate are associated with a poor outcome.

**Mortality Predictors.** Ten percent to 30% of children die of their injuries. Infants and young children admitted with hypotension, coma with severely abnormal brainstem reflexes, marked autonomic dysfunction, and retinal findings are more likely to die. Children with disseminated intravascular coagulation, severe sustained hyperglycemia, and severe endocrine derangements. Imaging signs, including reversal sign (brainstem compression) or other signs of herniation, also portend an earlier demise.

**SEQUELAE OF ABUSIVE HEAD TRAUMA**

In contrast to the majority of children with severe unintentional head injury, infants who were abused have significant sequelae. Microcephaly develops as a function of evolving cerebral atrophy.

## Posttraumatic Epilepsy

Posttraumatic epilepsy develops in 20% to 30% of young children after AHT, compared with children with unintentional injury or adults after closed head injury where the incidence is less than 2%.

## Cognitive and Executive Function

More than 50% of survivors have severe developmental disabilities, with a sizeable proportion completely dependent on caretakers for daily care. Cognitive and executive functions are often severely impaired, particularly attention and emotional regulation.

## Behavioral Sequelae

Behavioral problems are common, ranging from perseveration to oppositional behavior. Temper tantrums are frequent and may begin to manifest as the child reaches a functional age of 2 years. There are no systematic studies as to the most effective interventions for these behavioral disorders.

## Visual Sequelae

A large percentage (32% to 90%) of children with AHI have visual sequelae. Cortical visual impairment, most frequently a homonymous hemianopia, is more common than visual impairment from retinal hemorrhages. Persistent hemorrhages overlying the macula may affect central vision permanently.

## Motor Sequelae

Over 50% of survivors of early life AHT have motor deficits. Findings range from spastic hemiparesis or quadriparesis, typically with truncal hypotonia to mixed tone with elements of dystonia or choreoathetosis. Severe extensor posturing is not uncommon.

## Neuropathology

Neuropathologic findings of infants dying a period of months to years after injury include diffuse and focal cortical atrophy with multicystic encephalomalacia, microgyria and ulegyria, attenuated white matter, border-zone and arterial infarcts, and evidence of previous subdural hematomas.

## PATHOLOGIC FEATURES

Many physical findings are associated with AHT, but not all injuries must be present to make the diagnosis. No individual markers are pathognomonic of abusive injury. The major markers of injury are outlined in [Box 103-3](#).

## Extracranial Injuries

**Scalp.** The most common extracranial impact injuries after AHT are scalp bruising, soft-tissue swelling, cephalohematoma, and subgaleal hematoma (Fig. 103-1).

**Skull Fractures.** Skull fractures are found in 25% to 74% of infants and children with abusive neurotrauma. Simple linear fractures of the parietal and occipital regions are most common. Fractures that are complicated (bilateral, comminuted, multiple, or that cross suture lines) may be more likely in abused children, although, on occasion, these complicated fractures occur after falls.

## BOX 103-3 Abusive Head Injury: Markers of Injury

### INTRACRANIAL

- Extraaxial fluid collections
  - Subdural hematoma
  - Subarachnoid hemorrhage
  - Subdural effusions
- Brain injury
  - Brain swelling
  - Infarction syndromes
  - White-matter contusional tears
  - Evidence of shearing injury
  - Diffuse axonal injury
- Skull fractures

### EXTRACRANIAL

- Scalp and soft tissues
  - Subgaleal hematoma
  - Cephalohematoma
  - Soft tissue swelling
  - Hair loss
  - Bruising
- Ear
  - Pinna bruising
  - Hemotympanum
  - Ruptured ear drum
- Ocular
  - Periorbital edema and ecchymosis
  - Retinal hemorrhages
  - Peripapillary intrascleral hemorrhages
  - Retinal folds
  - Retinoschisis
  - Retinal detachment
  - Hyphema
  - Lens dislocation
- Mouth
  - Lip injury
  - Frenulum tear
  - Soft palate petechiae
  - Dental injury
- Other
  - Pattern bruising (e.g., from strangulation)
  - Long bone and rib fractures
  - Liver, kidney, or genital injury
  - Dehydration
  - Malnutrition
  - Burns
  - Excessive scarring

## Intracranial Injuries

In most severely injured children, neuroimaging reveals intracranial abnormalities, most often acute subdural hematoma, cerebral hypodensity, and, less commonly, intraparenchymal hemorrhage (Figs. 103-2, 103-3, 103-4, 103-5A, 103-6, and 103-9).

**Subdural Hematoma.** Subdural hematomas are the most common intracranial pathologic abnormality found in AHT. They are typically interhemispheric and unilateral or bilateral over the convexities.

**Mixed-Density or “Hyperacute” Subdural Hematoma.** Mixed-density subdural hematomas on CT are frequently misdiagnosed as “acute on chronic” subdural hematomas. The mixed-density subdural collection in an abused infant more

commonly results from rapidly accumulating blood in the potential subdural space, with fresh nonclotted blood found at surgery and no evidence of an organizing membrane.

**Chronic Subdural Hematoma.** Chronic subdural hematomas develop when an acute subdural hematoma fails to organize. There is a predictable sequence in their growth, the development of a membrane around the liquefying clot, and neovascularization, and finally ossification.

**Chronic Subdural Effusions.** Development of a chronic subdural collection (hygroma or effusion) may be associated with tears in the arachnoid and may not have the classic membrane structure. These subdural hygromas either resolve with time or persist because of evolving secondary atrophy.

**Subarachnoid Hemorrhage.** Subarachnoid hemorrhage develops after direct surface trauma to the brain, or from leakage of blood from injured cerebral vessels within the subarachnoid space. In the context of AHT, subarachnoid hemorrhage is not generally significant. On occasion, lesions that appear to be acute subdural hematomas resolve rapidly in 1 to 2 days.

**Epidural Hematomas.** Epidural hematomas are uncommon after AHT. The majority of arterial epidural hematomas develop from damage to the middle meningeal artery associated with skull fracture. Symptom progression parallels the rate of epidural blood accumulation. Lucid intervals are more common. These children generally have an excellent clinical outcome compared with abused infants consistent with their mechanism of injury.

## Brain Injuries

**Brain swelling.** Younger infants present more often with diffuse brain swelling, whereas older infants and children present with focal or hemispheric brain swelling subjacent to an acute convexity subdural hematoma (Figs 103-4, 103-5, 103-8, and 103-9). None of the patterns of focal brain swelling are specific for abusive TBI.

**Hemispheric swelling.** One third of abused infants and young children present with hemispheric hypodensities subjacent to an acute subdural hematoma. Several mechanisms have been proposed, but the etiology remains poorly understood.

**Cerebral infarction.** Posttraumatic cerebral infarction after TBI is usually caused by vascular compression. Patterns include posterior cerebral artery and branch anterior cerebral artery distribution and lenticulostriate-thalamoperforator distribution infarctions (Figs 103-7 and 103-9). Hemispheric necrosis and border zone infarction also occur frequently (Fig. 103-9).

**Diffuse axonal injury.** Diffuse axonal shear injury (DAI) or traumatic axonal injury (TAI) is a common feature of severe TBI in older children and adults. Its frequency is not established in infants after TBI, and there is conflicting evidence about the precise pathogenesis of axonal injury identified in AHT. Major angular deceleration forces are required for the development of widespread TAI. It occurs at the moment of injury and, when severe, is associated with loss of consciousness at the moment of impact. Imaging findings of shear injuries include punctate hemorrhages, particularly at the gray-white matter junction, and tearing of the corpus callosum (Fig. 103-8).

**Cerebral contusions.** An infant younger than 8 months is much less likely to develop cortical contusions in coup or contrecoup locations than an older child or adult. The incidence of contrecoup injuries increases rapidly from later

**TABLE 103-1** Terminology for Retinal Hemorrhages

Name	Location
Vitreous	Vitreous
Subhyaloid (sublaminal or boat)	Preretinal
Intraretinal	
Flame or splinter	Nerve fiber layer
Dot (dot and blot)	Inner retinal layers (including bipolar)

infancy to 3 years of age, when it approximates that of the adults.

**White-matter contusional tears.** White-matter gliding contusions or contusional tears occur where shear strain is greatest, namely deep to the gray-white matter junction most often in the frontal and temporal lobes (Figs 103-12 and 103-13). They range from 1 to 3 cm in length. They are most easily visualized on follow-up imaging studies (Fig. 103-12).

## Ocular Pathology

**Retinal Hemorrhages (Table 103-1).** Retinal and optic nerve sheath hemorrhages are the most common injuries to the globe, optic nerve, and surrounding tissues with a frequency of 47% to 100% depending on inclusion criteria. Explanations of the possible mechanism leading to retinal hemorrhages are discussed in the online chapter. Retinal hemorrhages in children with AHT have variable appearance and distribution (Figs 103-14 and 103-15). Younger age and greater hypoxic-ischemic injury correlate with more severe hemorrhages. Resolution rates of retinal hemorrhages after AHT have not been systematically studied but typically resolve within 10 days. Other documented findings include retinoschisis, retinal folds, retinal detachment, peripapillary intrascleral hemorrhages, periorbital edema and ecchymosis, subconjunctival hemorrhages, hyphema, and cataracts.

**Optic Nerve Sheath Hemorrhage.** Optic nerve sheath hemorrhages are found in the subdural and the potential subarachnoid space and tending to be more predominate in the distal optic nerve. They are found in 70% to 100% of abused children at postmortem examination.

## Spinal Injuries

Spinal trauma, whether ligamentous or bony, needs to be distinguished from clinically significant spinal cord injury. It is increasingly recognized that spinal trauma, particularly in the cervical cord, is commonly associated with AHT, and the majority of injuries are ligamentous and identified primarily with MRI. Clinically significant spinal cord injury in children who have sustained AHT has rarely been reported and predominantly involves the cervical cord.

## DIFFERENTIAL DIAGNOSIS

The range of clinical and physical findings in abusive neurotrauma is unique. It is extremely uncommon for infants to suffer severe brain injuries from unintentional mechanisms (falls and birth trauma) (Kuppermann et al., 2009). In establishing the likelihood that the injuries resulted from abusive versus unintentional mechanisms, the alternatives for each marker must be considered along with the patterns of injury to the craniospinal axis as well as other organ systems, along with the history of injury.

## Unintentional Injury

**Falls.** Fall data overwhelmingly support the conclusion that children younger than 2 years of age are extremely unlikely to sustain severe TBI and severe retinal hemorrhages in uncomplicated short falls (Kuppermann et al., 2009). Fall data should be interpreted cautiously. The majority of published data were collected retrospectively without consistent evaluation protocols. Routine neuroimaging is generally not performed in children who are not clinically symptomatic. Intracranial injuries, such as small, insignificant subdural hematoma, thus would be missed (Kuppermann et al., 2009). It is exceedingly unlikely that an infant presenting with a Glasgow Coma Score of 14 to 15 has significant brain injury.

*Short falls.* Short falls are generally low-impact, low-velocity injuries. The most common findings are concussions, scalp contusions, some fractures, an occasional epidural hematoma, and an occasional focal subarachnoid hemorrhage. In falls of less than 2 feet, clavicle fractures predominate; skull fractures are more common in falls of 2 to 4 feet. Similarly, household free falls from furniture of less than 3 feet do not generally result in significant brain injuries. The exception are epidural hematomas, which can be a life-threatening injury if not treated promptly.

Skull fractures that result from falls of 2 to 4 feet onto a hard surface, such as pavement, cement, linoleum, and wood, generally cause simple fractures. Rarely, complicated skull fractures occur in infants younger than 6 months of age. In very rare cases, a complicated short fall, usually with impact to the occiput, results in a more severe injury.

*Walker and stroller falls.* Walkers continue to be widely used in the United States despite the substantial amount of data detailing their risks. The majority of cases are because of falls down stairs, but tipping over is another mechanism. Most injuries include extremity bruises, skull and other skeletal fractures, and minor concussions. Rarely, infants sustain more significant intracranial injuries, including subdural hemorrhages and growing fractures.

*Falls down stairs.* Children falling down stairs (or infants dropped while being carried down stairs) typically do not sustain injury, although some falls may result in skull or skeletal injury. More severe injuries are occasionally seen when an adult falls on top of the child. Stairway falls usually are less serious than free falls of the same vertical distance regardless of the number of steps.

*Falls from heights.* Children falling from heights incur extremity injuries more than head injuries, and overall, recover better than adults. The brain and skull accelerate at the same rate in a high free fall. The brain may escape major injury, but the skull may shatter with impact because the skull absorbs much of the translational energy and there is little rotational component. A comminuted skull fracture with surface brain contusion, subarachnoid hemorrhage, or both in older children is consistent with a history of a high free fall.

## Birth Trauma

Symptomatic injuries arising from the birth process are uncommon. Extracranial injuries predominate (caput succedaneum, cephalohematomas, and subgaleal hematomas). Skull fractures are generally either linear or depressed. Complicated skull fractures usually herald serious intracranial pathologic processes such as epidural and subdural hematomas, subarachnoid hemorrhage, and intracerebral hemorrhage. Small, generally asymptomatic subdural hematomas may occur after a difficult delivery or when an infant is large for gestational age. Eleven percent to 50% of full-term newborns have retinal hemorrhages after vaginal delivery. These

hemorrhages are more frequent after complicated (vacuum extraction, protracted labor, premature, or traumatic) births. Although the types of hemorrhages are similar to those in infants with abusive injuries (flame, dot and blot, subhyaloid), they are rarely severe. Most of these hemorrhages are small and disappear within several days to 2 weeks.

Infants injured through the birth process exhibit symptoms perinatally. Review of the maternal and infant birth records, as well as any pediatric records, is exceedingly helpful. This review can firmly establish if birth-related complications or other conditions were or were not factors contributing to the acute clinical presentation.

## Neurometabolic Disease

There are rare case reports of infants with metabolic disease presenting with signs and symptoms suggestive of abusive injury. Children with metabolic disease do not typically present with the range of findings found in abused infants. Specific findings on the history, physical examination, and imaging characteristics usually suggest the possibility of a metabolic disease. The organic aciduria, glutaric aciduria type 1, has been found most frequently. The most common finding is ocular involvement including intraretinal hemorrhages, cataracts, pigmentary retinopathy, and gaze palsies. Infants with glutaric aciduria type 1 may present with encephalopathic crises, macrocephaly, retinal hemorrhages, chronic subdural effusions, and spasticity.

The neurologic crises are typically precipitated by an infectious illness to which the brain responds with swelling, metabolic depression, and necrosis of basal ganglia gray matter. These infants have microencephalic macrocephaly from birth. Other neuroimaging features include widened operculae, alterations of signal intensity in the basal ganglia, subdural effusions, and dilated transarachnoid vascular plexuses.

Menkes's disease is a rare, x-linked recessive neurodegenerative disorder of copper transport. Vascular abnormalities predispose these infants to spontaneous intracranial hemorrhage. Infants, typically less than a year of age, present with subdural fluid collections, seizures, and developmental delay. C2 posterior arch defects have been found in 11% of infants.

On rare occasions, osteogenesis imperfecta type I has been reported to present with subdural hematoma, with and without retinal hemorrhages after minor trauma.

Metabolic screening tests should be considered in infants presenting with somnolence, vomiting, seizures, dystonia, or dyskinesia and extraaxial fluid collections (either subdural effusion or subdural hematoma), particularly if ketoacidosis or basal ganglia involvement are present.

## DIFFERENTIAL OF SPECIFIC FINDINGS

### Retinal and Optic Nerve Sheath Hemorrhages

Whereas retinal hemorrhages are very common after AHT, they are reported rarely after accidental head injury and in association with epidural hematoma. In this case they are usually mild, small, and scattered. In these instances, they are typically superficial and confined to the posterior pole.

Retinal and optic nerve sheath hemorrhages are found in numerous disorders. They have been reported in newborns but also in children who are critically ill and have vascular malformations, coagulopathies, anemia, leukemia, meningitis, bacterial endocarditis, hypertension, infections, and papilledema. Vitreous hemorrhages and epidural hematomas have been reported with hypofibrinogenemia. Retinal hemorrhages are not associated with seizures, coughing, or vomiting.

In the presence of papilledema, retinal hemorrhages cannot be causally related to abusive head injury. Retinal hemorrhages are rare in the context of acute life-threatening events, sometimes heralding a diagnosis of trauma.

Optic nerve sheath hemorrhages are not specific to abusive injury, having been reported secondary to sudden or prolonged increases in intracranial pressure (e.g., extensive subarachnoid hemorrhage) and, in rare cases, with unintentional head injury.

## Extensive Subarachnoid Hemorrhage

Extensive subarachnoid hemorrhage can be seen in several conditions aside from AHT. These include vascular malformations, birth trauma, coagulopathy, meningitis, and unintentional trauma. These are uncommon causes of subarachnoid hemorrhage, and, in the presence of extensive subarachnoid bleeding, a vascular malformation is the most likely etiology. Vascular malformations (arteriovenous malformations, dural fistulas, and aneurysms) are exceedingly rare in young children (Chapter 111).

## CLINICAL ASSESSMENT

### General Examination

A detailed history of the injury and a timeline of the infant's behavior for a minimum of the 72 hours preceding the injury is invaluable. This history should be documented in a legible summary, with quotations from caregivers where possible. Histories of minor injury should be closely examined, and any available caretakers should be questioned independently if possible. The biomechanical history of the fall should include details such as the specific surface on to which the child fell, the location and type or types of injury, and the presence of corroborative witnesses. It is also useful to ask about exactly what happened after the event—"What did the child look like?" "What position was he or she in?" "What did he or she do next?" "What happened then?"—and so on. The age of the child and their developmental level should be documented. Documentation of inconsistencies in histories obtained from caregivers and family members is especially important, as are inconsistencies between the historical record and the clinicopathological findings (Christian et al., 2015).

### General Examination

After initial coma scale scoring and resuscitative efforts, an extensive physical examination should be completed. Serial vital signs, including temperature (rectal preferred), can be helpful in developing a postinjury timeline. Growth parameters, including head circumference, state of hydration, and any obvious signs of neglect, need to be documented. The examiner should palpate and inspect all skin surfaces, particularly the cranium, behind the ears, and the occiput. Battle's sign (bruising over the mastoid) and "raccoon eyes" (periorbital ecchymoses) are suggestive of a basilar skull fracture. Hemotympanum can result either from direct impact over the ear or from a basilar fracture. The examiner should inspect the frenula and the palate for tears and petechiae; forced feeding, smothering, and gagging can cause these injuries. Any unusual pattern of injuries should be documented, including both a complete written record of the examiner's involvement with the child, and appropriate photographic documentation. Serial photographs are also very helpful. These should be taken with a color bar and a ruler in the photograph.

Classic features of asphyxia are facial cyanosis, petechial hemorrhages of the eyes and face, foam in the nose and

mouth, and prominent bulging eyes. Some or all of these features may be present, depending on the amount of force applied to the neck, its rate and duration, and the surface area involved. Decreased carotid pulsations ipsilateral to neck bruising are suggestive of carotid injury. The neck should also be inspected closely, particularly along the mandible, to assess for subtle signs of strangulation.

The examiner should note the location and extent of any skin lesions, including bruises or bite marks. Bruises involving skin surfaces that are fairly protected, such as inner arms and other flexor surfaces, torso, ears, or neck, are of particular concern. A history of a simple fall is incongruous when there are multiple bruises of the same or different age, or if the bruises are on multiple and different body planes.

### Neurologic Examination

Serial neurologic examinations, including the level of coma, should be documented (Chapter 101). Repeated fundoscopic examinations are useful for documenting retinal hemorrhage development. Particular attention needs to be given to identifying and documenting asymmetries on the examination. The presence of a neurogenic bladder or bowel, or other findings that suggest a spinal level, should raise suspicion of spinal injury.

### Autonomic and Neuroendocrine Responses

Endocrine and autonomic reactions to TBI are reviewed in detail in the online chapter. Briefly, TBI and other critical illnesses are potent activators of the hypothalamic–pituitary–adrenal axis and the sympathetic efferent pathways. There is a significant correlation between injury severity and loss of adaptive negative feedback control mechanisms.

Within the first day after severe TBI, increased cortisol and adrenocorticotropic hormone may occur. Endocrinopathies develop in many survivors of AHT, and some are seen shortly after injury. Gonadotropin deficiency is common (up to 80%), as is vasopressin abnormalities (up to 40%), leading to diabetes insipidus or syndrome of inappropriate antidiuretic hormone release (SIADH), and corticotrophin and cortisol deficiencies.

Factors predictive of endocrine dysfunction include injury severity and the presence of skull fractures. Lower cortisol levels correlate with younger age, hypotension, hypoxia, anemia, and injury severity. In pediatric patients, adrenal insufficiency is more severe when intracranial hypertension is present. Acute adrenal insufficiency and central diabetes insipidus are predictive of mortality. During the acute hospitalization, many of these alterations are transient with cortisol and ACTH levels returning toward normal in the majority of patients.

Thirty to fifty percent of children have persistent evidence of hypopituitarism even up to 5 years after injury. Growth hormone deficiency and disturbances in puberty are the most common endocrine deficiencies, but children can also experience ACTH deficiency, diabetes insipidus, central hypothyroidism, and elevated prolactin levels. Every hormonal axis can be affected, although growth hormone deficiency and alterations in puberty are the most common (Personnier et al., 2014).

To date, there have been three studies examining hypothalamic–pituitary–adrenal function in infants after AHT (Personnier et al., 2014). In the only prospective study of 87 infants and children after accidental ( $n = 73$ ) or abusive ( $n = 14$ ) TBI, 30% of patients had persistently low growth hormone peak levels, with 15 meeting criteria for growth hormone deficiency and 5 had severe growth hormone deficiency. By 1 year

after injury, pituitary dysfunction only was detected in 8% of patients (Personnier et al., 2014). All children admitted with TBI should be assessed for endocrine dysfunction. If the basal cortisol level is less than 15 mg/dL or increases by over 9 mg/dL after stimulation, treatment should be considered. Intravenous hydrocortisone at 50 to 100 mg every 8 hours or by continuous infusion is usually sufficient but may be supplemented with a mineralocorticoid if hyponatremia persists. All patients sustaining severe TBI should be tested for abnormal endocrine function (adrenal, thyroid, and growth hormone) at 3 and 12 months after injury. Although many abnormalities will slowly improve, a significant subpopulation has persistent abnormalities that require long-term treatment.

Autonomic cardiac control in children with TBI can be altered depending on injury. When efferent sympathetic pathways are completely interrupted (i.e., autonomic failure), heart rate variability is lost and low-frequency heart-rate power decreases; these findings are highly correlated with brain death in children and adults.

## LABORATORY AND RADIOGRAPHIC EVALUATION

### Laboratory Evaluation

Infants who have sustained abusive head injuries are frequently anemic and acidotic when hospitalized. Leukocytosis is not uncommon. As in adults, hyperglycemia has been associated with a more severe head injury and a poorer prognosis and is also suggestive of more recent injury. The combination of lower GCS scores, lower hemoglobin levels, and increased glucose levels are associated with a greater risk of developing a coagulopathy. As in other TBI populations, secondary consumptive coagulopathy is associated with a higher mortality rate and more severe brain injury (Peiniger et al., 2012). These abnormalities do not appear to reflect preexisting coagulation abnormalities. In situations in which a clinical index of suspicion arises or an alternative diagnosis has been proposed, such as an inherited metabolic disease, additional studies or consultation with a metabolic geneticist may be useful.

**Biochemical Markers.** There is a remarkable body of literature evolving that is studying the acute-phase changes of numerous “biomarkers” after pediatric TBI as a means toward identifying therapeutic targets (Kochanek et al., 2013). This is reviewed in detail in the online chapter. Although many protein degradation products, S-100B, neuron-specific enolase, inflammatory mediators, soluble intracellular adhesion molecule, L-selectin, and endothelin, increase acutely after TBI, these changes have not differentiated abusive from unintentional injuries (Kochanek et al., 2013).

### Neuroimaging and Radiographic Evaluation

In symptomatic infants and children, the initial neuroimaging study of choice is a noncontrast CT scan with bone windows. A CT scan may miss skull fractures within the plane of the section, and so skull films should be included as part of the skeletal survey. A full skeletal survey should be obtained in any child younger than 2 years of age, or in any older child with multiple traumatic injuries suspected to be caused by abuse. In instances where there is a suspicion of fracture, repeating the survey 2 to 3 weeks after presentation may establish conclusively that a fracture occurred. A bone scan may be indicated in equivocal or negative cases in which there is a high level of suspicion of injury. If carotid or vertebral injury is suspected, cerebral angiography may be helpful.

MRI is more sensitive and accurate than CT scanning in defining the extent and age of extraaxial collections,

hemorrhagic and nonhemorrhagic injury, and evolution of ischemic changes, and in demonstrating infarctions. Repeat or serial imaging is often helpful in establishing the extent of injury.

Advanced imaging techniques (susceptibility-weighted imaging, diffusion-weighted imaging, MR spectroscopy, and diffusion tensor imaging) in addition to CT and standard MRI improve sensitivity in defining the extent of parenchymal injury and total injury volume as well as improving outcome prediction in young children with TBI. More detail about imaging techniques is discussed in the online chapter. A review of advanced neuroimaging modalities after TBI was published in 2014 (Ashwal et al., 2014).

There is considerable variability in the radiologic interpretation of neuroimaging data. Few clinicopathological studies have been published, and caution should be exercised in relying only on imaging to establish timing of injury. It is strongly recommended that clinicians review the neuroimaging studies themselves, and if possible with a neuroradiologist.

## POSTMORTEM EXAMINATION

A full postmortem examination, including examination of the eyes and testing for metabolic disease, is mandatory for any child with an unexplained death, as these findings frequently assist in establishing an unintentional or abusive etiology. This is particularly true in infants younger than 1 year of age, in whom the incidence of sudden infant death syndrome is higher than that of abusive head injury. At postmortem examination, evaluation of the reflected scalp allows for identification of galeal hemorrhage and impact sites (periosteal hemorrhages). The temporalis muscle and posterior cervical muscles are additional sites where internal soft tissue injury may be found. Small patchy areas of subarachnoid hemorrhages are almost universally found at postmortem examination in infants who die of abusive injury.

Aside from greatly assisting in documenting the full extent of injuries, the postmortem examination provides additional information about the pathologic timing of injury events. The presence of intraalveolar siderophages, for instance, is suggestive of previously imposed suffocation. Confirmation of specific findings, such as subdural neomembranes and positive retinal staining for hemosiderin and iron, can further assist in the timing of injuries (Figs 103-14, 103-18, and 103-19). However, in instances in which the infant has been kept alive while a brain death determination is being made and in which resultant necrosis evolves, clinical timing of injury is frequently more precise than timing based on pathologic findings.

## MAKING THE DIAGNOSIS OF ABUSIVE HEAD INJURY

### General Considerations

Child abuse is rarely premeditated. It occurs when caregivers lose control, often when trying to stop certain behaviors (such as crying) or when punishing perceived transgressions (such as toileting accidents). Abusive injuries may be one-time events, or repeated and complex scenarios occurring in 1 day, over days, weeks, or months. The sequence of injury events is highly variable. Events can include shaking, throwing, hitting, slapping, gagging, strangling, and smothering. Only children with injuries severe enough to frighten the caregiver are likely to be brought to medical attention. Resuscitation delay, while a potentially important factor, does not occur uniformly, and is not unique to abuse.

**BOX 103-4** Key Questions in the Evaluation of the Child With Suspected Abusive Head Injury

- What is the distribution of injuries?
- Are the injuries confined to the head?
- Are the brain injuries focal, diffuse, or both?
- What is the clinical timing of the injury?
- Are there injuries that suggest a specific injury mechanism (slap mark, strangulation bruising, etc.)?
- Are there other suspicious patterns of injury (e.g., rib fractures)?
- What forces were necessary to cause such injuries?
- Is the history congruent with the physical injuries?
- Is there an accidental mechanism that would explain these injuries?
- Is there a nonaccidental mechanism that would explain these injuries?
- Is there evidence of injuries of varying ages (e.g., old bite marks)?
- Was there a delay in seeking medical attention?
- Was the injury witnessed?
- Are there more than one history for the injury or injuries? Changing histories?
- If there is suspicion of a nonaccidental etiology, has the child been reported to the hospital child abuse team and to the local child protective services?

Establishing the diagnosis of abusive trauma is frequently problematic and requires a high index of suspicion. The fewer markers of injury and the more nonspecific the history, the more difficult it is to distinguish abusive from unintentional injury. The less severe the injury, the less pronounced the postconcussive syndrome. Findings indicating more significant force generation include injuries to the neck and rostral spine, contusions/lacerations of the olfactory system, partial or complete transection of the corpus callosum, tearing of the septum pellucidum, and evidence of diffuse axonal injury.

Children interface with the medical system at all points along their response curve after brain injury. It is unrealistic to expect findings in all children to be similar. Certain key questions should be asked and answered (**Box 103-4**). The physical findings, in conjunction with inconsistent historical features, usually point to trauma as the most likely etiology. Obvious cases are those with clear and convincing findings in the absence of an injury mechanism that accounts for the findings. The combination of acute serious brain injury, retinal hemorrhages, and posterior interhemispheric subdural hematomas appear to have greater specificity for an abusive etiology, but are not unique to abusive injury.

Evidence of impact is helpful in establishing abusive injury when caregivers have specifically denied trauma. Multiple impact injuries are not consistent with a history of a simple short fall, especially if the alleged fall did not occur the same day. On the other hand, complicated short falls do occur. In the infant who survives, however, the absence of external scalp bruising, soft-tissue swelling, or skull fracture does not conclusively exclude blunt-force trauma, as evidence of impact may be found only at the time of the postmortem examination.

Particular patterns of injury are more supportive of abusive injury, such as accompanying rib or long bone fractures, or pulmonary or liver contusions. Neck bruising and hyoid injury indicate that strangulation has occurred. Bruising in unusual regions (such as the neck, ears, abdomen, or buttocks), human bites, and acute genitoanal trauma may be evidence of abuse and is supportive of an abusive etiology.

**BOX 103-5** Factors Associated With an Abusive Etiology

- Age less than 1 year
- Greater severity of illness
- Unexplained injuries
- A biomechanically inconsistent history
- A changing history or one inconsistent with the child's developmental level
- A delay in seeking medical attention
- Parental risk factors
- History of past abuse and neglect
- Alcohol and drug use
- Previous social service intervention

Evidence of previous maltreatment or neglect does not necessarily assist in identification of the perpetrator, unless he or she is the only caregiver.

**Evaluating the History**

Histories given by perpetrators typically minimize actual injury events. Often, there is a history of minor trauma (such as a short fall with no neurologic symptoms) or no history at all. Changing histories, either by the same caregiver or by multiple caregivers, should raise concerns. In many situations, perpetrator admissions are not straightforward and event sequences are quite variable. Typically, the actual injury and timeline of the events are understated, whereas descriptions of the clinical behaviors of the infant are accurate. There are a number of clues that suggest an abusive etiology (**Box 103-5**).

**Timing**

The timing of injury events in the still-living child can usually be estimated by using a combination of clinical course, physical findings, and imaging data, although best estimates may be insufficiently precise to eliminate all possible perpetrators. Children who sustain moderate to severe TBI are almost always immediately symptomatic, and often demonstrate an immediate apneustic response to mechanical events, whether abused or not. Persistence of coma, apnea or respiratory distress, irritability, seizures, hypotonia, and vomiting reflects the severity of injury and evolving secondary pathophysiologic cascades. Early posttraumatic seizures should not be used to time injury events.

**Lucid Interval**

The lucid interval occurs after an initial loss of consciousness after a head injury consisting of a period of clinical improvement, not necessarily normalcy, followed by neurologic deterioration within minutes to hours. Lucid intervals occur in less than 3% of children after moderate to severe TBI of all etiologies, and generally result in a nonlethal injury if prompt care can be delivered. Periods of improved consciousness have been reported in children with GCS scores of less than 8 after initial unconsciousness followed by rapid secondary deterioration within minutes to hours.

**Dating by Neuroimaging**

Dating of parenchymal injuries by neuroimaging is confounded by variability in the rate of brain swelling, from within 20 to 30 minutes to several hours. In general, evolution

of cerebral parenchymal abnormalities occurs rapidly after injury in adults and similarly have been documented within 1 to 3 hours in abusive and accidental childhood TBI.

Dating of subdural hematomas by CT imaging is difficult because of differences in interpretation of signal densities, variability in development and resolution of findings, and influence of confounding variables. In general, hyperintense subdural collections on noncontrast CT imaging are less than 7 days old; isointense collections, 7 to 14 days old; and hypointense collections, more than 14 days old. In 43 abused infants with specific times of injury, the first hypointense component within the subdural hematoma appeared 0.3 to 16 days after injury and the last hyperdense component disappeared from 2 to 40 days after injury.

Attempts have been made to standardize dating estimation with some success. However, subdural hematomas may appear hypodense in the very anemic infant or if there is a mixture of cerebrospinal fluid with subdural blood or arterial blood contributes to the subdural collection. Subdural neomembranes, visualized with contrast CT scans, begin to develop between 7 and 10 days after injury. Mixed-density subdural collections on CT imaging should not be diagnosed as acute on chronic bleeding without confirmation of neomembranes (either at surgery or necropsy).

MRI, like CT, cannot date injuries precisely, and the finding of blood of different intensities does not always mean that there has been repeated trauma, in as much as blood in various compartments may have different signal characteristics. Without pathologic correlation, definitive dating of extra-axial blood collections by standard neuroimaging should be made cautiously.

## Medicolegal Issues

Child abuse and neglect were defined by the Federal Child Abuse Prevention and Treatment Act (CAPTA) 42 U.S.C.A. §5106g, and most recently amended in 2010.

Key elements of this definition are as follows:

- Any recent act or failure to act on the part of a parent or caretaker that results in death, serious physical or emotional harm, sexual abuse, or exploitation
- An act or failure to act that presents an imminent risk of serious harm

Assault of infants and children has specific medicolegal consequences and implications that accidental injuries do not have. As mandated reporters, when we report a suspected case of abuse or neglect, there are often concurrent civil and criminal investigations that cross jurisdictional lines. This is often confusing for medical professionals. Taking an infant off life-support may mean that the alleged perpetrator is charged with second-degree murder, rather than felony child abuse (this varies by state). Lastly, because both abusive and accidental injuries occur with a spectrum of findings and via a variety of mechanisms, more general terminology is helpful to avoid trying to fit all cases into narrow semantic and conceptual descriptors.

Mandated reporting laws require physicians and other healthcare professionals to report for investigation, patterns of injuries, and behavior when reasonable suspicion of abuse or neglect arises. Reasonable suspicion does not mean that the clinician must be certain of the diagnosis; it means only that the clinical picture warrants full investigation and possible protection of the injured child and any siblings. Healthcare providers actually fail to diagnose or misdiagnose about one third of abusive head injuries in infants and children during initial examinations, especially when injuries are not severe.

The law protects the physician if suspicion should prove erroneous but was made in good faith. Conversely, failure to report suspected abuse is actionable and places children at significant risk for further harm if they are returned to the setting in which they were injured. Although there is a cross-reporting mandate between social service and law enforcement officials, it may not happen immediately. When serious physical injury is suspected to have resulted from assault, notification of both law enforcement and social services is recommended.

Translating and interpreting complex information from the medical to the legal arena is a critical component of the evaluation of suspected abusive head injury for the protection of the child, other siblings, and the alleged perpetrator. This process begins with adequate written, photographic, and schematic documentation, and extends through communication with Child Protective Services, law enforcement agencies, legal counsel, and the judicial system. Documentation of inconsistencies in the histories obtained from various family members is especially important, as is inconsistencies between the historical record and the clinicopathological findings (Christian et al., 2015).

Investigating agencies want treating clinicians to know whether the injuries were abusive or not, but the clinician is sometimes unable to say more than that the injuries are clearly traumatic in origin. If there is uncertainty about the significance or timing of particular findings, an expert opinion, usually from a child abuse team physician, neurosurgeon, child neurologist, or forensic neuropathologist with expertise in this area, is often helpful. Ultimately, the diagnosis of abusive injury relies on the constellation of physical findings, a history of injury that is not biomechanically feasible, and the timing of injury. It is imperative to have either the services worker or law enforcement complete a scene investigation and obtain photographs, again with tape measures, as soon as a fall history is given. Optimally, these data will be reviewed by the clinicians who are determining whether the clinical and radiologic findings are consistent or inconsistent with the given history.

## CONCLUSIONS

Abusive childhood neurotrauma is a complicated form of traumatic injury with a well-defined continuum of injury findings. There is much that remains to be learned about early life TBI, regardless of whether injury occurred by assault or unintentional mechanisms. Systematic research studies using consistent definitions and methodology are the next step in elucidating mechanisms of injury and defining evidence-based practice.

## CARDIAC ARREST: ETIOLOGY, SURVIVAL, AND NEUROLOGIC OUTCOME

In the majority of cases, pediatric cardiac arrest results from asphyxia, in contrast with adult cardiac arrest, which is predominantly the result of ventricular fibrillation (VF). The morphologic pattern of brain damage is different in asphyxial and VF cardiac arrest because of the differences in patterns of cerebral blood flow (CBF). Cardiac arrests in children generally result from progressive tissue hypoxia and acidosis resulting from respiratory failure, circulatory shock, or both. Electrocardiographic rhythms of cardiac arrests in children usually progress through bradyarrhythmias to asystole or pulseless electrical activity rather than to VF. Although the outcomes from cardiac arrhythmias or shock in children are generally good, the outcomes from pulseless cardiac arrests in children are poor.

A multicenter study of children who had a sustained return of circulation after in-hospital cardiac arrest showed a rate of survival to hospital discharge of 48.7%. Of those who survived to discharge, 76.7% had a good neurologic outcome. In contrast, survival following out-of-hospital arrest ranges between 6% and 10%. Survival following cardiac arrest in the emergency department in a study of 16,782 patients over 10 years in the Get with the Guidelines—Resuscitation database found that survival to discharge was not different (23% vs. 20%) between children and adults, and there was no effect of age on outcome. A prospective international study of 502 children with in-hospital cardiac arrest found that only 9% survived to hospital discharge, but of these patients, 88 had good neurologic function at 1 year (Del Castillo et al., 2015), which is consistent with the results of a single-center study of recovery following in- and out-of-hospital arrest. A comparison of these two groups is presented in Table 104-1 and Table 104-2.

The incidence of cardiac arrest in infants approaches that of adults and is higher compared with that of children and adolescents. Outcomes have been improving, mainly because of increased understanding of the pathophysiology, expansion of resuscitation training programs, and improvement in resuscitation techniques. Postarrest care has evolved, and substantial attention has been paid to focused central nervous system (CNS) resuscitation and support because neurologic injury is one of the most significant complications of cardiac arrest (Donoghue et al., 2015).

## POSTCARDIAC-ARREST SYNDROME

Postcardiac-arrest syndrome includes brain injury, myocardial dysfunction, and systemic ischemia and reperfusion injury (Galland and Elder, 2014). The four phases of resuscitation in cardiac arrest are *prearrest* (events leading to cardiac arrest, i.e., hypoxia, bradycardia, hypovolemia, arrhythmia), *arrest* (no flow), *resuscitation* (chest compressions: low or no flow, and assisted ventilation), and *recovery after resuscitation*. The term *postcardiac-arrest syndrome* was proposed in a scientific state-

ment by the International Liaison Committee on Resuscitation, and four phases of this syndrome were described:

1. Immediate postarrest phase (first 20 minutes after return of spontaneous circulation)
2. Early postarrest phase (20 minutes to 6–12 hours)
3. Intermediate phase (6–12 hours to 72 hours)
4. Recovery phase (beyond 3 days)

Therapy targeting each of these phases has a defined goal; interventions in the early phases focus on limiting further injury and vital support, whereas those in the later phases focus on prognostication and then rehabilitation.

## RESPONSE TO INADEQUATE OXYGEN DELIVERY: MECHANISMS OF BRAIN INJURY

Asphyxia produces a state of hypoxemic, hypotensive perfusion before cardiac arrest. During ischemia, energy stores of the brain are depleted, and toxic metabolites accumulate (lactate and hydrogen ion). Upon reperfusion, injury to the brain is caused by excitotoxicity, calcium accumulation, protease activation, and formation of reactive oxygen and nitrogen species. The mechanism of neuronal damage after cardiac arrest is a combination of necrosis, apoptosis, autophagy, and inflammation. Necrosis is a process characterized by immediate mitochondrial and energy failure, leading to cellular swelling, loss of cell membrane integrity, and a prominent inflammatory response in surrounding tissue. Apoptosis is an energy-requiring process necessitating new protein synthesis. Enzymatic degradation of cytoskeletal proteins results in cell soma and nuclear shrinkage, and DNA is characteristically fragmented via endonucleases. In contrast to necrosis, apoptosis produces minimal inflammation and autophagy. Autophagy is an adaptive response to starvation and results in autodigestion of cellular proteins and organelles to feed the cell. Triggering of autophagy after acute insults may be beneficial or detrimental, likely depending on the degree or duration of injury.

## Brain Energy Failure

Because of its high metabolic demands, limited energy stores, and reliance on oxidative metabolism, the brain depends on large amounts of exogenous substrates (oxygen and glucose). Cellular energy depletion is postulated to be the triggering event that initiates the cascade of injury that occur during ischemia. Under normal conditions, this function accounts for nearly 50% of total cellular expenditure. Interruption of CBF results in loss of consciousness and reductions in electroencephalographic (EEG) activity within seconds. Within 5 to 7 minutes, complete energy failure occurs, accompanied by disturbances of neuronal and glial ion homeostasis, including sodium and water influx and efflux of potassium (Figure 104-1). When the extracellular potassium concentration

reaches a critical threshold, voltage-gated channels undergo depolarization, precipitating extracellular calcium influx. If flow remains inadequate and energy failure persists, calcium-mediated events, including phospholipase and protease activation, can lead to irreversible cellular injury and necrosis, as well as cerebral acidosis with elevated lactate levels and decreased hydrogen ion concentration (pH). If blood flow is restored, recovery of basal cellular metabolism (adenosine 5-triphosphate [ATP] levels, protein synthesis, oxygen consumption) and normal pH occurs if the ischemic injury is of limited duration. For an excellent recent review of cell death

mechanisms, see [Tovar, Penagos-Puig, and Ramirez-Jarquín \(2015\)](#).

Cell necrosis results from progressive reduction in cellular ATP content and involves a series of morphologic alterations, including swelling of cells and organelles, development of subsurface cellular blebs, amorphous deposits in mitochondria, condensation of nuclear chromatin, and breaks in plasma and cell organelle membranes. Cell death after hypoxic-ischemic insults can also occur by apoptosis. Apoptosis is an energy- and substrate-dependent process. The development of apoptosis involves new protein synthesis and the activation of endonucleases, with a resultant characteristic cleavage of DNA at linkage regions between nucleosomes to form fragments of

**TABLE 104-1** Comparison of the Etiology of Cardiac Arrest for In-Hospital and Out-of-Hospital Cohorts\*†

	In-Hospital Overall (n = 353), n (%)	Out-of-Hospital Overall (n = 138), n (%)	p
Cardiac (not congenital heart disease)	124 (36)	20 (15)	<0.01
Congenital heart disease	130 (37)	6 (4)	<0.01
Respiratory	145 (42)	98 (72)	<0.01
Neurologic	8 (2)	5 (4)	0.53
Drug overdose/ingestion	3 (1)	4 (3)	0.1
Trauma	22 (6)	15 (11)	0.09

**TABLE 104-2** Characteristics of Successfully Resuscitated Pediatric Patients with In-Hospital or Out-of-Hospital Cardiac Arrest

	Out-of-Hospital Cardiac Arrest	In-Hospital Cardiac Arrest
Initial rhythm (%)	Asystolic (46) Bradycardia (10) VF/VT (7)	Bradycardia (49) Asystole (16) VF/VT (10)
CPR duration (median, min)	31	9
Cause (%)	Respiratory (72)	Cardiac (73)
Preexisting chronic condition	49	88
Good neurologic outcome	24	47
Mortality rate (%)	62	51
Neurologic injury as the cause of mortality	69	20

CPR, cardiopulmonary resuscitation; VF, ventricular fibrillation; VT, ventricular tachycardia.

(Modified from Moler FW et al. *Crit Care Med* 2009;37:2259–2267.)

**Figure 104-1. Global ischemia results in a cascade of events.** These include reduction in adenosine triphosphate (ATP), loss of cellular ionic gradients, increases in extracellular  $K^+$  concentration, glutamate release with activation of *N*-methyl-D-aspartate (NMDA) and non-NMDA receptors, calcium influx and release of intracellular calcium, and activation of secondary messenger systems and a variety of destructive enzymatic processes.

double-stranded DNA. The stimuli triggering apoptosis are not clearly defined, although protease activation or oxidant injury to DNA has been proposed. After a global ischemic insult, DNA fragmentation is most pronounced in neurons of the CA1 region of the hippocampus, which suggests that apoptosis may play a role in both selective neuronal necrosis and delayed neuronal death. Apoptosis is also seen in penumbral regions around evolving cerebral infarctions. Because apoptosis occurs in stages, there exist several potential strategies for reducing cell death.

### Calcium-Mediated Injury

Calcium plays a critical role in the regulation of many cellular metabolic processes; therefore the concentration of cytosolic free calcium is tightly controlled. Hypoxic-ischemic injury interrupts intracellular calcium homeostasis, which results in massive increases in the intracellular concentration of calcium. This calcium accumulation is believed to promote irreversible cellular injury (Figure 104-2). Transient calcium accumulation occurs in all cells during ischemia, but secondary irreversible accumulation occurs in the selectively vulnerable zones many hours later.

The disturbance of intracellular calcium homeostasis is recognized as a final common pathway of neuronal death, either necrotic or apoptotic. These conditions, in concert with excessive release of calcium-dependent excitatory neurotransmitters (glutamate, aspartate), lead to uncontrolled excitotoxicity and cell death.

### Excitotoxic Injury

During hypoxic-ischemic damage, pathologically prolonged membrane depolarization occurs and, in certain neuronal populations, leads to excessive release of neurotransmitters into the synaptic cleft. The effect of these neurotransmitters is

prolonged by failure of the ATP-dependent presynaptic reuptake mechanisms. Glutamate and aspartate are the major excitatory amino acid neurotransmitters in the mammalian CNS.

### Activation of Intracellular Enzymes

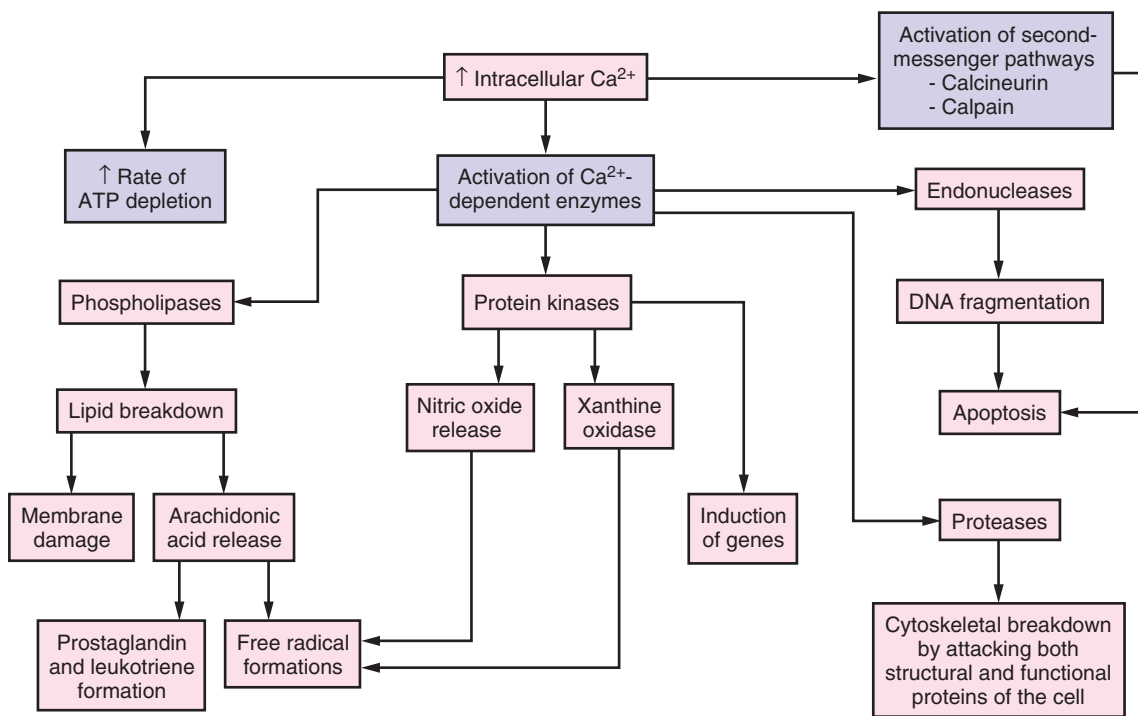

The marked increase in intracellular calcium concentration activates a number of important enzymes. Phospholipases break down the lipid cellular membrane, releasing arachidonic acid that generates prostaglandins and free radicals. Protein kinases activate enzymes in an unordered manner, including nitric oxide synthase and xanthine oxidase, which are also generators of free radicals. Proteases begin the uninhibited breakdown of the cytoskeleton, and endonucleases initiate DNA fragmentation.

### Phospholipase Release of Free Fatty Acids

Free fatty acids are released from neuronal membranes during ischemia and have potential detrimental effects through at least three mechanisms (Figure 104-3). First, free fatty acid metabolism via the cyclo-oxygenase pathway contributes to oxygen radical production during reperfusion. Second, free fatty acid and diacylglycerol directly increase membrane fluidity, inhibit ATPases, increase neurotransmitter release, promote brain edema, and uncouple oxidative phosphorylation. Third, enzymatic oxidation of arachidonic acid during reperfusion by cyclo-oxygenase, lipoxygenase, or cytochrome P-450 produces a large number of bioactive lipids (prostaglandins, thromboxanes, leukotrienes, and hydroxyl acids), many of which have detrimental effects.

### Activation of Nitric Oxide Synthesis

Nitric oxide plays a multifaceted role in the brain as a neurotransmitter and a regulator of CBF. Sites of nitric oxide

**Figure 104-2.** Increases in intracellular  $\text{Ca}^{2+}$  mediate several enzymatic pathways that cause cell injury. These include pathways of protein kinases, proteases, phospholipases, nitric oxide synthase, other free radical synthesis, and endonucleases, and other second-messenger systems. The net effect is related to the severity and duration of ischemia and a series of complex events that results in cell necrosis and apoptosis, and other forms of partial injury that remain poorly understood. ATP, adenosine triphosphate.

production include neurons, vascular endothelium, perivascular neurons, and astrocytes (Figure 104-4). If present in abnormally high concentrations, nitric oxide may exert neurotoxic effects.

Nitric oxide is produced in a reaction catalyzed by nitric oxide synthase, in which oxygen and L-arginine are converted into L-citrulline and nitric oxide. Neurons containing nitric oxide synthase are present throughout the brain, with the highest concentration in the cerebellum and the lowest concentration in the medulla.

As part of the excitotoxic cascade of injury, glutamate release activates both endothelial and neuronal nitric oxide synthase, which increase nitric oxide production during focal and global ischemia. Nitric oxide produced under conditions of ischemia contributes to the cytotoxicity of glutamate, presumably through hydroxyl radical production (Figure 104-4). Nitric oxide and superoxide radical react to form peroxynitrite, which then decomposes to yield nitrogen dioxide and the

toxic hydroxyl radicals. An established pathway of nitric oxide-mediated neuronal cell death is nitric oxide activation of the nuclear enzyme poly-adenosine diphosphate (ADP)-ribose-synthetase (PARS). Nitric oxide activates PARS by damaging DNA. (Nitric oxide synthase isoforms are shown in Table 104-3).

Depending on its source, nitric oxide may be toxic or protective in the brain under ischemic conditions. Overproduction of nitric oxide from either neuronal or inducible nitric oxide synthase leads to neurotoxicity; however, nitric oxide production from endothelial nitric oxide synthase protects brain tissue by maintaining regional CBF.

## Formation of Oxygen Radicals

Toxic oxygen radical species, produced during postischemic reperfusion, are important contributors to reperfusion injury and delayed cell death. Oxygen free radicals are formed during ischemia when oxygen becomes unavailable as the terminal electron acceptor in the electron transport chain (Figure 104-5).

The brain may be particularly vulnerable to free radical injury for several reasons. One is the high concentration of polyunsaturated fatty acids, especially arachidonic acid. As noted previously, free fatty acids are released throughout ischemia. On exposure to oxygen radical species, these free fatty acids are vulnerable to lipid peroxidation. Lipid membranes are a natural target of free radicals, especially in the brain, because they are abundant, and their polyunsaturated nature makes them easy to oxidize. The effects of free radicals on membranes include changes in membrane fluidity and alteration of ion channels and transport proteins. In addition to disruption of the cell membrane, fragmentation of the mitochondrial membrane results in a decrease in cellular energy production.

The ability of the cell to defend itself against free radicals is limited, and free radical-scavenging enzymes, such as superoxide dismutase and catalase, may be overwhelmed after an ischemic area is reperfused. Surprisingly, restoration of blood flow to hypoxic-ischemic areas is potentially detrimental because the influx of oxygen can be used as a source of oxygen free radicals through the processes noted previously. Stimulated by high tissue carbon dioxide tension, low oxygen tension, and low pH, restored blood flow to an ischemic area is often increased above normal (luxury perfusion).

**Figure 104-4.** Excessive nitric oxide is formed on sustained glutamate stimulation of *N*-methyl-D-aspartate receptors (NMDA-Rs). Nitric oxide (NO) freely diffuses to adjacent target neurons, in which it combines with the superoxide anion ( $O_2^-$ ), produced by mitochondria and xanthine oxidase, to yield the peroxynitrite anion ( $ONOO^-$ ), which is an extremely potent oxidant.  $ONOO^-$  also is protonated and decomposes to the hydroxyl (OH) free radical and the nitrogen dioxide ( $NO_2$ ) free radical, which are potent activators of lipid peroxidation. Damaged DNA activates the nuclear enzyme poly-adenosine diphosphate (ADP)-ribose synthetase (PARS). PARS transfers ADP-ribose units to nuclear proteins by using nicotinamide adenine dinucleotide (NAD) as the source of ADP-ribose. For every mole of NAD consumed in this reaction, it takes four energy equivalents of adenosine triphosphate to regenerate NAD from nicotinamide. PARS can transfer more than 100 ADP-ribose units/protein in a matter of seconds. This rapid consumption of energy can deplete a cell of its energy stores. It is hypothesized that if there is sufficient DNA damage and free radical production, the activation of PARS initiates a futile cycle, resulting in the complete depletion of cellular energy stores, impairment of the ability to regenerate those energy stores, and, subsequently, cell death. CaM, calmodulin; L-arg, L-arginine; L-cit, L-citrulline; NOS, nitric oxide synthase;  $ONOOH$ , peroxynitrous acid.

## Neuroinflammation, Glia, and the Neurovascular Unit

Numerous studies have implicated activation of astrocytes and microglia and formation of the "inflammasome" after global hypoxia-ischemia. The release of proinflammatory cytokines and activation of complement contributes to recruitment of microglia and breakdown of the blood-brain barrier. Failure of normal astrocyte function results in increased synaptic excitation associated with increase in extracellular potassium (as a result of downregulation of Kir4.1 inward rectifying potassium channels), an increase in glutamate (as a result of downregulation of astrocyte glutamate transporters), and cerebral edema (through compromise of aquaporin-4 transporters). The neurovascular unit (comprising neurons, astrocytes, endothelial cells of blood-brain barrier, myocytes, pericytes, and extracellular matrix components) regulates CBF. By regulating cerebral blood vessel diameter, astrocytes play a central role in neurovascular coupling, a mechanism by which CBF is directly coupled to the fluctuating metabolic requirements of neurons. The functioning of the neurovascular unit is

disrupted by focal or global ischemic insult. Compromise of neurovascular coupling may contribute to long-term symptoms following cerebral hypoxia-ischemia, as has been shown for traumatic brain injury (TBI).

### Genetic Damage and Regulation

Ischemia and reperfusion can induce gene damage in the CNS. Reactive oxygen species generated by cerebral oxidative stress interact with nucleic acids and cause the formation of oxidative DNA and RNA lesions that result from DNA base modifications or single-stranded breaks in neurons or astrocytes. Oxidative DNA lesions cause a change in coding properties during DNA and RNA synthesis (replication and transcription) or may terminate chain elongation during transcription and translation. Either process can affect protein synthesis.

### Autophagy

Autophagy is a normal homeostatic mechanism that allows cells to recycle intracellular proteins, lipids, and damaged organelles into their constituent molecules (amino acids, fatty acids). Autophagy is essential for the normal function of neurons and the brain. Under normal conditions, this process is constant, energy dependent, tightly regulated, and it occurs at a low level. Defects in autophagy may result in a cell's inability to eliminate toxic macromolecules that result from a variety of normal cellular processes or are synthesized in response to a stress. Following hypoxic-ischemic insults, autophagy may cause cellular injury by intracellular accumulation of toxic substances.

## CLINICAL PATHOPHYSIOLOGY

### Cerebral Blood Flow and Metabolism After Resuscitation

A pattern of early transient postischemic hyperemia and subsequent delayed postischemic hypoperfusion has been observed almost universally in global cerebral ischemia models, including asphyxia-induced cardiac arrest. The level of hyperemia and subsequent hypoperfusion varies in relation to the duration of the insult. Although these phases of increased and decreased CBF characterize the net global effect, regional CBF is often heterogeneous, particularly during postischemic hypoperfusion, when areas of decreased and increased perfusion may coexist. Metabolism, as assessed by the cerebral metabolic rate for oxygen, is reduced during the early postischemic period and then progressively recovers to a level that varies depending on the model used and the duration of ischemia.

The concept of "no reflow" was suggested by [Ames and colleagues in 1968](#). These investigators noted that, after a period of global cerebral ischemia, flow could not be reestablished. At a microscopic level, areas of "no reflow" are interspersed with areas of restored blood flow and microinfarcts. Brain regions that are selectively vulnerable include the thalamus, amygdala, hippocampus, and striatum. Vasospasm, perivascular edema, and increased blood viscosity have been proposed as potential mechanisms. The second phase of the CBF response to global hypoxia-ischemia is characterized by increased global CBF and is often referred to as the "hyperemic" phase.

In summary, immediately after cardiac arrest accompanied by restoration of systemic hemodynamic stability, transient global brain hyperemia occurs and is followed by a period of patchy hypoperfusion. The magnitude and duration of these CBF alterations appear to be related to the duration of the

insult. In patients with good outcomes, global CBF recovers over a subsequent 24 to 72 hours, and CO<sub>2</sub> reactivity remains intact. In patients who do not regain consciousness or progress to brain death, CBF is reduced, and autoregulation of CBF is compromised or lost.

### MAJOR DISORDERS CAUSING CARDIAC ARREST

Table 104-4 lists common causes, by category, of pediatric cardiorespiratory arrest taken from major published pediatric cardiac arrest series. Common specific disease entities resulting in cardiac arrest include nonaccidental trauma, drowning, sudden infant death syndrome, strangulation, and lightning/electrical injury.

### Abusive Head Trauma

Please see Chapter 103 for a discussion of this topic.

### Sudden Infant Death Syndrome

Sudden infant death syndrome (SIDS) is defined as the sudden death of an infant younger than 1 year that remains unexplained after a thorough case investigation, including performance of a complete postmortem examination, examination of the death scene, and review of the medical history. The diagnosis remains one of exclusion. This topic also is discussed in Chapter 90.

### Drowning (Submersion Injury)

Drowning is defined as the process resulting in respiratory impairment from submersion or immersion in a liquid medium. In the United States drowning is the second leading cause of unintentional injury death for children and accounts for more than 1000 deaths per year. Pediatric hospitalization rates for drowning have been increasing over the past 19 years ([Bowman, Aitken, Robbins, and Baker, 2012](#)).

### Epidemiology

In the United States submersion accidents remain the second most common cause of injury and death in children 1 to 4 years of age. Children younger than 5 years have the highest drowning mortality rates. Annually, about 1100 drowning deaths occur in the United States in children younger than 19 years. Approximately 75% of these victims are children of the ages of 1 to 4 years. Just over one-half of these drowning deaths occur in residential pools. The distribution of submersion accidents by age follows a well-defined bimodal pattern. Children younger than age 5 years represent the first peak, which is followed by a second peak at ages 16 to 24 years.

**Management.** Rapid application of cardiopulmonary resuscitation (CPR) provides the best chance for neurologic perfusion and recovery after a drowning event. [Table 104-2](#) lists factors associated with successful resuscitation for in- and out-of-hospital arrest. In the event of respiratory arrest without cardiac arrest, rescue breathing alone, with reestablishment of ventilation and oxygenation, may be sufficient to ensure good neurologic recovery. In the setting of drowning, reestablishment of ventilation and oxygenation via rescue breathing is, along with chest compressions, essential to effective resuscitation.

As with other forms of acute brain injury and resuscitation, hypoxemia should be identified and corrected as soon as possible, preferably in the field. Airway management and mechanical ventilation are often required to maintain oxygenation and ventilation. Drowning victims present with concomitant

respiratory and metabolic acidosis and hypoxemia; efforts to repair these metabolic conditions should begin with initiation of resuscitation. Similarly, hypotension may have a negative effect on the recovery of the ischemic brain and should be identified and reversed as soon as possible.

### Strangulation Injury

Strangulation injuries result from external compression of the neck. Several forms have been described according to the method of application of compression, including hanging, postural strangulation, manual strangulation, and ligature strangulation. Children who are pulseless when discovered after hanging are at significantly higher risk for death or disability, with one study finding an 84% mortality rate (Davies, Lang, and Watts, 2011).

### Lightning and Electrical Injuries

Lightning is an uncommon form of electrical injury. Only 150 to 300 people die each year in the United States of injury secondary to lightning strike; the death rate is highest in adolescents. Nearly two-thirds of people struck by lightning survive, although many have significant sequelae.

The primary effect of lightning results from a massive direct-current insult to the entire myocardium and CNS, which is highly sensitive to electrical injury. Myocardial injury may result in secondary CNS anoxic insult. The pathophysiologic mechanism of CNS injury includes coagulation in the cortex, formation of epidural or subdural hematomas, paralysis of the respiratory center, and intraventricular hemorrhage. Symptoms of CNS injury include loss of consciousness, confusion, transient disorientation, seizures, restlessness, retrograde amnesia, and varying degrees of transient paralysis. Coma and symptoms of cerebral edema are not unusual. Lightning strikes may also cause transient autonomic dysfunction, which may result in fixed and dilated pupils, mydriasis, anisocoria, loss of the red reflex, and Horner's syndrome. Pupillary responses cannot be used reliably as an indicator of brainstem function.

### Electrical Shock

Electrical shock is associated with a fatality rate of 0.5 per 100,000 per year in the United States and accounts for approximately 1000 deaths annually. Cardiopulmonary arrest is the primary cause of immediate death from electrical injury. Respiratory arrest may occur immediately after electrical shock. Electrical injuries cause an additional 5000 patients to require emergency treatment and constitute 4% to 7% of burn center admissions. More than 20% of all electrical injuries occur in children. Risk-taking behavior among adolescent boys can expose them to high-tension electrical sources. The inquisitive nature of toddlers and their habit of exploring their environment with their mouths contribute directly to the most common electrical injury in childhood, the perioral burn, which affects 4000 children per year.

### Sudden Cardiac Arrest in Children and Adolescents

Sudden cardiac arrest is the sudden cessation of cardiac activity, so that the victim becomes unresponsive, with no normal breathing and no signs of circulation. Without immediate CPR and other treatments to restore normal cardiac activity, the victim will die. Although the precise incidence of sudden cardiac arrest in children is unknown, it is not a leading cause of death.

When sudden cardiac arrest does occur in children and adolescents, it may be precipitated by ventricular fibrillation or rapid ventricular tachycardia (pulseless ventricular tachycardia). Ventricular fibrillation occurs in 5% to 15% of all pediatric victims of out-of-hospital cardiac arrest and is reported in up to 20% of pediatric in-hospital arrests at some point during resuscitation. The incidence increases with age. These abnormal heart rhythms in children are typically caused by inherited or congenital cardiac conditions or by acute medical problems that cause inflammation of the heart. Examples of such conditions include long QT syndrome, hypertrophic cardiomyopathy, abnormal development of the coronary arteries, aortic dissection, myocarditis, coronary artery aneurysm associated with Kawasaki's disease, and congenital aortic stenosis. If a child develops sudden cardiac arrest caused by ventricular fibrillation or pulseless ventricular tachycardia, immediate CPR by a bystander and early defibrillation are needed.

### NEUROLOGIC COMPLICATIONS AFTER CARDIAC ARREST

There is now an accepted role for the use of continuous (cEEG) monitoring in adults and children for the detection of secondary injuries, including seizures and ischemia, in critically ill patients with altered mental status, and for prognostication after cardiac arrest (Herman et al., 2015). This recommendation also applies to neonates. In a study of 90 term neonates treated with therapeutic hypothermia for HIE who underwent cEEG monitoring on day of life 1, 48% had electrographic seizures, of which 9 (10%) had electrographic status ellipticus. Importantly, only the initial EEG background, but not any clinical variables, was predictive of the occurrence of seizures.

### Delayed Posthypoxic Injury

Delayed posthypoxic injury may occur 24 to 48 hours after the initial recovery of consciousness after coma. In children, this injury occurs most frequently after near-drowning accidents or cardiac surgery in which profound hypothermia and either low-flow bypass or circulatory arrest were used. Magnetic resonance imaging (MRI) studies may reveal evidence suggestive of edema or demyelination, which may be postanoxic or osmotic in etiology. In addition, diffusion-weighted imaging may reveal restricted diffusion, typically in the basal ganglia, cerebellum, and cortex. These changes are seen initially in gray matter and later in white matter.

### Postischemic Seizures

The use of EEG as a prognostic tool in critically ill patients has been limited by a lack of consensus on EEG classification systems. However, in a study of 35 children treated with therapeutic hypothermia (TH) after cardiac arrest who underwent cEEG monitoring, a simple classification system (continuous and reactive; continuous but unreactive; any degree of discontinuity, burst suppression, or lack of cerebral activity) was predictive of short-term outcome (Pediatric Cerebral Performance Category Score scale at hospital discharge). At present, despite the progress still needed for uniform definitions of EEG abnormalities, it is reasonable to conclude that mild slowing and rapid improvement of the EEG are predictive of good outcome, whereas lack of reactivity, attenuation, or burst suppression are not. Another prospective study of all children admitted to a pediatric and cardiac intensive care unit has provided some of the best evidence that electrographic seizure burden independently is associated with a poorer outcome.

Whether treatment of such seizures improves outcome will require additional studies.

### Delayed Postanoxic Myoclonic Seizures

Myoclonus usually appears within the first 24 to 48 hours after cardiac arrest and is generalized, involving all voluntary muscles. The EEG is usually abnormal, with generalized synchronous spike discharges or burst-suppression activity. The presence of postanoxic myoclonus is usually indicative of a high risk for long-term neurologic sequelae.

In one study of comatose adult patients after cardiac resuscitation, myoclonic seizures developed in 37%, and all of those patients died. The authors concluded that myoclonic status epilepticus in comatose survivors after cardiac resuscitation indicates devastating anoxic brain injury (Table 104-5).

### Paroxysmal Sympathetic Hyperactivity

Disturbance in autonomic nervous system function may present after any brain injury, and a brain suffering from global ischemia, as in cardiac arrest, is particularly susceptible. Historical reports estimate that up to 8% to 33% of patients suffering TBI and 6% to 29% of patients with global anoxic injuries may exhibit paroxysmal sympathetic hyperactivity (PSH). PSH is characterized by sudden, paroxysmal changes in vital signs manifest as hyperthermia, tachycardia, hypertension, and/or tachypnea. Associated findings on examination may include pupillary dilatation and diaphoresis. Patients suffering from PSH may exhibit agitation and hypertonia with extensor posturing during events.

A recent retrospective analysis examined the medical records of 249 children admitted to an intensive care unit with acute brain injuries (TBI, global ischemia, focal ischemia, CNS infection) over a 7-year period. Overall, 13% of patients had treatment for dysautonomia. Most individuals with PSH manifest symptoms over a week after the initial CNS insult.

The timing of onset of symptoms of PSH is variable, and identification of PSH requires a high index of suspicion. To establish the diagnosis the clinician should assess for other events that might cause similar physiologic derangements, including narcotic or other drug withdrawal, pain in response to an occult injury (fracture, dislocation), urinary retention or ileus, seizure, and occult infections. Treatment of acute bouts of PSH includes administration of medications aimed at providing symptomatic relief and reducing sympathetic tone, including propranolol or clonidine, narcotics (morphine), benzodiazepines (lorazepam), and antipyretic agents (acetaminophen or ibuprofen). No single drug has proven effective, but combinations of long-acting benzodiazepines, gabapentin, and baclofen are often used.

### NEUROLOGIC PROGNOSIS AFTER CARDIAC ARREST

Currently, the most powerful individual predictor of neurologic outcome after cardiorespiratory arrest is the neurologic examination. Sequential observations of a patient's breathing pattern, eye movements, body posture, and reflexes provide essential information to help predict outcome. A study involving 109 comatose children with hypoxic-ischemic encephalopathy documented that the absence of a motor response on the third day after admission was associated with an unfavorable outcome. Nevertheless, in 23% of the children, clinical evaluation was difficult because of neuromuscular paralysis or heavy sedation. This reinforces the importance of other early prognostic factors, such as electrophysiologic data.

The absence of a pupillary reaction to light suggests a poor prognosis but has unclear specificity when assessed early after a cardiac arrest. Early after an arrest the pupillary reflex might be absent; however, studies have demonstrated that persistence of pupillary dysfunction at day 3 after cardiac arrest can reliably predict a poor outcome. After review of existing evidence in adults in coma, the American Academy of Neurology stated that outcome is invariably poor when there is absent pupillary light reflex, absent corneal reflex, and no or only extensor motor response to pain 3 days after cardiac arrest.

### Electroencephalography Following Cardiac Arrest

There is now a specific recommendation for the use of cEEG monitoring for the detection of nonconvulsive seizures and to aid in prognosis after supratentorial brain injury, including cardiac arrest, in children and adults (Herman et al., 2015). Specific EEG patterns can be used to predict outcome. Background EEG features such as continuity, spontaneous variability, reactivity, and sleep patterns suggest good outcome, whereas an isoelectric EEG or burst suppression increases the likelihood for an unfavorable outcome.

### Somatosensory- and Auditory-Evoked Potentials

Evoked potential monitoring has been used in an attempt to provide early prognostic outcome information after CPR (Figure 104-6). Evoked potentials can be obtained within the intensive care unit; their advantages over EEG are that the responses are not affected by sedative medication and they are insensitive to environmental electrical noise. In a study of sensory-evoked potentials (SEPs) in 441 adults after successful resuscitation from cardiac arrest, 20% of the patients had no N<sub>20</sub> response. The presence or absence or the prolongation of the cortical N<sub>20</sub> peak reliably differentiated between poor versus favorable outcome with 100% predictive ability. A preserved N<sub>20</sub> peak was not useful for discriminating whether an individual patient would survive. Testing was performed within 48 hours of resuscitation, which is a clinically relevant time frame. In a single-center study of 56 unconscious children and adults (age range 10–73 yr), the presence of an N<sub>20</sub> response was an independent predictor of recovery of awareness up to 1 year after injury.

Brainstem auditory-evoked testing has been used in children who experienced cardiac arrest after submersion accidents. Normal evoked responses were observed in all children who recovered neurologically intact. Children who recovered with significant handicaps demonstrated reduction in wave V amplitude over time and prolonged wave I through V interpeak latencies.

### Neuroimaging

Please see the online version of this chapter as well as Chapter 12 for an overview of this topic as it relates to neuroimaging findings after hypoxic-ischemic injury (HII), Chapter 19 on neonatal HII because the findings in older children are similar to those in newborn, and Chapter 103 on post-TBI imaging findings because frequently there is a component of HII in this patient population.

The majority of the data using diffusion-weighted imaging (DWI) and apparent diffusion coefficient (ADC) MRI sequences are from adult studies of cardiac arrest outcomes. Reduction in ADC values is highly predictive for poor outcome after cardiac arrest in adults. Reports in children also suggest

that cortical and/or basal ganglia lesions detected with DWI/ADC, FLAIR, or T2-weighted imaging are associated with poor outcomes. An example of the differences in MRI findings between a good and poor outcome following cardiac arrest is shown in Figure 104-7. Overall, the available neuroimaging data suggest that the regional patterns of brain injury and changes in magnetic resonance spectroscopy produced by global hypoxic-ischemic insults are similar in adults and children, although many of these studies are limited by the lack of long-term outcomes.

Issues that require further study for children include the optimal time to acquire MRI for the purpose of predicting long-term outcome, whether regional versus whole-brain data are more sensitive/specific, and whether such imaging data can provide more granular information regarding the degree of disability that are superior to currently used measures such as the Glasgow Outcome Scale (GOS) or Pediatric Cerebral Performance Category Scale score.

## TREATMENT

Treatment of children with global hypoxic-ischemic brain injuries involves multiple specialties and a systematic approach to providing emergency care in the field, emergency department, and intensive care unit (Donoghue, et al., 2015). Urgent neuroimaging studies and early neurologic evaluation are helpful in the initial evaluation to determine the presence of a neurosurgical condition that necessitates immediate treatment, the etiology of injury, and the appropriate course of treatment specific to each of the four phases of cardiac arrest (Table 104-6).

### Temperature Control

The effect of hypothermia on the injured brain is complex. For each 1°C decrease in temperature, the cerebral metabolic rate for oxygen decreases by 6% to 7%. However, hypothermia's main beneficial effect is to provide protection against numerous deleterious biochemical mechanisms as described previously.

Despite the great promise of therapeutic hypothermia, enthusiasm for the clinical application for treatment of out-of-hospital cardiac arrest has waned following the first results from the THAPCA study (Moler et al., 2015). The THAPCA trials included two multicenter, randomized controlled trials in which patients were assigned to either a controlled normothermia (36.8°C) protocol or a moderate hypothermia (33.0°C) protocol. Results of the out-of-hospital cardiac arrest study showed no treatment benefit with TH. In this study, 295 patients were enrolled and randomized, and 1-year survival and neurologic outcome analysis demonstrated no statistically significant difference in good neurologic outcome (20% in hypothermia vs. 12% in normothermia; 95% confidence interval [CI], 0.86–2.76;  $P = 0.14$ ). or survival (38% in hypothermia vs. 29% in normothermia; 95% CI, 0.93–1.79;  $P = 0.13$ ). A concurrent trial is examining the effects of TH on neurologic outcome and survival of pediatric patients suffering cardiac arrest while admitted to the hospital. These results have not yet been published. Hyperthermia is common after cardiac arrest in children and is associated with poor neurologic outcome. This may represent either noxious effects of hyperthermia on the injured brain or a worse insult overall with multiorgan system failure and impaired autonomic control of thermoregulation. As little as 1°C of hyperthermia appears to be important (Bowman et al., 2012). Therefore, postcardiac-arrest temperature elevations should be actively prevented and treated. Indeed, patients in the control group in the THAPCA study were maintained within a narrow

temperature range, preventing hyperthermia, and this itself was likely neuroprotective.

## Resuscitation

For pediatric cardiac arrests in the prehospital setting, CPR and advanced life support from emergency medical service providers may be applied late, after prolonged hypoxia and hypoperfusion of vital organs. Animal and human data both show that basic life support delivered early is more important than advanced life support delivered late. Prompt action by a citizen bystander in the prehospital setting is generally more effective than late heroic efforts in the intensive care unit. On-scene time spent resuscitating the patient is critical. A study of 2244 children using the Resuscitation Outcomes Consortium cardiac arrest database from 11 North American regions from 2005 to 2012 showed the highest survival (10.2%) among those with a duration of resuscitation of 10 to 35 minutes and those who received fluid resuscitation.

### Intracranial Pressure Monitoring and Control

See Chapter 105 for a discussion of this topic.

### Glucose Homeostasis

Observations in animals and humans have suggested that an elevated serum glucose level at or about the time of an ischemic insult is associated with enhanced postischemic damage of cerebral tissue. Preexisting hyperglycemia worsens the outcome from global hypoxic-ischemic injury in adult and juvenile animals. Outcome from out-of-hospital cardiac arrest is worse in adults with elevated glucose concentrations at admission and in hyperglycemic children after submersion injury.

The optimal level of either low or elevated blood glucose determinations after resuscitation from either a global or focal hypoxic-ischemic event has not been determined. From a practical standpoint, it seems wise to avoid hypoglycemia in a neonate with hypoxic-ischemic injury and to avoid hyperglycemia (i.e., > 300 mg/dL) in older patients.

### Cardiovascular Support

Persistent circulatory insufficiency is common in the postarrest state when there is return of spontaneous circulation. Arterial hypotension can result from a combination of factors, including myocardial stunning, neurally mediated cardiac dysfunction, relative adrenal insufficiency, and a profound proinflammatory response related to global ischemia and reperfusion injury that induces a sepsis-like state. Although the optimal cerebral perfusion pattern for neuronal recovery remains to be defined, blood pressure fluctuations adversely affect outcome. The phase of therapy following return of spontaneous circulation is a critical window of opportunity to influence survival and neurologic function after cardiac arrest.

A recent retrospective observational study examining blood pressure in adults after in-hospital cardiac arrest demonstrated that maintaining mean arterial pressures within a predefined range during the immediate postresuscitation phase was associated with survival and good neurologic function. Among the 319 adult arrest victims, 56 survived with a favorable neurologic outcome; the mean arterial pressure (MAP) in this group was 95 mm Hg, and favorable outcome was statistically correlated with postresuscitation MAP greater than 85 mm Hg. Subphysiologic and supraphysiologic blood pressures both trended toward nonsurvival and poor functional survival. This study did not control for preexisting hypertension, but these results suggest that extremes of blood pressure after cardiac arrest are important contributors to neurologic recovery.

## Extracorporeal Membrane Oxygenation-Cardiopulmonary Resuscitation

Perhaps the ultimate technology to control postresuscitation temperature and hemodynamic parameters is extracorporeal membrane oxygenation (ECMO). In addition, the concomitant administration of heparin may optimize microcirculatory flow. The use of venoarterial ECMO to reestablish circulation and provide controlled reperfusion following cardiac arrest has been published, but prospective, controlled studies are lacking. See the online chapter for additional discussion.

## Postcardiac-Arrest Brain Injury—Potential Therapies

Despite validation of numerous therapeutic targets in pre-clinical studies, none of the interventions tested thus far in prospective clinical trials has improved outcomes after out-of-hospital cardiac arrest. The gap between compelling preclinical data and translation to effective clinical therapy is common to other forms of acute CNS injury. For example, the PROTECT investigators examined the effects of early progesterone administration in the setting of severe TBI in adults. This therapy, for which convincing animal evidence demonstrating improved recovery and neuroprotection had been obtained, demonstrated no benefit over placebo when administered in adult humans.

Other evidence from pediatric neurotrauma suggest that expertise with a particular condition and adherence to evidence-based guidelines can result in improved survival and functional outcome. In addition, the development of formal pediatric multidisciplinary neurocritical care clinical programs may have some effect on improved outcomes after critical CNS injury. Introduction of such a team for the treatment of severe TBI resulted in a decrease in mortality from 52% to 33%. Collectively, these studies suggest that in the absence of new cellular or molecular therapeutics, we may still be able to improve outcomes with available care and monitoring strategies for cardiac arrest. A meta-analysis of more than 18,000 episodes in 16 data sets of children with cardiopulmonary arrest who received an attempt at resuscitation suggested that the lack of consistent outcome reporting and short-term neurologic outcome measures limit conclusions about recovery from cardiac arrest in children (Phillips, et al., 2015). This underscores the need for caution in conclusions about success or failure of therapies such as therapeutic hypothermia.

## DILEMMA OF NEUROLOGIC MORBIDITY

Although young children are considered more likely than adults to survive anoxic-ischemic events, much of this pediatric survival appears to result from brainstem recovery. Thus after prolonged ventilatory support, a child may be more likely to recover the ability to breathe and survive, but there will be little or no return of cortical functions. Indeed, survival following cardiac arrest has significantly improved over the last decade (Table 104-5). Physicians are often faced with decisions about the degree of continued medical support to be given to patients who do not awaken after cardiac arrest and, to a lesser degree, with decisions about specific treatment modalities. The degree of medical support that a patient needs after cardiac arrest is straightforward and is based on medical indications. Certain treatment modalities, such as mechanical ventilation, pharmacologic support of the heart, and intravenous nutrition, however, may be considered heroic or futile by the physician or the family. Brain damage in these severely injured survivors is typically profound, and long-term improvement is limited.

Children in such situations require long-term intensive care, which is financially expensive, whether they are supported at home or in long-term care facilities. In addition to issues of the child's well-being and the financial burden, the effect on the family's quality of life is profound, although difficult to quantify. Some of these issues are reviewed in Chapter 164 on ethical issues in child neurology.

## INTRODUCTION

The most robust evidence for the contribution of intracranial hypertension (IIH) to neurologic injury in children is provided by studies of outcomes after severe traumatic brain injury (TBI). Numerous studies involving pediatric patients have demonstrated an association between IIH and neurologic morbidity or survival. Since the last edition of this textbook, new studies have called into question the benefit of intracranial pressure (ICP) monitoring (Chesnut et al., 2012), published updated recommendations for the management of severe TBI (Kochanek et al., 2012), and provided evidence that adherence to these guidelines, including maintaining cerebral perfusion pressure (CPP), improved outcome (Vavilala et al., 2014).

The online version of this chapter contains more extended discussion of the following topics: (1) age dependence of cerebral blood flow (CBF) and normal ICP; (2) noninvasive approaches to ICP monitoring; (3) evidence for pathologic “doses” of increased ICP and abnormal CPP; (4) ICP-directed therapy in nontraumatic causes of increased ICP; (5) clinical manifestations of increased ICP; (6) evaluation and management of intracranial hypotension and idiopathic IIH; (7) effects of gender on ICP; and (8) cellular mechanisms regulating CBF, including the glymphatic system (Iliff et al., 2012).

## PATHOPHYSIOLOGY OF RAISED INTRACRANIAL PRESSURE

The skull is a rigid cavity and its contents are relatively non-compressible, consisting of the brain parenchyma, intravascular blood, and CSF. Expansion in the volume of one component can be offset by a decrease in the volume of the others (Monro-Kellie doctrine). When the reserve of each compartment to accommodate increases in volume is exhausted, the slope of the pressure-volume relationship becomes hyperbolic, and small increases in volumes cause large increases in ICP (Figure 105-1 and Box 105-1).

## Compliance and Cerebral Blood Flow Changes with Age

The pressure-volume relationships in the brain are expressed by the equation  $C \sim dV/dp$ , where  $C$  represents compliance and  $dV$  represents the change in volume that accompanies a change in pressure ( $dp$ ). As ICP rises, compliance decreases. In the healthy brain, compliance is along the horizontal segment of the curve, whereas in a damaged, swollen brain, compliance is located along the vertical segment of the curve. The overall slope of the pressure-volume curve is steeper in infancy than in older children (Figure 105-2). An increase in intracranial volume by 10 mL is not likely to cause as much of an increase in ICP in an adolescent as in an infant.

CBF decreases from age 3 years (approximately 60 mL/100 g/min) to 18 years (approximately 50 mL/100 g/min) after a transient increase at age 6 years (approximately 70 mL/100 g/min). The relationship between ICP and blood flow is a

function of changes in systolic (S) and diastolic (D) arterial pressure (AP) expressed as follows:  $CPP = MAP - ICP$ , or  $CPP = [(SAP + 2DAP)/3] - ICP$  (CPP, cerebral perfusion pressure; MAP, mean arterial pressure).

## Cerebral Autoregulation

CPP reflects the vascular pressure gradient across the cerebral beds, and is determined by both the CPP and cerebrovascular resistance (CVR), according to the formula  $CBF = CPP/CVR$ . Under normal conditions, CBF can be maintained as a constant of approximately 50 mL/100 g/min over a wide range (60–150 mm Hg in the healthy brain) of CPP (Figure 105-3). When autoregulation is preserved, increasing blood pressure leads to a progressive compensatory decrease in the caliber of cerebral resistance, thereby maintaining a constant CBF by increasing CVR. As CVR increases, cerebral blood volume decreases and ICP falls if autoregulation is intact. When CPP falls below the lower limit of autoregulation (LLA) (40–50 mm Hg), CBF decreases as the autoregulatory reserve is exhausted, and the system becomes pressure-passive. The severity of the resulting ischemic injury will depend on the degree and duration of decreased CBF, with ischemic injury beginning at approximately 18 to 20 mL/100 g/min. Conversely, when compliance is impaired and shifted to the steep segment of the pressure-volume curve, autoregulation is also impaired, and even minor increases in CBF can lead to hyperemia and significant rises in ICP.

## Effects of Intracranial Hypertension on Autoregulation

Autoregulation of CBF in healthy adults is constant, between a CPP of 50 and 150 mm Hg or a MAP of 60 and 160 mm Hg. Under these conditions, changes in CPP or MAP have little effect on CBF. Autoregulation is compromised after TBI, and maintaining adequate CPP to overcome the effects of increased ICP is a cornerstone of medical management in the algorithms for treatment of TBI in adults. In children, the incidence of impaired cerebral autoregulation increased with the severity of injury, and ranges from 17% after mild injuries up to 42% after severe injuries. After TBI, autoregulation may be compromised without radiographic evidence of injury. Dysfunction of autoregulation may worsen over 9 days after severe TBI.

The LLA of CBF is the CPP at which vascular reactivity fails and CBF cannot be maintained despite arterial hypotension (see Figure 105-3). As CPP decreases below the LLA, the relation of CBF to CPP is passive and CBF falls linearly with CPP. The relationship of ICP to changes in the LLA is not well understood. Evidence from a piglet model of controlled cortical impact suggests that the upper limit of CBF autoregulation is decreased as ICP increases.

If this relation is shown to occur in children with IIH, this implies that (1) monitoring autoregulation should be included in the management of these patients; (2) treating acute increases in ICP with an equal increase in arterial blood pressure may be insufficient to maintain CBF as the LLA increases with increased ICP; and (3) the zone of autoregulation narrows

**Figure 105-3. Schema of cerebral autoregulation.** When mean arterial pressure (MAP) and cerebral perfusion pressure (CPP) are maintained in the normal range for age, cerebral blood flow (CBF) is constant. When pressure falls below the lower limit of autoregulation, or autoregulation is compromised by either increased intracranial pressure (ICP) or other metabolic derangements, the resulting fall in CBF causes ischemia and then infarction. Conversely, when MAP or CPP becomes too high, autoregulation fails and CBF becomes pressure-passive, resulting in hyperemia, increased cerebral blood volume (CBV), loss of compliance, increased ICP, and cerebral tamponade.

as ICP increases requiring meticulous control of blood pressure to preserve optimal CPP.

## Regulation of Cerebral Blood Flow

CBF is mostly regulated at the level of precapillary cerebral resistance by a combination of glial, neurogenic, myogenic, and metabolic processes, which maintain CBF over a wide range of arterial pressures. Astrocytes play a pivotal role in neurovascular coupling, another mechanism by which cerebral blood vessel diameter is directly coupled to the fluctuating metabolic requirements of neurons. Compromise of neurovascular coupling may contribute to long-term symptoms after TBI.

## INTRACRANIAL PRESSURE MONITORING

### History

ICP measurements were first reported in patients with a variety of intracranial lesions by Guillaume and Janny in 1951, using an electromagnetic transducer to measure ventricular fluid pressure signals. Subsequently, Lundberg in 1960 laid the foundation for modern ICP monitoring by providing a method for ventricular cannulation that had a low risk of infection and leakage, enabled continuous recording of ICP, and was minimally traumatic. Lundberg described the following three basic patterns of physiologic changes in ICP:

- Plateau or A waves: increases of ICP in the range of 540 to 650 mm H<sub>2</sub>O (40–50 mm Hg) that are sustained for 2 to 10 minutes
- B waves: brief elevations of a moderate degree (range of 272–408 mm H<sub>2</sub>O [20–30 mm Hg]); related to fluctuations in respiration and also indicative of decreased compliance
- C waves: small-amplitude fluctuations related to intracranial transmission of arterial pulses

## Methods of Intracranial Pressure Monitoring

ICP monitors are classified both anatomically (ventricular, parenchymal, subdural, or extradural) and by mechanism (fluid-coupled or non-fluid-coupled). The external ventricular drain remains the gold standard for reliable and accurate ICP monitoring. This is a fluid-coupled system that provides real-time measurement of ICP, allows CSF drainage to control ICP, and can be recalibrated in situ.

## Noninvasive Approaches to Intracranial Pressure Monitoring

Noninvasive approaches to the measurement of ICP, including tonometry, tympanic membrane displacement, and optic nerve sheath diameter, have been reviewed and critiqued for their lack of accuracy or availability for continuous monitoring. Several such methods have been proposed, including transcranial Doppler (TCD), changes in optic nerve sheath diameter, estimated middle-ear endolymph pressure, and visual-evoked potentials. None of these approaches is in routine clinical use. TCDs can be used in children to estimate ICP, CBF, and CPP and to measure autoregulation.

## THRESHOLDS AND DOSES OF RAISED INTRACRANIAL PRESSURE

The concept of a specific threshold for ICP from which to guide the clinical management of children at risk for increased ICP may be an oversimplification of the pathophysiological processes involved. It is reasonable to think that there are age-dependent differences in the limits of ICP and CPP that may be compatible with survival after acute brain injuries. A number of pediatric studies have sought to determine age-specific changes, and thresholds associated with good outcome, and to develop methods to assess the effects of amplitude and duration of increased ICP.

Using age-specific values, Jones and colleagues examined the relation between the “dose” of abnormal CPP (duration of exposure to abnormal pressure) and favorable or unfavorable outcome. The percentage duration of low CPP, but not raised ICP, was significantly associated both with mortality and the likelihood of poor (nonindependent) outcome.

As part of a larger prospective study of CPP and ICP thresholds affecting outcome after severe TBI, Chambers and colleagues recorded ICP and CPP, acquiring data between 6.3 and 173 hours in 84 children (age 3 months to 16 years) every 2 minutes, and assessed outcome at 6 months using the Glasgow Outcome Scale score (Chambers et al., 2005). Over each 1-hour interval, they calculated the maximum ICP and minimum CPP as a summary measure. They calculated receiver operating characteristic curves for  $ICP_{max}$  and  $CPP_{min}$ , and dichotomized outcome to independent (good recovery or moderate disability) and dependent (severely disabled, vegetative, or dead). These results suggested that the  $ICP_{max}$  threshold for independent outcome was 35 mm Hg, and for  $CPP_{min}$  43 to 45 mm Hg.

### Evidence Supporting Age-Dependent Physiologic Thresholds

The lack of age-specific CPP thresholds was addressed in a study using an online Internet database, TBI-trac, containing data from 22 of the 46 designated trauma centers in New York State (Allen et al., 2014). In this study of 317 children, they measured the survival rates and relative risks of mortality for patients with severe TBI based on predefined age-specific higher and low CPP thresholds (60 and 50 mm Hg for 12 years old or older, 50 and 35 mm Hg for 6–11 years, and 40 and 30 mm Hg for 0–5 years). Based on the significant decrease in survival found in groups with CPP below the goal threshold, this analysis supported age-specific CPP targets above 50 or 60 mm Hg in adults, above 50 mm Hg in 6- to 17-year-olds, and above 40 mm Hg in 0- to 5-year-olds.

This study supported other evidence that a CPP below 35 mm Hg might be a minimal threshold to aim for, as it is associated with reduced mortality. The authors assumed that the zero point for the ICP and blood pressure transducer was uniform across institutions and both set at the level of the foramen of Monro. Since these data were not collected, some patients may have had the head of bed elevated and this may have led to variability in the calculation of CPP. In addition, the authors derived the threshold for increased mortality based on the lowest CPP a patient experienced. Thus a comparison with the “dose” of abnormal ICP or CPP as proposed by other investigators is not possible.

These data suggest that there are age-dependent differences in ICP and CPP after TBI, and that these differences are associated with outcome. Nevertheless, these data do not indicate whether treating ICP or CPP improves outcome, or what the optimal strategies for such management should be.

### Lessons and Limitations of These Studies

Collectively, these data show that elevated ICP and low CPP are associated with poor outcome. Treatment should aim to maintain ICP below 20 mm Hg and CPP above a minimum of 40 mm Hg. There appear to be age-dependent thresholds of ICP, although these thresholds require validation in larger, prospective studies. In general, ICP above 40 mm Hg and CPP below 49 mm Hg are associated with unfavorable outcomes, and CPP may be a superior predictor of outcome. Overall, the interpretation of these pediatric studies is limited by their

mostly retrospective design, relatively short durations of recovery, variable outcome measures, small sample sizes, varying indications for ICP monitoring, and limited data on medical management and therapies to treat IHH.

### INTRACRANIAL HYPERTENSION RELATED TO COMPROMISE OF AUTOREGULATION

Ideally, therapy would be individualized to select the optimal CPP and ICP for each patient. A number of studies have sought to determine the age-dependent thresholds for outcomes associated with abnormal ICP and CPP after TBI, and to calculate the “dose” of physiologic derangement predictive of outcome.

### Calculation of Cerebrovascular Reactivity

Other pressures can also be derived from measurement of ICP and CPP. These include the correlation coefficient between slow waves of the ICP and arterial blood pressure, defined as the pressure reactivity index (PRx). This index reflects the changes in the vasoreactivity of the cerebral vasculature associated with the perturbation of physiologic vascular responses to changes in arterial blood pressure, and is expressed as the correlation coefficient of the linear regression of arterial blood pressure and ICP signals. Under normal conditions, when autoregulation is preserved, a fall in MAP leads to cerebral vasodilatation, and an increase in cerebral blood volume. As MAP falls and cerebral blood volume increases, subject to cerebral compliance, this will lead to an increase in ICP. Conversely, as MAP increases, cerebral vessels vasoconstrict, leading to a decrease in cerebral blood volume and ICP. Thus when the cerebral vascular bed is reactive and autoregulation is preserved, slow waves of arterial blood pressure and ICP values are inversely related and PRx is negative. When pressure reactivity is compromised, slow waves of arterial blood pressure and the ICP change in concert and PRx is positive.

### Autoregulation-Directed Therapy in Pediatric Neurotrauma

In the first study to monitor PRx in pediatric patients with TBI, Brady and colleagues (2009) prospectively studied 21 children with severe TBI to test the hypothesis that intact pressure reactivity would be associated with survival. The average ICP in the survivors ( $11 \pm 4$  mm Hg) was significantly lower than that in nonsurvivors ( $73 \pm 17$  mm Hg,  $p = 0.0005$ ). There was a significant association of PRx with survival. In the survivors ( $n = 15$ ), the mean PRx ( $0.08 \pm 0.19$ ) was significantly lower than that in nonsurvivors ( $0.69 \pm 0.21$ ,  $p = 0.0009$ ). Notably, PRx was dependent on CPP with greater reactivity at higher CPP values, particularly, above 40 mm Hg. These data suggest that measurement of pressure reactivity using PRx can be used in pediatric TBI to identify optimal and harmful CPP ranges. Indeed a feasibility study of 36 children using autocorrelation of NIRS and MAP to determine the optimal MAP for preservation of cerebrovascular reactivity autoregulation after cardiac arrest suggests great promise for this approach (Lee et al., 2014). Whether autoregulation-directed therapy for IHH after pediatric TBI will improve functional outcome will require further study.

### Linking Intracranial Pressure and Cerebral Metabolism

Combining precise control of cerebral metabolism and cerebral perfusion may be more effective at reducing neurologic

**TABLE 105-2** Clinical Manifestations of Increased Intracranial Pressure

Signs and Symptoms	Mechanism	Clinical Findings
Headache	Traction on dura with pain mediated by trigeminal nerve	Exacerbated by coughing, bending, sneezing Worse when recumbent
Diplopia	Traction on abducens nerve	Uni- or bilateral paresis. Binocular diplopia, worse in direction of gaze of paretic muscle. False localizing sign because not caused by intrinsic lesion in pons
Decreased sensorium or change in personality	Compression of edematous hemisphere by other hemisphere, or compression of reticular activating system	Symptoms begin in adults when ICP reaches 15–40 mm Hg. No comparable pediatric data. May be subtle, ranging from irritability or poor attention to stupor
Impaired upgaze	Pressure over pretecal region of midbrain	Mild retraction of eyelids caused by sympathetic overactivity. Prominent eyes with downgaze in infants (sunset sign)
Increased head size	Chronic or acute mass effect	Tense anterior fontanel, bulging scalp veins, splitting of sutures, acceleration of head growth
Papilledema	Edema in nerve fiber layer of retina caused by impaired retinal venous return	Early: loss of venous pulsations Later: elevation of disk margins, tortuous retinal veins. Visual acuity is normal until late stages
Cushing response	Compression of brainstem	Slowing of respiratory rate, bradycardia, and increased blood pressure. Triad is variable, with tachycardia also seen with increased ICP. Triad present only in up to one third of cases in intracranial hypertension

ICP, intracranial pressure.

injury than ICP- or CPP-directed therapy alone. Experience with multimodality monitoring in conditions with abnormal ICP is increasing (Padayachy et al., 2012). Children with severe TBI underwent continuous brain tissue oxygen (PbtO<sub>2</sub>) monitoring in the uninjured frontal cortex. For these 46 children, CPP was the only factor that was independently associated with a favorable outcome at 6 months. Indeed, the authors found some cases in which PbtO<sub>2</sub> was preserved in the goal range but outcome was poor. This may reflect loss of autoregulation and uncoupling of the neurovascular unit. Differences in the site for probe placement and the thresholds selected for treatment make comparisons between all studies using this technology impractical. More generally, the interpretation of PbtO<sub>2</sub> values is limited because they do not solely reflect the presence of ischemia and may be influenced by other factors such as arterial partial pressure of oxygen, and are a measure of local tissue conditions but may miss hypoxic-ischemic insults in other brain regions.

### Utility of Measurement of Intracranial Pressure

An important multicenter controlled trial of 324 patients aged 13 years or older with severe TBI was carried out in Bolivia and Ecuador (Chesnut et al., 2012). These patients were randomly assigned either to guidelines-based management using a protocol for monitoring ICP or to a protocol in which treatment was based on imaging and clinical examination. There was no significant difference either in the primary outcome (a composite measure of functional and cognitive status) or in 6-month mortality. The external validity of this study with respect to practice in Europe and North America is limited in part by the differences in postdischarge care as none of the subjects received any rehabilitative therapy or extensive medical care after hospital discharge.

It is clear that ICP values associated with many types of CNS injuries cannot adequately be interpreted in the absence of data on cerebral perfusion, autoregulation, metabolism, and metabolic demand. This approach to multimodal brain monitoring has not been investigated in children. Precedent from adult neurotrauma in a study of severe TBI suggests that specific CPP targets can be set for individual patients using

real-time monitoring of a combination of cerebral oximetry, CBF, and ICP to measure autoregulation (PRx) and define an optimal CPP.

## CLINICAL MANIFESTATIONS OF RAISED INTRACRANIAL PRESSURE

### Physical Examination Findings

The clinical signs of increased ICP range from subtle changes in higher cognitive function to stupor and focal neurologic findings (Table 105-3). Brain imaging may be normal in the early stages of increased ICP. Each herniation syndrome has a specific clinical correlate (Table 105-2). See Chapters 101, 102, and 104 for further discussion of herniation syndromes.

## MANAGEMENT OF ACUTELY ELEVATED INTRACRANIAL PRESSURE

A guideline for the treatment of ICH in the management of severe TBI has been published (Kochanek, 2012). An algorithm for the evaluation and management of a child with suspected increased ICP is shown in Figure 105-4.

### Initial Assessment, Imaging, and Surgical Intervention

The first key steps in management are to establish a baseline neurologic examination and to identify and, if possible, reverse the primary cause of increased ICP. The medical management proceeds in a tiered approach, but if the initial imaging study shows a surgically operable lesion (e.g., epidural or subdural hematoma), unilateral edema with mass effect, or hydrocephalus caused by obstructed CSF outflow, the first intervention is neurosurgical.

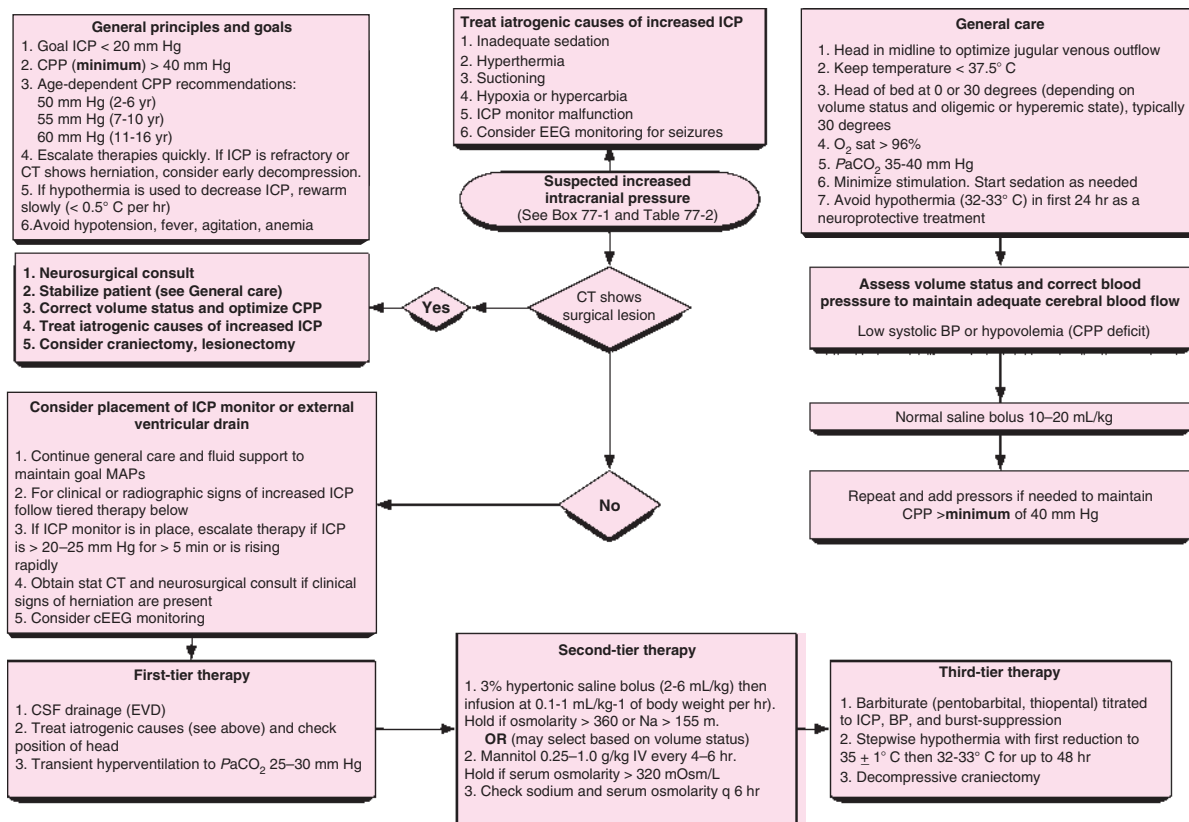

### General Principles of Medical Management

Therapies are directed at minimizing extremes of blood pressure, temperature, oxygenation, glucose, and PCO<sub>2</sub>, with the

**TABLE 105-3** Brain Herniation Syndromes

Type	Mechanism	Clinical Findings
Transtentorial	Medial and caudal displacement of uncus portion of temporal lobe with entrapment in the tentorial notch. Compression of the ipsilateral third cranial nerve, midbrain, cerebral peduncle, and posterior cerebral artery	Ipsilateral dilated pupil (compression of pupilloconstrictor fibers); progressive decline in consciousness; loss of oculocephalic reflexes; decorticate posturing; ipsilateral hemiparesis (pressure on contralateral cerebral peduncle)
Central	Swelling of both hemispheres, leading to compression of diencephalon and midbrain	Early: decline in consciousness, constricted pupils (sympathetic dysfunction), Cheyne–Stokes respiration Late: loss of oculocephalic reflexes, central neurogenic hyperventilation, decerebrate posturing
Tonsillar	Cerebellar tonsils affected in the foramen magnum, leading to compression of medulla and upper cervical spinal cord. Most common with posterior fossa mass lesions	Abrupt loss of consciousness, opisthotonic posturing, stiff neck, irregular respiration, apnea
Cingulate	Displacement of edematous cingulate gyrus under the free edge of the falx cerebri. Compression of ipsilateral or bilateral anterior cerebral arteries and internal cerebral vein	Variable symptoms. Often a precursor to other herniation syndromes, commonly associated with uncal herniation
Late stages	Later stages of uncal, central, and tonsillar herniation manifest as coma, flaccid limbs, midsize unresponsive pupils, loss of corneal and oculocephalic reflexes, and irreversible apnea	

**Figure 105-4.** Approach to the evaluation and management of the child with suspected increased intracranial pressure. BP, blood pressure; CPP, cerebral perfusion pressure; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; EVD, external ventricular drain; ICP, intracranial pressure; IV, intravenous; MAP, mean arterial pressure. For an example of these approaches, see [Hutchinson et al. \(2010\)](#).

goal of preventing secondary injury, and to maintain ICP less than 20–25 mm Hg, CPP greater than 50 mm Hg, and systolic blood pressure within age-dependent limits. This may require sedation. Interventions (suctioning, line placement) that may increase ICP should be minimized. If the child is normovolemic, elevation of the head of the bed to 30 degrees will reduce ICP. The head is secured in a neutral position to optimize CSF

outflow via the jugular veins. The lowest ICP is usually, but not invariably, achieved by the highest bed elevation. Although this relation is usually linear, it is dependent on the patient's height, which determines the difference in distance between the foramen of Monro (ICP) and the right atrium (MAP). Thus a given bed elevation may have less impact on ICP in younger (shorter) patients.

## Evidence in Support of Guideline-Directed Management of Intracranial Pressure

The extent of adherence to the 2003 Brain Trauma Foundation Guidelines and the impact of adherence on outcome for children with severe TBI were measured in a retrospective study from 5 academic U.S. centers (Vavilala et al., 2014). The overall adherence rate was 72.8%. In the prehospital setting, absence of hypoxia was associated with lower mortality. In the intensive care unit and operating room, maintaining CPP greater than 40 mm Hg was associated with a favorable discharge Glasgow Outcome Score. Overall, the results of this study showed that a 1% increase in adherence was associated with a 1% decrease in the change of poor functional outcome among survivors. This is the first study to provide evidence in support of the benefit of guideline-based acute care in these children and further supports a minimum goal CPP in the first 72 hours after TBI in children. In this context, ICP monitoring may be beneficial to ensure that CPP is preserved about this minimum value.

### Intracranial Pressure-Directed Therapy

If there is clinical, radiographic, or monitoring evidence of elevated ICP, a series of stepwise maneuvers are undertaken. In practice, for many pediatric disorders other than TBI, this management is undertaken without an ICP monitor in place because of the lack of evidence that such monitoring improves outcome and concerns over the complications of placement. If ICP is elevated, despite appropriate temperature control, oxygenation,  $PCO_2$  35 to 40 mm Hg, and sedation, the next intervention comprises hypertonic (3%) saline beginning with a bolus of 2 to 6 mL/kg and followed by continuous infusion range between 0.1 and 1 mL/kg/hr. Mannitol (0.25–1 g/kg of body weight, repeated every 4–6 hours as required, up to serum osmolarity of 320) is commonly used but no studies in support of this practice met criteria for inclusion in the Brain Trauma Injury Guidelines. Selection of one agent over the other may need to be guided by the patient's volume status, as mannitol is a diuretic. Brief hyperventilation ( $PCO_2$  less than 35 mm Hg) may be effective; however, for each 1 mm decrease in  $PCO_2$ , there is a 3% drop in CBF, and so this is only a short-term option. If the patient is hemodynamically stable, high-dose barbiturate therapy may be used for treatment of refractory IIH.

The third tier of interventions for refractory increased ICP includes decompressive craniotomy or moderate hypothermia

(32–34°C). Importantly, the decision for decompression should be made before irreversible neurologic injury occurs, although this is clearly a challenging assessment in the intubated, sedated patient. Hypothermia is effective in reducing ICP. Three major clinical trials of therapeutic hypothermia in pediatric TBI have failed to show improvement in outcome (Adelson et al., 2013), or have shown increased mortality in the hypothermia group. The slower rate of rewarming than the 24 hours used in this study may be needed, and accompanied by meticulous use of volume and pressors to maintain CPP (Hutchinson et al., 2010).

The experience with therapeutic hypothermia for severe TBI in children suggests that early hypothermia, irrespective of ICP, does not improve outcome and may increase the risk of death. If hypothermia is used in the management of severe TBI, the 2012 Brain Trauma Foundation Guidelines recommend continuing for less than 24 hours. Importantly, rewarming should be carried out at a rate slower than 0.5°C every 2 hours. Hypothermia may still be considered for the treatment of refractory IIH when other therapies have failed. This intervention should be undertaken only in centers with expertise in its use, particularly with experience in the controlled rewarming after hypothermic therapy.

## SPONTANEOUS INTRACRANIAL HYPOTENSION

Spontaneous intracranial hypotension is rare, compared with the occurrence of elevated ICP after trauma. However, the clinical manifestations of low pressure, including persistent daily headaches in young adults, may be easily overlooked and result in a delay in diagnosis (Table 105-4). Spontaneous intracranial hypotension is believed to result from development of a spontaneous CSF leak after minor trauma. Postural headache is the distinctive symptom of low-pressure headaches, but other headache patterns (nonpositional, exertional) occur as well. Other associated symptoms may include neck stiffness, vomiting, vague auditory symptoms, and even coma likely caused by deformation of the diencephalon. A connective tissue disorder should be considered in these patients.

## CHRONIC INTRACRANIAL HYPERTENSION

### Idiopathic Intracranial Hypertension

Primary idiopathic IIH (previously termed pseudotumor cerebri) may develop at almost any age. IIH has an annual

**TABLE 105-4** Clinical Features of, Diagnostic Criteria for, and Conditions Associated with Intracranial Hypotension

Clinical Features	Diagnostic Criteria for Headache Caused by Spontaneous CSF Leak and Intracranial Hypotension	Differential Diagnosis for Low-Pressure Headache Symptoms
Orthostatic headache	1. Diffuse and/or dull headache worsening within 15 min of sitting or standing and $\geq 1$ of a. Tinnitus b. Nausea c. Photophobia d. Neck stiffness e. Hyperacusia	Primary headache disorder Chronic daily headache
Worsens in upright position		Secondary headache Spontaneous intracranial hypotension Carotid or vertebral dissection
Improves when lying down	2. At least one of a. CSF opening pressure < 60 mm H <sub>2</sub> O in sitting position b. Evidence of CSF leakage by myelography c. MRI evidence of low CSF pressure	Cerebral sinovenous thrombosis Benign intracranial hypertension Posttraumatic headache
Typically occipital	3. No history of dural puncture 4. Headache resolves within 72 hr of epidural blood patching	Meningitis

CSF, cerebrospinal fluid; MRI, magnetic resonance imaging.

incidence of 0.9/100,000 persons and 3.5/100,000 in women aged 15 to 44 years. To some extent, it is a diagnosis of exclusion, dependent on excluding identifiable causes of raised ICP. IIH presents subacutely, with daily headache that is made worse by maneuvers that raise ICP, such as coughing and bending. Infants may manifest irritability, the sunset sign, and a bulging anterior fontanel. Cranial nerve VI paresis from traction on the nerve caused by raised ICP may lead to diplopia that worsens with lateral gaze. Other manifestations include pulsatile tinnitus, transient visual obscuration, photopsia, retinobulbar pain, vertigo, and decreased visual acuity. Adolescents with IIH may be obese.

The differential diagnosis for IIH should include evaluation for cerebral sinovenous thrombosis that may also present with these symptoms and requires MR or CT venogram to establish the diagnosis.

The major morbidity associated with IIH is vision loss, and management is directed at preventing this complication. Bedside and formal visual field testing may demonstrate enlargement of the blind spot but, in general, only in advanced stages. Snellen acuity and visual-evoked potential testing are insensitive measures to follow vision loss in patients with IIH. These patients should be followed with perimetry. MRI, MR venography, and CT studies usually yield normal results. Infrequently, the ventricles may appear slit-like. Lumbar puncture is needed to establish a definitive diagnosis. It reveals significantly raised opening and closing pressures and normal white blood cell count, protein, and glucose. Disorders associated with secondary IIH are listed in Box 105-2.

### Treatment of Idiopathic Intracranial Hypertension

Any contributing factors (weight, diet, drugs) should be eliminated. The treatment of IIH depends on whether visual function is compromised. In patients with unimpaired visual function, the treatment consists of agents that decrease the formation of CSF (acetazolamide, 20 mg/kg/day in 2 divided doses) or diuretics, such as furosemide (1 mg/kg/day in 2 divided doses). There are no evidence-based data for this therapy. Patients receiving acetazolamide should be monitored for the following side effects: drowsiness, anorexia, nausea, numbness of the hands and feet, and signs of dehydration.

Serial lumbar punctures, carried out every 5 to 7 days, with drainage of 20 to 25 mL of CSF on each tap, are also helpful in lowering the closing pressure below 200 mm Hg. Although common, this approach is controversial because CSF pressure returns to prelumbar puncture levels within 82 minutes. Visual acuity and formal visual field assessment should be performed every 1 to 3 months. Patients who demonstrate compromise of visual function, despite medical therapy, may need optic nerve sheath fenestration, a surgical procedure that reduces pressure around the nerve. A number of series have reported good outcome with this procedure.

### CONCLUSIONS

Increased ICP is a major determinant of neurologic morbidity after TBI and other neurologic insults common to children, including CNS infections, metabolic disorders, acute liver failure, stroke, cardiac arrest, and diabetic ketoacidosis. The cumulative evidence now supports a minimum CPP of 40 mm Hg for the management of severe TBI. The benefits of ICP-directed therapy in other disorders, including acute liver failure (ALF) and diabetic ketoacidosis (DKA), are at present unproven. The emergence of noninvasive ICP monitoring approaches is promising, but there remains a need to link data on pressure, tissue perfusion, and cerebral metabolism in order to optimize neuroprotection strategies. There is great

potential for the automated, high-frequency collection of these data, and integration with other physiologic measures. Progress in ICP-directed care will require real-time integration and analysis of multiple physiologic variables and must demonstrate that ICP-, CPP-, and autoregulation-directed therapy improves long-term functional neurologic outcome in pediatric neurocritical care.

# 106 Spinal Cord Injury

Chellamani Harini and N. Paul Rosman

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## EPIDEMIOLOGY

Acute spinal cord injury occurs worldwide, with an annual incidence of 5 to 40 cases per million. Most pediatric spinal injuries occur in conjunction with motor vehicle accidents (52%), followed by sports-related injuries (27%), falls (15%), child abuse (3%), and other less frequent accidents (Huisman et al., 2015). For 2012, the estimated annual incidence in the United States was ~12,000 new cases per year. Spine fractures constitute 3% to 5% of all pediatric fractures. Approximately 55% of injuries involve the cervical spine, 30% involve the thoracic spine, and 15% involve the lumbar spine. Determinants of injury severity include the following: (1) nature, direction, and degree of the insult; (2) site of injury; (3) presence of preexisting spine anomalies; (4) extent of tissue damage; (5) degree of vascular compromise; and (6) rapidity and efficacy of treatment. See online chapter for additional information.

## ANATOMY

Figure 106-1 demonstrates the anatomy of the spinal cord showing the spinal cord root levels in relation to the vertebral bodies. For discussion of the anatomy and blood supply of the bony spine, ligaments and spinal cord, please see the online chapter.

## PATHOGENESIS: MECHANISMS OF SPINAL CORD INJURY

The pediatric cervical spine is more flexible than the adult cervical spine. It is therefore possible to injure the spinal cord without suffering an obvious injury to the bony spine, resulting in *spinal cord injury without radiographic abnormality* (SCIWORA).

There are five major ways in which spinal trauma results in cord injury: forward flexion, lateral flexion, rotation, axial compression, and hyperextension (Chilton and Dagi, 1985). The forces generated by these movements can result in vertebral distraction, dislocation, fracture, and disk herniation. Often several forces act at the same time (Glasser and Fessler, 1996).

Vertebral fractures are less frequent in young children than in adults. By contrast, dislocations, ligamentous injuries, epiphyseal detachments, and lesions of the ossification centers are more frequent. The pediatric craniocervical junction and upper cervical spine are particularly vulnerable to sudden acceleration and deceleration forces and trauma-related injuries. Most pediatric spinal traumas occur in the cervical spine (80%). In children younger than 8 years, primarily the first three cervical segments are involved. With progressive age, the fulcrum of flexion gradually shifts caudally from C2/3 to C5/6. In older children and young adults, the lower cervical spine is more frequently affected. The thoracic spine is less frequently affected than the cervical spine because of the stabilizing effects of the adjacent rib cage. The lumbar spine is more mobile (Huisman et al., 2015). As children approach the age of 9 years, the vertebrae start to mature and

ossify. Anteriorly, the wedge-shaped vertebral body becomes more rectangular, the orientation of the facets becomes less horizontal and more vertical, and the uncinat processes begin to protrude. These features predispose older children to lower spine injury similar to that found in the adult population.

Forward flexion can lead to wedge or teardrop fractures, which usually begin at or near the intervertebral disk (Figure 106-2). These fractures are often encountered in motor vehicle accidents in passengers not wearing seat and shoulder belts, but also can be seen in children wearing ill-fitting adult types of lap-sash belts (cervical seat-belt syndrome). Excessive lateral flexion of the cervical spine is always accompanied by rotation and can cause a unilateral locked facet (Figure 106-3).

Axial compression occurs in diving accidents, falls, and sports injuries and can result in a burst fracture in which the vertebral end plate is injured, allowing the intervertebral disk to rupture into the vertebral body, which then bursts. In the Jefferson fracture, a direct blow to the top of the head, for example from diving into shallow water, results in axial compression that is transmitted through the occipital condyles to the atlas, the arch of which bursts, allowing fragments to be displaced outward (Figure 106-4). Severe hyperextension is often encountered in rear-end motor vehicle accidents (whiplash injury) and in the head-shaking injury of child abuse. This hyperextension can result in transverse fractures of the neural arches of the cervical spine, usually accompanied by tearing of the anterior longitudinal ligament. The so-called hangman's fracture occurs from a hyperextension injury through the synchondrosis between the odontoid and the arch of C2. Because the vertebral arteries lie in the transverse processes of these vertebrae, they can be torn or thrombosed after such injuries with resultant ischemia to the anterior two thirds of the spinal cord. Such injuries have been reported after neck hyperextension in football games and in infants with C1-C2 instability. Displacement of the vertebrae during spinal trauma can compress the arteries of the spinal cord, resulting in ischemic injury, often without radiographic abnormalities. A *Chance fracture* is a compression injury to an anterior portion of a vertebral body, with a transverse fracture through its posterior elements. It is caused by violent forward flexion. The most common site is midlumbar in children. These were often seen in children restrained in automobiles by lap seat belts alone, but since shoulder belts were added, they have become much less common.

## CLINICAL ASSESSMENT

### History

A detailed history should obtain details concerning the mechanism of injury, the activity of the child, and the use of restraining devices as well as the possible presence of any genetic disorders or blood dyscrasias (e.g., hemophilia) that may render a child more vulnerable.

### General Physical Examination

Particular attention should be directed to the child's respiratory and cardiovascular status, looking for a traumatic

**Figure 106-1.** Spinal cord root levels in relation to the vertebral bodies. (With permission from Haymaker W, Woodhall B. *Peripheral nerve injuries*, 2nd ed. Philadelphia: WB Saunders, 1953.)

pneumothorax or diaphragmatic paralysis. Hypotension with tachycardia may result from intraabdominal bleeding from a ruptured spleen. The entire spine should be palpated for any point tenderness, deformities, crepitus, or muscle spasm.

## Neurologic Examination

Patients with spinal cord injury can present with any combination of the following symptoms and signs: neck or back pain, weakness, sensory loss, decrease in deep tendon reflexes, loss of bladder or bowel control, autonomic dysfunction, and meningismus. Such symptoms may be: acute, subacute, chronic, intermittent, delayed or late, or progressive. After the initial neurologic deficit in acute spinal cord injury, secondary deterioration is sometimes seen. This can be (1) early (<24 hours) (e.g., from spinal immobilization and traction), (2)

### BOX 106-1 Asia/IMSOP Spinal Cord Impairment Scale\*

- A. Complete: No motor or sensory function is preserved in sacral segments S4 to S5.
- B. Incomplete: Sensory but not motor function is preserved below the neurologic level and includes sacral segments S4 to S5.
- C. Incomplete: Motor function is preserved below the neurologic level, and more than half of key muscles below the neurologic level have a muscle grade less than 3.
- D. Incomplete: Motor function is preserved below the neurologic level, and at least half of key muscles below the neurologic level have a muscle grade of 3 or more.
- E. Normal: Motor and sensory function is normal.

\*This scale distinguishes complete spinal cord injury and three degrees of incomplete injury from an absence of injury with normal motor and sensory function.

ASIA, American Spinal Injury Association; IMSOP, International Medical Society of Paraplegia.

delayed (1–7 days) (e.g., from hypotension complicating fracture-dislocation, or (3) late (>7 days) (e.g., from vertebral artery injury). Signs of spinal cord injury usually include impairment of motor and sensory function. The degree of motor involvement can vary from subtle weakness to complete quadriplegia. Loss of sensation is often ascertainable at an obvious dermatomal level. In 1992 the American Spinal Injury Association (ASIA) and the International Medical Society of Paraplegia (IMSOP) published a Standard Neurologic Classification of Spinal Cord Injury. The seventh edition of the International Standards for Neurologic Classification of Spinal Cord Injury (ISNCSCI) provided some clarifications and revisions and a modest update of the accompanying worksheet (Figure 106-5). This classification systematically documents motor, sensory, and sphincter function in acute spinal cord injuries. Ten key muscle groups are tested for motor function (using the Medical Research Council 0-to-5 muscle grading) and sensation (tested over 28 dermatomes on both sides of the body). The neurologic levels and completeness or incompleteness (partial preservation) of spinal cord injury are documented (Kirshblum et al., 2011).

The ASIA/IMSOP Spinal Cord Impairment Scale (Box 106-1), differentiates *complete* and *incomplete* spinal cord deficits. *Complete* injury is defined as loss of all motor and sensory function in all segments below the neurologic level, including the sacral dermatomes (S4-S5). The anorectal examination, a frequent determinant of completeness of injury, is less reliable in young children than in adults. With preservation of any sensory or motor function below the neurologic level, the injury is classified as *incomplete* (Figure 106-5). The examiner identifies the most caudal spinal cord segment with normal sensory and motor function on both sides. The zone of partial preservation is defined as the dermatomes caudal to the neurologic level with partial preservation of function in an otherwise complete injury. This zone implies injury of multiple spinal cord segments, whereas its absence implies injury at only one level. An abbreviated sensory examination (16 dermatomes) was recently developed to replace the 56 dermatome examination, and the shortened version was found to correlate well with the longer one.

After injury to the spinal cord, the deep tendon reflexes are depressed or absent, with this lack of response persisting until spinal shock has resolved (1–12 weeks). Thereafter, hyperreflexia and extensor posturing are evident below the level of the lesion, with autonomic dysfunction a frequent accompaniment.

## Laboratory Studies

### Radiographic Evaluation

This should begin in the emergency department with plain films of the entire spine to look for unstable fractures or vertebral dislocations that may require emergency surgery. It is crucial to obtain anteroposterior, lateral, and oblique views of the spine (Huisman et al., 2015; Klein, 2015). Care must be taken not to misinterpret normal variations in cervical spine anatomy, such as pseudosubluxation of C2 on C3, and the synchondrosis between the dens and body of C2 (often mistaken for a fracture). Also, the physiologic anterior wedging seen in young vertebral bodies might be misinterpreted as compression fractures. In patients who cannot be assessed adequately by plain radiography, early CT or MRI may be needed (Figure 106-6).

In children, spondylolisthesis (malposition of one vertebral body over another) is most often caused by spondylosis, and is seen most often in the lower lumbar spine, especially following repetitive trauma.

In spine-injured children, the upper cervical spine is especially susceptible to injury. Specific injuries to this region include (1) occipitoaxial dislocations, (2) atlantoaxial

instability, (3) fractures of the atlas (C1) (Jefferson fracture), (4) odontoid fractures, and (5) fractures of the axis (C2) (hangman’s fracture).

Further limitations of plain radiographs of the spine include 40% false-positive and 20% false-negative interpretations. Plain radiographs may miss 20% to 40% of cervical spine fractures. Also, significant spinal cord injury frequently occurs in children without radiographic abnormality (SCIWORA) (e.g., vertebral fracture or dislocation), with this discrepancy observed in 15% to 70% of all pediatric spinal cord injuries. SCIWORA is seen most frequently in infants and young children and most often affects the cervical spine, typically producing signs of a central cord syndrome. The finding of fracture, subluxation or abnormal intersegmental motion excludes SCIWORA as a diagnosis. With MRI, many such cases show radiologic evidence of injury to the spinal cord or spinal cord ligaments.

Klein has recently summarized imaging modalities, sequences, and appearance of different structures seen in spine imaging (Figure 106-7).

### Electrophysiologic Evaluation

For discussion, please see the online chapter.

## Lumbar Puncture

 For discussion, please see the online chapter.

## CLINICAL SYNDROMES

A recent review has summarized many of these clinical syndromes (Cho, 2015).

### Intraspinal Intramedullary Injuries

Intraspinal intramedullary injuries can cause complete or incomplete loss of spinal cord function. With complete loss, there is absence of all motor, sensory, and reflex function below the level of injury. With incomplete loss, some motor, sensory, and reflex function persists (Box 106-1).

### Complete Spinal Cord Injuries

Complete loss of spinal cord function, can be physiologic or pathologic. In physiologic loss, there is no morphologic alteration of the spinal cord, which becomes dysfunctional after impact. This dysfunction can occur with transient compression of the cord by a dislocated vertebra. With more sustained cord compression, anatomic disruption may result, with accompanying pathologic loss of function. The frequency of complete spinal cord injury in pediatric patients ranges from 20% to 95%.

The initial phase of complete loss of spinal cord function is characterized by spinal shock. The truncal and extremity muscles below the level of the lesion are flaccid, deep tendon and superficial reflexes are depressed or lost, plantar responses are absent, anesthesia to all modalities is present, and autonomic dysfunction (hypotension and bradycardia) is seen. The mechanism of spinal shock is unknown, but its physiologic effects must be differentiated from the more permanent pathologic effects of spinal cord injury. Motor and sensory deficits resulting from spinal shock alone resolve within 1 hour. Persistence of motor and sensory deficits beyond 1 hour implies that more permanent injury has occurred. After 6 to 13 weeks in adults and within 1 week in children, tendon reflexes return, and muscle tone improves. The reflexes later become pathologically active, spasticity ensues if the injury is more permanent, and there usually is no significant return of motor or sensory function. A four-phase model of the sequential changes seen in spinal shock and the neuronal mechanisms that may underlie these changes have been described: phase 1 (0–1 day), areflexia/hyporeflexia (from loss of descending facilitation); phase 2 (1–3 days), initial reflex return (from denervation supersensitivity); phase 3 (1–4 weeks), initial hyperreflexia (from axon-supported synapse growth); and phase 4 (1–2 months), final hyperreflexia (from soma-supported synapse growth).

Autonomic dysfunction can persist for weeks to months. Ventilation may be compromised if the intercostal muscles are involved. Flaccid paralysis of the bladder can develop, with urinary retention and overflow incontinence. The gastrointestinal tract can be atonic. Vasomotor dysfunction can develop, with orthostatic hypotension, impaired shivering, sweating, and disturbances in temperature regulation persisting for weeks to months, and at times years. After complete injury of the cervical or upper thoracic spinal cord, an acute syndrome of bradycardia, hypotension, and hypothermia can occur, probably because of disturbed sympathetic outflow at the cervical and upper thoracic levels; most patients with quadriplegia after spinal cord injury have chronic hypothermia with poor temperature control related to loss of sympathetic peripheral vascular control. Recovery from complete cord injury is rare, for less than 2% of patients recover some

distal cord function. More encouraging was a comprehensive review of several large series of patients with complete spinal cord injury that found that 2% of the patients became ambulatory.

### Incomplete Spinal Cord Injuries

Incomplete spinal cord injuries warrant special attention because the children often show significant functional recovery. These include cervical nerve root/brachial plexus neuropraxia, cervical cord neuropraxia, the cervicomedullary syndrome, central spinal syndrome, syndromes of the anterior spinal cord and posterior spinal cord, Brown-Séquard syndrome, and conus medullaris syndrome.

### Cervical Nerve Root/Brachial Plexus Neuropraxia

American football, a high energy contact sport, places players at particularly risk for cervical neuropraxic injuries. The relatively common “stinger” is a reversible peripheral injury resulting from neuropraxia of cervical nerve root(s) or brachial plexus causing a temporary physiologic block in nerve conduction. It is characterized by unilateral burning pain radiating from the neck down the arm to the hand, usually lasting seconds to hours. There may be associated weakness of the deltoid and/or supra/infra spinatus muscles that resolves within 24 hours to 6 weeks. Less often, such injuries can involve one or both lower limbs. The most common mechanism of injury is hyperextension, often with lateral flexion of the neck and an axial load, resulting in cervical nerve root compression caused by intervertebral foraminal narrowing. Additional injury mechanisms are traction or stretching of the brachial plexus and direct trauma to the brachial plexus. Radiographs are usually normal. Cervical stenosis is a predisposing cause. Most patients are managed with 2 weeks of cervical immobilization with a hard collar.

### Cervical Cord Neuropraxia

Less common and more serious is cervical cord neuropraxia, due to hyperextension, hyperflexion, or axial loading of the cervical spine. Clinically, it is characterized by burning pain, paresthesias and loss of sensation and/or weakness (ranging from no weakness to complete paralysis) in more than one limb, with rapid and complete resolution of symptoms within 10 minutes to 48 hours. Mechanically, the posterior-inferior margin of the vertebral body above and the anterior-superior portion of the lamina of the vertebra below combine to produce spinal cord compression (Penning's pincer mechanism) with local anoxia and an increase in intracellular calcium temporarily disrupting spinal cord function. Radiographs often show congenital abnormalities such as cervical stenosis and Klippel-Feil syndrome. Cervical cord neuropraxia occurs in 0.2 per 100,000 participants at the high school level and 2 per 100,000 at the collegiate level.

### Cervicomedullary Syndrome

With upper cervical injury, there is often injury to the medulla, causing diaphragmatic weakness, respiratory failure, hypotension, quadriparesis, and facial and upper cervical (C1 to C4) anesthesia. Obstruction of CSF outflow at the foramen magnum may lead to downbeat nystagmus and papilledema. The facial anesthesia is of an ‘onion skin’ or Dejerine type. It is important that facial sensation be tested carefully in all patients with spinal cord injury. As in the central spinal cord syndrome, there can be selective weakness in the arms, with little if any weakness in the legs. This pattern is due to the crossing of fibers subserving the arms in the pyramidal

decussation so that they come to be located more centrally than the leg fibers, which cross at a lower level. Several authors have challenged this concept, pointing to evidence that the fibers of the corticospinal tract may not be layered but are intermingled and that pathologically there is little evidence of central necrosis or hydromyelia in such patients. An “around the clock” pattern of weakness can be seen because upper extremity pyramidal fibers cross more rostral to lower extremity pyramidal fibers and the fibers for one side frequently cross completely before those from the other side, resulting in weakness that spreads from ipsilateral upper limb, to ipsilateral lower limb, to contralateral lower limb, to contralateral upper limb (Cho, 2015). The mechanisms of injury causing cervicomedullary syndrome include atlantoaxial dislocation, atlanto-occipital dislocation, odontoid fracture, burst fracture of C1, and a ruptured C1 to C2 disk.

### Central Spinal Cord Syndrome

Central spinal syndrome can complicate hyperextension injury, particularly when there is a preexisting spinal abnormality, such as spinal canal stenosis, disk herniation, bony spurs, or compression by an abnormal ligamentum flavum. Conversely, this syndrome often can occur, particularly in young children, without an accompanying radiographic abnormality. Here the central portion of the cord (usually cervical) is damaged, probably from ischemia because the central cord is perfused by end arteries from the anterior spinal artery, making it vulnerable to states of low perfusion. As these lesions commonly affect the lower cervical and upper thoracic cord, the sensory loss is classically seen in a “cape” or “vest” distribution across the neck and shoulders or trunk. Initial quadriplegia evolves into a more prominent upper extremity weakness with relative sparing of the lower extremities. Neurologically, the motor and sensory deficits are partial, with the greatest impairment in the distal upper limbs. The resulting distribution of deficits is referred to as the “man-in-the-barrel” syndrome. Bowel and bladder function can be lost early, but usually return. Patients are generally ambulatory with a spastic gait; painful arm dysesthesias may persist for years. There is still debate whether early surgery is warranted because many patients recover spontaneously.

### Anterior Spinal Cord Syndrome

Anterior spinal cord syndrome, which can follow hyperflexion spinal injury, is characterized by paresis with loss of pain and temperature sensation below the level of the lesion, with preservation of proprioception, light touch, and vibration. Bladder control is impaired. This condition is usually caused by direct compression of the anterior and lateral white matter tracts by a herniated disk or by a fractured vertebra with posterior dislocation. The posterior columns are spared. There is no evidence for compression of the anterior spinal artery in this disorder. Early surgery is probably warranted in all cases.

### Posterior Spinal Cord Syndrome

Posterior spinal cord syndrome is an extremely rare disorder (some doubt its existence), characterized by major damage to the posterior spinal cord, resulting in loss of vibration sense and proprioception below the level of the lesion. This results in a pronounced sensory ataxia and a “stomping” gait, with residual anterior cord function, with retained perception of pain and temperature.

### Brown-Séquard Syndrome

Brown-Séquard syndrome is caused by injury of the lateral half of the spinal cord (usually cervical) and is characterized by

ipsilateral motor paralysis, ipsilateral loss of vibration sense, proprioception and touch, and contralateral loss of pain and temperature sensation below the level of the lesion. Because the involvement of the descending autonomic pathways is unilateral, bladder dysfunction does not occur. Although this syndrome is often caused by penetrating trauma to the spine, cases also have been caused by hyperextension injury, compression fractures, and disk herniation. Blunt trauma with central cord injury sometimes can result in asymmetric pareses and sensory impairment that can mimic the true syndrome. Recovery is variable.

### Conus Medullaris Syndrome

Conus medullaris syndrome causes early flaccid bladder and bowel dysfunction, late and mild pain, and symmetric sensory impairment in a saddle distribution, often with sacral sparing. Motor impairment is relatively mild and symmetric. This syndrome can be impossible to differentiate from cauda equina syndrome on clinical grounds. The lumbar cord is positioned opposite the T12 vertebra, and the sacral cord is opposite L1. Dislocation, displaced fractures, and disk herniation of T12 and L1 can produce this injury. Prognosis for recovery is poor.

### Intraspinal Extramedullary Injuries

Intraspinal extramedullary injuries include hemorrhage into the epidural, subdural, and subarachnoid spaces; spinal epidural abscess; spinal arachnoid cysts; spinal epidural tumor; herniation of the nucleus pulposus; cauda equina injuries and catastrophic spinal cord injuries.

### Spinal Epidural Hematoma

Spinal epidural hematoma can occur with substantial trauma to a normal spine, particularly in a newborn after breech delivery, or with mild trauma to the spine in a patient with a bleeding diathesis, with a spinal epidural hemangioma, or after multiple lumbar punctures. In contrast to most intracranial epidural hematomas, spinal epidural hemorrhage is of venous (not arterial) origin. The main venous structure within the spinal epidural space lies ventrolateral to the cord and comprises a “rope ladder” plexus of thin-walled veins lacking true valves. This internal plexus connects with an external plexus of veins around the spinal column, with segmental spinal veins draining into the inferior vena cava, and with intracranial dural sinuses. Signs of spinal epidural hematoma can be acute, chronic, or intermittent. A newborn with acute spinal epidural hematoma typically manifests respiratory depression, hypotonia, areflexia, and other signs of spinal shock. The occurrence of clinically significant traumatic spinal epidural bleeding is uncommon after infancy. When it occurs in older children (as with minor trauma complicating a blood dyscrasia), there is usually severe neck or back pain that is worsened by pressure over the spine, neck flexion, or the Valsalva maneuver. Over the ensuing hours to weeks, signs of spinal cord compression usually develop.

### Spinal Subdural Hematoma

Spinal subdural hematoma occurs much less commonly; the source of bleeding in this hematoma is unclear. Similar to spinal epidural hematoma, it occurs mainly in the neonatal period, although occasionally it is observed in children and adolescents with bleeding diatheses who sustain an otherwise insignificant injury to the spine, such as that occurring at the time of lumbar puncture. It also has been reported in a

4-month-old infant following nonaccidental trauma. Clinical features include back and radicular pain. In 18 infants with abusive head injury, 8/18 (44%) had accompanying spinal subdural hematomas; in all eight, there were accompanying intracranial (supratentorial and infratentorial) subdural hematomas; all eight of the spinal subdural hematomas were clinically occult. This suggests that in many of these cases the spinal subdural hemorrhage developed consequent to a tracking downward of intracranial subdural blood. In a retrospective study of 252 children with *abusive* head trauma, there was complete clinical and radiologic data in 67. A spinal subdural bleed was found in 31/67 cases (46%). Of 29 children with evaluable cervical imaging results, 7/29 (24%) had cervical subdural hemorrhage; of 38 children with evaluable thoracolumbar imaging results, 24/38 (63%) had thoracolumbar subdural hemorrhage. By contrast, in 70 children with *accidental* injury and complete clinical and radiologic data, there was only 1 case of spinal subdural hemorrhage, thoracolumbar in location. Proposed mechanisms for the occurrence of subdural blood in abusive head injury include: (1) tracking downward of intracranial subdural blood into the spinal canal; (2) direct injury to intradural vessels around the spinal cord; (3) spinal vessel rupture from hyperflexion of the spine and/or increased intraabdominal pressure; (4) increased intracranial pressure causing shearing intraspinal injury with bleeding from the inner dural layer of the spine. Surgical evacuation of spinal subdural hematomas is generally reserved only for those cases with evidence of spinal cord compression.

### Spinal Subarachnoid Hemorrhage

Traumatic subarachnoid hemorrhage caused by injury to the spine is uncommon. This hemorrhage can occur after penetrating injury, but most often occurs after birth trauma (often with accompanying epidural, subdural, or intraspinal hemorrhage). The amount of blood that accumulates is usually not great, and significant compression of the cord is rare. Signs of spinal subarachnoid hemorrhage are difficult to distinguish from signs of other spinal hemorrhages (e.g., epidural) that often coexist. Spinal subarachnoid hemorrhage should be suspected when back pain, meningismus, or fever occurs. The diagnosis is indicated by the presence of blood in the spinal fluid or by cerebrospinal fluid xanthochromia. Occasionally, blood obstructs the subarachnoid space, resulting in a "dry tap." Spinal subarachnoid hemorrhage must be differentiated from subarachnoid bleeding of intracranial origin and from blood caused by a traumatic lumbar puncture. As spinal subarachnoid hemorrhage mixes with CSF, it does not show any distinct margins on MRI. When bleeding is acute, spinal hemorrhage, as with intracranial hemorrhage, is usually isointense on T1 sequence and hypointense on T2. When subacute, blood becomes hyperintense on T1 and T2 MRI sequences (Figure 106-8).

### Spinal Epidural Abscess

Infections of the skin overlying the spine or of the bony spine itself (osteomyelitis) can occur after spinal trauma and may result in a spinal epidural abscess. *Staphylococcus aureus* is the organism most often responsible for such infections. The signs and symptoms of spinal epidural abscess are difficult to differentiate from the signs and symptoms of spinal epidural hematoma. Usually, other signs of inflammation and local infection of the overlying skin or bone can be identified. Spinal epidural abscesses are potentially increasing in incidence consequent to an increase in risk factors, including spine trauma, skin infection, intravenous drug use and immunodeficiency. Also, enhancement of imaging studies has allowed for increased detection.

### Spinal Arachnoid Cysts

Spinal arachnoid cysts are rare. They can be congenital or acquired, and extradural or intradural in location. The lesions reflect an outward bulging of arachnoid tissue through a congenital or acquired defect in the dura; acquired defects are usually traumatic in etiology. The most common symptoms are limb weakness, sensory loss and radicular pain. In an extensive literature review, of 21 pediatric cases of idiopathic intradural spinal arachnoid cysts, most of the anterior cysts were cervical in location, while most of the posterior ones were thoracic or thoracolumbar. Most children presented with motor deficits. In many of the reports there was a history of trauma; in some, there were associated neural tube defects. Open microscopic surgical fenestration was the treatment of choice, with favorable outcomes and a low recurrence rate.

### Spinal Epidermoid Tumor

Intraspinal epidermoid tumors can be congenital or acquired. Acquired epidermoid tumors are extremely rare. About 40% occur as infrequent, late complications of lumbar puncture, resulting in implantation of epidermal and subcutaneous tissues into the spinal subarachnoid space. Other causes include spinal trauma, spinal anesthesia, surgery, bullet wounds and myelography. The clinical symptoms are slowly progressive and include leg weakness, muscle atrophy, limited straight leg raising, sensory loss, back pain, and gait abnormalities. These tumors can develop 1 to 20 or more years after a lumbar puncture.

### Herniation of Nucleus Pulposus

Herniation of the nucleus pulposus (protrusion of central intervertebral disk tissue) can result from severe flexion/compression of the spine and can cause compression of the underlying spinal cord. Symptoms may include low back pain, sciatica, spinal rigidity, sensory loss, weakness and impaired reflexes.

### Cauda Equina Injuries

A special category of extramedullary injury comprises injury involving the cauda equina, which is technically not a spinal cord injury. The level of spinal column and ligament displacement in these injuries varies with age, depending at which vertebral level the spinal cord terminates. When any of the extramedullary pathologies are localized below the spinal cord, they can cause injury to the cauda equina. Because of involvement of lumbosacral nerve roots, these injuries are typically heralded by radicular pain in one or both lower limbs. There is accompanying asymmetric sensory loss to all modalities in the lumbosacral dermatomes, with bladder and bowel dysfunction later in the course, compared with the conus medullaris syndrome, where bladder and bowel dysfunction is early. Weakness is generally more marked and asymmetric than with the conus medullaris syndrome, where it is relatively mild and symmetric. The prognosis in cauda equina injury is better than in spinal cord injury because the lower motor neuron apparently has a greater capacity to recover than the upper motor neuron.

### Catastrophic Spinal Cord Injuries

Although quite rare, catastrophic neurologic injury refers to a complication of a cervical spinal cord injury, most often caused by a neck injury suffered while playing tackle football, resulting in permanent neurologic injury or death. The incidence of this injury is 0.5 per 100,000 participants at a high

school level and 1.5 per 100,000 at the collegiate level. The mechanism of injury is most often forced hyperflexion, as occurs with “spear tackling,” in which the player initiates contact with the crown of his helmet, with his neck in a slightly flexed position, resulting in an axial force applied to the helmet being transmitted to the cervical spine, with fracture and/or subluxation or dislocation of the subaxial spine. Of the permanent neurologic injuries that occur in football, 70% occur in defensive players, usually while tackling or blocking.

### Supraspinal Changes

 For discussion, please see the online chapter.

## MANAGEMENT

Medical management of spinal cord injury includes measures aimed at treating the acute cord injury and more long-term management.

### Short-Term Management

#### Spine Immobilization and Supportive Care

Treatment acutely must include stabilization of the spine to prevent further injury, in addition to maintenance of vital signs. At the scene of the accident, the child should be placed on a rigid stretcher or firm backboard and the head fixed by sandbags or towel rolls with tape over the forehead to prevent movement of the head on the spine. Because the high cervical region is the most likely level of injury, neck flexion is particularly dangerous. Flexion can be avoided with a special board with a recess for the occiput, allowing the head to rest in line with the body, or by placing something under the child’s shoulders to elevate the neck in line with the head. A spine board eases transfer of the patient to and from an ambulance stretcher. Because the head is proportionately larger than the body in children, children under age 8 years require a mean of 2.5 cm of thoracic elevation with respect to the occiput to achieve a neutral position. When the patient arrives at the hospital, a hard cervical collar and a firm mattress adequately immobilize the patient before application of traction or definitive stabilization.

A patent airway must be established, which may necessitate endotracheal intubation, which is frequently required in complete cervical cord injury (with impairment of diaphragmatic and intercostal muscle function). Intubation should be accomplished by chin lift without or with minimal neck extension. Cardiac rate and rhythm should be monitored, and intravenous, central venous and arterial lines should be placed. Cervical spinal cord trauma is often associated with significant hemodynamic deficits, including hypotension. In addition, injury to other organs (e.g., a ruptured liver or spleen) can cause significant blood loss and hypotension, which must be treated promptly with intravenous crystalloid or blood. Intravenous norepinephrine or dopamine may be needed to maintain normal blood pressure after volume depletion is corrected. Hypotension is treated with a combination of volume resuscitation and the use of vasopressors with chronotropic properties (norepinephrine, dopamine). Vasopressors, such as dopamine, which functions as both an  $\alpha$ 1 and  $\beta$ 1 agonist, can be used to treat symptomatic hypotension with associated bradycardia seen in neurogenic shock. Persistent bradycardia may require atropine. Aggressive treatment of hypotension after spinal cord injury may significantly improve outcome. The stomach should be emptied by a nasogastric tube. With urinary retention, the bladder should be catheterized. Radiologic studies usually should be per-

formed. With cervical spine trauma, if the child is alert and interactive and has no neurologic deficits, no midline cervical tenderness, no painful distracting injury, and no evidence of intoxication, cervical spine films are probably not needed. Spinal alignment is an important next step that usually can be accomplished with skeletal traction (see section on Long-Term Management).

## Completed Randomized Controlled Clinical Trials

### Methylprednisolone, Naloxone, and Tirilazad

Steroids have often been used in the treatment of acute spinal cord injury in an attempt to reduce cord swelling and limit central cord necrosis.

The National Acute Spinal Cord Injury Study (NASCIS 1,2,3) had studied the use of intravenous methylprednisolone in SCI. NASCIS 1 (no placebo group) compared high-dose methylprednisolone to standard-dose and found no significant differences in recovery of motor or sensory function at 1 year. NASCIS 2, a randomized controlled study, compared methylprednisolone with naloxone and placebo. Methylprednisolone given within 8 hours of injury was associated with a significant improvement in motor function and sensation at a 6-month follow up. At 1-year follow-up, the methylprednisolone group still exhibited significantly improved motor scores, but there were no significant differences in sensory scores among the three groups. NASCIS 3 (no placebo) compared methylprednisolone given for 24 or 48 hours or tirilazad, a 21-amino steroid lipid peroxidation inhibitor, given for 48 hours.

Among patients who started treatment with methylprednisolone between 3 and 8 hours of injury, those given 48 hours of methylprednisolone recovered significantly more motor function at 6 weeks and 6 months than those given 24 hours of methylprednisolone. Patients treated with tirilazad for 48 hours showed motor recovery rates equivalent to patients who received methylprednisolone for 24 hours.

Currently in adults, new recommendations (2013) of the American Association of Neurologic Surgeons (AANS) and the Congress of Neurologic Surgeons (CNS) concluded that methylprednisolone should not be given for the treatment of acute spinal cord injury because of its associated harmful side effects, including infection, sepsis, gastrointestinal bleeding, poor wound healing, psychiatric side effects, and death (Hurlbert et al., 2013). Yet some controversy continues to exist regarding steroid use in acute spinal cord injury. Some authorities feel that although high-dose methylprednisolone cannot be recommended as a standard of care, it remains an option until supplanted by future evidence-based therapies.

A review of high dose methylprednisolone in children with acute spinal cord injuries highlighted the lack of evidence to support its use, noting that the majority of pediatric spinal cord trauma patients are managed on the basis of evidence extrapolated from adult studies. They recommended that steroids in acute spinal cord injuries in children should be reserved for research purposes until better evidence of its efficacy has been found (Pettiford et al., 2012).

Please see the online chapter for discussion of: 

1. additional randomized controlled clinical trials with agents that did not result in long term benefits (*GM1 Ganglioside, Nimodipine, Lithium*);
2. additional pharmacologic clinical trials (*Minocycline, Riluzole, Erythropoietin [EPO]*);
3. nonpharmacologic clinical trials (*Hypothermia, Oscillating Field Stimulation [OFS]*);

4. molecular mechanisms and therapeutic approaches (*myelin-associated Inhibitors, glial scar-associated Inhibitors*);
5. *cell transplantaton therapies (activated autologous macrophages [AAM], schwann cells, olfactory ensheathing cells [OECs], stem cell therapy, and bone marrow stromal cells*;
6. therapeutic approaches currently undergoing human investigation (*nogo, rho pathway antagonists*), gene therapy for spinal cord injury and the "Future and Concerns" section.

## ADDITIONAL BENEFICIAL TREATMENTS

### Long-Term Management

#### Cervical Spine Immobilization

In childhood spine and spinal cord injuries, the main imperatives are to decompress the neural elements and to stabilize the spine to prevent further injury (Proctor, 2002). A rigid collar combined with supplemental devices that partially enclose the head (e.g., Kendrick Extrication Device®) and tape provide the best prehospital immobilization of the pediatric cervical spine. Cervical collars can lead to supraphysiologic distraction and neurologic injury in the presence of occipitotantal dislocation. Sandbags and tape should be used in this situation.

There are five low-risk criteria for clearing the cervical spine put forth by the National Emergency X-Radiography Utilization Study (NEXUS). These include: (1) no posterior midline cervical spine tenderness; (2) no evidence of intoxication; (3) normal alertness (score of 15 on the Glasgow Coma Scale score); (4) no focal neurologic deficits; (5) no painful distracting injuries. If all five criteria are met, there is no obvious need for cervical spine radiography; with fewer than five, radiography should be done. The Canadian C-Spine (cervical-spine) Rule (CCR), includes five low-risk and three high-risk criteria and made note of the patient's ability to rotate his/her head actively. In the presence of any high-risk criterion, or with an inability to rotate the neck actively, cervical spine radiography should be done. Some authorities have added the ability for appropriate verbal communication before the cervical spine can be cleared.

Cervical traction serves to immobilize the spine and reduce fractures. Reduction of fractures or subluxation must be undertaken with care in young patients because overdistraction can worsen the patient's neurologic dysfunction. Manual positioning under fluoroscopy often is required in cases of cervical ligamentous injury. Crown halo rings can be applied in younger patients. In older patients, cervical traction can be used with relative safety. Many spine-injured children can be managed with external stabilization without a need for later surgery (Proctor, 2002). Various devices can be used, depending on the level and severity of injury, including the Philadelphia cervical collar, Yale braces, SOMI braces, four-poster braces, halo rests, crown halo rings, and thoracolumbar orthoses. When such devices are used, frequent radiographic reevaluations are needed to ensure continuing proper alignment of spinal elements because adequate external (and internal) fixation can be difficult to achieve in a young child (Proctor, 2002).

#### Supportive Medical Care

After cervical spine injury, respiratory, cardiovascular, and neurologic failure are frequently found, while renal, hepatic, and hematologic failures are uncommon. Patients with acute cervical cord injury frequently develop hypotension, hypoxemia, cardiovascular instability and pulmonary dysfunction,

often despite being initially stable. Although patients with midcervical cord injuries initially may have adequate spontaneous ventilation, their ventilatory ability may deteriorate within several days consequent to ascending spinal cord edema. Children with high cervical lesions who are ventilator dependent may be candidates for phrenic nerve pacing.

Both the ASIA motor score and the AIS correlate with development of organ dysfunction and failure. Tracheostomy is often needed after cervical cord injury. Lower ASIA motor scores and "complete" cervical spinal cord injury are significantly associated with the need for tracheostomy, but the anatomic level of cervical spinal cord injury was not.

Complications are not limited to patients with complete spinal cord injury. Transient life-threatening cardiovascular instability and respiratory insufficiency may be seen and may recur in the first 7 to 10 days after injury. Patients with spinal cord lesions above T7 requiring long-term management have decreased cardiac output, hypotension, and problems with temperature regulation, limiting adaption to exercise.

Retrospective studies consistently report that volume expansion and blood pressure augmentation, in an ICU setting, are linked to improved ASIA scores in patients with acute spinal cord injury compared with historical controls. Class III evidence suggests that maintenance of mean arterial pressure (MAP) at 85 to 90 mm Hg after acute spinal cord injury for a duration of 7 days is safe and may improve cord perfusion and neurologic outcome.

Nutritional support to meet caloric and nitrogen needs, not to achieve nitrogen balance, is safe and may reduce the deleterious effects of catabolic, nitrogen wasting that occurs after acute spinal cord injury. Early enteral nutrition (initiated within 72 hours) is safe, but has not been shown to affect neurologic outcome, the length of hospital stay, or the incidence of complications.

Nasogastric tube feeding after restoration of normal intestinal activity, antacids, hyperalimentation when bowel atonia persists, and rectal digital stimulation, especially in young children, may be needed. In some children, gentle disimpaction is indicated. The use of enema continence catheters for bowel dysfunction after spinal cord trauma may significantly facilitate bowel care. Intermittent catheterization of the bladder is preferred to placement of an indwelling catheter to reduce the risk of urinary tract infection and renal failure.

Renal and urologic problems can occur after spinal cord injury. Anticholinergic and botulinum toxin therapy can reduce the effects of detrusor hyperreflexia (neurogenic bladder), present in approximately 60% of patients rendered quadriparetic from spinal cord injuries. Renal failure is a major cause of mortality in patients with chronic spinal cord injury.

Autonomic dysreflexia (AD) is a well-known clinical emergency in subjects who have had a spinal cord injury, especially at T6 or above. It is defined as "an increase in systolic blood pressure of at least 20% associated with a change in heart rate (and either tachycardia or bradycardia) and is accompanied by at least one of the following signs (sweating, piloerection, facial flushing) or symptoms (headache, blurred vision, anxiety, stuffy nose). Profuse sweating, flushing and piloerection occur above the level of injury and dry and pale skin below the injury. The higher the injury level, the more severe is the AD.

Untreated episodes of AD can have serious consequences, including intracranial hemorrhage, retinal detachment, seizures, and death. Physiologically, AD is caused by massive sympathetic discharge, triggered by either a noxious or non-noxious stimulus, originating below the level of the spinal cord injury. The more complete the spinal injury, the more likely is AD to occur. The most frequent triggers are irritation

of the urinary bladder or colon. Symptoms usually are short-lived, although there have been reports of AD sustained for days to weeks. It is usually evident a month or more postinjury, although cases has been reported after 1 week. Management of an episode of AD includes placing the patient upright, loosening tight clothing, eliminating any precipitating stimulus (bladder distention or bowel impaction in 85% of cases) and antihypertensive drugs in the presence of sustained hypertension.

Other general measures include chest physiotherapy to prevent pneumonia, frequent repositioning of the patient and the use of spinal beds (Stryker frame RotaBed) to avoid decubiti, and the use of Jobst stockings to minimize the risk of deep vein thromboses complicating pulmonary emboli. Occasionally, ventilation-perfusion scanning and pulmonary angiography are needed to establish the diagnosis of pulmonary emboli. The use of miniheparin treatment (continuous infusion) or intermittent low-dose heparin therapy may reduce the risk of pulmonary embolism. The risk of deep vein thrombosis in children younger than 12 years is low enough that chemoprophylaxis is not routinely recommended, unless other significant risk factors are present. Spine or spinal cord injury are at high risk for venous thromboembolism, with more severely injured patients at higher risk. Additional factors impacting on that risk are injury type and the presence of a central venous catheter. Vena cava filters are not recommended as a routine prophylactic measure, but are recommended for selected patients who fail anticoagulation or who are not candidates for anticoagulation and/or mechanical devices.

The healing of decubitus ulcers is aided by treatment with vitamin C (15–20 mg/kg/day). Muscle relaxants, such as diazepam, baclofen, cyclobenzaprine, and intravenous orphenadrine citrate may be helpful in the long-term management of spasticity after spinal cord injury. Additional antispasmodic treatments include intrathecal baclofen and tizanidine. Progressive spinal deformity is common in children after spinal cord injury, particularly after laminectomy. Chronic pain is also common, and its management can be difficult, necessitating intervention by pain management specialists and pediatric orthopedists. In patients in whom there is delayed deterioration of neurologic functioning, the presence of a syrinx should be sought; if one is found, the syrinx may need to be shunted (Proctor, 2002).

## Physical Therapy

Physical therapy is an important component of the long-term care of all patients with spinal cord injury. It should begin early and continue indefinitely. Proper limb positioning and passive muscle stretching can be instituted when the patient is medically and surgically stable. Later, after spinal shock has resolved, and early spasticity is evident, inhibitive casting can be used to minimize the development of limb contractures. Despite such measures, many patients later require botulinum toxin injections, phenol blocks, tendon lengthenings, and tendon transfers.

## Functional Electrical Stimulation (FES)

FES involves using electrical current to activate muscles through the stimulation of intact peripheral motor nerves to promote functional activities. By using FES across a certain sequence of muscle groups, a cycling motion can be produced, so-called FES cycling (FESC). FESC demonstrates limited yet encouraging results improving maximum volume of oxygen utilized in 1 minute (VO<sub>2</sub>) compared with passive cycling and quadriceps strengthening.

Despite spectacular videos in selected patients, FES has not yet fulfilled expectations with respect to achievable gait

function. To date, there remains an absence of randomized clinical trials to access the true efficacy of FES to improve walking.

## Gait Training

In the early 1990s, treadmill training with partial body weight support was used for patients with incomplete spinal cord injuries. Numerous open studies have suggested efficacy of body-weight supported treadmill training in improving gait ability and function in spinal cord injury patients. FES and gait training have often been used together. Treadmill training can induce significant improvement in walking speed, endurance, mobility and specific activities of daily life in incomplete spinal cord injury patients, whereas overground locomotor training can result in greater improvements in functional walking capacity.

Individuals with incomplete motor spinal cord injuries have demonstrated gains from locomotor training during the acute phase (up to 12 months post injury) as well as in the chronic phase (over 12 months post injury) of rehabilitation. The use of locomotor training in individuals with complete spinal cord injury has not produced gains in walking ability. For this population, the benefits of locomotor training may be limited to the advantages of exercise, such as a reduction of secondary complications of spinal cord injury (e.g., bone loss, muscle atrophy, impaired circulation, pressure sores, weight gain, diabetes) and improvements in quality of life (Filli and Schwab, 2012). Optimal onset and amount of training are still under active investigation but are not strictly standardized among centers, often complicating the interpretation and comparison of treatment effects between different treatment sites (Filli and Schwab, 2012).

Gradual mobilization out of bed should include increased sitting tolerance, with proper weight shifts and pressure relief techniques; ambulation should be instituted early. Early initiation of the rehabilitation process is considered fundamental to enhance plasticity, but the best timing of treatment interventions is not known. Locomotor training with practiced walking might improve a person's ability to walk, but there are many additional helpful strategies as well, including treadmill training, body weight support, robotic-assisted gait training and electrical stimulation. A very comprehensive overview of therapies used to regain ambulatory function can be found in SCIRE 2006, a user-friendly, online neurotrauma research evidence resource (<http://www.scireproject.com>).

In a systematic review comparing different locomotor therapies for adults with incomplete spinal cord injury, it was not possible to identify the superiority of one locomotor treatment over another. A Cochrane review had similar conclusions citing insufficient evidence from randomized controlled trials. Additionally, the effects of robotic-assisted locomotor training are not clear.

## Adaptive Technology

While in bed, patients who are unable to mobilize their ankle dorsi- or plantar flexors should wear pressure relieving ankle-foot orthoses to prevent muscle shortening of the gastrocnemius complex and to prevent pressure injury of the heels. Molded wrist-hand orthoses can help to maintain a functional position and prevent flexion contractures of the digits in those with flexor spasticity. FES can be used along with adaptive technology. A power-assisted wheelchair for those who are able to use their hands can facilitate functional independence. The use of strollers should be limited to infants and toddlers. Children, as young as 1 year of age, should be encouraged to utilize a powered or manual wheelchair to facilitate independence. An ankle-foot orthosis provides ankle and foot support

for the user who has sufficient hip and knee strength to control the knee during stance and swing. For incomplete motor spinal cord injury (AIS C and AIS D), the decision to use an orthosis and ambulation potential are determined by the strength and function of individual lower limb muscle groups, as well as biomechanical alignment, proprioception, and range of motion, in addition to upper extremity strength. For children without cognitive disabilities, power mobility training can be started within the first year of life. It is natural for children with spinal cord injury to progress to different orthotics, different assistive devices, and ultimately to a wheelchair. Progression to increased reliance on a wheelchair must be viewed as a natural process and not as a failure.

Future directions in assistive device technology include brain-based command integration for the manipulation of neuroprostheses or other assistive devices as shown by a person with chronic tetraplegia performing consistent, natural, and complex movements with an anthropomorphic robotic arm to regain clinically significant function.

### Psychological Therapy

 For discussion, please see the online chapter.

### The Multidisciplinary Needs of the Child With a Spinal Cord Injury

The spectrum of possible needs of a child who has suffered a spinal cord injury is vast, as is the spectrum of available services. Children do best when a team of health care professionals work together, with one member the “quarterback” of the team. Depending on the severity/complexity of the case, health professionals who could be helpfully involved include: *physicians* (cardiologist, gastroenterologist, generalist, intensivist, nephrologist, neurologist, neurosurgeon, orthopedist, pain specialist, pediatrician, physiatrist, pulmonologist, urologist); *nurses and nurse practitioners; nutritionists; therapists* (physical; occupational; speech/language); mental health specialists (social worker, psychologist); educators (teacher, tutor); job coaches; home health aides.

### Surgical Management

The Surgical Timing in Acute Spinal Cord Injury Study (STASCIS), a multicenter prospective cohort study in adult patients with cervical cord injury compared early surgery (mean 14.2 hours) and late surgery (mean 48.3 hours). Decompression within 24 hours of injury was associated with improved neurologic outcome, defined as at least a two-grade improvement on the ASIA scale at 6-month follow up. This study reflects a growing consensus among spine surgeons favoring early surgery.

One reasonable approach might be to limit surgery to patients with partial cord injuries and a progressing neurologic deficit and patients with bilaterally locked facets, an unstable fracture and/or dislocation; surgery in the latter group would minimize the risk of later development of curvature of the spine. Additional indications for surgery might include: (1) inadequate reduction of a spinal fracture by traction alone, (2) epidural hematoma, (3) traumatic disk herniation, and (4) spinal cord compression by bony fragments (Figure 106-9).

 A recent review assessing management of pediatric cervical spine and spinal cord injuries reported difficulty in collecting criteria for operative intervention in children with such injuries. From the available literature, the following guidelines were provided, based on class III evidence: (1) For odontoid injuries in children younger than 7 years of age, closed reduction and halo immobilization; (2) For acute atlantoaxial

rotatory fixation (AARF) (< 4 weeks duration) that does not reduce spontaneously, reduction with manipulation or Halter traction; (3) For chronic AARF (> 4 weeks duration), reduction with Halter traction or tong/halo traction; (4) Internal fixation and fusion for patients with recurrent and/or irreducible AARF.

Primarily ligamentous injuries of the cervical spine in children may heal with external immobilization alone, but these injuries are associated with a relatively high rate of persistent or progressive deformity when treated nonoperatively. Therefore operative treatment should also be considered for primary ligamentous injury, particularly when accompanied by unstable or irreducible fractures/dislocations associated with deformity. (class III evidence).

About 7.5–30 % of patients with thoracolumbar fractures need operative treatment. In one prospective study of children with thoracolumbar vertebral fractures, indications for surgery included: unstable fractures, fracture dislocations, fractures with more than 20° kyphosis, canal compromise of more than 50% with neurologic deficits. Spinal fusion and instrumentation were reported to have a favorable radiologic and functional outcome. Minimally invasive spinal (MIS) surgery techniques have been used sporadically in thoracolumbar junction spinal trauma cases for the past 5 years, and have been used successfully in select cases of burst fractures.

### PROGNOSIS

Mortality rates in pediatric patients with cervical spine injuries ranges from 16% to 18%, with morbidity and mortality especially high in children with an upper cervical spine injury or atlantooccipital dislocation (Huisman et al., 2015). In-hospital mortality in the infant/toddler group (ages 0–3 y), where cervical spine injuries, particularly of the upper spine, were much more common than in the younger group (4–9 y), was significantly greater in the infant/toddler group (25% vs 9%). Two-year survival rates were better in younger patients (16–30 years old) than in older ones (61–86 years old), 95% versus 59%.

In the past, renal failure was the leading cause of death. More recently, it has been replaced by sepsis, pneumonia and respiratory failure. Age, level and severity of injury are important factors affecting prognosis including mortality. Most motor recovery occurs within the first 2 months of rehabilitation. Recovery depends on the severity of injury, segment of the spinal cord where the injury occurs and which nerve fibers are damaged (NINDS, 2006). An important outcome predictor is the amount of damage to the sensory pathways. If sensory function is spared, the motor outcomes appear to be better. For patients with incomplete sensory lesions (AIS: B), with preserved sacral sensitivity to pin, often more than 50% of individuals become ambulatory; for patients with incomplete motor lesions (AIS: C) 75% will recover community ambulation.

In a review of the role of MRI in acute spinal cord injury, patients were stratified by the AIS scale and the MRI findings on T2 weighted images into: normal cord, single level edema, diffuse edema, and hemorrhage. Patients with hemorrhage are initially ASIA A about 95% of the time and improved one ASIA grade about 5% of the time. Single-level edema patients showed an improvement of about two grades in ASIA score, compared with an improvement of one grade for patients with diffuse edema. Based on Delphi discussions, it is strongly recommended, based on moderate evidence, that an MRI (sagittal T2 MRI sequence) be done in the acute period following a spinal cord injury to assist with prognostication.

In a study looking at complications of spinal cord injury in 159 children 5 years or younger, 96% developed scoliosis,

57% had hip dysplasia, and 7% had latex allergy. Thirty-four percent with injuries at or above T6 experienced autonomic dysreflexia, 41% developed pressure ulcers, and 61% experienced spasticity. Of those without bowel or bladder control, 82% were on intermittent catheterization and 69% were on a bowel program. Median age of initiating wheelchair use was 3 years 4 months (range 1y 2mo to 12y 5mo). Twenty-four were community ambulators, and were more likely to have AIS D lesions. Using manual or powered mobility, 98% of participants in this study were capable of independent wheelchair propulsion.

## PREVENTION

Spinal cord injuries are devastating at any age, but are especially tragic and expensive in children. Preventing these injuries is probably the greatest challenge in dealing with spinal cord injuries. Continued investment in educational programs, with ongoing efforts to heighten public awareness of the risks and consequences of spinal cord injuries, is crucial. Highway driving speed limits should be strictly enforced. People who drink alcohol should not drive. Risk-taking behavior must be minimized, particularly in people taking sedating medications, alcohol or illicit drugs. The need for protective helmets, in sports such as baseball, skiing, snowboarding, soccer and bicycling, cannot be overstressed. Diving into unfamiliar waters, particularly if shallow, must be avoided. Certain sports, particularly tackle football, carry with them a substantial risk of spinal injury, and this needs to be recognized. Other sports placing the child at potential risk for spinal cord injury include hockey, gymnastics, skiing, snowboarding, lacrosse, rugby and mountain biking. Appropriate use of rear-facing car seats, forward-facing car seats and booster seats, until the child is old/large enough to be secured by seat belts, saves lives and prevents spinal and accompanying injuries. Airbags also save lives and neurologic function, particularly since side airbags have been added to motor vehicles previously equipped with only frontal airbags. Further, any efforts that can result in reduction of societal violence, particularly involving guns and knives, can be expected to result in a corresponding reduction in spinal cord injuries.

# 107 Determination of Brain Death in Infants and Children

Mudit Mathur and Stephen Ashwal

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

The diagnosis of brain death in infants and children is made after careful review of the medical history and performance of a detailed neurologic examination establishing irreversible cessation of brain function. In the United States and most other countries, the 1987 pediatric guidelines of the American Academy of Pediatrics (AAP) provided the basis for brain death determination in children (AAP Task Force on Brain Death in Children, 1987). These guidelines were revised in 2011 (Nakagawa et al., 2011). Revisions include updates related to the initial waiting period before conducting the first brain death examination, who should conduct the examination, the number of examinations, the interexamination interval, the number of apnea tests, partial pressure of carbon dioxide (Paco<sub>2</sub>) thresholds during apnea testing, and when an ancillary test may be used to reduce the interexamination observation interval or assist with the diagnosis of brain death (Nakagawa et al., 2011). Further clarification is provided regarding the determination of brain death in newborns. A checklist is included to assist clinicians with consistent performance and documentation of examination elements and ancillary testing (see Fig. A-2 in Appendix A).

## HISTORICAL PERSPECTIVE

A state beyond coma, or coma dépassé, was proposed in 1959 by Mollaret and Goulon to describe a premonitory clinical condition with loss of sensation, motor activity, consciousness, and vegetative functions, and in 1968 an ad hoc committee of the Harvard Medical School faculty recommended clinical guidelines that subsequently shaped the development of brain death concepts. Failure of improvement over 24 hours established a diagnosis of brain death in a normothermic patient, with drugs capable of maintaining coma excluded. Two isoelectric electroencephalograms (EEGs) performed 24 hours apart were considered confirmatory, but not essential, in the declaration of brain death. Reports in the 1970s from the Medical Royal College and Faculties in the United Kingdom recommended that brainstem death be considered death, and in 1980 the National Institute of Neurologic and Communicative Disorders and Stroke (NINCDS) Collaborative Study of Brain Death emphasized that the combination of loss of the pupillary light reflex, corneal reflex, oculocephalic reflex (doll eye phenomenon), and oculovestibular reflex (caloric eye deviation) was highly predictive of death. Apnea, coma, and absence of brainstem reflexes, combined with an electrocerebral silent EEG, were highly associated with pathology in a brain that had experienced long-term ventilator exposure. The report concluded that drug screening and EEG monitoring were mandatory before declaring brain death. Subsequent reports in adults and children documented that EEG activity could persist in unequivocally brain dead patients.

In 1981, a U.S. presidential commission established brain death guidelines based on the irreversible cessation of function of the entire brain and noted that adult criteria might not be applicable to children younger than 5 years of age. The American Academy of Neurology (AAN) published adult (i.e.,

individuals older than 18 years of age) brain death guidelines in 1995 and revised them in 2010, with the more recent guidelines recommending that only one examination be required, that ancillary testing is not necessary, and that the diagnosis could be made solely on clinical criteria. Box 107-1 summarizes the recommendations section of the 2010 American Academy of Neurology (AAN) parameter that provides practical (non-evidence-based) guidance for determination of brain death in adults.

It was suggested that if the examination is equivocal, additional neurodiagnostic testing could be done (Wijdicks et al., 2010). As noted, the first pediatric brain-death guidelines were published in 1987 by the AAP (AAP Task Force on Brain Death in Children, 1987) and substantially revised in 2011 (Nakagawa et al., 2011); these guidelines are summarized in Boxes 107-2 and 107-3.

## LEGAL DEFINITION OF BRAIN DEATH

The American Medical Association and the American Bar Association supported enactment of the Uniform Determination of Death Act (UDDA) of 1980, which defined death, stating that “an individual who has sustained either (1) irreversible cessation of circulatory and respiratory functions; or (2) irreversible cessation of all functions of the brain including the brainstem is dead.” Brain death is legally accepted as death under the UDDA in almost all states and recognized in the rest through judicial opinion.

## EPIDEMIOLOGY

### Incidence of Brain Death

It is estimated that approximately 1800 children in the United States are declared brain-dead every year (Figure 107-1). Studies from pediatric intensive care units in the 1990s reported that the incidence of brain death in older infants and children ranged from 0.65% to 1.2% of admissions. A recent case series reported that brain death occurred in 16% of 192 patients who died, with withholding or withdrawal of life support being the predominant mode of death (in 70%). The length of stay for 80% of the patients declared brain-dead was less than 7 days (median of 2.9 days). In some pediatric intensive care units, the percentage of patients diagnosed as brain-dead has been reported to be up to 38% of all deaths.

### Etiologies of Brain Death

Brain death most commonly occurs in adolescents and less so in infants younger than 1 year of age (see Table 107-1). Closed head injury is the most common clinical presentation leading to brain death (50%), followed by intracranial hemorrhage and stroke (12%). Asphyxial injury usually occurs as a complication of septic or hemorrhagic shock, with unexplained out-of-hospital cardiac arrest, or from strangulation or suffocation. Sudden infant death syndrome is a rare cause of brain

**BOX 107-2** Summary Recommendations for the Diagnosis of Brain Death in Neonates, Infants, and Children from the 2011 Pediatric Guidelines**1. DETERMINATION OF BRAIN DEATH**

- Determination of brain death in neonates, infants, and children relies on a clinical diagnosis that is based on the absence of neurologic function with a known irreversible cause of coma. Coma and apnea must coexist to diagnose brain death. This diagnosis should be made by physicians who have evaluated the history and completed the neurologic examinations.

**2. PREREQUISITES FOR INITIATING A BRAIN DEATH EVALUATION**

1. Hypotension, hypothermia, and metabolic disturbances that could affect the neurologic examination must be corrected before examination for brain death.
2. Sedatives, analgesics, neuromuscular blockers, and anticonvulsant agents should be discontinued for a reasonable time period, based on elimination half-life of the pharmacologic agent, to ensure that they do not affect the neurologic examination. Knowledge of the total amount of each agent (mg/kg) administered since hospital admission may provide useful information concerning the risk of continued medication effects. Blood or plasma levels to confirm that high or supratherapeutic levels of anticonvulsants with sedative effects are not present should be obtained (if available), and repeated as needed or until the levels are in the low to middle therapeutic range.
3. The diagnosis of brain death based on neurologic examination alone should not be made if supratherapeutic or high therapeutic levels of sedative agents are present. When levels are in the low to middle therapeutic range, medication effects sufficient to affect the results of the neurologic examination are unlikely. If uncertainty remains, an ancillary study should be performed.
4. Assessment of neurologic function may be unreliable immediately following cardiopulmonary resuscitation or other severe acute brain injuries, and evaluation for brain death should be deferred for 24 to 48 hours or longer if there are concerns or inconsistencies in the examination.

**3. NUMBER OF EXAMINATIONS, EXAMINERS, AND OBSERVATION PERIODS**

1. Two examinations, including apnea testing, with each examination separated by an observation period, are required.
2. The examinations should be performed by different attending physicians involved in the care of the child. The apnea test may be performed by the same physician, preferably the attending physician who is managing ventilator care of the child.
3. Recommended observation periods are as follows:
  - a. 24 hours for neonates (37 weeks' gestation to term infants 30 days of age)
  - b. 12 hours for infants and children (>30 days to 18 years)
4. The first examination determines that the child has met neurologic examination criteria for brain death. The second examination, performed by a different attending physician, confirms that the child has fulfilled criteria for brain death.
5. Assessment of neurologic function may be unreliable immediately following cardiopulmonary resuscitation or other severe acute brain injuries, and evaluation for brain death should be deferred for 24 to 48 hours or longer if there are concerns or inconsistencies in the examination.

**4. APNEA TESTING**

1. Apnea testing must be performed safely and requires documentation of an arterial  $\text{PaCO}_2$  20 mm Hg above the

baseline  $\text{PaCO}_2$  and  $\geq 60$  mm Hg, with no respiratory effort during the testing period, to support the diagnosis of brain death. Some infants and children with chronic respiratory disease or insufficiency may only be responsive to supranormal  $\text{PaCO}_2$  levels. In this instance the  $\text{PaCO}_2$  level should increase to  $\geq 20$  mm Hg above the baseline  $\text{PaCO}_2$  level.

2. If the apnea test cannot be performed because of a medical contraindication or cannot be completed because of hemodynamic instability, desaturation to  $< 85\%$ , or an inability to reach a  $\text{PaCO}_2$  of 60 mm Hg or greater, an ancillary study should be performed.

**5. ANCILLARY STUDIES**

1. Ancillary studies (electroencephalogram and radionuclide cerebral blood flow) are not required to establish brain death, unless the clinical examination or apnea test cannot be completed.
2. Ancillary studies are not a substitute for the neurologic examination.
3. For all age groups, ancillary studies can be used to assist the clinician in making the diagnosis of brain death to reduce the observation period, or in the following situations:
  - a. When components of the examination or apnea testing cannot be completed safely because of the underlying medical condition of the patient.
  - b. When there is uncertainty about the results of the neurologic examination.
  - c. When medication effect may interfere with evaluation of the patient.  
If the ancillary study supports the diagnosis, the second examination and apnea testing can then be performed. When an ancillary study is used to reduce the observation period, all aspects of the examination and apnea testing should be completed and documented.
4. When an ancillary study is used because there are inherent examination limitations (i.e., i–iii), the components of the examination done initially should be completed and documented.
5. If the ancillary study is equivocal or if there is concern about the validity of the ancillary study, the patient cannot be pronounced dead. The patient should continue to be observed until brain death can be declared on clinical examination criteria and apnea testing, or a follow-up ancillary study can be performed to assist with the determination of brain death. A waiting period of 24 hours is recommended before further clinical reevaluation or a repeat ancillary study is performed. Supportive patient care should continue during this time period.

**6. DECLARATION OF DEATH**

1. Death is declared after confirmation and completion of the second clinical examination and apnea test.
2. When ancillary studies are used, documentation of components from the second clinical examination that can be completed must remain consistent with brain death. All aspects of the clinical examination, including the apnea test, or ancillary studies must be appropriately documented.
3. The clinical examination should be carried out by experienced clinicians who are familiar with infants and children and have specific training in neurocritical care.

### BOX 107-3 Neurologic Examination Criteria for Brain Death in Infants and Children from the 2011 Guidelines

1. Coma: The patient must exhibit complete loss of consciousness, vocalization, and volitional activity.
2. Apnea: The patient must have a complete absence of documented respiratory effort (if feasible) by formal apnea testing demonstrating a  $\text{PaCO}_2 \geq 60$  mm Hg and  $\geq 20$  mm Hg increase above baseline.
3. Loss of all brainstem reflexes, including the following:
  - Midposition or fully dilated pupils that do not respond to light
  - Absence of movement of bulbar musculature, including facial and oropharyngeal muscles
  - Absent gag, cough, sucking, and rooting reflexes
  - Absent corneal reflexes
  - Absent oculovestibular reflexes.
4. Flaccid tone and absence of spontaneous or induced movements: excluding spinal cord events, such as reflex withdrawal or spinal myoclonus.
5. Reversible conditions or conditions that can interfere with the neurologic examination: must be excluded before brain death testing.

death, as are meningitis, rare metabolic diseases, perioperative insults, acute hydrocephalus, and other rare disorders that affect the brain.

### Outcome after Diagnosis of Brain Death

Most children are removed from life support or undergo organ donation within a 2-day time period after the diagnosis of brain death is confirmed. Some children are continued on ventilator support until cardiac arrest occurs, and their "survival" has averaged about 17 days. In rare cases, children have been maintained on ventilator support for 6 months to 5 years.

### NEUROLOGIC EVALUATION

Variability exists in the diagnosis of brain death in children, including the use of apnea testing. Issues involved in this variability include lack of documentation of the history and examination findings, insufficient knowledge of brain death criteria, inappropriate use of ancillary testing, failure to perform serial examination, and lack of awareness that brain death can be diagnosed without ancillary testing in children older than 1 year of age. The 2011 guidelines update (Nakagawa et al., 2011) facilitates completeness of the neurologic evaluation and seeks to reduce practice variability by providing a checklist for the determination and documentation of brain death (see Fig. A-1 in Appendix A).

### Clinical Examination

#### Cerebral Unresponsivity

Clinicians should first identify an underlying etiology for coma and exclude potentially reversible diagnoses. The initial period of stabilization and diagnostic workup before clinical evaluation for brain death may be 24 hours or longer following severe acute brain injuries. Normalizing body temperature (core temperature greater than or equal to  $95^\circ\text{F}$  [ $35^\circ\text{C}$ ]) and

blood pressure, correcting severe metabolic disturbances, and ensuring that sedative or neuromuscular blocking agents have had adequate time to be metabolized are important prerequisites. Assessment for cerebral unresponsivity, loss of cranial nerve function, and determination of apnea (tested with a hypercapnic stimulus) must then be performed and documented. Cerebral unresponsivity or coma can be quantified using the Glasgow Coma Scale score (Chapter 101). In young children, recovery may occur after unresponsiveness has occurred for prolonged periods, and even when serious structural nervous system abnormalities are present. If the neurologic evaluation is uncertain or inconsistent, the examination may be repeated to exclude reversible or changing neurologic function; alternatively, supportive ancillary tests may be considered.

### Brainstem Examination

Cessation of brainstem reflexes is generally accepted as the hallmark of brain failure. The NINCDS report indicated that although the combination of the loss of the pupillary light response and oculocephalic and oculovestibular reflexes had the greatest specificity, this combination included 4% of patients who retained other brainstem reflexes. The 2011 pediatric guidelines (Nakagawa et al., 2011) recommend that doing cold caloric testing is sufficient and that oculocephalic testing (which involves turning the patient's head) is not necessary; the guidelines also state that because some individuals could have spinal cord injury, such testing might pose additional risk. Box 107-4 in the online chapter outlines the procedures used to assess the cold caloric (oculovestibular) response. Premature infants of less than 32 weeks' conceptual age do not have completely developed cranial nerve function. Clinicians examining these infants should be aware of the development of the different cranial nerve reflexes during gestation (see Table 107-2). Newborns often present obstacles to examination. Ear canals are frequently small and may be plugged, pupils are small, adhesive tape obscures the face and extremities, and neuromuscular blocking agents alter the examination. The 2011 pediatric guidelines (Nakagawa et al., 2011) include recommendations for term infants from 37 weeks' gestation. Recommendations for preterm infants younger than 37 weeks were not included because of insufficient evidence. Brain death rarely occurs in preterm infants, so clinicians will likely not have to confront the issue of trying to diagnose brain death in this population.

#### Number of Examinations, Examiners, and Observation Periods

**Number of Examinations and Examiners.** The 2011 guidelines (Nakagawa et al., 2011) recommend performance of two examinations separated by an observation period and that the best interests of the child and family would be served if at least two different attending physicians participate in diagnosing brain death to ensure that (1) the diagnosis is based on currently established criteria, (2) there are no conflicts of interest in establishing the diagnosis, and (3) there is consensus of at least two physicians involved in the care of the child that brain death criteria are met. The 2011 guidelines also note that because the apnea test is an objective test, it may be performed by the same physician, preferably the attending physician who is managing ventilator care of the child. The recommendation for two complete clinical examinations has been criticized for making the diagnosis of brain death in children unnecessarily complicated and creating delays in the possibility of organ donation. The opinion of the committee members who drafted the 2011 guidelines was based on the fact that cases

with “improvement” and apparently reversible brain death days after brain injury often have diagnostic errors when critically reexamined.

**Duration of Observation Periods.** A literature review of 171 children diagnosed as brain-dead found that 47% had ventilator support withdrawn, on average, 1.7 days after the diagnosis of brain death was made (Ashwal and Schneider, 1987). Of those continued on ventilator support, 46% suffered a cardiac arrest an average of 22.7 days later. These data and the reports of more recent studies suggest that there is likely no biological justification for using different durations of observation to diagnose brain death in infants greater than 1 month of age. Although some authors have reported apparent reversibility of brain death, review of these cases reveals that these children would not have fulfilled currently used criteria.

Based on the data just noted, current literature, and clinical experience, the 2011 guidelines recommend that the observation period between examinations should be 24 hours for neonates (37 weeks up to 30 days) and 12 hours for infants and children (>30 days to 18 years). The first examination determines that the child has met neurologic examination criteria for brain death. The second examination confirms brain death, based on an unchanged and irreversible condition.

### Apnea Testing

Documentation of apnea is the most important determination in the clinical evaluation of brain death. Virtually all protocols recommend a period without assisted ventilation. The normal physiologic apneic threshold (minimum  $PCO_2$  at which respiration begins) depends on many factors, and can be altered by anesthetic agents, narcotics, sedatives, and certain disease states. The maximal  $PCO_2$  apneic threshold in children is probably similar to that in adults (60 mm Hg); the data from previous pediatric studies is summarized in Table 107-3 in the online chapter. Apnea testing of patients who are hypothermic or receiving medications that suppress respiration is not valid for documenting brainstem failure. It still can be performed, however, because the presence of respiratory effort would eliminate brain death as a diagnosis. Several case reports involving only a few patients have raised related issues concerning apnea testing in young infants and children that also apply to newborns. These cases were associated with compressive brainstem lesions and the return of ineffective minimal respiratory effort, but are too few in number to draw any conclusions.

**Technique for Performing Apnea Testing.** An apnea test should be performed with each brain death examination unless a medical contraindication (e.g., high cervical spine injury) exists. Recommendations for performing apnea testing in term newborns, infants, and children are provided in the 2011 pediatric brain death guidelines (Nakagawa et al., 2011; see Box 107-5). This includes normalization of the pH and  $PaCO_2$ , measured by arterial blood gas analysis, maintenance of core temperature greater than 35°C (95°F), normalization of blood pressure appropriate for the age of the child, and correction of factors that could affect respiratory effort as a prerequisite to testing. The patient must be preoxygenated, using 100% oxygen, before initiating this test. Intermittent mandatory mechanical ventilation should be discontinued once the patient is well oxygenated and a normal  $PaCO_2$  has been achieved. The patient can then be changed to a T piece attached to the endotracheal tube (ETT), or a self-inflating bag-valve system. Tracheal insufflation of oxygen using a catheter inserted through the ETT has also been used; however, caution is warranted to ensure adequate gas excursion and to prevent barotrauma. High gas-flow rates with tracheal insufflation may also promote  $CO_2$  washout, preventing adequate  $PaCO_2$  rise during apnea testing. Physicians performing apnea

testing should continuously monitor the patient’s heart rate, blood pressure, and oxygen saturation while observing for spontaneous respiratory effort. If no respiratory effort is observed from the initiation of the apnea test to the time the measured  $PaCO_2$  is greater than or equal to 60 mm Hg and greater than or equal to 20 mm Hg above the baseline level, the apnea test is consistent with brain death. The patient should be placed back on mechanical ventilator support and medical management should continue until the second neurologic examination and apnea test confirming brain death is completed. If oxygen saturations fall below 85%, hemodynamic instability limits completion of apnea testing, or a  $PaCO_2$  level of greater than or equal to 60 mm Hg cannot be achieved, the patient should be placed back on ventilator support with appropriate treatment to restore normal oxygen saturations, normocarbia, and hemodynamic parameters. Another attempt to test for apnea may be performed later, or an ancillary study may be pursued to assist with determination of brain death. Evidence of any respiratory effort is inconsistent with brain death, and the apnea test should be terminated and the patient placed back on ventilatory support.

### ANCILLARY NEURODIAGNOSTIC STUDIES

Virtually all guidelines have stressed that the historical events leading to coma, when combined with the clinical triad of coma, absence of brainstem reflexes, and a failed apnea challenge, are fundamental to brain death diagnosis. Many physicians have sought an absolute laboratory test to confirm brain death. The combination of clinical evaluation and pertinent diagnostic studies (EEG, cerebral blood flow [CBF] studies) can yield a sound clinical decision. However, data acquired over the past two decades have clearly shown that some patients may have EEG activity or demonstrable CBF when they meet clinical criteria for irreversible brain death. Because of such observations and general consensus, the 2011 pediatric guidelines (Nakagawa et al., 2011) note that ancillary studies are not required to establish brain death and should not be viewed as a substitute for the neurologic examination. The guidelines (Nakagawa et al., 2011) recommend ancillary studies to assist the clinician in making the diagnosis of brain death in the following situations:

1. When components of the examination or apnea testing cannot be completed safely because of the underlying medical condition of the patient;
2. If there is uncertainty about the results of the neurologic examination;
3. If a medication effect may be present;
4. To reduce the interexamination observation period.

The 2011 guidelines also recommended that, similar to the neurologic examination, hemodynamic and temperature parameters should be normalized before obtaining EEG or CBF studies. Pharmacologic agents that could affect the results of testing should be discontinued and levels determined as clinically indicated (see Table 107-4). The 2011 guidelines note that therapeutic levels of barbiturates in the low to middle range should not preclude the use of EEG testing, and that a CBF study could be used in patients with high-dose barbiturate therapy to demonstrate absence of CBF.

### Electroencephalogram

Despite limitations of the EEG, many physicians tend to equate an isoelectric EEG (electrocerebral silence [ECS]) with brain death. An isoelectric EEG, combined with the clinical triad of coma, absent brainstem reflexes, and apnea, remains a common method to determine brain death. The American

**Electroencephalographic Society (1994)** developed criteria for brain-death recordings. According to these guidelines, the recording should be isoelectric for a minimum of 30 minutes and show no electrical activity beyond 2  $\mu\text{V}$  at a sensitivity of 2  $\mu\text{V}/\text{mm}$ , with filter settings at 0.1 or 0.3 second at 70 Hz.

### Electroencephalogram in Pediatric Brain Death

Pediatric patients present unique difficulties in interpretation of the EEG because of shorter interelectrode distances, greater electrocardiogram contamination, reduced cortical potentials in premature infants, and delayed metabolism of barbiturates. Reversible ECS may occur with the use of drugs that depress the activity of the central nervous system, hypothermia, cardiovascular shock, or metabolic encephalopathies. In children, the most common medications causing the reversible loss of brain electrocortical activity include barbiturates, benzodiazepines, narcotics, and certain intravenous and inhalation anesthetics.

A core temperature greater than 32.2° C (>90° F) has been regarded as a prerequisite for reliably determining brain death by EEG. In children, suppression of EEG activity does not appear until 24° C (75.2° F), and complete loss of EEG activity does not occur until the temperature is less than 18° C (<64.4° F). The average temperature when EEGs are obtained for confirmation of brain death is 36.2  $\pm$  0.8° C (97.3° F  $\pm$  1.4° F). Reversible ECS may occur soon after a child has had a cardiac arrest.

Although not well documented, electrolyte, acid-base, and blood-gas abnormalities; severe hepatic and renal dysfunction; and certain inborn errors of metabolism all have been considered capable of decreasing brain electrocortical activity to the point of causing complete cortical inactivity. In selected children in whom the etiology of brain death is uncertain, evaluation for metabolic diseases should be considered.

Extensive literature exists documenting persistent EEG activity in brain-dead infants, children, and adults. Table 107-5 in the online chapter and Table 107-8 summarize data from the 2011 guidelines (Nakagawa et al., 2011). The data show that 76% of all children who were evaluated with EEG for brain death had ECS on the first EEG. Multiple EEGs increased the yield to 89%. For those children who had ECS on the first EEG, 97% had ECS on a follow-up EEG. Of those patients with EEG activity on the first EEG, 55% had a subsequent EEG that showed ECS. The remaining 45% either had persistent EEG activity or additional EEGs were not performed. All died (spontaneously or by withdrawal of support).

Since a 1972 report of two infants who displayed the return of some EEG activity after an initial ECS recording, there have only been a few reports of additional infants in whom EEG activity returned. A previous report, based on these cases, estimated that the return of EEG activity when the initial study was isoelectric was approximately 0.02% (Ashwal, 1997). Concerns about the return of EEG activity have been overemphasized. If one considers issues related to subsequent clinical status of the patients in whom EEG activity returned, no patients have made significant clinical recoveries.

### Measurements of Cerebral Perfusion

Several technologies are available for estimating or measuring CBF (see Table 107-6).

#### Cerebral Angiography

Direct visualization of the cerebral circulation with angiography that shows the complete cessation of CBF was long accepted as the standard for comparing all other neuroimaging modalities for brain-death confirmation. This technique

has multiple limitations and is no longer used for documenting cessation of CBF in children.

#### Radionuclide Imaging

Several radionuclide techniques have been used in brain-dead patients to determine noninvasively whether there has been cessation of cerebral circulation. Circulation can be assessed during an early “dynamic” phase and later by examining static images for cerebral uptake of the specific radionuclide (technetium-99m pertechnetate, technetium-99m glucoheptonate, or technetium-99m diethylene-triamine-pentaacetate [DTPA]) (see Figure 107-2). During the dynamic phase, a radionuclide bolus is injected rapidly, and isotopic cranial images are obtained similar to those of carotid arteriograms. In the arterial phase, cerebral activity is detectable within several seconds, followed by sagittal sinus activity within 6 to 8 seconds. If activity is not detectable in this early phase, CBF is considered absent, resulting from either low cardiac output or very high intracranial pressure. Because most tracers have a half-life of several hours, the static phase of a radionuclide imaging study usually is done later, to look for the absence or presence of diffuse parenchymal isotopic uptake. Most centers use single-photon emission computed tomography scanning and technetium-99m hexamethylpropylene amine oxime (HMPAO) as the isotopic agent.

Multiple studies have documented radionuclide imaging to be accurate, reproducible, and similar to other methods of CBF detection. This technique is particularly useful when hypothermia or elevated barbiturate levels preclude valid EEG interpretation. Premature and full-term newborns, despite having extremely reduced CBF compared with older children, can be evaluated using radionuclide measurements.

The 2011 guidelines (Nakagawa et al., 2011) summarize CBF data from 12 studies in 681 suspected brain-dead children (see Table 107-7). Absent CBF was found in 86% of clinically brain-dead children, and the yield did not significantly change if more than one CBF study was done (89%). It was found that 92% of patients who initially had absent CBF also had no flow on follow-up studies. The two exceptions, in whom flow developed later, were newborns. In those patients with preserved CBF on the first CBF study, 26% had a second CBF study that showed no flow. The remaining 74% had preserved flow or no further CBF studies were done, and all but one patient died (either spontaneously or after withdrawal of support).

#### Computed Tomographic Angiography and Perfusion

The computed tomographic angiography (CT-a) and perfusion (CTP) techniques combine conventional CT with rapid bolus infusion of a contrast agent to examine the vascular structure and flow of any organ system. Several recent studies have examined their use in adults who met brain death criteria; these studies report very good sensitivity and specificity. There have been several case reports documenting that CT-a may not show findings confirming the absence of CBF. CT-a is a promising method for use in determining the absence of intracranial circulation, but studies in pediatric brain-dead patients have not yet been published.

#### Magnetic Resonance Imaging and Magnetic Resonance Angiography

Magnetic resonance imaging (MRI) and magnetic resonance (MR) angiography also have been used to evaluate cerebral circulation in brain dead adults. Characteristic features include transtentorial and foramen magnum herniation, absent intracranial vascular flow void, poor gray–white matter

differentiation, no intracranial contrast enhancement, carotid artery enhancement (intravascular enhancement sign), and prominent nasal and scalp enhancement. Presumably, similar neuroimaging findings would be present in children, but this has not yet been well established.

### Transcranial Doppler Ultrasonography

Transcranial Doppler ultrasonography has advocates because of its obvious portability, noninvasiveness, and isolette accessibility. Recent studies document a high rate of false-negative test results and lower levels of specificity and sensitivity, which suggest sufficient limitations in the use of this technique for brain-death confirmation.

### Digital Subtraction Angiography

Digital subtraction angiography can be used to assess the intracranial circulation. A small amount of nonionic contrast material is injected intravenously or intraarterially while digital subtraction imaging of the cerebral vasculature is completed. This procedure allows visualization of contrast within the major intracranial vessels; lack of such visualization indicates absence of CBF. There are few reports of use of this technique in children and only one case report in a neonate diagnosed with brain death.

### Xenon Computed Tomography

Stable xenon CT and 133-xenon CT are examples of reliable and well-documented tests that are seldom available because of cost and limited personnel, and these methods are seldom if ever used in children being evaluated for brain death. Xenon CT allows quantitative and regional measurement of CBF, and previous studies have documented marked CBF reductions in brain-dead adults and children compared with comatose patients.

### Positron Emission Tomography

The results of positron emission tomography (Chapter 12) have been reported for only a few brain-dead patients. Because of limited availability, cost, and lack of comparison studies, positron emission tomography offers no advantages over the more standardized techniques and is not used for confirmation of brain death.

### Magnetic Resonance Spectroscopy

In the 1980s and 1990s, phosphorus ( $^{31}\text{P}$ ) and proton ( $^1\text{H}$ ) MR spectroscopy were used to measure aspects of brain metabolic activity noninvasively (Chapter 12). Studies in neonates, older infants, and children have reported significant abnormalities, with loss of metabolic activity associated with severe acute central nervous system insults and with poor long-term outcomes. The advantage of spectroscopy is that it can be done in conjunction with MRI, which allows acquisition of anatomic and metabolic data. There are no published case reports concerning proton MR spectroscopy and brain death in children. At Loma Linda University Children's Hospital, 10 brain-dead children were studied with proton MR spectroscopy. All spectra were markedly abnormal but were similar to spectra from patients who became vegetative or severely disabled, suggesting that the specificity for brain death determination of MR spectroscopy is insufficient.

## Comparison of Electroencephalogram and Cerebral Blood Flow Studies

Table 107-8 summarizes the comparative diagnostic yield of EEG versus CBF determinations in children who had both

**TABLE 107-8** Electroencephalogram and Cerebral Blood Flow Diagnostic Screening Yield by Age Groups

	ECS	EEG+	Total	Diagnostic Screening Yield
<b>ALL CHILDREN (N = 149)</b>				
No CBF	86	18	104	% patients with ECS = 70%
CBF+	19	26	45	% patients with no CBF = 70%
Total	105	44	149	
<b>NEWBORNS ONLY (&lt;1 MONTH OF AGE; n = 30)</b>				
No CBF	8	11	19	% patients with ECS = 40%
CBF+	4	7	11	% patients with no CBF = 63%
Total	12	18	30	
<b>CHILDREN (&gt;1 MONTH OF AGE; n = 119)</b>				
No CBF	78	7	85	% patients with ECS = 78%
CBF+	15	19	34	% patients with no CBF = 71%
Total	93	26	119	

CBF, cerebral blood flow; CBF+, cerebral blood flow present; ECS, electrocerebral silence; EEG+, activity on electroencephalogram. (Adapted from Nakagawa TA et al. *Crit Care Med*, 2011;3 [9]:2139–55.)

studies done as part of the initial brain death evaluation. Data from the studies cited in Table 107-5 and 107-7 in the online chapter were stratified by three age groups: all children, newborns, and children greater than 1 month in age to 18 years. The data in Table 107-8 for the all-children group show that when both studies were initially performed, the diagnostic yield was the same (70% had ECS; 70% showed absent CBF). The diagnostic yield for children greater than 1 month of age was similar for both tests (EEG with ECS, 78%; no CBF, 71%). For newborns, EEG with ECS was less sensitive (40%) than absence of CBF (63%) when confirming the diagnosis of brain death, but even in the CBF group, the yield was low.

## Evoked Potentials

Brainstem auditory evoked potentials and somatosensory evoked potentials have been studied extensively as ancillary tests for brain death. The portability, rapidity, and noninvasiveness seem ideal, but multiple studies have raised significant doubts as to their reliability. Most clinicians do not rely on evoked potential studies as an ancillary test for brain death; rather, such testing remains useful as a prognostic indicator in children who survive catastrophic brain injury.

## Brain Tissue Oxygenation

The brain tissue oxygenation technique uses invasive monitors to directly assess brain tissue oxygenation in an attempt to optimize neurocritical care therapy in patients with elevated intracranial pressure. Incidentally, it was observed that brain tissue oxygenation decreased to zero in five children who progressed to brain death, and remained above this threshold in 80 other children who did not. Comparative data are needed to evaluate the utility of this potential ancillary test against established modalities.

## BRAIN DEATH IN NEWBORNS

The revised 2011 pediatric brain-death guidelines (Nakagawa et al., 2011) state that brain death can be diagnosed in term infants of more than 37 weeks' gestation, provided the physician is aware of the limitations of the clinical examination and ancillary studies in this age group. Recommendations for preterm neonates of less than 37 weeks' gestation were not included in the guidelines because of insufficient data.

Preterm and term infants of less than 7 days of age were excluded from the 1987 pediatric brain-death guidelines (AAP Task Force on Brain Death in Children, 1987). Several years after the publication of these guidelines, data on 18 brain-dead neonates were published, and it was suggested that brain death could be diagnosed in full-term newborn infants and preterm infants of more than 34 weeks' gestational age within the first week of life (Ashwal, 1997). Because a newborn has patent sutures and an open fontanel, increases in intracranial pressure after acute injury are not as significant as in older patients. These observations may account for the relatively large proportion of clinically brain-dead newborns who have detectable EEG activity and CBF. The use of whole-brain death criteria might not be appropriate in a newborn. It might be more medically justifiable to use brainstem death as the major criterion for brain death in newborns. In many situations, the issue of whether a neonate is brain-dead or just catastrophically and irreversibly brain-injured is resolved by the decision of physicians caring for the neonate with the understanding and agreement of the family to withdraw ventilator support and redirect to compassionate care.

## Epidemiology

It has been estimated that there are about 550 newborns diagnosed each year as brain-dead out of a total of 3,900,089 live births (Ashwal, 1997). Etiologies of neonatal brain death include hypoxic-ischemic encephalopathy, birth trauma, central nervous system malformations, central nervous system hemorrhage, infection, sudden infant death syndrome, nonaccidental trauma, and metabolic disorders.

## Clinical Examination

Examination of preterm infants of less than 37 weeks' gestation to determine whether they meet brain-death criteria may be difficult because some brainstem reflexes may not be completely developed (see Table 107-2) and because it is difficult to assess the level of consciousness in a critically ill, sedated, and intubated neonate. The revised 2011 guidelines (Nakagawa et al., 2011) emphasize the importance of carefully and repeatedly examining term newborns, with particular attention to examination of brainstem reflexes and apnea testing. As with older children, assessment might be unreliable immediately following an acute injury; therefore, a period of 24 hours or longer is recommended before evaluating the term newborn for brain death.

## Duration of Observation

The consensus-based recommendations in the 2011 guidelines recommend a 24-hour observation period between the two neurologic examinations for term infants (>37 weeks' gestation). Data from 87 newborns allowed an estimation of the duration of coma after the insult until brain death was initially diagnosed (37 hours), duration of time before brain-death confirmation (75 hours), and duration of time to transplantation (20 hours) (Ashwal, 1997). The average duration of brain death in these patients was about 95 hours (i.e., 4 days). Recovery of brainstem function was not observed in any patients, despite a variety of EEG and CBF results. Other studies in neonates undergoing cardiac transplantation reported that the total duration of brain death (including time to transplantation) averaged 2.8 days in neonates less than 7 days of age and 5.2 days in neonates 1 to 3 weeks old. The data suggest that a 24- to 48-hour observation period in

neonates less than 7 days of age should be sufficient to confirm the diagnosis of brain death.

## Apnea Testing

Neonatal studies reviewing PaCO<sub>2</sub> thresholds for apnea are limited. Data from 35 neonates who were determined to be brain-dead revealed a mean PaCO<sub>2</sub> of 65 mm Hg, suggesting that the threshold of 60 mm Hg is also valid in the newborn.

## Ancillary Studies

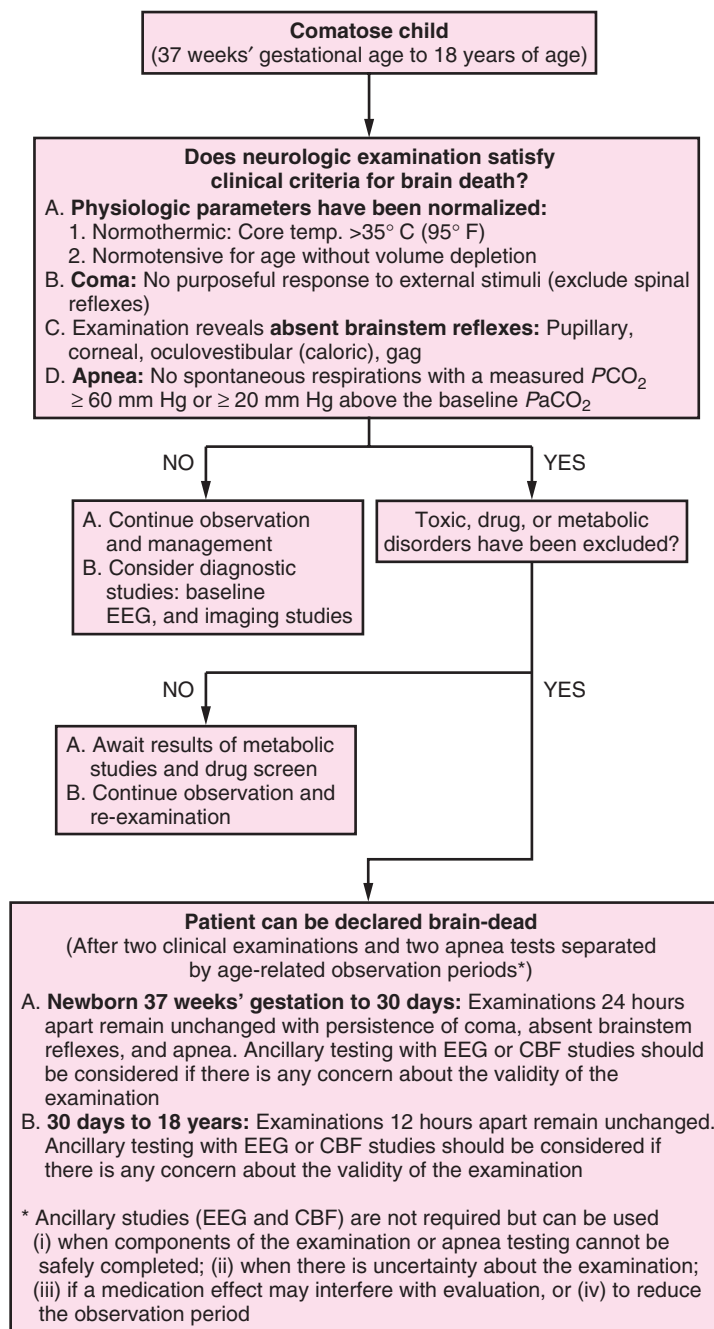

EEG and radionuclide imaging techniques remain the most commonly used ancillary studies to confirm the diagnosis of neonatal brain death. Ancillary studies are less sensitive in detecting the presence or absence of brain electrical activity or CBF than in older children (Table 107-8). Of the two studies, detection of absence of CBF (63%) was more sensitive than demonstration of ECS (40%); however, even in the CBF study group, the sensitivity was low. Previous studies also have reported that about one-third of neonates with ECS showed evidence of CBF, and 58% with absent CBF had evidence of EEG activity. These data suggest that, in neonates, clinical rather than laboratory data may be more appropriate, provided that a sufficient period of observation is allowed. Because of these data, the 2011 guidelines (Nakagawa et al., 2011) emphasize that the diagnosis should be made clinically and based on repeated examinations over longer periods of observation rather than relying exclusively on ancillary studies.

## Determination of Brain Death in the Comatose Pediatric Patient

An algorithmic approach to the evaluation of a comatose child to determine whether the child is brain-dead is presented in Figure 107-3. The question of whether a comatose child is brain-dead arises within the first days of hospitalization. Occasionally, this issue occurs later because the long-term use of sedative and paralytic agents does not permit the necessary screening to assess for the presence of coma and loss of brainstem function. Assessment may also be delayed in patients receiving therapeutic hypothermia. Assessment must include determination of the proximate cause of coma, with review of all neuroimaging, neurophysiologic, metabolic, and toxicology screening studies that were performed. Serum and urine studies should include toxicology screens and serum electrolytes, glucose, calcium, urea nitrogen, creatinine, liver enzymes, lactate, pyruvate, and ammonia determinations. If the history suggests a metabolic disorder, serum amino acid and urine organic acid studies should be considered. Neuromuscular blocking agents and all sedative agents also should be discontinued for several elimination half-lives to exclude medication effect as a confounding variable. Clearance of neuromuscular blocking agents can be established at the bedside with the use of a nerve stimulator.

It is necessary to ensure that the core body temperature and blood pressure are within the normal range. The presence of purposeful movements in response to external stimuli or spontaneous (not spinal-related) movements, posturing, or occurrence of seizures would obviate the diagnosis of brain death. A careful examination and documentation of the absence of brainstem reflexes is crucial and may be difficult to perform. Generally, parents should be allowed to observe the process, and nursing and respiratory therapy staff should be informed of the findings if they are not present at the bedside during the clinical examination.

The duration of observation between examinations to confirm the diagnosis of brain death depends on the child's

**Figure 107-3.** Algorithm for the evaluation for brain death in a comatose child. It is assumed that patients have had an extensive clinical and laboratory evaluation to determine the etiology of coma, including toxicology testing and, if indicated, evaluation for structural, infectious, and metabolic diseases. This algorithm suggests the process for confirmation of brain death in patients in whom this condition is suspected. CBF, cerebral blood flow; EEG, electroencephalogram. (This algorithm is based on Nakagawa TA, Ashwal S, Mathur M, et al. *Crit Care Med*. 2011 Sep;39[9]:2139–55.)

age, as do recommendations for ancillary testing (Boxes 107-2 and 107-3). Ancillary studies, depending on the child's age, are recommended as outlined in Box 107-2. Results of these tests provide physicians with an opportunity to discuss with the child's family the concept of brain death and the loss of electrocortical activity and CBF. The time of the second brain death examination (including apnea test and ancillary study if needed) is the legal time of death.

## Discussions with Family Members and Staff

Most pediatric brain-death determinations are done on children who were healthy just hours or days before the injury, and even after extensive discussions with family members, the concept of brain death remains unclear for many. Grieving parents may not understand the futility of continued ventilator support. Without being confrontational, physicians

caring for the child should discuss the prognosis with parents. A conference with family members involving various members of the healthcare team is helpful in educating the family members and assuring them that the healthcare professionals are in agreement with the diagnosis and recommendations.

## Organ Donation

The National Organ Transplant Act of 1987 requires that every hospital in the United States develop a protocol for requesting organ donation. Most hospitals have formulated protocols stipulating that trained personnel from the regional Organ Procurement Organization (OPO) are the designated requestors. "Uncoupling" the request for donation from the pronouncement of death, early referral to the OPO, and a trained requestor making the request improve overall consent rates. Refusal from parents with whom donation has been explored should be respected. If the family declines organ donation, ventilator support can be discontinued.

Strategies for stabilization of consented donors and retrieval of organs should be in place in the pediatric intensive care unit. Brain-dead child abuse victims represent a significant percentage of brain-death diagnoses and, as such, require medicolegal evaluation before organ donation can proceed. Maintenance of brain-dead patients requires careful management in anticipation of organ donation (Lutz-Dettinger et al., 2001). Maintenance of temperature and provision of adequate fluids and supplemental oxygen to achieve satisfactory perfusion are necessary, as is consideration for hormone replacement with corticosteroids, vasopressin, and thyroxine. Diabetes insipidus, hypernatremia, hyperglycemia, and coagulopathies commonly occur in brain-dead children and require special management if transplantation is being considered (Lutz-Dettinger et al., 2001). Anticipatory and protocol-driven donor management improve donor stability and increase organ yield (Rosendale et al., 2003). Optimal donor management has the potential to help thousands of potential recipients waitlisted for solid organ transplantation.

## INTRODUCTION

Since the beginning of the 20th century, the fetal cerebral circulation has attracted the research interests of a broad variety of investigators using methods of ever increasing sophistication. The earliest studies focused on fetal cerebrovascular anatomy, and by the 1960s the first studies of fetal cerebral blood flow and oxygen consumption were reported. Since those early beginnings, the development of high resolution analytical tools for the detailed study of cellular and molecular biology have expanded dramatically our ability to probe the dynamic relations between structure and function in the developing fetal and neonatal cerebral circulation. This chapter summarizes some of the recent advances in this field, which are presented in three main sections: 1) brain vascular formation and differentiation; 2) fetal and neonatal cerebral artery contractility; and 3) fetal and neonatal whole brain cerebrovascular reactivity.

## BRAIN VASCULAR FORMATION AND DIFFERENTIATION

The processes that govern cerebral vessel development are highly dynamic and plastic. Even in the adult brain, cerebral arteries continuously undergo angiogenesis, differentiation, and even dedifferentiation in response to stress or injury. These adult processes, however, depend directly on modulation of existing vasculature that is formed during embryonic vasculogenesis.

### Vasculogenesis and Angiogenesis

Brain vasculature begins as a leptomeningeal plexus at 24 days that develops into distinct arteries, veins, and capillaries by 28 days. This plexus undergoes waves of differentiation that begin at the base of the brain and spread toward the midbrain convexity. By day 44, the internal carotid artery has formed from a merger of sections from the first and third aortic arch and the dorsal aorta. At this time, the Circle of Willis is also recognizable. Thereafter, an extensive leptomeningeal vascular bed arborizes to supply vasculature to the developing cortex. This vascularization process is not complete at birth and continues through the third postnatal month at which time the number of leptomeningeal anastomoses declines. In tandem is a progressive expansion of capillary density that is near complete at term in telencephalic white matter but can continue to expand in cerebral gray matter well beyond the third or fourth year of life. This time course demonstrates the highly

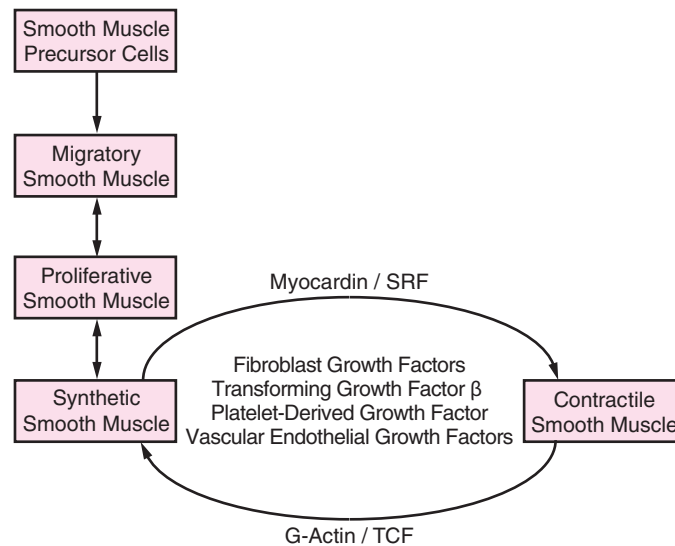

dynamic nature of fetal cerebral vasculogenesis and emphasizes the fragility and vulnerability of the fetal and neonatal vasculature to metabolic and mechanical injury.

Whereas vasculogenesis is driven by the proliferation and migration of mesodermal angioblasts that differentiate into endothelial cells to form the initial vascular structures, these vessels subsequently give rise to new branches through angiogenesis (Lee, et al., 2009), which exquisitely matches vessel density to local metabolic activity. When increased metabolic activity or decreased oxygen delivery produce local tissue hypoxia, multiple parenchymal cell types produce the transcription factor hypoxia inducible factor-1 $\alpha$ , which translocates to the nucleus where it combines with its coactivator HIF-1 $\beta$ . The resulting complex promotes transcription of multiple genes that promote angiogenesis, including vascular endothelial growth factor and erythropoietin (Semenza, 2000). The influences of these factors integrate with those of other angiogenic factors, including angiopoietin, transforming growth factor- $\beta$  and Wnts to determine the extent of new vessel growth. In turn, the direction and pattern of new vessel growth is governed by a variety of dual-purpose axon guidance cues, including ephrins and semaphorins, along with locally produced neurotrophins such as nerve growth factor, brain-derived neurotrophic factor, and NT-3 (Lee, et al., 2009). The diversity of mechanisms regulating angiogenesis might suggest a delicate system with many vulnerable components, but in actuality it is a highly robust system with multiple redundancies that assure a tight matching of vascular density to local metabolic demand. This highly dynamic system is essential to support the rapid growth and expansion of the fetal and neonatal brain.

### Smooth Muscle Differentiation

Recent advances in genomic biology have elucidated numerous molecular factors that govern smooth muscle proliferation and differentiation (Owens, et al., 2004). Smooth muscle was first categorized as either synthetic or contractile based largely on morphologic characteristics. Increased availability of immunologic tools capable of detecting subtle changes in contractile protein abundance and distribution, together with major improvements in high resolution confocal microscopy, has established that smooth muscle exists not in just two phenotypes but in a continuum of different cell types that include broad variations in the capacity for migration, proliferation, secretion, and contraction (Owens, et al., 2004) (Fig. 108-1). In turn, the transformation of one smooth muscle phenotype into another is governed by a large family of growth factors, including fibroblast growth factors, platelet-derived

**Figure 108-1. Smooth Muscle Differentiation.** Smooth muscle cells arise from mesodermal precursor cells, of which several cell types have been proposed, including fibroblasts, myofibroblasts, pericytes, and bone marrow-derived cells. These precursor cells progressively acquire smooth muscle characteristics, the first of which is expression of smooth muscle alpha actin. With further differentiation in response to growth factors, chemical factors, and mechanical influences, the smooth muscle cells sequentially exhibit the capacity for migration, proliferation, and synthesis followed by secretion of extracellular matrix proteins. The synthetic phenotype also sequentially expresses virtually all the contractile proteins, pumps, ion channels, and receptors required for contractile function. The pace and pattern of this synthetic activity is regulated by the integrated influence of multiple growth factors, as well as mechanical, chemical, and metabolic factors unique to each vascular bed. At the molecular level, stimuli that increase the cytosolic availability of the transcription factor myocardin, along with its coactivator serum response factor (SRF), promote contractile differentiation. Conversely, factors such as injury or stress that increase cytoskeletal depolymerization and increased cytosolic concentrations of monomeric G-actin, and/or increased availability of ternary complex factor (TCF), promote dedifferentiation of contractile smooth muscle back into a synthetic phenotype. Importantly, the interconversion between synthetic and contractile smooth muscle is highly plastic and dynamic, particularly in immature neonatal arteries.

growth factor, vascular endothelial growth factors, and many others. The receptors for these growth factors include both receptor tyrosine kinases and G-protein coupled receptors that regulate multiple signaling pathways within the vascular smooth muscle cytoplasm. The majority of these cytosolic pathways influence the phosphorylation and/or nuclear translocation of key transcription factors including serum response factor, ternary complex factor, elk-1, and myocardin (Parmacek, 2007). Together, these mechanisms determine the exact characteristics of every smooth muscle cell in cerebral arteries and thereby determine smooth muscle structure and function.

Smooth muscle cells in the immature artery wall are phenotypically very heterogeneous. Numerous smooth muscle cells in fetal cranial arteries express nonmuscle myosin heavy chain, which is a marker for synthetic smooth muscle. With advancing postnatal age, the nonmuscle myosin heavy chain isoform gradually disappears to be replaced by smooth muscle myosin heavy chain, a marker of complete contractile differentiation. Because of incomplete contractile differentiation, fetal cerebral arteries exhibit higher secretory activity and reduced contractility, compared with fully mature adult cerebral arteries.

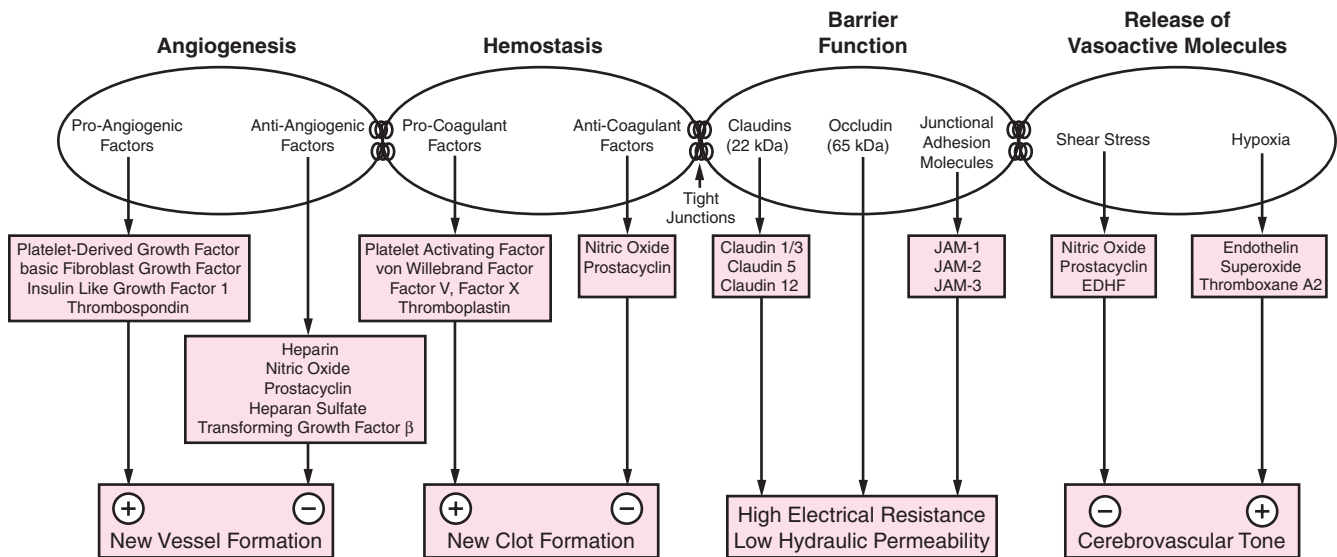

An important feature of smooth muscle phenotype in neonatal cerebral arteries is that, just as Yamanaka's Nobel-winning work demonstrated with fibroblasts (Takahashi and Yamanaka, 2006), the phenotypic characteristics of smooth muscle cells are reversible. In the event of injury, contractile smooth muscle can dedifferentiate into synthetic, proliferative, or even migratory phenotypes. This reversibility demonstrates that smooth muscle is never "terminally differentiated" and instead remains somewhat plastic in regards to smooth muscle phenotype. Correspondingly, phenotypic transitions,

whether induced physiologically by growth factors or pathophysiologically by injury, ultimately determine the contractile characteristics of cerebral arteries not only in the fetus and neonate, but also in the adult.

## Endothelial Differentiation and the Blood-brain Barrier

The vascular endothelium serves four main functions, including: 1) initiation of angiogenesis; 2) hemostasis; 3) barrier function; and 4) release of vasoactive factors (Fig. 108-2). Each of these functions matures at slightly different rates. The ability of the vascular endothelium to initiate angiogenesis is one of the first endothelial functions to develop fully in the fetus. The fetal vascular endothelium is highly active and can release multiple proangiogenic factors, including platelet-derived growth factor, basic fibroblast growth factor, insulin-like growth factor 1, and thrombospondin. The fetal vascular endothelium also can release growth-inhibiting factors including heparin, heparan sulfate, transforming growth factor  $\beta$ , nitric oxide, and prostacyclin. The ability of the fetal vascular endothelium to support high rates of angiogenesis is essential for the rapid expansion of the cerebral vasculature characteristic of the neonatal period.

The hemostatic functions of the vascular endothelium also appear well-developed at term. Fetal endothelial cells contain tissue factor (also known as thromboplastin), platelet activating factor, factor V, factor X, and von Willebrand Factor (Andrew, et al., 1990). These factors can be released upon endothelial injury to promote hemostasis. Conversely, intact fetal endothelium continuously releases nitric oxide and prostacyclin, which inhibit initiation of hemostasis (Andrew,

**Figure 108-2. Endothelial Functions.** Summarized in this diagram are the four main functions of the vascular endothelium. In response to either locally released or circulating growth factors, the endothelium can release a variety of proangiogenic factors that stimulate new vessel formation (angiogenesis). Some stimuli also promote the release of antiangiogenic factors that help control the rate of angiogenesis. Intact endothelial cells also continuously release anticoagulant factors, but injured endothelial cells release multiple procoagulant factors that rapidly facilitate local clot formation. In the cerebrovasculature, endothelial cells are connected by tight junctions, including claudins, occludin, and junctional adhesion molecules; together these proteins confer high electrical resistance and low hydraulic permeability. Endothelial cells also contain other proteins important for barrier formation including zona occludens, cingulin, and cadherens. Finally, in response to shear stress caused by blood flow, endothelial cells continuously release multiple vasoactive factors that promote vasodilation. Under some conditions, including hypoxia, endothelial cells can also release factors that stimulate vasoconstriction and reduced local blood flow. All four functions of the vascular endothelium change with developmental age; see text for details.

et al., 1990). Although the relative abundances of many endothelial components of the hemostatic cascade change during fetal and postnatal maturation, it is clear that the fetal vascular endothelium is functionally mature in relation to its role in hemostasis.

Endothelial barrier function is uniquely important in the cerebral circulation, in which the endothelium constitutes a “blood-brain barrier” that efficiently restricts the movement of most blood-borne constituents into the brain parenchyma. This barrier function is the consequence of tight junctions between adjacent endothelial cells and is due in large part to the presence of the integral membrane protein occludin, which spans the intracellular gap between adjacent endothelial cells and effectively binds the cells together. Another family of intercellular proteins present in the blood-brain barrier is the claudins, which further bind adjacent endothelial cells together and help increase hydraulic and electrical resistance across the endothelial cell layer. Other cell adhesion proteins also appear to be present in the tight junctions that are characteristic of the blood-brain barrier (Lee, et al., 2009).

At birth, the blood-brain barrier is not fully developed and continues to tighten with advancing postnatal age. This delayed tightening of the blood-brain barrier is a consequence of the high rates of new vessel formation in the fetal brain and the time required to synthesize, secrete, and position the main barrier proteins. In addition, astrocytes also play a major role in the development of the blood-brain barrier by virtue of their direct contact with capillary endothelial cells. Astrocyte maturation, however, is not complete at birth and continues throughout early postnatal life, which may contribute to the slow development of complete blood-brain barrier function in the neonate. Pericyte proliferation and maturation are also closely coupled with the development of the blood-brain barrier and may further influence the timing of blood-

brain barrier tightening (Lee, et al., 2009). Overall, this pattern of development reinforces the view that the blood-brain barrier is functional but vulnerable throughout the neonatal period.

The fourth function of the cerebrovascular endothelium is the release of factors that influence local vascular tone, such as nitric oxide, which can diffuse into adjacent vascular smooth muscle in which it activates synthesis of the vasodilator compound cyclic GMP (Moncada, et al., 1991). The immature endothelium is less responsive to shear stress and produces less NO than the mature endothelium. In contrast, the mechanisms mediating endothelial release of the vasodilator prostacyclin appear fully functional in the immature cerebral endothelium of human infants. Another important vasodilator released from the endothelium is endothelium-derived hyperpolarizing factor, but the importance of this molecule has yet to be examined in the immature cerebral circulation. Conversely, the cerebral endothelium also can release several constricting factors including superoxide, thromboxane A<sub>2</sub>, and endothelin, but endothelial synthesis and release of these compounds has yet to be demonstrated in fetal or neonatal cerebrovascular endothelium. Consistent with the developmental delay in NO synthesis and release and the gradual development of blood-brain barrier tightening, it is reasonable to expect that endothelial release of most vasoactive molecules also is attenuated relative to adult cerebrovascular endothelium. This hypothesis awaits further investigation.

## FETAL AND NEONATAL CEREBROVASCULAR CONTRACTILITY

Compared with adult cerebral arteries, fetal cerebral arteries have greater water content, smaller smooth muscle cells, a

larger extracellular space, and reduced stiffness (Pearce, et al., 1991). During early postnatal maturation, hydration decreases, wall thickness increases, and stiffness increases due to the secretion and increasing organization of extracellular matrix proteins. As maturation proceeds, remodeling of the extracellular matrix continues with the production of relatively more type III and less type I collagen and increases in the collagen to elastin ratio that are greatest in the largest cerebral arteries.

Accompanying postnatal changes in cerebral artery composition and stiffness are major changes in contractility and vascular reactivity. These shifts are due to progressive changes in smooth muscle phenotype that, in turn, are driven by major changes in circulating levels of growth factors and hormones during the early postnatal period. In the fetus and neonate, for example, plasma levels of adenosine, arginine vasopressin, T3, and T4 are all higher than in adults. Increased circulating levels of neonatal glucocorticoids also can induce major changes in vascular differentiation and maturation. Together, these influences drive a continuous transformation of fetal vascular and cerebrovascular contractility during the early postnatal period.

### Calcium Handling and the Contractile Apparatus

A main determinant of contractility in all vessel types is the cytosolic calcium concentration (Horowitz, et al., 1996). In fetal cerebral arteries, the internal stores of releasable calcium are small, and contraction is more dependent on calcium influx compared with adult arteries. Correspondingly, the density of the L-type calcium channel is greater in fetal than in adult cerebral arteries. The reduced ability to release intracellular calcium is due in part to the presence of low-affinity inositol triphosphate (IP3) receptors, which are more abundant in immature than in mature arteries. In response to receptor activation, fetal arteries tend to synthesize and mobilize greater concentrations of IP3, but these increased IP3 responses do not fully offset the reduced affinity of fetal IP3 receptors. The net result is that receptor-induced increases in cytosolic calcium are generally much smaller in fetal than adult arteries.

For any vascular contraction, the magnitude of the force produced is the product of the cytosolic calcium concentration and the myofilament calcium sensitivity (Horowitz, et al., 1996). In fetal and neonatal cerebral arteries, their reduced ability to increase cytosolic calcium is offset by increased myofilament sensitivity. This is another major theme of cerebrovascular development: with advancing postnatal age, cerebral artery contractions depend less on calcium influx, less on myofilament sensitization, and more on intracellular calcium release. Increases in myofilament calcium sensitivity are mediated by receptor-mediated activation of rho-kinase, and these g-protein dependent effects are more pronounced in fetal than adult cerebral arteries.

### Ion Pumps and Channels

In tandem with calcium influx and intracellular release, the calcium pumps that extrude or sequester calcium, and the numerous proteins that bind and buffer calcium (Horowitz, et al., 1996) are also major determinants of cytosolic calcium concentrations but remain largely unstudied in the immature cerebrovasculature. In contrast, ion channels have received greater attention, due in large part to the critical influence of the membrane potential on calcium entry through the potential dependent L-type calcium channels. Smooth muscle cells tend to be less polarized in fetal than in adult cerebral arteries,

and this is coincident with greater outward current through calcium-dependent potassium channels (BK channels) in fetal compared with adult cerebral arteries. Despite the greater BK channel activity, calcium spark activity is depressed in immature compared with mature cerebral arteries. As a result, truncation of contraction and initiation of relaxation are more poorly developed in immature arteries. Similarly, ATP-sensitive potassium channels, which couple metabolic activity to membrane hyperpolarization, are also less sensitive in immature compared with mature cerebral arteries, and voltage-dependent potassium channels are more functional in adult than fetal arteries. Overall, these results demonstrate that electrophysiological contractile regulation is not fully functional in immature compared with adult cerebral arteries. This feature of immature cerebral arteries, again, is due to the high proportion of synthetic, noncontractile smooth muscle cells, which regulate membrane potential and calcium movements differently than smooth muscle in the contractile phenotype.

### Vasoactive Ligands and Receptors

The outer plasma membrane of all smooth muscle cells is populated with numerous receptor subtypes, and fetal smooth muscle is no exception to this general rule. In turn, the smooth muscle response to any receptor ligand is primarily determined by three factors: 1) ligand concentration; 2) receptor density; and 3) coupling of the receptor to intracellular signal transduction pathways. All three factors undergo major developmental changes, but in a highly receptor-dependent manner. For contractile amines, sensitivity to norepinephrine and serotonin are upregulated in immature compared with mature cerebral arteries, and this effect is largely attributable to increased receptor density. Coupling of adrenergic and serotonergic receptors to the contractile apparatus appears fully developed at birth and changes little during postnatal maturation. In contrast, cerebral artery reactivity to the contractile peptide endothelin-1 increases postnatally, due to increases in ET-B receptor vascular expression. For the potent vasodilator adenosine, cerebral production is lower in the immature compared with the adult brain and increases with postnatal age. Conversely, cerebrovascular reactivity to adenosine appears fully developed at birth, which allows the neonatal cerebrovasculature to dilate in response to any perturbation, such as hypoxia or hypoglycemia, which increases the local adenosine concentration. These patterns of reactivity emphasize that the neonatal cerebral circulation is fully capable of responding to changes in circulating and locally produced vasoactive agents that mediate cerebrovascular homeostasis. More importantly, the cerebrovascular capacity to respond to these vasoactive agents develops in advance of the ability of cerebral tissues to produce these agents. The overall capacity to produce vasoactive molecules such as adenosine, endothelin, and amines increases steadily throughout postnatal maturation.

Prostaglandins are another category of receptor-dependent vasoactive compounds that are particularly important in the immature circulation. Prostaglandins, which are derived from the precursor arachidonic acid by the action of cyclooxygenases, maintain the patency of the ductus arteriosus before birth and, throughout the perinatal period, regulate hydraulic resistance in multiple vascular beds. Total prostaglandin concentrations are higher in cerebrospinal fluid taken from the cortex than from the cisterna magna or from the arterial blood, suggesting that the cerebral cortex is an active site of neonatal prostaglandin synthesis. Given that indomethacin, an inhibitor of prostaglandin synthesis, increases cerebrovascular resistance and decreases cerebral perfusion, prostaglandins appear to exert an overall vasodilating effect in the immature cerebral circulation.

One of the most important prostaglandins for neonates is PGE<sub>2</sub>. Both plasma concentrations and the cerebrovascular vasodilator potency of PGE<sub>2</sub> are greater in fetuses and neonates than in adults, suggesting that PGE<sub>2</sub> contributes to the low cerebrovascular resistance characteristic of the immature cerebral circulation. PGE<sub>1</sub> is also an effective dilator that is somewhat selective for the cerebral circulation, and similar to PGE<sub>2</sub>, its potency is greatest in the neonate and diminishes over time. Prostacyclin (PGI<sub>2</sub>) is another important vasodilator in the immature cerebral circulation, but this prostanoid retains its vasodilator potency throughout postnatal maturation and is an effective vasodilator in most vascular beds regardless of postnatal age. At very low concentrations, the prostaglandin PGF<sub>2</sub> $\alpha$  can dilate neonatal cerebral arteries, but at higher concentrations PGF<sub>2</sub> $\alpha$  is a strong vasoconstrictor in immature and mature cerebral arteries. Many other derivatives of arachidonic acid, including multiple members of the leukotriene and thromboxane families, are potent vasoconstrictors in the immature cerebral circulation.

In a more general sense, the importance of prostaglandins and other eicosanoids in the newborn is a natural consequence of heightened lipid metabolism characteristic of the developing brain. The free fatty acid metabolism necessary to support myelination is very active during the peripartum period, and some of the same phospholipids needed for myelination also can give rise to arachidonic acid through the action of phospholipases. The arachidonic acid thus liberated can fuel the synthesis and release of numerous prostanoids and eicosanoids, as determined by local enzyme activity. This high level of arachidonic acid availability and metabolism explains why prostanoids and eicosanoids act as both primary signal molecules and secondary paracrine signals in so many vascular and metabolic responses of the immature cerebral circulation.

## FETAL AND NEONATAL WHOLE BRAIN Cerebrovascular Reactivity

When considering whole brain patterns of cerebrovascular reactivity, it is critically important to bear in mind another main theme of the immature brain: heterogeneity. Different regions of the brain vasculature, such as pial arteries, brainstem arteries, parenchymal arteries, and arteries of the Circle of Willis, all have distinct characteristics in terms of smooth muscle phenotype, innervation, receptor expression patterns, and others. In addition, all cerebral arteries exhibit developmental heterogeneity such that their structure and reactivity change with age and at very different rates. Finally, there is chronologic heterogeneity, which is the change in vasoreactivity over relatively short time periods due to an artery's local contractile and metabolic history. This diversity in regional, developmental, and chronologic heterogeneity can complicate recognition of global patterns of cerebrovascular regulation but is also the fundamental feature that enables the immature brain to dynamically maintain cerebrovascular homeostasis under constantly changing conditions. Among these changing conditions, one of the most universally important is local cerebral metabolic rate.

## Flow-Metabolism Coupling

In all vascular beds, close coupling between blood flow and tissue metabolic rate is a fundamental requirement for cardiovascular homeostasis. Because of the unique reliance of cerebral metabolism on glucose, flow-metabolism coupling in the brain normally manifests as a three-way coupling between rates of glucose oxidation, oxygen consumption, and cerebral blood flow. In human neonates, cerebral blood flow and total

cerebral metabolic rate are low at birth, and both variables increase steadily through the first 6 years of life, after which cerebral flow and metabolism gradually decline throughout the remainder of life. Throughout fetal and postnatal development, oxygen consumption and cerebral blood flow appear tightly coupled not just in human neonates (Pryds, et al., 1990) but in other mammalian newborns as well.

The molecular mediators of flow-metabolism coupling have been intensively investigated for many years, and this work reveals that one of the most important mediators is adenosine, which is released from cells when the oxygen supply to demand ratio falls. The metabolic pathways for the synthesis, release, and degradation of adenosine are well developed in the fetus and neonate, and free adenosine under resting conditions increases with postnatal age. In parallel, the A<sub>2a</sub> receptors that bind adenosine and promote cerebral vasodilation are expressed early in brain development and persist throughout adult life. Given these characteristics, adenosine may exert feedback regulation that matches oxygen delivery to oxygen demand in the immature brain. This regulation is particularly important in the neonate due to the transition from fetal hemoglobin to adult hemoglobin, which gradually increases the amount of tissue extractable oxygen per unit of blood flow as maturation proceeds.

## Hypercapnic Vasodilation

Carbon dioxide is one of the oldest known cerebral vasodilators and can increase cerebral perfusion in preterm and newborn (Pryds, et al., 1990) human infants. The magnitude of hypercapnic vasodilation increases with postnatal age, an effect that may be a consequence of reduced reactivity to acidosis in immature cerebral arteries. Age-related changes in hematocrit also might play a role, given that in newborn baboons, the hematocrit is inversely proportional to cerebral CO<sub>2</sub> reactivity. In some species, neonatal vasodilator prostaglandins mediate up to half of cerebrovascular responses to hypercapnia, although the importance of these pathways for human neonatal responses to CO<sub>2</sub> remains unclear. On the other hand, neonatal hypercapnic cerebral vasodilation does not involve reflex changes in sympathetic vascular tone or effects on cerebral metabolic rate.

## Hypoxic Vasodilation

Because of the inaccessibility of the human fetal cerebral circulation to investigation, understanding of cerebrovascular responses to acute hypoxia has arisen mainly from studies in animal models. In neonates of virtually all mammalian species, acute hypoxia elicits potent cerebral vasodilation. Limited studies in premature human infants have yielded similar results. In general, the brain regions with the highest metabolic rates, such as the brainstem, demonstrate the most robust responses to acute hypoxia. Mild hypoxia produces a graded increase in cerebral perfusion that maintains the oxygen supply to demand ratio with little initial change in the oxygen extraction fraction. Worsening severities of hypoxia can gradually increase the oxygen extraction fraction and once extraction is maximal, cerebral oxygen consumption decreases with attendant increases in anaerobic glycolysis and lactic acidosis. In many respects, the cerebrovasodilation produced by hypoxia is an extended response mediated by the same mechanisms responsible for flow-metabolism coupling. Adenosine release plays a major role in neonatal hypoxic cerebral vasodilation in most species. Acute hypoxia also can promote the release of vasodilator prostaglandins. Finally, hypoxia can exert direct vasodilating effects on the vascular smooth muscle and endothelium of immature cerebral arteries through

mechanisms that are developmentally regulated. This rich mechanistic redundancy assures that neonatal cerebral blood flow and metabolism are well coupled under all but the most severe conditions.

## Autoregulation

Another important component of cerebrovascular regulation is blood flow autoregulation (Fig. 108-3), which is defined as the maintenance of near constant blood flow independent of changes in cerebral perfusion pressure. In the cerebral circulation, perfusion pressure is defined as the difference between arterial pressure and either cerebral venous pressure or intracranial pressure, whichever is greater. This is a particularly important consideration for cases of intracranial hypertension, which can dramatically reduce overall cerebral perfusion. In most mammalian species, including humans (Pryds, et al., 1990), cerebral autoregulation is fully functional at birth. Cerebral autoregulation in the immature brain is effective until perfusion pressure falls lower than approximately 30 to 40 mm Hg, which is the lower limit of cerebral autoregulation in most mammalian neonates, including human infants. The upper limit of cerebral autoregulation typically ranges from 70 to 100 mm Hg, but this relatively low upper limit renders the immature brain vulnerable to vessel leakage and rupture secondary to hypertensive transients that exceed this upper limit. As average arterial pressures rise progressively during postnatal maturation, so too do the upper and lower limits of cerebral autoregulation. In the adult brain, the

**Figure 108-3. Cerebral Autoregulation** As in adults, neonates exhibit cerebral autoregulation, although over a lower range of cerebral perfusion pressures. In neonates, the lower limit of cerebral autoregulation is a perfusion pressure of approximately 30 to 40 mm Hg, and lower than this threshold the neonatal brain is at risk for ischemic injury. The upper limit of cerebral autoregulation in neonates ranges from 70 to 100 mm Hg, and higher than this threshold the neonatal cerebrovasculature is at risk for hyperperfusion, possible small vessel rupture, and hemorrhage. The lower (50 to 60 mm Hg) and upper (140 to 150 mm Hg) limits for cerebral autoregulation are proportionately higher in adults than in neonates and correspond with resting levels of mean arterial pressure. Cerebral perfusion pressure is defined as mean arterial pressure less either cerebral venous pressure or intracranial pressure, whichever is greatest. At any given level of cerebral perfusion pressure, the level of cerebral blood flow that is “autoregulated” is determined by cerebral metabolic activity ( $CMRO_2$ ); higher metabolic activity shifts the autoregulated level of cerebral flow to a higher level, as does either hypercapnia or hypoxia. Autoregulation is a complex, multifactorial behavior that integrates myogenic, metabolic, and neurogenic mechanisms.

lower and upper limits of cerebral autoregulation usually range from 50 to 60 mm Hg and from 140 to 150 mm Hg, respectively.

The cellular mechanisms responsible for cerebral autoregulation have been actively investigated since autoregulation was first discovered in the 1930s. The model of autoregulation that has emerged from this work portrays autoregulation as a composite response that integrates myogenic, metabolic, and neurogenic mechanisms. The myogenic component is perhaps the most fundamental because it operates at the level of individual arteries and can be demonstrated *in vitro*. At the level of individual smooth muscle cells, stretch mobilizes intracellular calcium, and many mechanisms have been proposed to explain this response including activation of integrins and TRP calcium channels. Acting in concert with myogenic mechanisms are metabolic mechanisms that establish the level of blood flow that is protected. Thus autoregulation can be observed at many different levels of metabolic activity, each with its appropriate level of blood flow, once oxygen supply and demand become balanced. Consistent with this view, decreases in perfusion pressure in neonates increase adenosine, prostanoids, and opioids. In addition, sympathetic autonomic mechanisms extend the upper limit of autoregulation in neonates as in adults. The complex composite nature of cerebral autoregulation helps explain why this response is highly vulnerable to numerous neonatal insults including metabolic acidosis, severe hypoxia, asphyxia, cerebral ischemia, and intracranial hemorrhage.

## Neurovascular Mechanisms

Adult cerebral arteries are innervated by adrenergic, cholinergic, and peptidergic perivascular nerves. Each of these nerve types exhibit three phases of development, including the outgrowth of new axons, the development of transmitter synthesis and storage, and the differentiation of nerve varicosities. In general, the postsynaptic receptors that communicate the effects of neurotransmitter release become functional before the perivascular nerves fully mature. Consistent with the fundamental concept of heterogeneity, the time course of functional development for each neurotransmitter system varies uniquely with brain region and chronologic age.

The adrenergic sympathetic innervation is the best-understood category of perivascular nerves that innervate neonatal cerebral arteries. Sympathetic nerves develop first in the most rostral regions of the human fetal brain and appear with varicosities between 19 and 23 weeks of gestational age. Exogenous norepinephrine elicits contractile responses in neonatal cerebral arteries through activation of  $\alpha_1$  adrenergic receptors in resistance arteries and  $\alpha_2$  adrenergic receptors in pial arterioles. The action of norepinephrine on postsynaptic adrenergic receptors can stimulate the release of PGE<sub>2</sub>, which in turn can limit the vasoconstrictor response to norepinephrine. Electrical stimulation of cerebrovascular sympathetic innervation can decrease cerebral blood flow up to 25%, depending on age and region. Interestingly, cerebrovascular contractile reactivity to norepinephrine is greatest in the fetus and diminishes with postnatal age, emphasizing that adrenergic neurovascular mechanisms are uniquely important in the immature cerebral circulation.

Cholinergic perivascular nerves appear at the adventitia-medial junction of fetal human cerebral arteries between 19 and 23 weeks of gestational age but become fully functional near term. Unlike adult cerebral arteries, neonatal cerebral arteries contract in response to high concentrations of acetylcholine and dilate only at very low acetylcholine concentrations. Contractile responses to acetylcholine in neonatal cerebral arteries can be blocked by indomethacin, suggesting

that vasoconstricting prostaglandins such as PGF<sub>2</sub>α or thromboxane A<sub>2</sub> mediate these responses.

Perivascular nerves containing neuropeptide-Y and vasoactive intestinal polypeptide also innervate human fetal cerebral arteries. These nerves are most prominent in the major arteries of the Circle of Willis and the large pial arteries. Fetal cerebral arteries can also be innervated by sensory fibers from the trigeminal ganglion that synthesize and release substance-P, vasoactive intestinal polypeptide, cholecystokinin, somatostatin, and calcitonin gene-related peptide. Although the vasodilating effects of these peptides have been well characterized in adult cerebral arteries, their uncertain roles in cerebrovascular regulation in the immature cerebral circulation remain a topic of active investigation.

## CONCLUSIONS

The principles of cerebrovascular developmental physiology, anatomy and biochemistry outlined in this chapter represent many of the fundamental concepts needed to understand mechanisms involved in the cerebrovascular disorders described in later chapters. Hopefully, these fundamentals also will facilitate interpretation of results obtained with advanced, noninvasive, bedside methods for imaging and monitoring multiple cerebrovascular variables in neonates, infants, and children. The advent of new analytical tools, together with deep understanding of the physiological and pathophysiological processes involved, offers unprecedented promise to advance understanding of both the normal and injured immature brain and will ultimately help improve age-related strategies for the clinical management of neonatal and pediatric patients with cerebrovascular disorders.

## OVERVIEW AND DEFINITIONS

Ischemic stroke is defined as sudden, focal infarction of brain tissue on neuroimaging or autopsy. Imaging findings typically correspond to an acute neurologic deficit but occasionally can be “silent” as seen in children with sickle cell disease. Arterial ischemic stroke (AIS) occurs when there is sudden occlusion of cerebral arteries, usually because of thromboembolism. In children, fundamental biological differences from adults create unique issues in the pathophysiology, risk factors, clinical presentations, diagnosis, treatment, and outcomes of AIS.

This chapter provides a clinically focused review of AIS in infants and children based on the best available evidence through February 2015. Chapter 20 reviews AIS in newborns.

## Epidemiology, Mortality, and Burden of Pediatric Stroke

Multiple population-based studies report incidence rates of 1.3 to 1.8/100,000 children/year for childhood AIS (Mallick and O’Callaghan, 2010; Mallick et al., 2014). Increasing incidence rates reflect more sensitive diagnostic tests, particularly magnetic resonance imaging (MRI), and increased survival in previously lethal pediatric diseases predisposing to stroke such as congenital heart disease, sickle cell disease, and childhood malignancies. Incidence rates are increased in infants, and in black and Asian populations. Childhood stroke has a mortality of 5% to 10% and is among the top 10 causes of death in children but may be declining. Childhood stroke is associated with significant economic and social burden as survivors face many years of living with disability. Health care costs vary by age at onset, associated risk factors, and stroke subtype.

## Pathophysiology

### Arterial Circulation: Anatomy and Vascular Patterns of AIS

The brain receives arterial blood via the “anterior” circulation, consisting of the paired internal carotid arteries, and the “posterior” circulation, consisting of the paired vertebral arteries that join to form the basilar artery (“vertebrobasilar system”). The major cerebral arteries arise from the Circle of Willis as the paired anterior, middle, and posterior cerebral arteries. Small “perforating arteries” arise from these major cerebral arteries to supply the deep brain regions, including basal ganglia, thalamus, and midline brainstem structures, whereas the lateral brainstem and cerebellum receive blood via the larger circumferential arteries (posterior inferior, anterior inferior, and superior cerebellar arteries). Collateral flow

via the Circle of Willis and distal smaller leptomeningeal anastomoses can enhance brain perfusion during vaso-occlusive stroke. Peripheral wedge-shaped lesions involving cortex and white matter are characteristic of infarction caused by occlusion of large-caliber arteries. Most AIS involves the middle cerebral artery (MCA) (see Figure 109-8), in recognizable vascular patterns based on the site of arterial occlusion, including 1) proximal M1 occlusion (entire MCA infarcted), 2) distal M1 (basal ganglia spared), 3) anterior or posterior trunk M2 occlusion (frontal or parietal/temporal respectively), and 4) lenticulostriate only (basal ganglia and deep white matter only) (see Figure 109-8). Specific topographic patterns help predict the underlying etiology with lenticulostriate AIS commonly associated with focal arteriopathy.

Topographic patterns within the posterior circulation include P1 (proximal PCA) infarction in occipital and mesial temporal lobes and perforator thalamic infarcts. Basilar artery thrombosis often combines multiple infarcts involving brainstem perforators, cerebellar branches, and the PCA. Diffuse hypoperfusion can cause apparently focal ischemic lesions within “watershed zones” at arterial borders.

Diffuse hypoperfusion can cause apparently focal ischemic lesions within “external” watershed zones at arterial borders. Although typically bilateral, they can also be asymmetric in the setting of proximal arterial steno-occlusive disease. In Moyamoya syndrome, low-flow infarcts may appear as a “string of pearls” within periventricular white matter “internal” watershed zones.

## Mechanisms of Thromboembolism

Thrombotic occlusion of a cerebral artery is the principal mechanism underlying AIS. Thrombus may develop locally within arteries or travel there from an embolic source. Thrombosis is a product of both the coagulation (fibrin-forming) and the platelet hemostatic systems (Chapter 113). The balance of which system predominates varies with flow rate, shear stresses, endothelial integrity, concentrations of circulating anticoagulants, and other factors. In situations of blood stasis or slow blood flow, the coagulation system may predominate but the relative balance depends on the specific disease. Exposure of blood to arterial wall inflammation (e.g., vasculitis) or disruption of the endothelium with exposure to collagen and tissue factor (e.g., dissection) activates both platelets and fibrin formation. Maturation changes to coagulation and platelets across childhood are also likely important.

In AIS with large-artery occlusion, thrombi usually arrive as an embolus from the heart or another proximal artery. Venous thromboemboli can also reach the cerebral arteries via paradoxical right-to-left intracardiac shunting across a patent foramen ovale, atrial septal defect, or complex congenital heart lesions. Embolism of infectious material (in endocarditis), fat, air, and inert surgical matter can also cause AIS.

## Mechanisms of Infarction

In AIS, severity of cerebral tissue damage is a function of multiple factors, including 1) duration and extent of ischemia and timing of reperfusion, 2) availability of collateral arterial blood supply, 3) volume and functional components of brain structures affected, 4) maturational status of the brain, and 5) concurrent disease processes and metabolic demands of the ischemic brain tissue.

Initial ischemic neuronal dysfunction evolves to irreversible infarction with increasing duration and/or degree of ischemia, or increased rates of neuronal metabolic activity. Transient ischemic attacks (TIAs) have no permanent parenchymal lesion on MRI. In AIS a central core zone of decreased perfusion results in irreversibly damaged brain. Surrounding this core is an unstable “penumbral zone” where collateral perfusion may sustain neuronal viability. In the penumbra, factors that increase the discrepancy between metabolic rate and the delivery of oxygen and glucose may result in additional tissue injury and cell death. Secondary insults include seizures and alterations in temperature, blood pressure, and serum glucose. The primary objective of acute neuroprotective stroke treatment is to rescue this “at-risk” penumbral tissue to salvage functional brain.

## Risk Factors

Multiple factors have been described in association with childhood AIS (Mackay et al., 2011; Mallick et al., 2014). There is increasing evidence for causality of AIS by vasculopathy, infection, trauma, and cardiac and hematological disorders from case-control and population-based studies. Contrasting with adults, atherosclerosis is a rare cause for childhood AIS. Chronic diseases of childhood frequently underlie childhood AIS; however, approximately half of children are previously healthy. Multiple risk factors converge in >50% of children with AIS. At least 10% remain idiopathic. A comprehensive list of potential risk factors for childhood AIS is included in Table 109-1. It is critical to determine all active AIS mechanisms and implement appropriate corrective treatments.

## Infection

Fever and recent infectious symptoms are frequent in children with AIS. Population-based case-control studies have confirmed that recent infection is associated with a fourfold increased odds of stroke. Emerging data from the Vascular Effects of Infection in Pediatric Stroke (VIPS), an international multicenter case-control study, implicate herpes group viruses as a major contributor to pediatric stroke. Arterial or venous stroke has been identified in 5% to 12% of children and 75% of infants with bacterial meningitis. Tuberculous meningitis is an important cause of childhood AIS in developing countries. AIS has also been associated with mycoplasma, toxoplasmosis, rocky mountain spotted fever, Lyme disease, cryptococcus, Japanese encephalitis, coxsackie B4 and A9, influenza A, enterovirus, parvovirus B19, HIV, and chlamydia.

## Arteriopathies

Diseases that directly affect the craniocervical arteries supplying the brain have emerged as the leading cause of childhood AIS and are the most important predictor of recurrence and poor outcome. Arteriopathy is present in >50% of children with AIS (Amlic-Lefond et al., 2009). Vascular imaging is essential for accurate initial identification and classification of arteriopathy. Given the progressive nature of some arteriopathies, ongoing

surveillance with vascular imaging is also important and may dictate specific treatment. Important arteriopathy categories are 1) focal or transient cerebral arteriopathy (Figure 109-4), 2) primary angiitis of the central nervous system, 3) arterial dissection, 4) moyamoya syndrome (Figure 109-7), and 5) congenital or genetic arteriopathies.

**Focal or Transient Cerebral Arteriopathy.** Focal cerebral arteriopathy (FCA), also termed “transient cerebral arteriopathy” (TCA), is associated with 1) unilateral intracranial arteriopathy affecting distal internal carotid and proximal middle or anterior cerebral arteries; 2) lenticulostriate infarcts within basal ganglia; 3) narrowing, banding, or stenosis of the affected vessel wall; and 4) serial arterial imaging often showing instability in the initial 3 to 6 months, followed by

**Figure 109-4.** Large-vessel arterial infarct in the right middle cerebral artery territory associated with “transient cerebral arteriopathy” of childhood in an 11-year-old female presenting with hemiparesis. **A**, T2-weighted magnetic resonance imaging shows right middle cerebral artery infarct maximally involving the cortex. **B**, Conventional angiogram shows irregular stenosis in the proximal right middle cerebral artery. stabilization or improvement. Early descriptions of this condition used the term “transient cerebral arteriopathy” (TCA), and subsequent studies have confirmed the nonprogressive nature of the disorder in over 90% of children. An example of the angiographic appearance of TCA is shown in [Figure 109-4](#). The pathophysiology of this arteriopathy remains undetermined but an association between infection and TCA/FCA arteriopathy is well recognized. However, it is yet to be established whether TCA represents an inflammatory arteriopathy and, if so, whether it is provoked by active viral infection, postviral inflammation, or “idiopathic” inflammation.

Postvaricella angiopathy (PVA) provides some evidence for an association between infection and arteriopathy. PVA shares imaging features with TCA with the main difference being a history of clinical varicella infection within 12 months. Proposed mechanisms include viral reactivation from trigeminal ganglion with spread to proximal cerebral arteries. Rare histopathological studies have revealed viral particles or antigens in cerebral artery smooth muscle cells. Naturally occurring PVA is expected to decrease with varicella vaccination becoming routine and there is no known association between varicella vaccine and childhood stroke.

**Figure 109-7. Moyamoya disease.** An 8-year-old boy presented with acute-onset left hemiplegia after 10 months of transient alternating hemiplegia related to hyperventilation. **A**, A large-arterial ischemic stroke of the right frontal lobe is accompanied by additional large-vessel and watershed lesions bilaterally. The patient has severe motor disability bilaterally, with cognitive delays, and is nonverbal. **B**, His 15-year-old sister mentioned having headaches at her brother's follow-up visit and was imaged. She has several small ischemic lesions in the periventricular white matter (arrow), but is an honors student with normal examination findings. Both children have moyamoya. **C** and **D**, The girl's angiogram (anteroposterior view) shows severe narrowing (**C**) and occlusion (**D**) of the distal internal carotid arteries, with abnormal collateral development (arrows). Both patients have been asymptomatic after bilateral revascularization surgery.

#### **Primary Angiitis of the Central Nervous System and Other Conditions Associated with Cerebral Arteriopathy.**

Noninfectious arterial inflammation or vasculitis is referred to as childhood primary angiitis of CNS (cPACNS). Unilateral large-vessel versions are interchangeable with TCA terminology but bilateral large- and small-vessel varieties tend to be progressive. For the latter, aggressive anti-inflammatory treatment may be required to prevent rapid deterioration and multifocal strokes. cPACNS limited to distal, small cerebral arteries ("angiogram-negative") typically presents with insidious symptoms, including headaches, seizures, cognitive decline, and behavioral or personality change, and MRI demonstrating multifocal enhancing lesions. Conventional angiography is

indicated but may be negative, and brain biopsy is often required for definitive diagnosis.

Systemic vasculitides and connective tissue diseases occasionally involving cerebral arteries include Kawasaki disease, Henoch-Schönlein purpura, polyarteritis nodosa, Wegener granulomatosis, systemic lupus erythematosus, Behcet syndrome, mixed connective tissue disease, Sjogren syndrome, and inflammatory bowel diseases. These conditions are reviewed in Chapter 121.

The range of infectious/inflammatory arteriopathies must be a primary consideration in all children with AIS with important implications for investigation, treatment, and risk of recurrence and poor outcome. Diagnostic investigations

should be clinically tailored but may include screening for specific infections (serology, virology, PCR) in addition to routine hematological blood work, and inflammatory (ESR, CRP) and vasculitic (ANA, extractable nuclear antigens, complement, etc.) markers and cerebrospinal fluid analysis. Treatment trials for the infectious/inflammatory cerebral arteriopathies are lacking in children but antivirals and corticosteroids may be considered. Other immunosuppressive agents such as cyclophosphamide, azathioprine, and mycophenolate are indicated in progressive cPACNS.

**Dissection and Other Physical Injury.** Craniocervical dissection causes intraluminal thrombosis or wall hematoma with frequent artery-to-artery thromboembolism. Dissection accounts for up to 20% of childhood. Extracranial arterial dissection occurs at predictable locations, including proximal ICA and the vertebral arteries at C1–C2 level. Intracranial dissection also occurs, and carries a theoretical added risk of secondary subarachnoid hemorrhage. It may be difficult to distinguish intracranial dissection from TCA on vascular imaging. Dissection may result from trauma to the neck, spine, or retropharyngeal area but many cases occur spontaneously. Symptoms and signs of dissection include head or neck pain, ipsilateral Horner's syndrome, and cervical bruit, and stroke onset may be delayed by 7 to 10 days. Stroke recurrence rates are estimated at 20% or higher.

The medical management of dissections is controversial with no randomized controlled trials. Current guidelines suggest consideration of anticoagulation in children with stroke because of extra cranial dissection but adult meta-analyses have found no difference in outcomes between anticoagulation and antiplatelet therapy. Intracranial dissection may be a relative contraindication to anticoagulation due to the risk of subarachnoid hemorrhage.

**Moyamoya Disease and Moyamoya Syndrome.** Moyamoya is characterized by progressive occlusion of distal internal carotid arteries (ICAs) and branches of the Circle of Willis. Compensatory angiogenesis forms collateral vessels resulting in an abnormal network termed "moyamoya" (Japanese for "puff of smoke") (see [Figure 109-7](#)). Moyamoya disease, the idiopathic form, is an important cause of childhood stroke, particularly in Asians in whom mutations in the ring finger 213 gene (*RNF213*) are common. Moyamoya syndrome is associated with systemic conditions, including sickle cell disease (Sickle Cell Disease), Down syndrome, neurofibromatosis type 1, postirradiation vasculopathy, and congenital arteriopathies. Moyamoya is therefore a syndrome and not a single disease.

In contrast to other forms of AIS, an important mechanism for moyamoya-associated infarction is hypoperfusion, which often affects watershed zones. Impaired cerebrovascular autoregulation in chronically underperfused territories appears to predict infarction. Stroke or TIA symptoms may be precipitated by alterations in  $PCO_2$  such as during hyperventilation (cerebral vasoconstriction) or breath-holding (cerebral vasodilation with "steal"). Moyamoya progresses slowly over time, causing accumulating injury and poor neurologic outcomes. In addition, artery-to-artery occlusion of larger cerebral arterial branches can result in more typical AIS. Hemorrhagic stroke can also occur from the compensatory basal collateral vessels (*rete mirabile*) and risk increases in early adulthood. Headaches, often with migrainous features and hypertension, are common in moyamoya.

MRI findings include multifocal infarcts (see [Figure 109-7](#)) particularly affecting subcortical white matter, vascular flow voids in the basal ganglia, and the "ivy sign" on FLAIR imaging, which correlates with impaired autoregulation. MR

angiography (MRA) is sensitive at detecting moyamoya arteriopathy but conventional angiography is required to confirm collaterals, characterize disease extent, and determine options for revascularization surgery (see [Figure 109-7](#)).

Treatment of moyamoya is complex. Antiplatelet therapy with ASA is often employed and is likely safe. Carbonic anhydrase inhibitors, including acetazolamide, may shift acid–base balance to favor vasodilation but may also cause a steal phenomenon with risk of stroke. Use of antihypertensives in children with moyamoya must be avoided or carefully titrated as even small decreases in cerebral perfusion can lead to infarction. Surgical revascularization procedures are highly successful at improving perfusion in children with moyamoya. Direct revascularization connects extracranial blood vessels such as the superficial temporal artery to distal portions of intracranial vessels, usually the middle cerebral artery. These are technically difficult in small children and carry some risk of reocclusion. Indirect procedures are more often employed in children, in whom extracranial vessels are approximated to the cortical surface overlying areas of decreased perfusion. Studies comparing the different surgical approaches are lacking. Perioperative infarctions occur in <10% of patients.

**Congenital or Genetic Arteriopathies.** An increasing number of congenital or genetic cerebral arteriopathies are recognized. NF1, ACTA2, COL4A1, Alagille syndrome, CADASIL, CARASIL, and possibly fibromuscular dysplasia are examples each with unique imaging characteristics.

## Cardiac

Cardiac disorders are associated with 10% to 31% of infants and children with AIS ([Figure 109-8](#)) ([Sinclair et al., 2015](#)). Congenital heart defects account for the majority of cases with a 19-fold increased stroke risk. Cardiac surgery carries a 1:185 risk, and cardiac catheterization a 1:600 to 700 risk of symptomatic AIS with increased risk for interventional catheterization. High-risk procedures include Fontan and balloon atrial septostomy.

Atrial septal defects (ASD) and patent foramen ovale (PFO) remain controversial risk factors for stroke in young adults that have not been well studied in children. Associations between PFO and cryptogenic stroke have been demonstrated in young adults but randomized trials do not support surgical closure of uncomplicated PFO over medical treatment.

Infective endocarditis predisposes to AIS and intracerebral hemorrhage and is suggested by subacute constitutional symptoms, fever, Janeway lesions, and Roth spots. Anticoagulation is relatively contraindicated because of bleeding risk from mycotic aneurysms. Other acquired cardiac defects include infectious or metabolic cardiomyopathy, valvular heart disease (e.g., rheumatic fever, artificial valves), dysrhythmias, atrial myxoma, extracorporeal membrane oxygenation (ECMO), and ventricular assist devices.

Multifocal infarcts across different vascular territories and hemorrhagic transformation may suggest a cardiac source. Children with cryptogenic AIS should undergo prompt cardiac evaluation, including an electrocardiogram and echocardiography. Agitated saline "bubble studies" can help exclude PFO and atrial septal defects. Screening for prothrombotic states is recommended. Recurrent strokes are not uncommon in children with congenital heart disease and associated with mechanical valves, prothrombotic states, acute infection, and lack of antithrombotic treatment.

Consensus-based pediatric stroke guidelines suggest anticoagulant treatment over antiplatelet therapy for cardiogenic AIS. A randomized controlled secondary prevention trial in children undergoing the Fontan procedure found no difference between anticoagulant or antiplatelet therapy but did not

**Figure 109-8. Acute cardioembolic arterial ischemic stroke.** An 11-year-old girl presented with weeks of fatigue, low-grade fever, and skin lesions. She suddenly developed left-sided hemiplegia in hospital. **A**, Computed tomography (CT) scan at 90 minutes shows hypodensity (arrows) and loss of cortical ribbon in the right frontal lobe. She did not receive thrombolysis because of suspicion of endocarditis. Diffusion-weighted magnetic resonance imaging (MRI; **B**) and magnetic resonance angiography (**C**) confirm arterial ischemic stroke secondary to occlusion (arrow, **C**). The patient subsequently grew streptococcus and required aortic valve replacement. **D**, Follow-up imaging at 6 months included gradient ECHO MRI, which demonstrated hypodensity in the area of previous occlusion (arrow). **E** and **F**, CT angiography confirmed a mycotic aneurysm (arrow, **F**), which grew over the next month and was clipped surgically with success.

address asymptomatic cerebrovascular events. Bacterial endocarditis requires urgent antibiotic treatment and investigation for mycotic aneurysm. Specific guidelines for prevention and treatment of thrombosis for children with congenital heart disease are available. Chapter 157 also discusses the neurologic disorders associated with cardiac disease.

### Prothrombotic and Hematological Disorders

Prothrombotic disorders refer to abnormalities of the coagulation, fibrinolytic, and platelet systems that predispose to pathologic thrombus formation. Inherited or acquired coagulation disorders have been identified in 20% to 50% of children with AIS but interpretation of the data is limited by inconsistent testing and variability in laboratory methods. Meta-analyses have demonstrated a predisposing role for prothrombotic disorders in childhood AIS, with frequent coexistent “triggering” risk factors (Kenet et al., 2010). Genetic prothrombotic factors associated with childhood AIS include Factor V Leiden (odds ratio 3.7 to 4.3), prothrombin G20210A (odds ratio 2.6 to 3.5), lipoprotein (a) (odds ratio 6.5), and protein C deficiency (odds ratio 6.5 to 11.0). Protein S and

antithrombin III may also be associated with increased risk of stroke. Acquired prothrombotic factors include antiphospholipid antibodies and lupus anticoagulant (odds ratio 6.95). Coexistent multiple prothrombotic factors are associated with the highest risk (combined odds ratio 11.9). Coagulation testing should be performed in all children with AIS, even in the presence of other risk factors, because prothrombotic disorders may be associated with increased recurrence. Children with stroke and a significant prothrombotic disorder should be counseled in prevention strategies such as the avoidance of dehydration and possible prophylactic dosing of anticoagulation in high-risk situations. These conditions are discussed further in Chapter 113.

### Sickle Cell Disease

SCD is the most common hematological disorder associated with cerebrovascular disease in children and increases ischemic stroke risk 400-fold. About 25% of SCD children develop cerebrovascular complications, with risk being highest during acute sickle crises. Stroke is responsible for 10% of SCD mortality. There are two main mechanisms for AIS in SCD:

1) a progressive internal carotid (large vessel) Moyamoya arteriopathy and 2) occlusion of small cerebral end arteries. Extracranial carotid disease, anemia, hypertension, and proinflammatory genetic polymorphisms may also contribute to cerebrovascular disease.

Transcranial Doppler (TCD) studies are a noninvasive means of following flow rates related to large-vessel vasculopathy with flows >200 cm/s, predicting increased stroke risk. The STOP randomized controlled trial demonstrated that regular transfusion therapy (hemoglobin S <20% to 30%) produced a 90% relative risk reduction in initial stroke in children with elevated velocities. Recurrent stroke rates were also reduced. A follow-up study showed that stroke risk returns with discontinuation of transfusions. MRI surveillance can detect silent infarcts secondary to small-vessel disease, large-vessel disease, and possible Moyamoya syndrome. In children with radiologic evidence of silent cerebral infarction, regular transfusions also confer protection against cerebrovascular events but the relative risk-benefit ratio is not well defined (DeBaun et al., 2014). Additional stroke prevention strategies under evaluation include hydroxyurea and nocturnal oxygen supplementation. Antithrombotic therapy has not been studied but aspirin should be considered, especially in cases with large-vessel vasculopathy, prothrombotic abnormalities, or recurrent stroke.

### Additional Considerations

A comprehensive list of additional conditions associated with childhood AIS is in Table 109-2. Iron deficiency anemia is an important and treatable risk factor, present in up to 40% of childhood AIS but the underlying pathophysiology has not been established. Migrainous infarction is rare in children, and preventative treatment with ASA and flunarizine is indicated, and vasoconstrictor agents such as triptans and sympathomimetics should be avoided. Reversible cerebral vasoconstriction syndrome, another rare vasospastic condition, occurs in children and may respond to similar interventions. Use of medications and illicit drugs should be determined. Inborn errors of metabolism predisposing to AIS include homocystinuria and Fabry disease, and mitochondrial disorders can mimic AIS. The role of other genetic factors in stroke and cerebral vasculopathies is complex, ranging from single-gene disorders imparting a high risk to complex, multigene polymorphisms influencing additional risk factors.

### Clinical Features and Diagnostic Delays

Prompt diagnosis is essential to enable emergent neuroprotective management, and interventions to promote recanalization and prevent early recurrence. Unfortunately, multiple studies confirm long diagnostic delays, often beyond 24 hours from symptom onset. Physician recognition and quick availability of sensitive imaging are probably important contributors to delayed diagnosis.

The acute onset of focal neurologic deficits in childhood is a stroke until proven otherwise. Hemiparesis is a common presenting deficit that may be erroneously attributed to stroke mimics, including migraine, Todd's paresis, encephalitis/meningitis, demyelination, or tumors. Other focal deficits include dysarthria, dysphasia, facial weakness, vertigo, abnormal eye movements, sensory disturbance, ataxia, and neglect (Mallick et al., 2014). The frequent occurrence of seizures in childhood AIS is a notable difference to adults. Nonfocal neurologic signs such as headache, irritability, and altered mental state are also common, particularly in infants. Stroke-induced deficits usually begin suddenly and severity is maximal at the onset, aiding differentiation from mimics such as migraine

and demyelination. However, fluctuating or stuttering onset of symptoms can occur, and may be clues to specific etiologies such as arteriopathies.

Specific historical and examination findings may provide clues to the stroke mechanism and etiology. History of infection is important, including varicella within 12 months. Head or neck trauma, including chiropractic neck manipulation within the preceding weeks, may suggest dissection. Previous TIA is important and symptoms switching sides suggest a proximal embolic source or bilateral arteriopathy (e.g., Moyamoya syndrome). Migraine history in the child and family may be relevant. Previous head or neck irradiation and medication history including oral contraceptives, chemotherapy, sympathomimetics, or illicit drugs should be sought. Family history should screen for early onset thrombotic events, cardiovascular disease, and genetic disorders. Important elements of the physical examination include cardiovascular examination with blood pressure, peripheral pulses, and auscultation of the head and neck for bruits. Ophthalmologic examination may suggest arteriopathic diseases or increased intracranial pressure. Skin lesions may suggest neurofibromatosis, Fabry disease, or PHACES syndrome (posterior fossa abnormalities, hemangiomas, arterial cervicocerebral anomalies, cardiac defects, eye anomalies, sternal defects, and/or supraumbilical raphe).

### Diagnosis: Neuroimaging

Appropriate and timely neuroimaging is essential to confirm the diagnosis of AIS, exclude stroke mimics, and guide initial management decisions. Computed tomography (CT) can exclude intracranial hemorrhage but has low detection rates for acute brain ischemia, ranging from 16% to 56% in pediatric studies. Therefore magnetic resonance imaging (MRI) is the neuroimaging investigation of choice. Diffusion-weighted MRI (DWI) reliably detects early brain ischemia characterized by combined DWI hyperintensity (see Figure 109-8) and apparent diffusion coefficient (ADC) map hypointensity. This pattern normalizes over 1 to 2 weeks. Abnormalities appear on T2-weighted and FLAIR sequences within several hours and persist. Susceptibility-weighted methods can detect blood. Perfusion-weighted imaging demonstrates regional brain perfusion abnormalities but pediatric studies have been limited.

Vascular imaging of the intracranial and neck vessels should be performed simultaneously. Time-of-flight MRA can image the major first- and second-order cerebral arteries but because it relies on flow signal, signal dropout artifact can mimic occlusion in areas of turbulent flow or stenosis. An abrupt arterial "cutoff" suggests embolic stroke, whereas stenosis or irregularity favors arteriopathy. Gadolinium-enhanced MR angiography has better resolution and specificity than time-of-flight imaging. MRI "wall imaging" may demonstrate concentric vessel wall enhancement suggesting inflammation, a potentially valuable marker in pediatric arteriopathies.

Conventional angiography (CA) remains the gold standard for cerebrovascular imaging (see Figures 109-4 and 109-7). Specific arteriopathies may only be diagnosed by CA, including "string," "double lumen" or intimal flap signs in dissection, "string of beads" in vasculitis, and arteriopathies limited to smaller-caliber arteries. CA should be performed in children with AIS in whom a specific etiology remains undetermined after initial MRA or CTA and considered in others to better characterize probable arteriopathies.

### Treatment

Current treatment of pediatric stroke is informed by multiple consensus-based guidelines, generated from panels of child

neurologists, thrombosis experts, and others experienced in pediatric stroke (Roach et al., 2008; Monagle et al., 2012). These guidelines are concordant for major treatment recommendations although they differ in certain areas because of the paucity of data from randomized controlled trials.

### Stroke Unit Care and Neuroprotection

There is substantial evidence in adults of the benefits of stroke units in reducing length of hospital stay, morbidity, and mortality. The general principles of specialized teams providing stroke care can be applied at pediatric centers meeting key infrastructural requirements. Therefore children with stroke should be rapidly transferred to centers with expertise in management of cerebrovascular disorders after stroke diagnosis.

Immediate measures to prevent secondary brain injury are a crucial, easily overlooked aspect of emergency stroke care in children. Neuroprotective therapy is aimed at optimizing perfusion, delivering oxygen and glucose to penumbral tissue, and reducing neuronal metabolic demand through control of fever and seizures. Hypertension is associated with increased mortality and hypotension compromises perfusion of penumbral tissue. Although ideal blood pressure parameters for treatment of hypertension in acute childhood stroke are unknown maintenance of blood pressure up to 15% above the 90% percentile seems reasonable for most patients. Maintenance of normal blood oxygen and carbon dioxide levels is also prudent in the face of tenuous cerebral perfusion and acute alterations in autoregulation.

Both hyper- and hypoglycemia are associated with poorer neurologic outcomes in adult stroke and critically ill children but there are no specific data in pediatric stroke. Ischemic brain injury is clearly exacerbated by hyperthermia in animal models and adult stroke and guidelines recommend temperature control. Therapeutic hypothermia has not been studied in childhood AIS but results are predominantly negative in childhood traumatic brain injury and adult stroke. Acute seizures are common in childhood AIS, likely worsen ischemic brain injury, and should be monitored for and treated with anticonvulsant medications.

### Thrombolysis and Thrombectomy

There is a paucity of efficacy and safety data for tissue plasminogen activator (tPA) or thrombectomy in children because of exclusion of subjects <18 years from clinical trials. As a consequence, pediatric stroke guidelines do not recommend these approaches in children. The following discussion is presented to educate the reader and does not represent a recommendation for such interventions.

Thrombolytic agents such as tPA promote the conversion of plasminogen into plasmin to dissolve thrombi. Meta-analyses of published adult trials demonstrate a time-dependent benefit for tPA outweighing early risks of intracranial hemorrhage within 4.5 hours of onset. The safety and efficacy of thrombolysis in children remains poorly studied. Developmental differences in the fibrinolytic system, including decreased plasminogen and free tissue plasminogen levels and higher plasminogen activator inhibitor-1 (PAI-1) levels, may substantially alter both the benefits and anticipated risks of thrombolysis. Off-label usage of tPA is reported in up to 2% of children in large multicenter data sets often beyond recommended time windows and with higher rates of symptomatic intracranial hemorrhage. Up to 10% of children may be eligible for thrombolysis using adult selection criteria but several obstacles exist, including paucity of age-appropriate safety data and long diagnostic delays. Tools allowing identification of children with the worst prognosis such as the Pediatric NIH Stroke Scale are available. Emerging

evidence in adults suggests that mechanical thrombectomy may be the most effective means of achieving recanalization but only anecdotal data are available for children. Therefore the role of mechanical thrombectomy is unclear in children.

### Antithrombotic Therapies

Managing childhood AIS without antithrombotic agents is no longer considered appropriate in most cases because of the high risk of early recurrence and the availability of safety data for these agents in acute childhood stroke. However, choosing between antiplatelet and anticoagulation treatments in the acute setting is not well informed by evidence, reflected by discordant practices among pediatric stroke experts and differing recommendations across consensus guidelines. Prompt initiation of antithrombotic therapy aims to prevent thrombus propagation or reemolization and promote early recanalization. The first option is anticoagulant treatment with agents including heparin, low-molecular-weight heparins (LMWH), or warfarin. Anticoagulants may be theoretically favored in certain circumstances such as cardiogenic embolism, paradoxical venous embolism, slow flow with severe stenosis, a major prothrombotic disorder, and possibly dissection. The second option is antiplatelet treatment with aspirin, which may be more appropriate in the arteriopathies in which high flow thrombus formation theoretically favors platelet-rich thrombi. These treatment approaches are not mutually exclusive and their indications may vary across acute, subacute, and chronic timeframes as the cause of a child's stroke becomes more evident.

**Anticoagulation.** The decision to employ acute anticoagulation therapy (ACT) in childhood AIS rests on balancing the potential benefit of reducing thrombus extension or recurrence with risk of hemorrhage. Decisions should be based on suspicion of pathologic fibrin clot formation (coagulation system) playing a dominant role. Evidence suggests that clinically significant hemorrhagic transformation of childhood AIS is rare and not significantly increased with anticoagulation. Large adult clinical trials across different stroke populations have shown only modestly improved efficacy of heparin over ASA that is generally negated by an increased risk of hemorrhagic complications. Post hoc analysis of the Warfarin Aspirin Recurrent Stroke Study (WARSS) found a 30% risk reduction for recurrent stroke with warfarin over aspirin among adults with cryptogenic strokes, which may be relevant to children. Acute anticoagulation has an established role in certain adult stroke situations where there is high risk of thrombus extension or embolic recurrence, such as nonvalvular atrial fibrillation. Relative ACT contraindications include intracranial hemorrhage, uncontrollable hypertension, or bleeding diathesis.

Although there are no large-scale clinical trials of anticoagulation therapies in children with AIS, extensive pediatric experience has established safety. The American College of Chest Physicians and AHA guidelines support the initial use of anticoagulation in childhood AIS, after diagnosis, pending further investigations, whereas the UK guidelines favor initial use in only selected circumstances such as cardiogenic stroke. Dosing guidelines for anticoagulant treatment in children with AIS are available.

*Unfractionated heparin (UFH)* potentiates antithrombin's inactivation of thrombin and other enzymes. Children require lower doses than adults. Dose monitoring includes activated partial thromboplastin times (APTT) and heparin levels. Rapid and complete reversal of the anticoagulation effects of heparin with protamine confers a potential advantage in situations of higher bleeding risk or impending surgery. *Low-molecular-weight heparins (LMWH)* are molecular subcomponents of

unfractionated heparin. Advantages of LMWH include more reproducible pharmacokinetics, subcutaneous injection, less frequent monitoring, and modestly increased safety profiles. Antifactor Xa levels are used to monitor treatment. LMWH carries a low risk of thrombocytopenia. Oral anticoagulation with *warfarin* is generally reserved for children requiring long-term anticoagulation, such as those with complex congenital heart diseases or severe prothrombotic disorders. Warfarin antagonizes the activity of vitamin K–dependent coagulation factors in a dose-dependent manner. A target INR (international normalized ratio) of 2.0 to 3.0 is appropriate for most children (2.5 to 3.5 for mechanical heart valves). Relative contraindications include infants or children with unpredictable vitamin K levels, gastrointestinal disorders, and older children unwilling to forgo contact sports.

**Antiplatelet Therapy.** Management guidelines recommend antiplatelet agents as secondary prevention for non cardioembolic AIS. *Aspirin* is the primary antiplatelet agent for children with a well-established safety profile and inhibits platelet aggregation by decreasing thromboxane A<sub>2</sub> production. Reye syndrome is likely related to rare inborn errors in metabolism and has never been reported in pediatric stroke but some physicians recommend reduction of therapy during a febrile illness and annual influenza vaccination. Alternative antiplatelet agents include clopidogrel, extended release dipyridamol, ticlopidine, or the glycoprotein IIb/IIIa antagonists.

### Malignant Cerebral Edema

Poststroke cerebral edema is a life-threatening early complication of childhood AIS. Malignant MCA syndromes, large hemorrhagic transformations and cerebellar infarcts carry the highest risk of brain herniation. Urgent imaging should be performed for any neurologic deterioration within the first 72 hours, especially decreased level of consciousness or unilateral pupillary dilatation. Medical management includes measures to reduce increased intracranial pressure, including sedation, paralysis, manipulation of PCO<sub>2</sub>, and osmotic therapy. Decompressive hemicraniectomy is lifesaving.

## Outcomes and Chronic Management

### Sequelae of AIS

More than 50% of childhood stroke survivors have long-term moderate to severe neurologic impairments or epilepsy (deVeber et al., 2000). Rehabilitation must target the physical, occupational, language, cognitive/behavioral, and psychosocial consequences of stroke for the child and their family. Compared with adults with stroke, children have improved potential for recovery; however, among children, younger age at time of injury is associated with higher risk of long-term impairment. Stroke in adults results in loss of function, whereas similar injury in children results in both loss of function and reduced ability to acquire new abilities. Therefore pediatric rehabilitation treatments must incorporate knowledge of normal age-related developmental skills, trying to distinguish differences between relearning a brain function versus acquiring it for the first time.

Hemiparesis and motor disabilities are common sequelae of childhood stroke. Hemidystonia can emerge months after basal ganglia stroke. Neuroimaging may facilitate early prediction of poor motor outcomes in childhood AIS, possibly identifying those in need of aggressive rehabilitation. Rehabilitation programs that combine strength and aerobic conditioning, task-specific training, and assistive devices are generally recommended in children. Constraint induced movement therapy (CIMT) is a therapeutic approach to promote

functional use of an impaired limb after stroke. The results from pediatric CIMT studies in children with perinatal stroke and hemiplegic cerebral palsy are encouraging but clinical trials are required in childhood stroke. Bimanual therapy approaches, focusing on function of the unaffected extremity may complement CIMT. Noninvasive neuromodulation such as repetitive transcranial magnetic stimulation (TMS) has been shown to improve motor functions in chronic adult stroke, and preliminary data suggest that it may also have a role in childhood stroke. Peripheral electrical stimulation, robot-assisted rehabilitation, and virtual reality training strategies being explored in adult stroke are yet to be tested in children.

Assistive devices, including ankle-foot orthoses and Lycra hand splints, may facilitate joint positioning and function, and are supported by evidence in adult stroke. Spasticity interventions must include comprehensive, objective, and blinded pre- and postinterventional outcome measures of efficacy. Botulinum toxin may alleviate increased tone though effects on motor function and quality of life in children have been questioned. Careful selection criteria and better evidence of efficacy are also required for surgical interventions such as tendon-lengthening procedures. Physical growth asymmetries with resultant leg length discrepancy and scoliosis may require orthopedic intervention.

Neuropsychological impairments are common in children with stroke, limiting academic, social, and independent functional success. On average, childhood stroke survivors exhibit mildly compromised global intellectual function. Younger age at stroke does not appear to predict better cognitive outcomes. Language function, verbal learning, and memory are also often impaired, usually related to dominant hemisphere injury. Comprehensive, serial testing of cognitive, language, and other higher brain functions by pediatric neuropsychologists using standardized measures is important because defects in higher brain function often emerge over time in young children. Emotional, behavioral, and socialization problems after childhood stroke may occur and potentially affect all aspects of quality of life. Bilateral lesions may increase the risk of emotional or behavioral problems.

Remote symptomatic epilepsy complicates childhood AIS in approximately 15% to 20% of cases. Predictors of childhood epilepsy include large cortical lesions, acute seizures, and younger age at presentation. Treatment usually consists of anticonvulsants but some children with medically refractory poststroke epilepsy may require epilepsy surgery. Headache disorders are also common after stroke, occurring in 33% of individuals with risk factors including preexisting conditions (e.g., migraine), the underlying disease (e.g., Moyamoya syndrome), and psychosocial stressors. Most established pharmacologic interventions are safe in children with AIS with the exception of vasoconstricting agents, including triptans.

Psychosocial and social support of families is essential. Adverse effects of stroke on quality of life are frequent. A family-centered treatment approach should consider the individual child's lifestyle, goals, and level of functioning and be well-integrated into the school and home environments. Alleviation of parental guilt may also provide substantial benefit. Parents also require guidance in the interpretation of a growing number of therapeutic options, including those with legitimate potential such as stem cells and "pseudo therapies" such as hyperbaric oxygen, which are unfairly marketed to families, offering incredible but unsubstantiated claims of efficacy. The treating physician must therefore guide families to make informed decisions, respecting their motivations to help their children, while advocating on their behalf for responsible and equal regulation of all therapies offered to children with disabilities.

## Stroke Recurrence

Stroke recurrence is significant, mandating a thorough approach to secondary stroke prevention over the long-term. Stroke and TIA recurrence risks range from 7% to 35%, with population-based data suggesting 5-year recurrence rates approaching 50%. Presence of arteriopathy is the most important risk factor for recurrence with rates >65%. With no randomized trials, the relative efficacy of various secondary stroke prevention interventions is unknown. Antiplatelet therapy is the mainstay of long-term secondary stroke prevention in childhood AIS. Certain cardiac and prothrombotic conditions may require long-term anticoagulation with warfarin. Additional treatments may include immunosuppression for inflammatory vasculitis, transfusions for SCD, and revascularization surgery for Moyamoya syndrome. Attention to arterial health with balanced diet, exercise, avoidance of smoking and drugs, and surveillance for hypertension, dyslipidemia, or insulin resistance may also help prevent recurrence over the long-term.

# 110 Sinovenous Thrombosis in Infants and Children

Lori Billingham and Mahendranath Moharir

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Cerebral sinovenous thrombosis (CSVT) is included under the “ischemic stroke” category in children. In CSVT, brain dysfunction occurs due to thrombotic occlusion of cerebral veins and/or dural venous sinuses. CSVT is rare but remains underrecognized in children due to nonspecific presentation, resulting in delayed or missed diagnosis. CSVT is distinct from arterial ischemic stroke (AIS) even though there is an overlap in predisposing conditions. Although randomized controlled trials (RCTs) have established the usefulness of anticoagulation therapy (ACT) in adults, pediatric data are limited to observational and cohort studies. Timely diagnosis and management is essential as CSVT is a potentially life-threatening condition. This chapter will focus on CSVT in infants (older than 28 days) and older children. Neonatal CSVT is comprehensively reviewed in Chapter 20.

## EPIDEMIOLOGY

CSVT includes all children with thrombosis of the structures of the intracranial venous system with or without radiologically evident parenchymal lesions. Isolated thrombosis of the internal jugular vein (IJV) is not included under CSVT. Published epidemiologic studies suggest an incidence of 0.25 to 0.67 per 100,000 children per year. The ratio of pediatric CSVT to AIS cases is estimated at 1:4 annually. Like AIS, CSVT occurs more frequently in neonates and in males. Awareness of CSVT has increased in the last decade after the seminal population-based study of pediatric CSVT from Canada (deVeber and Andrew, 2001). Several large case series, cohort studies (Moharir et al., 2010; Grunt et al., 2010), and multicenter registry studies (Ichord et al., 2015) have now been published.

## PATHOGENESIS

### Sinovenous Circulation: Anatomy and Vascular Patterns

Cerebral venous drainage occurs through a network of veins and sinuses that comprise broadly the superficial and deep venous systems (Fig. 110-1). In the superficial venous system (SVS), cortical veins drain cortical and subcortical white matter (WM) from both hemispheres medially toward the superior sagittal sinus (SSS), which remains the largest conduit for venous drainage. The deep venous system (DVS) includes internal cerebral (ICV), medullary, thalamic, and choroidal veins that converge centrally at the vein of Galen (VOG), which drains into straight sinus (STRS). The DVS predominantly drains basal ganglia, thalamic, and deep WM. The SVS and DVS unite posteriorly at the torcula. Bilateral, often asymmetric, transverse sinuses (TS) then drain laterally into sigmoid sinus (SIGS), which connects to the IJVs. The SVS usually drains into larger right TS whereas DVS drains into the smaller left TS. Additional venous drainage pathways connect with this system at recognizable locations including the cavernous and petrosal

sinuses and large superficial cerebral veins (e.g. Trolard, Labbé). Although the IJVs are the major exit for cerebral venous drainage, extrajugular pathways such as vertebral venous plexus (VVP) appear to be active, but poorly understood.

Adult and more recent pediatric data suggest that patterns of parenchymal brain lesions following CSVT may have some predictability (Fig. 110-2). Bilateral, parasagittal lesions, with or without hemorrhage are associated with SSS thrombosis. DVS thrombosis involving ICV, STRS and/or VOG produces lesions of deep WM, basal ganglia, and thalamus. Hemorrhagic lesions close to the ventricles can result in intraventricular hemorrhage (IVH) in young infants.

## Intracranial Venous Physiology

The cerebral sinovenous system lacks valves and is a low-pressure, slow-velocity circuit. The dura of venous sinuses is rigid and noncollapsible, resulting in passive drainage of blood to the heart. The flow in sinuses is gravity- and respiration-dependent and can be bidirectional depending on the venous pressure gradient. The IJV appears to drain blood primarily in the supine position whereas the VVP appears to drain blood mainly in the upright position in humans. Reduction in systemic blood pressure can lead to stasis or reversal of blood flow. Venous sinus caliber is probably unresponsive to changes in systemic blood pressure. As the SSS and TS are main sites for CSF reabsorption through arachnoid granulations into the venous circulation, thrombosis or hypertension of these structures can cause communicating hydrocephalus. In supine infants with open fontanelles, mechanical compression of SSS by occipital bone may compromise venous drainage causing stasis and increased thrombosis risk.

## Mechanisms of Thrombosis

CSVT essentially results from a “hypercoagulable” state secondary to Virchow’s triad: abnormalities of blood (prothrombotic state), blood flow (stasis), and blood vessel (veins/sinuses). As in systemic venous thrombosis, but in contrast to most AIS, the role of the coagulation cascade and thrombin-rich thrombosis predominates. Platelets appear to play a minor role, hence antiplatelet therapy like aspirin is not considered in CSVT treatment. Inherited/acquired coagulation abnormalities play a prominent role in pathogenesis. A relative thrombomodulin deficiency in the cerebral venous endothelium may increase thrombotic tendency. In septic CSVT, infection within or immediately adjacent to venous structures directly provokes thrombophlebitis. In many cases, the exact mechanism of thrombosis is not evident. Slower, passive venous flow may favor initial formation and subsequent propagation of thrombosis. Dehydration, a potent risk factor for CSVT, may result in hemoconcentration and impaired laminar flow. Mechanical compression or injury (trauma, neurosurgery, venous catheter insertion, compressive masses, and occipital bone compression in supine infants) of venous structures may result in both venous stasis and/or endothelial

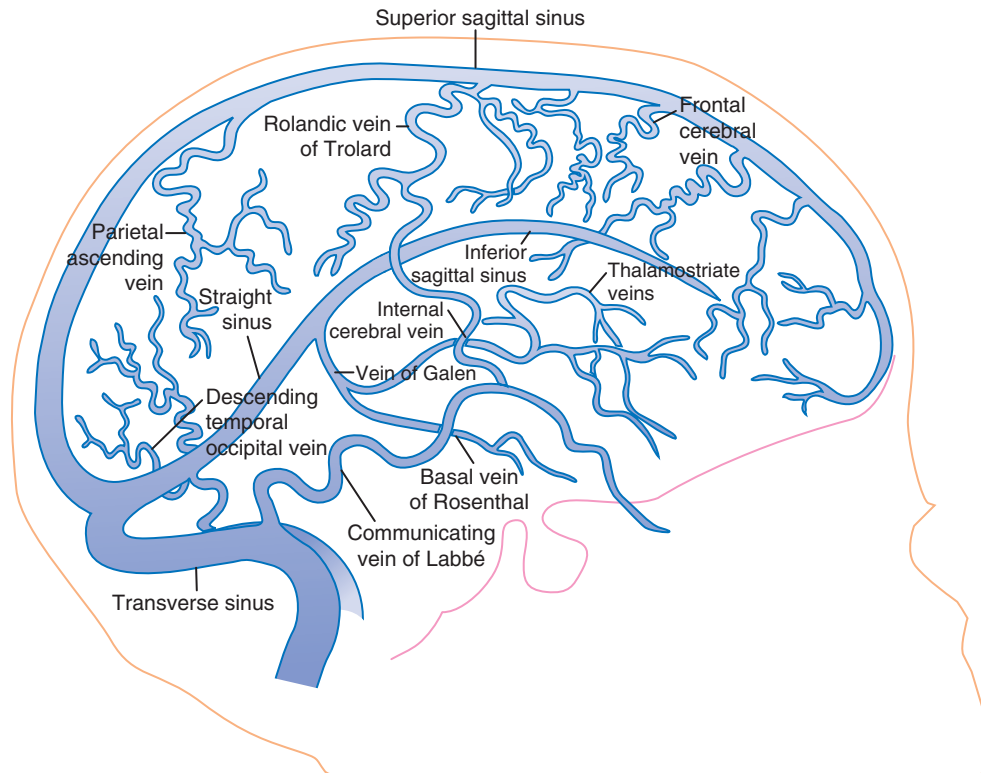

Figure 110-1. Cerebral venous anatomy.

Figure 110-2. Intracranial venous drainage patterns. Diagram of cerebral venous drainage territories. Axial section at the level of the basal ganglia (A) and corona radiata (B). Coronal section at the level of the basal ganglia (C) and thalamus (D). The venous drainage of the intracranial venous structures is depicted; superior sagittal sinus (SSS), transverse sinus (TS), cavernous sinus (CS), and galenic venous system (GVS). (With permission from Teksam, M., Moharir, M., deVeber, G., Shroff, M., 2008. Frequency and topographic distribution of brain lesions in pediatric cerebral venous thrombosis. *Am J Neuroradiol* 29, 1961–1965.)

damage. In essence, CSVT results from a net imbalance between “procoagulant” forces (excess) and intrinsic “fibrinolytic” mechanisms (relative deficiency).

### Mechanisms of Brain Injury

Thrombosis within the venous system results in outflow obstruction and decreased venous drainage. This causes retrograde venous pressure elevation. It may occur locally in a single venous territory resulting in local/regional effect or globally when major venous sinuses are involved resulting in diffusely elevated intracranial pressure (ICP). This in turn causes elevated local capillary hydrostatic pressure resulting in

fluid transudation across capillary channels. Hemorrhage can result from diapedesis of red cells through leaky capillaries. This explains the high rate of spontaneous hemorrhage in CSVT. Hemorrhage occurs mainly in intraparenchymal and intraventricular (IVH) compartments and more frequently in younger infants. Initially, the increased hydrostatic pressure may produce only parenchymal edema and neuronal dysfunction resulting in symptoms without infarction. Further rise in regional tissue pressure may eventually exceed the arterial inflow pressure causing critically low cerebral perfusion and permanent infarction. Alternative venous drainage can develop but this may require time. Therefore total and rapid thrombotic occlusion carries the highest risk of infarction and

permanent damage. The severity and duration of clinical symptoms associated with CSVT depend on the involved anatomic site(s), thrombosis acuity and collateral drainage. If collateral venous circulation develops adequately and rapidly, significant venous obstruction is tolerable without decompensation. Embryonic venous collaterals can sometimes develop even in older children as a compensatory mechanism.

## CLINICAL FEATURES

Clinical diagnosis of childhood CSVT is challenging due to the nonspecific nature of presenting neurologic symptoms and signs that can develop gradually over many hours, days, or even weeks. Abrupt onset can also occur. Diffuse neurologic signs and seizures are more common. Headache, lethargy, nausea and vomiting, and signs of raised ICP including papilloedema and sixth nerve palsy are seen frequently. These are clinically indistinguishable from idiopathic intracranial hypertension (IIH); hence, CSVT must be ruled out in all children with suspected IIH. Acute symptomatic seizures are more common than in AIS ranging from 23% to 90%. Altered mental status ranging from isolated lethargy and irritability on the milder end of the spectrum, to frank coma on the severe end, may occur. However, frank coma can also occur. The clinical features of associated risk factors (see following section) are usually present at diagnosis. Given the nonspecific clinical manifestations of childhood CSVT, a low index of suspicion is essential in any child with unexplained raised ICP, seizures and encephalopathy.

## RISK FACTORS

Risk factors readily are identifiable in most children. Multiple risk factors may co-exist in the same child and a broad range of investigations should be considered. Head and neck infections occur in nearly one in every three preschool children whereas other associations like systemic disease and trauma are clustered in older children.

### Infection

Infection is a major risk factor for childhood CSVT reported in 24% to 62% of published cohorts. "Septic" CSVT is defined as thrombosis of venous sinuses associated with head and neck infections like otitis media, mastoiditis, sinusitis, meningitis, and, less frequently, intracranial abscess. Although the relative proportion of septic to nonseptic CSVT has decreased in general, infection remains an important and treatable cause of CSVT. Mechanisms include direct extension of infection from structures adjacent to venous sinuses causing thrombophlebitis. The infectious state per se also increases the risk of dehydration and a transient systemic prothrombotic state. Given the frequency of septic CSVT, thorough infectious disease history, physical examination, and diagnostic investigations must be sought in childhood CSVT.

### Anemia

Anemia is reported in 10% to 20% of children with CSVT, though the pathophysiologic mechanism of CSVT is unclear. Iron-deficiency anemia (IDA) (Fig. 110-3) is most commonly reported in pediatric cohorts, though chronic anemias secondary to hemolysis, thalassemia, and sickle cell disease, have also been reported. Screening for anemia in CSVT is recommended though diagnosis may be difficult due to hemoconcentration in dehydrated children and the dilutional effect of parenteral hydration.

## Prothrombotic Disorders

Prothrombotic disorders are reported in 20% to 80% of children with CSVT; their pathogenic role remains uncertain. These figures exceed adult CSVT estimates (15% to 20%). Several case-control studies have reviewed the role of prothrombotic risk factors in CSVT. In a recent pediatric meta-analysis, thrombophilia increased the risk of AIS or CSVT, particularly when more than one abnormality was detected (Kenet et al., 2010). The detection of specific prothrombotic disorders has varied across studies due to lack of systematic and variable testing methods and normative ranges across different laboratories. These include genetic thrombophilias such as mutations in Factor V Leiden and Prothrombin G20210A genes, and deficiencies of protein C, protein S, and antithrombin. Prothrombin gene mutation significantly increases recurrent thromboembolism risk in children older than 2 years, especially in the setting of additional risk factors. Other disorders include anticardiolipin antibodies, elevated lipoprotein (a), hyperhomocysteinemia, and MTHFR homozygosity. Elevated D-dimer may be present in CSVT, but its clinical utility in children has not been determined. Most children with CSVT undergo prothrombotic testing, but the cost-effectiveness and yield of comprehensive testing is unknown.

## Acute Systemic Conditions

Dehydration is the most common acute risk factor for CSVT. History and physical examination should screen for decreased fluid intake, excessive sensible and insensible volume losses, potential fluid shifts and third-spacing in systemic disease, urinary output, and physical signs of dehydration. Isolated emesis without diarrhea should not be presumed to be secondary to gastroenteritis. It may, especially when accompanied by headache, be one of the first clinical indicators of increased ICP. Nausea and emesis from increased ICP can compound preexistent dehydration and place the child at higher risk of thrombus propagation and venous infarction. Head trauma or cranial surgery may also lead to CSVT. Head injury-associated CSVT may result from a mechanical shearing injury of the venous endothelium and extrinsic compression of dural sinuses causing stasis. Head injury, as an associated risk factor in pediatric CSVT cohorts, ranges from 6% to 9% (Xavier et al., 2014). It is also important to consider CSVT in the differential diagnosis of infants with suspected nonaccidental head trauma due to overlapping radiologic features.

## Chronic Systemic Conditions

Several chronic systemic diseases increase CSVT risk. Childhood cancers and their treatments carry potential risks including chemotherapy-related hypercoagulable states (L-asparaginase), antithrombin deficiency, infections secondary to compromised immunity, direct CNS involvement of cancer, cranial surgery, and neck venous catheters. CSVT occurs at a rate of 1 in 50 to 200 cases of acute lymphoblastic leukemia. In inflammatory bowel disease (IBD), systemic inflammation may combine with gastrointestinal disease factors such as dehydration, medications, and IDA. Conditions that lose protein (enteropathies, nephropathies, liver failure) may lead to relative deficiencies in antithrombin-III. Systemic lupus erythematosus is associated with procoagulants like lupus anticoagulant and antiphospholipid antibodies. Cardiac disease increases CSVT risk probably due to decreased venous return (cerebral venous hypertension) or treatments (jugular lines, ECMO, etc.). CSVT is also reported in association with steroid and estrogen-containing contraceptive use in teenagers (Fig. 110-3).

**Figure 110-3. Iron deficiency anemia and birth control pill related CSVT in a teenager.** A 14-year-old girl presented with increasing headache and new-onset focal seizures. She was being treated with iron supplements for iron deficiency anemia secondary to heavy menstrual bleeding. She was also on the birth control pill to regulate her periods. **A**, Axial plain head CT scan showing area of bilateral frontal parenchymal hypodensities. **B**, Sagittal CT venogram. **C**, Axial Diffusion-weighted imaging showing diffusion restriction of the frontal parenchymal lesions that eventually completely reversed on follow-up imaging. She was treated with low-molecular-weight heparin for 6 months with full recanalization of the thrombus. **D**, Sagittal T1-weighted MRI showing an occlusive thrombus in the anterior half of superior sagittal sinus. CT, computed tomography. MRI, magnetic resonance imaging.

## DIAGNOSIS: NEUROIMAGING

Radiologic diagnosis of childhood CSVT poses some challenges. Awareness of pitfalls and limitations of imaging modalities and knowledge of variations in intracranial venous anatomy is needed to prevent misdiagnosis. The goals of imaging include direct visualization of the thrombus and parenchymal brain injury. Noninvasive modalities include cranial ultrasound (cUS) (applicable in newborns), computed tomography (CT), and magnetic resonance imaging (MRI). Each imaging modality has its own advantages and disadvantages. Imaging in pediatric CSVT has been extensively reviewed (Shroff and deVeber, 2003).

### Computed Tomography

Plain CT (noncontrast) with estimated sensitivity of only 40% to 60% is not adequate to exclude CSVT. It can miss early edema or infarction and may underestimate as well as overestimate thrombosis extent. Caution is required to avoid false positive results, particularly in young infants with higher hematocrit, slower venous flow, and unmyelinated brain that may create an illusion of sinus hyperdensity. Subdural hemorrhage layering along the tentorium can mimic TS thrombosis.

Plain CT may be quite sensitive for deep system CSVT where there is STRS hyperdensity along with thalamic hypodensity or hemorrhage into thalamus or ventricles. Contrast-enhanced CT venography (CTV) is highly sensitive and specific for childhood CSVT diagnosis. Thrombus is represented by a filling defect in the vein/sinus in which contrast flows through a narrowed channel or bypass via venous collaterals. The empty triangle or “empty delta” sign is an example, seen with occlusion of the larger dural sinuses like SSS and TS. The “empty delta” refers to the shape of the enhancing dura encompassing the nonenhancing intraluminal clot on axial CT slice. A multislice contrast-enhanced CT with submillimeter slices and multiplanar reformations for axial, coronal, and sagittal views have significantly improved yield of CSVT. As CTV requires additional radiation exposure and most children will require serial scanning, age-adjusted radiation dosages must be considered.

### Magnetic Resonance Imaging

MRI is the diagnostic modality of choice for pediatric CSVT. MRI lacks radiation and provides additional details of both brain parenchyma and the venous system. The need for sedation remains a drawback in young children. Combining MRI

modalities sensitive to vasogenic edema (e.g., fluid-attenuated inversion recovery [FLAIR]), cytotoxic edema and infarction (e.g., diffusion-weighted imaging [DWI]) and blood products (e.g., susceptibility-weighted imaging [SWI]) can both confirm and characterize CSVT-related parenchymal changes. MRI can also image the thrombosis itself, providing more information on both the age and nature of the lesion. Subacute thrombus often appears hyperintense on T1/T2-weighted images. This can be helpful in cortical vein thrombosis in which filling defects are hard to visualize amid numerous artifactual mimics. Approximation of the age of the thrombus can be attempted on MR pulse sequences, but ultimately, this is difficult due to poor correlation between age of thrombus and its signal characteristics. Diffusion-weighted imaging (DWI) can be helpful in investigating the location and extent of associated parenchymal abnormalities, including edema and infarction. However, lesions with diffusion restriction must be interpreted with caution as many resolve on follow-up imaging. Restricted diffusion may also be directly observed within a thrombus and has been reported to predict incomplete recanalization in adults. An SWI is exquisitely sensitive to blood products and is very sensitive to detect hemorrhage and thrombus in smaller venous channels.

MR-venography (MRV) can employ time-of-flight (TOF-MRV), phase-contrast (PC-MRV) or contrast-enhanced methods to image the venous system in a comparable fashion to CTV. The TOF-MRV depends on flow signal characteristics and vessel orientation and is therefore subject to artifacts. As such, apparent “filling defects” on TOF-MRV are not equivalent to those observed with CTV and must be interpreted with caution. Expert interpretation is essential and confirmatory CTV may be required if abnormalities on TOF-MRV are equivocal. Contrast-enhanced MRV appears superior to TOF-MRV in adults but is less studied in children. The effects of flow turbulence are less than what is observed with TOF-MRV and contrast-enhanced MRV is better at delineating smaller veins and collaterals. The PC-MRV can overcome the limitations of TOF-MRV to a large extent, but has not been widely adopted yet in children.

## Catheter Angiography

CA is rarely employed for CSVT diagnosis nowadays due to vastly improved CT and MRI. CA is typically performed only when thrombolytic or endovascular intervention is being considered. It adds dynamic information regarding the presence of collateral veins, delayed venous emptying, reversal of normal venous flow, or anatomic venous abnormalities.

## TREATMENT

The three pillars of management of CSVT in children include: (1) antithrombotic therapy, and nonantithrombotic strategies such as (2) neuroprotection and (3) treatment of associated risk factor.

## ANTITHROMBOTIC THERAPY

### Anticoagulation Therapy

The role of anticoagulation therapy (ACT) in childhood CSVT is supported by adult clinical trials and pediatric cohort studies and ACT experience in systemic thrombosis. The goal of ACT is to maintain sinovenous system patency by preventing thrombus propagation and new thrombosis. The exact frequency with which children are anticoagulated is unknown as practice patterns vary even among pediatric stroke experts. Factors influencing treatment decisions include the child’s age,

thrombus extent/location, CSVT propagation, ICH, reversibility of associated risk factors, and capacity to monitor ACT.

Randomized controlled trials in adults, although relatively small in sample-size, and large cohort studies have demonstrated improved survival and outcome in patients treated with ACT. Metaanalysis of adult data suggests good safety and a trend for efficacy, as well reduction in death and disability. In children, ACT safety is supported by recent cohort studies (Moharir et al., 2010; Grunt et al., 2010) though randomized controlled trials are lacking. In a single-center prospective study of 79 children, among 56 (71%) who received ACT only 3 (5%) had significant, but nonfatal, ICH due to ACT (Moharir et al., 2010). The study was underpowered to determine the effect of hemorrhagic complication on outcome. Two consensus-based pediatric-specific guidelines for AIS and CSVT management have been published by the American Heart Association (AHA) (Roach et al., 2008) and the American College of Chest Physicians (ACCP) (Monagle et al., 2012). These address the safety and efficacy of antithrombotic therapies in children and generally agree on the indications, contraindications, and duration of ACT for CSVT. More recently, specific guidelines for adult and pediatric CSVT have been published (Sapoznik et al., 2011) that relatively contraindicate ACT only in the presence of “major” intracerebral/systemic bleeding. If ACT is not initiated at diagnosis, early repeat venous imaging (5 to 7 days) is indicated to exclude thrombus propagation and/or new venous infarction. It is important to note that one third of children with CSVT who are not treated with ACT will propagate their thrombus in the first week after diagnosis and 40% of these will develop additional parenchymal infarction and worse outcome (Moharir et al., 2010). A recent retrospective review of head injury-associated CSVT in 14 of 20 children anticoagulated in the subacute phase post-injury did not find any fatality or major hemorrhagic complication even with significant ICH (Xavier et al., 2014).

ACT options include intravenous (IV) unfractionated heparin (UFH), subcutaneous low-molecular-weight heparin (LMWH), and oral warfarin. LMWH is considered first-line in many centers. Intravenous UFH may be used initially when there is concern for increased hemorrhage risk, as UFH may be more easily reversed than LMWH. Warfarin is a reasonable alternative although there are challenges to maintain a satisfactory international normalized ratio (INR), particularly in young children. ACT needs close monitoring by periodic assessment of activated partial thromboplastin time (APTT), anti-Xa level, and INR. The duration of ACT typically follows common adult practice and is planned for 3 to 6 months (Moharir et al., 2010). Repeat venous imaging is performed at 3 to 6 months. If complete recanalization has occurred and none of the provoking risk factors remain, ACT can be discontinued. Longer-term ACT is required only if there are persistent risk factors for CSVT is expected or severe inherited/acquired prothrombotic states.

## Endovascular Treatment and Thrombolysis

Neither the AHA nor ACCP guidelines endorse use of recombinant tissue plasminogen activator (tPA) or other thrombolytic therapies for pediatric CSVT given the lack of safety and efficacy data. Thrombolysis is usually reserved for cases in which there is a high risk of mortality (extensive CSVT, multifocal/diffuse infarction) or clinical deterioration despite adequate ACT during acute/subacute stage of CSVT. The decision to initiate this therapy must be carefully weighed using a multidisciplinary consensus approach. There is some adult data suggesting possible efficacy of thrombolytics/endovascular interventions in select circumstances. Publications in children

are even more limited and include small case series only. Success has been reported with local catheter-mediated thrombolysis tissue plasminogen activator (tPA), mechanical thrombectomy, and agents like abciximab.

### Nonantithrombotic Therapies

In addition to ACT, supportive and neuroprotective care is vital in CSVT treatment. Simple measures, such as maintenance of normal blood pressure, blood volume, glucose, and temperature, have been shown in adults to limit the extent of brain injury and are recommended in infants and children with CSVT (AHA Class 1, level of evidence C) (Roach et al., 2008; Saposnik et al., 2011). Head elevation to 30 degrees is also suggested.

### Increased Intracranial Pressure

Screening, recognition, surveillance, and management of raised ICP are of paramount importance. Malignant ICP and resulting ischemic optic neuropathy can occur acutely or over the long term and be secondary to thrombosis, narrowed venous sinuses, or communicating hydrocephalus. Baseline fundoscopy at diagnosis and regular follow-up are required given that many children are not able to reliably report changes in vision. At-risk patients require repeat visual field testing and imaging. Treatment options include the temporary use of carbonic anhydrase inhibitors (acetazolamide, topiramate) or furosemide to lower CSF production, serial lumbar punctures, and, in resistant cases, lumboperitoneal shunting or optic nerve fenestration. Decompressive craniectomy in children with severely raised ICP secondary to ICH and impending herniation has been employed on a case by case basis, but there is no published data to guide the clinician at the bedside.

### Seizures

Given the high incidence of acute symptomatic seizures during presentation, particularly in presence of parenchymal lesions (deVeber and Andrew, 2001), a low threshold for anticonvulsants is necessary. Timely recognition and treatment of seizures with standard anticonvulsants is warranted to prevent added brain injury. Consideration may be given for routine and/or continuous electroencephalogram (EEG) monitoring in selected cases. There is no evidence to support prophylactic use of anticonvulsants.

### Steroids

Adult evidence suggests that steroids are not beneficial and may be harmful and/or a risk factor for CSVT. Therefore, routine pediatric use is not supported. However, this needs to be balanced for children with systemic inflammatory diseases such as irritable bowel syndrome (IBD), nephropathy, or malignancy.

### Risk Factor Management

Judicious treatment of CSVT-associated infection in consultation with an infectious disease expert is essential. Surgical approaches may be necessary for localized infections in selected patients. Dehydration should be corrected and iron replacement considered in patients with IDA. Treatment of other systemic diseases that provoked CSVT is important. Other modifiable risk factors include removing jugular venous lines, altering chemotherapy protocols, or possibly replacing depleted anticoagulation factors.

## OUTCOME

Outcome data are available in pediatric CSVT, although few studies have employed standardized outcome measures. Long-term follow-up is required to account for the full spectrum of morbidity after childhood brain injury. Consistent with this, 25% of children with CSVT followed in the CPISR showed increased severity of their neurologic deficits over time (deVeber and Andrew, 2001). Several large studies have shown that only 10% to 15% of adult CSVT patients have adverse neurologic outcomes. By contrast, the range of adverse outcomes reported in children ranges from 25% to 74%, implying heterogeneity in outcome measures and worse prognosis. Neurologic deficits range from mild to severe sensorimotor impairments, developmental delay, cognitive and behavioral difficulties as well as remote symptomatic seizures and epilepsy. The largest population-based, prospective cohort study of childhood CSVT (mean follow-up: 1.6 years) reported favorable outcomes in 48% only, including 35% with neurologic deficit and 20% with epilepsy (deVeber and Andrew, 2001). Mortality rates (comparatively higher in neonates) range from 4% to 25%, though the primary causes of death are often not described (deVeber and Andrew, 2001).

Adult predictors of poor outcome include presentation with coma, ICH, and DVS involvement. Predictors of poor outcome in children include comorbid neurologic conditions, ICH, and longer follow-up duration (Moharir et al., 2010). Of note, radiologic recanalization *beyond* the acute period after diagnosis does not seem to have any effect on the clinical outcome, but recanalization *rate in* the acute period may influence prognosis and thrombus propagation may potentially affect it adversely (Moharir et al., 2010).

In adults, recanalization rates appear maximal after 4 months of ACT, whereas in children maximal recanalization is achieved by 6 months (Moharir et al., 2010).

Persistent intracranial hypertension, communicating hydrocephalus, and visual sequelae have been reported in one of every three children. Twenty percent develop recurrent cerebral or systemic thrombosis (deVeber and Andrew, 2001). Fifty percent of these recurrences are systemic. These rates are comparable to adults (CSVT—12%; pulmonary embolism—11%). Recurrences are less common in children younger than 2 years of age at diagnosis.

## Vascular Malformations, Intracerebral Hemorrhage, and Subarachnoid Hemorrhage in Infants and Children

Lauren A. Beslow, Lori Jordan, and Edward Smith

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

### INTRODUCTION AND EPIDEMIOLOGY

Intracerebral hemorrhage (ICH) refers to bleeding into the brain parenchyma and/or ventricles, whereas subarachnoid hemorrhage (SAH) refers to bleeding into the subarachnoid space. Approximately half of childhood stroke is ICH and SAH. Incidences of ICH and SAH in pediatric patients obtained from a California-wide discharge database are 0.8/100,000/year and 0.4/100,000/year, respectively (Fullerton et al., 2003). This chapter focuses on nontraumatic or spontaneous ICH and SAH caused by ruptured vascular malformations.

Most childhood spontaneous ICH and SAH are caused by secondary causes such as ruptured vascular malformations, tumors, cerebral infections, or hematological abnormalities (Beslow et al., 2010). Even after a complete workup, 9% to 23% of childhood ICH/SAH remains idiopathic. Depending on the series, vascular malformations are responsible for approximately 17.5% to 73.5% of pediatric ICH; arteriovenous malformations are more common than cavernous malformations (cavernomas or cavernous angiomas) or aneurysms. Presentation and indicated studies will be included under each subtype and discussed in full online.

### INITIAL MANAGEMENT

Stabilization of the patient and minimizing secondary brain injury are the goals of acute management. A neurosurgeon should be consulted promptly upon diagnosis of ICH or SAH. Basic management includes frequent neurologic examinations to assess for deterioration, keeping the head of bed elevated to at least 30 degrees to facilitate venous drainage, isotonic fluids, and maintenance of normoglycemia and normothermia. Children with seizures should be treated with an antiseizure medication.

There are no data from clinical trials regarding medical treatment in children with ICH. It may be a reasonable goal to lower blood pressure to the 95th percentile for age and sex. Elevated blood pressure in the setting of ICH can be an autoregulatory mechanism to maintain cerebral perfusion. Therefore caution must be utilized when lowering blood pressure in a child with ICH so that secondary ischemia is not caused, and ICP monitoring should be considered.

### ACUTE MEDICAL AND SURGICAL MONITORING AND MANAGEMENT

#### Increased Intracranial Pressure: Signs, Symptoms, and Monitoring

Increased ICP can occur as a result of direct mass effect from an ICH or from intraventricular hemorrhage and hydrocephalus that can occur with ICH or SAH. Monitoring for increased

ICP should be considered in any pediatric patient with ICH or SAH with abnormal or deteriorating mental status.

An intraventricular catheter (IVC), also called an extraventricular drain (EVD), is often the monitoring tool of choice because it can measure ICP and manage ICP via drainage of cerebrospinal fluid or intraventricular blood. A subdural bolt can be used to measure ICP if an IVC is not an option.

#### Increased ICP: Medical Management

Medical management for reducing ICP acutely is typically temporizing and includes hyperventilation to PCO<sub>2</sub> of 25 to 30 mm Hg, maintaining the patient's head midline and at least 30 degrees to facilitate venous drainage, and hyperosmolar therapy with either hypertonic saline or mannitol. Sedation is sometimes used. Corticosteroids have not been helpful in adult trials.

#### Increased ICP: Surgical Management

##### Intraparenchymal Hemorrhage Evacuation

Emergent supratentorial hematoma evacuation did not improve outcome in adults with spontaneous ICH in the Surgical Trial in Intracerebral Hemorrhage, but few young adults were enrolled. The 2010 adult ICH guidelines state that patients with cerebellar hemorrhage, with clinical deterioration, with brainstem compression, or with obstructive hydrocephalus from compression of the ventricles should undergo surgical hemorrhage evacuation. Children are less likely to have cerebral atrophy than older adults, and typically have lobar hemorrhages rather than deep hemorrhages. Urgent hematoma evacuation may be required to reduce mass effect and to prevent or relieve herniation syndromes.

##### Hemicraniectomy

Decompressive craniectomy may be both life-saving and function-sparing when there is rapid deterioration in the setting of a large arterial ischemic stroke or ICH in adult trials. In a series of 10 children with malignant MCA infarction, 7 underwent hemicraniectomy and all survived and had moderately good recovery. In a pediatric prospective cohort, 3 of 22 children with ICH had decompressive craniectomy; all were functionally independent (Beslow et al., 2010).

#### Seizures: Monitoring and Treatment

Seizures are a common presenting symptom and sequela of ICH and SAH. In a prospective cohort, over 40% of children with ICH presented with a seizure. For those who have seizures it is reasonable to treat with an antiseizure medication, at least in the acute period. The American Heart Association pediatric stroke guidelines recommend against prophylactic

anticonvulsant use in the setting of ischemic stroke and do not make recommendations in ICH.

Continuous EEG monitoring should be considered in children who have 1) persistently altered mental status, or 2) movements or vital sign changes that are suggestive of seizure that cannot be captured on a routine EEG. Although continuous EEG has been used in children in the setting of SAH to detect vasospasm, there are no studies to demonstrate its utility for this indication in children.

## RECURRENT HEMORRHAGE

In a population-based cohort of 116 children with ICH, 11 (9.5%) had recurrent ICH at a median of 3.1 months from the initial hemorrhage. Nine of 11 recurrences were in children with vascular malformations, 6 of which were not treated. The two children with medical etiologies of ICH recurred within 1 week of the incident hemorrhage.

## OUTCOMES

Estimates of mortality after childhood ICH range from 5% to 54%. Predictors of mortality in one study included Hispanic ethnicity, older age at presentation (11 to 18 years vs. 1 to 10 years), coagulopathy, and coma. Poorer outcomes have been associated with ICH volume, altered mental status within 6 hours of presentation, infratentorial location, Glasgow Coma Score (GCS) less than or equal to 7 at admission, aneurysmal cause of hemorrhage, age younger than 3 years at the time of ICH, and underlying hematological disorders. In one prospective cohort of 72 children and neonates with ICH, 1- and 2-year seizure-free survival rates were 82% and 67%, respectively.

## HIGH FLOW LESIONS

### Arteriovenous Malformations

Cerebral arteriovenous malformations (AVMs) are characterized by abnormal connections of arteries and veins in the brain without intervening capillaries. Epidemiology and pathogenesis are discussed online.

#### Evaluation

Magnetic resonance angiography (MRA) or computed tomography arteriogram (CTA) can diagnose or suggest AVM in many cases. Conventional catheter angiogram (CCA) is more sensitive and should be considered when an underlying vascular malformation is not seen on MRI. Even when MRA or CTA diagnosis of AVM is made, a CCA should still be performed to characterize the lesion better and to assess for associated aneurysms, which may influence treatment. When a CCA is negative acutely after a hemorrhage, a follow-up CCA should be considered because a compressed AVM might become evident when the hematoma has resolved.

Treatment indications: The risk of hemorrhage from a cerebral AVM in children has been estimated at 2% per year (Fullerton et al., 2005), so most should be evaluated for treatment. Some AVMs may not be treatable because of their location or size. In a patient who presents with hemorrhage and is stable, it may be reasonable to wait a month or more for the hematoma to regress before definitive AVM treatment. In a comatose or deteriorating patient with an AVM, acute treatment may be required. The timing of AVM treatment after a hemorrhage is often dependent on the interventionalist and surgeon. The Spetzler–Martin system grades AVMs based on their characteristics in order to predict surgical risk of morbidity. AVMs are graded on size, adjacent eloquent cortex, and

venous drainage. Total score ranges from 1 to 5 points, with higher scores conferring greater risk. One study found that children have better outcomes than adults after microsurgical resection of AVMs, which is not explained by hemorrhage rates or AVM characteristics (Sanchez-Mejia et al., 2006). Therefore, surgical resection should be carefully considered in each pediatric case.

## Treatment

Treatment options include surgical resection, embolization, stereotactic radiosurgery, or a combination (Fig. 111-1). Embolization rarely obliterates AVMs, and is more often used as an adjunct therapy to surgical resection or radiosurgery. Some pediatric data suggest that embolization alone may increase the rate of posttreatment hemorrhage relative to the natural history. Embolization before operative resection reduces flow to the AVM, thereby reducing the bleeding risk during surgery. Moreover, preoperative embolization in high-flow lesions may provide a staged reduction in blood flow over 24 to 48 hours, potentially reducing the risk of intraparenchymal hemorrhage. Embolization may also facilitate subsequent radiosurgery by reducing the nidus volume and immediately addresses the risks related to AVM-associated intranidal and extranidal aneurysms.

Surgical approach (microsurgery vs. radiosurgery) is typically based on both AVM location and anatomy. In children, evidence supports use of surgical resection (with or without embolization) as a first-line therapy in the majority of low- to moderate-risk AVMs contrary to the more controversial data in adult patients from the ARUBA trial.

Outcome/follow up: In a small series, intraoperative CCA was helpful because it detected residual AVM in 4/18 children who underwent intraoperative CCA, which resulted in immediate repeat resections. In this series, recurrent AVMs were found in 4/28 children with a recurrence risk of 0.08 per person-year. Recurrence was associated with diffuse AVMs. A second series demonstrated that intraoperative catheter angiography reduced postoperative residual/recurrent AVM rates from 14% to 0% in a cohort of 117 patients and that 1- and 5-year follow-up data indicated an overall annual hemorrhage rate of 0.3% and a recurrence rate of 0.9%. Therefore, although the duration and interval of long-term follow up for pediatric AVMs is not clear, data suggest that at least 5 years of imaging surveillance may be justified. Compared with adults, outcome after AVM resection seems to be more favorable in children.

## Arteriovenous Fistulas

### Definition

Arteriovenous fistulas (AVF) represent the least structurally complex variation of arteriovenous malformations, consisting of direct arterial-to-venous connections without intervening capillaries, occurring in the cerebral hemispheres, brainstem, and spinal cord. Connections can be single or multiple between an artery and vein. They differ from AVMs by the absence of a discrete nidus between the arterial feeder and draining vein. Two subtypes of AVF exist, defined by their location: pial or dural. Pathogenesis, epidemiology, and associated conditions are discussed online.

### Presentation

AVFs pose a high risk of hemorrhage in addition to brain and spine injury secondary to high flow. Dural AVFs may also present with hemorrhagic venous infarctions secondary to venous outlet restriction. Overall, risk of hemorrhage has been reported at 1.5% annually, with specific risk factors, including fistulas at the vein of Galen, petrosal or straight sinus, venous

**Figure 111-1. Left frontal arteriovenous malformation with hemorrhage.** **A**, Noncontrast axial computerized tomography (CT) scan with left frontal intraparenchymal clot (black arrowhead). **B**, CT angiogram (CTA) in axial plane showing nidus of vessels at posterior aspect of clot, representing arteriovenous malformation (AVM; white arrowhead). **C**, Intraoperative view of cortical surface with AVM present; dark area (black arrowhead) represents visible intraarterial embolic agent (Onyx).

varices (especially with aneurysmal dilatation), and extensive cortical venous drainage. Specific to the pediatric population, AVFs may present with high-output cardiac failure, developmental delay, cognitive impairment, macrocrania, seizures, or with focal neurologic deficits from large venous varices exerting mass effect. Venous congestion may impair CSF absorption, leading to hydrocephalus. On physical examination in the case of carotid-cavernous fistulas (CCF), proptosis, chemosis, and loss of cranial nerve function in II–VI may be present.

### Evaluation

Catheter angiography remains the gold standard for evaluation of AVFs. Seminal to the diagnosis is evidence of arteriovenous shunting directly into a dural sinus from meningeal branches of the external and internal carotid and vertebral arteries or a direct connection into a pial vein.

MRI is useful in the evaluation of AVF, but has limitations. Cross-sectional imaging may be nondiagnostic or may show only sinus thrombosis or dilated vessels. Cortical venous reflux may manifest as engorged cortical vessels without a clear fistulous connection. Cerebral venous hypertension may produce other findings, such as cerebral edema, hydrocephalus, and ischemic atrophy or infarction.

### Treatment

Indications for treatment and recommendations for timing of treatment have evolved with development of novel technologies. Any symptomatic, high-flow lesion should be considered for treatment (Weon et al., 2005).

Dural AVFs involving the cavernous sinus (CCF) and transverse sinuses are distinct groups of AVFs relative to indications for treatment. Slow-flow, smaller lesions with minimal or absent symptoms may be followed with observation, as there is a possibility of spontaneous closure. However, high-flow lesions, or CCFs with symptoms—particularly visual deterioration—are high risk and warrant aggressive treatment.

Successful treatment of pediatric AVFs requires a team approach. AVF treatment involves endovascular or microsurgical techniques to close the fistulous connection (with isolated reports of radiation therapy for some cases). Recent data from pediatric AVF series suggest that dural AVFs have a higher likelihood of successful treatment using solely endovascular techniques (85%), whereas pial AVFs have a greater probability of combined endovascular-open surgical approaches (71%).

## Outcome

Outcomes for children with AVFs are strongly related to age at time of treatment. For those older than 2 years, 72% had a good clinical outcome, whereas children under age 2 had higher complication rates and more frequently needed multiple procedures. Current reports of AVF treatment suggest high rates of lesional obliteration (86%), with age-appropriate outcome scores at an average of 16 months of follow up.

The risk of catastrophic complications from treatment is about 3% for adults, but the risk seems much higher in children, with procedural complication rates of up to 60% and major complications (and death) in the range of 10% to 12%. These risks are related most strongly to age, with children under 1 year having very high complication rates (up to 85%), and children older than 2 years having much lower complication rates (closer to 33%).

After treatment of AVFs, patients should be monitored for development of hydrocephalus, which may be a result of venous thrombosis, altered venous outflow, or deranged CSF dynamics.

## Vein of Galen Malformations

### Definition

Vein of Galen malformations (VOGM) are an AVF type.

**Pathogenesis:** There is abnormal development of cerebral midline venous structures. The choroidal arteries drain into a dilated vein, the median prosencephalic vein of Markowski, the embryonic precursor of the vein of Galen. Normally, this vein is present from 8 to 11 weeks of gestation, and then the anterior two thirds of this vein regress and the posterior one third persists as the normal vein of Galen. This regression does not occur in VOGM. Instead, arteriovenous shunts are present and the anterior segment of the median prosencephalic vein does not regress and instead progressively enlarges. Therefore a VOGM is a cluster of AVFs draining into a persistent and dilated median prosencephalic vein of Markowski. There are two types of VOGM, choroidal and mural. The choroidal type involves multiple feeders, including thalamoperforating, choroidal, and pericallosal arteries that are located in the subarachnoid space in the choroidal fissure. These vessels converge on a fistula site at the anterior aspect of the median prosencephalic vein and have little outflow restriction. This type of direct fistula has multiple shunts and tends to be seen in neonates with severe symptoms. The mural type corresponds to interposition of an arterial network between the arterial feeders and the venous structure. The fistulas may be single or, more often, multiple and converge into a single venous chamber or into multiple venous pouches. Presentation of the mural type is often with macrocephaly and is less severe. Combined or mixed types exist. Epidemiology is discussed online.

### Evaluation

Ultrasonography is helpful for monitoring VOGM flow in an ill neonate. MRI assesses brain parenchyma; cerebral atrophy and ischemia may be present before treatment as a result of steal of cerebral blood flow by the VOGM. An echocardiogram assesses cardiac function.

### Treatment

Urgent treatment in the neonatal period is necessary when a child has heart failure that cannot be managed medically. In neonates, high-output cardiac failure can lead to renal insufficiency, hepatic insufficiency, and rarely myocardial ischemia. In infants and older children, treatment is to prevent cerebral atrophy and cognitive delays.

**Treatment:** Endovascular treatment is the treatment of choice. The endovascular approach is typically staged. In the modern era, transarterial embolization is preferred at most centers, reserving transvenous embolization for instances in which transarterial embolization has been exhausted (Lasjaunias et al., 2006). In the neonate, the goal of treatment is to reduce flow through the VOGM so that heart failure can be medically managed. If the patient is stable, additional treatment is typically completed after 5 months of age. Hydrocephalus can be treated with CSF diversion. However, hydrocephalus can significantly improve with embolization of the VOGM, and therefore embolization should precede hydrocephalus treatment if possible. In rare cases of trans-torcular embolization, a surgical window is created to provide venous access. Primary surgical repair of VOGM is not indicated.

### Outcome

In a series of 27 children treated at a single center, outcome was worse for those with choroidal VOGM than for those with mural VOGM. Features associated with worse outcome were perinatal presentation, presence of CHF, and choroidal angio-architecture. In a series of 233 patients with VOGM treated with embolization, overall mortality was 10.6%. Young age is a risk factor for death. Notably, 74% of surviving children were neurologically normal.

## LOW FLOW LESIONS

### Cavernous Malformations

#### Definition

Cavernous malformations (CMs) consist of dilated sinusoidal vessels lined by endothelium without intervening neural parenchyma (Gross et al., 2011, 2013). They are low-flow lesions that can range in size from submillimeter to several centimeters in diameter. Pathogenesis, epidemiology, and associated genetics are discussed online.

#### Presentation

CMs can occur anywhere in the central nervous system, with symptomatic lesions most commonly presenting with hemorrhage, seizure, or focal neurologic deficits. New seizure rates after the diagnosis of CM range from 1.5% to 4.3% per patient/year, and a history of previous seizure increases this rate to 5.5% per patient/year.

#### Evaluation

Evaluation of CMs usually begins with CT or MRI. CMs are generally poorly visualized with angiography. MRI studies are distinctive—typically, a “popcorn” appearance with an associated “bloom” on susceptibility imaging, suggesting hemosiderin deposition. If multiple CMs are seen on imaging, a familial or postradiation etiology should be considered. Developmental venous anomalies (DVA) are often found in association with CMs, approaching 100% in some series.

In patients presenting with acute hemorrhage, it may be difficult to ascertain the diagnosis. In children presenting with cystic or calcified lesions, the differential diagnosis may include tumors. Susceptibility imaging may aid in identifying evidence of previous hemorrhage or other CMs.

#### Treatment

Even though there are no evidence-based guidelines delineating indications for treatment in children with CMs, data generally support surgical excision of symptomatic lesions (seizure,

focal headache, neurologic deficits), lesions with recurrent hemorrhage, or lesions with high risk of neurologic deficits (such as large lesions or those located in the posterior fossa). There has been debate regarding the utility of extirpation of asymptomatic lesions. The decision to intervene is especially difficult in the patient who presents with symptoms and has multiple lesions. If the symptoms can be localized to a single lesion, which is amenable to surgical resection, then that lesion should generally be removed.

## Treatment

If treatment is planned for a CM, surgical resection is the preferred option. Radiation therapy is controversial and generally reserved for surgically inaccessible lesions with a demonstrated malignant natural history.

## Outcome

Surgical outcomes have been remarkably good, with most series reporting a near 0% mortality rate and a 4% to 5% rate of new permanent deficits. Surgical resection of the most common type of CM in children, supratentorial lobar lesions, provides high rates of symptomatic improvement. With nearly 5 years of follow up, one large series demonstrated a 98% resection rate, no rebleeding in completely resected lesions, and abrogation of seizures in 96% of patients, with a 5% complication rate.

Close follow up is indicated in patients who have undergone surgical resection of a CM. CMs can recur if not excised *in toto*, and generation of new lesions has been documented, particularly in the setting of radiation-induced lesions and in familial cases. The length and frequency of monitoring with imaging remains a topic of debate; many institutions perform annual MRI studies for the first 3 to 5 years after surgery and then at greater intervals thereafter.

## Aneurysms

### Definition

Aneurysms are one of the most common vascular anomalies of the central nervous system, but are far less common in children than in adults. These structurally abnormal areas of arterial wall can cause bleeding, compression of adjacent structures, and concomitant loss of neurologic function. Pathogenesis, epidemiology, and genetic conditions associated are discussed online.

### Presentation

Most aneurysms are asymptomatic and often are never detected. For those that are found because of symptoms, headache is most common (80%), followed by loss of consciousness (25%), seizure (20%), focal neurologic deficits (20%), and visual changes (10%). Children with SAH from aneurysm often present with less severe symptoms compared with adults.

### Evaluation

Up to 80% of all nontraumatic SAH in children results from a structural lesion. A CTA can be a means of identifying the presence of an aneurysm. Patterns of hemorrhage in pediatric aneurysm CT studies include SAH (60%), intraventricular hemorrhage (10% to 15%), IPH (10% to 15%), and subdural (1% to 3%).

MRI is also useful in the diagnosis and delineation of the three-dimensional anatomy of an aneurysm, particularly with MRA. Use of catheter-based digital subtraction angiography

(DSA)—the “gold standard” of imaging in aneurysm—was able to identify lesional pathology in 97% of patients, versus 80% of the time without DSA. Three-dimensional angiography with computer-generated reconstruction is increasingly employed to depict lesional anatomy.

If the aneurysm is fusiform, the segment of vessel involved, delineation of normal borders, and involvement of perforators are important.

## Treatment

If treatment is planned, success is predicated on removing the lesion from circulation while preserving normal blood flow. This can be achieved by open surgery, endovascular techniques, or a combination.

The advent of endovascular therapy has revolutionized the treatment of pediatric aneurysms. There is a great deal of evolution of this field, limiting long-term outcome data. Consequently, it is important, when possible, to have cases reviewed at institutions that offer both endovascular and open techniques in order to provide a balanced approach to formulating care plans (Hetts et al., 2009).

In general, aneurysms that have ruptured or that demonstrate enlargement over time or symptomatic lesions should be considered for treatment. Depending on location and patient status, it may be reasonable to treat aneurysms greater than 3 mm in size, particularly given the long expected lifespan of children. Mycotic aneurysms sometimes will regress with effective antibiotic therapy. In addition, flow-related aneurysms located proximal to a lesion like an AVM may regress after definitive treatment of the primary lesion, demonstrating another scenario when direct aneurysm treatment might not be required.

Although debatable, lesions 2 mm or smaller in size and those located outside the subarachnoid space are sometimes followed.

## Outcome

Overall treatment morbidity and mortality vary widely dependent on age, aneurysm type, and presentation. Recent series describe average mortality rates of 1% to 3% and morbidity rates of 8% to 14% (Hetts et al., 2009; Kakarla et al., 2010). However, it is important to note that treatment of aneurysms often includes management of the posttreatment and post-hemorrhage issues. These can include stroke, hydrocephalus, vasospasm, and electrolyte derangements.

Most patients spend a period of time after treatment in the intensive care unit. For patients with SAH, the first week or so after ictus is the key period for developing hydrocephalus, vasospasm, and cerebral salt wasting. Some patients may benefit from “triple-H” therapy—hypertension, hypervolemia, and hemodilution—in order to reduce the risk of vasospasm (only after aneurysm treatment). The benefit of calcium channel-blocking agents, such as nimodipine, is unclear in children.

There is a wide range of reported outcomes for pediatric aneurysms, with “good” posttreatment outcomes ranging from 13% to 95% and treatment-related mortality ranging from 3% to 100%. Shunting will be required for 14% of patients with hydrocephalus after SAH. Of patients who survive treatment, 91% (with a mean of 25 years of follow up) go on to enjoy independent living, with high rates of university graduation and employment. In one study of 59 patients with aneurysms treated in childhood and an average follow up of 34 years, 41% developed recurrent or de novo aneurysms after treatment. The annual rate of hemorrhage was 0.4%, with 4 deaths. The only identified risk factor for recurrent or de novo aneurysm development was smoking.

In addition to the periprocedural angiogram to confirm obliteration of the aneurysm, MRI and MRA at 6 months may be helpful as a baseline study, to then be compared with subsequent annual MRIs and MRAs. Imaging is performed annually for 5 years if feasible, with some centers suggesting lifetime imaging every 3 to 5 years thereafter. An angiogram is often performed 1 year postoperatively to confirm cure.

# 112 Cerebral Arteriopathies in Children

Catherine Amlie-Lefond and Dennis W. Shaw

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## CEREBRAL ARTERIOPATHIES IN CHILDREN

The importance of cerebral arteriopathy in childhood stroke cannot be overestimated. The reported incidence of cerebral arteriopathy is 18% to 68% in children presenting with acute stroke, reflecting variable vascular imaging practices and challenges in diagnosis. More recently, in the Vascular Effects of Infection in Pediatric Stroke (VIPS) (Wintermark et al., 2014) study, vascular imaging on 355 children with arterial ischemic stroke (AIS) revealed definite arteriopathy in 36% and possible arteriopathy in 9.6% of patients. The incidence of arteriopathy among the 184 previously healthy children enrolled in the VIPS study was 42% with definite arteriopathy, 13% with possible arteriopathy, and 45% with no arteriopathy.

Recognition of cerebral arteriopathy is critical because it is a significant risk factor for primary and recurrent stroke in childhood. In addition, acute cerebral arteriopathy is a risk factor for poor outcome after stroke. Importantly, cerebral arteriopathy has been found in children in whom traditionally stroke has been ascribed to cardioembolic phenomenon, such as those with congenital heart disease. Despite increasing appreciation of the importance of arteriopathy in childhood stroke, diagnosis and management remain challenging.

Cerebral arteriopathy can be classified by etiology: genetic, traumatic, infectious, and inflammatory causes; and by pattern of vessel involvement: focal vs. multifocal, large vs. small vessel, anterior vs. posterior circulation. Sébire and colleagues have grouped arteriopathies into inflammatory vs noninflammatory (Sébire et al., 2004). These types of categorizations are confounded by the multiple and overlapping risk factors and etiologies. Multiple etiologies can result in a common pattern on arterial imaging. For example, the moyamoya pattern can be associated with underlying genetic syndromes, follow trauma such as radiation, or be idiopathic.

Arteriopathies traditionally considered noninflammatory—such as focal or transient cerebral arteriopathy and moyamoya—may have an inflammatory component to them. The picture is further hindered by the fact that the natural history of childhood cerebral arteriopathies is not well known, although arteriopathy often progresses after stroke in childhood. In addition, in children with AIS and cerebral arteriopathy, the risk of recurrent stroke is three times higher in children with progressive arteriopathy than those without progression (Danchaivijitr et al., 2006). Current classifications will need to evolve to incorporate these overlapping etiologic, radiographic, and pathophysiologic features.

## FOCAL CEREBRAL ARTERIOPATHY/TRANSIENT CEREBRAL ARTERIOPATHY

Focal cerebral arteriopathy (FCA), characterized by focal intracranial arterial stenosis, accounts for approximately one fourth of arteriopathies in childhood AIS. A viral or inflammatory trigger has been proposed. FCA typically involves large and medium-sized arteries and is usually well visualized on MRA. Infarction of the basal ganglia is frequently seen, whereas

associated cortical infarction is less common. FCA has been well associated with varicella zoster virus infection. Focal cerebral artery stenosis occurring within a year of primary varicella infection has also been called post-varicella arteriopathy.

A subset of FCA is classified as transient cerebral arteriopathy (TCA), defined as lack of progression or improvement of FCA at 6 months. In TCA, arterial narrowing will most commonly be seen unilaterally in the proximal middle cerebral artery (MCA). Similar to other FCA, TCA is believed to be likely a large and medium vessel acute vasculitis that occurs as a sequela of infection, most likely viral, and/or inflammatory (Figs 112-1, A and 112-1, B). If arteriopathy is stable at 6 months, it is most likely to represent TCA, but follow-up vascular imaging is a consideration because later progression can occur.

## MOYAMOYA ARTERIOPATHY

In the setting of progressive FCA, there is often development of basal collateral vascularization representing moyamoya arteriopathy. Moyamoya is a progressive steno-occlusive disease typically involving the distal internal carotid artery (ICA), proximal MCA bilaterally, and not infrequently the anterior cerebral arteries (ACA). This arterial steno-occlusive disease is associated with development of extensive collaterals at the base of the brain, most commonly enlargement of lenticulostriate vessels producing the “moyamoya” (Japanese for “puff of smoke”) configuration seen on catheter cerebral angiogram (Fig. 112-2, A-C). Basal collaterals are absent in both FCA and stage 6 moyamoya, but moyamoya will demonstrate external carotid collaterals.

Although the diagnostic criteria for moyamoya do not address the posterior circulation, steno-occlusive disease of the posterior cerebral arteries is present in approximately one fourth of cases. In addition, moyamoya can also occur unilaterally, or markedly asymmetrically, particularly moyamoya syndrome (discussed later). Involvement or progression of arteriopathy in the less affected hemisphere can occur over time in some cases.

Moyamoya has a bimodal incidence with a peak at 5 years and a smaller peak in the fourth decade. Moyamoya usually presents with bland ischemic stroke in childhood, whereas adults frequently present with hemorrhagic stroke. Moyamoya is often not diagnosed until stroke occurs. Acute stroke heralds the diagnosis of moyamoya in approximately half of all children with the disease, despite a history of transient ischemic attacks (TIAs) in many patients. The clinical picture can be unappreciated because TIAs are difficult to detect, particularly in very young children, who are most at risk of an aggressive course and poor outcome.

Children with moyamoya may present with headache and TIAs. TIAs frequently precede a sentinel stroke, which is confirmed by imaging. Signs of anterior circulation ischemia are often seen, including aphasia, dysarthria, hemiparesis, and seizures, but less common presentations, such as syncope, visual changes, and chorea can occur. Symptoms are often

**Figure 112-2. Moyamoya arteriopathy.** A 10 year old boy with moyamoya and developmental delay presenting with TIAs then developing acute right hemiparesis and aphasia. Axial FLAIR image (**A**) demonstrates prior large left MCA stroke (straight arrows) and flow voids resulting from enlarged lenticulostriate collaterals (curved arrows). Vertebral injection on a catheter angiogram in early (**B**) and mid (**C**) arterial phases demonstrate extensive central collaterals (curved arrows), corresponding to flow voids on MR FLAIR, which provide delayed supply to the right MCA distribution.

provoked by hyperventilation, for example with crying or exercise, as a result of hypocarbia-induced vasoconstriction.

Moyamoya may be idiopathic (“moyamoya disease”) or occur in association with syndromes (“moyamoya syndrome”), such as sickle cell disease and trisomy 21 or as the sequela of injury. The term “moyamoya disease,” however, is often used more loosely to include both moyamoya disease and syndrome (Scott & Smith, 2009). Moyamoya is associated with many underlying genetic disorders, including sickle cell disease, trisomy 21, Noonan syndrome and neurofibromatosis type 1 (Table 112-1. See conditions associated with moyamoya online.)

Moyamoya disease is likely a genetic disease, most probably polygenic, based on the high prevalence of moyamoya in Asia and familial aggregation in 5% to 10% of cases. Approximately 15% of patients with nonsyndromic moyamoya (moyamoya disease) have a family history of moyamoya. The mode

**TABLE 112-1** Conditions Associated With Moyamoya Arteriopathy

Genetic Syndromes	Trisomy 21 Noonan syndrome Alagille syndrome Williams syndrome
Neurocutaneous	Neurofibromatosis Type 1 Hypomelanosis of Ito
Hemoglobinopathy	Sickle cell disease
Metabolic	Glycogen storage disease type 1a
Trauma	Radiation injury
Infection	Tuberculous meningitis Human immunodeficiency syndrome
Autoimmune	Hyperthyroidism Antiphospholipid syndrome
Cardiovascular Disease	Coarctation of the aorta Pulmonary stenosis

of inheritance appears to be autosomal dominant with incomplete penetrance. Familial moyamoya in the Asian population has been linked to a susceptibility region on 17.q25.3, a ring finger domain containing protein 213 or RNF213.

Given the high risk of stroke in moyamoya, revascularization surgery is recommended for symptomatic patients to decrease the risk of further TIAs and ischemic and hemorrhagic stroke, as well as for asymptomatic patients who are at risk of progression. Revascularization can be performed by direct or indirect measures. Direct revascularization most commonly employs anastomosing the superficial temporal artery to the middle cerebral artery. Indirect revascularization usually involves pial synangiosis where the superficial temporal artery is placed on the surface of the brain. Direct revascularization has the advantage of immediate improvement in flow but is technically demanding, requiring a minimal artery size and therefore is not an option in very young children. Indirect revascularization has the advantage of not being limited to a particular arterial territory but requires months to show benefit as collaterals take time to develop. In children, direct and indirect revascularization appears equally efficacious with most centers preferring indirect revascularization due to lower surgical morbidity.

A 2005 review of the revascularization of pediatric moyamoya reported in the literature found that symptomatic benefit was independent of whether indirect or direct/combined approach was used. Revascularization not only reduces the incidence of ischemic stroke in childhood, but appears to decrease the risk of hemorrhagic stroke in adulthood as well. Revascularization should be pursued promptly in eligible children, particularly very young children, in whom the disease can be more aggressive with poor outcome.

## ARTERIOPATHY OF SICKLE CELL DISEASE

Patients with sickle cell disease (SCD) are at an increased risk of stroke, including silent stroke. The Cooperative Study of Sickle Cell Disease (CSSCD) found that the incidence of ischemic stroke peaks in children between 2 and 10 years and again in adults older than 30 years. Without treatment, 11% will have stroke by 20 years of age and 37% will have silent strokes by age 14 years. The risk of recurrent stroke is decreased by regular red blood cell transfusions, or if this is not possible, hydroxyurea therapy. The risk of a recurrent stroke is approximately 20% even with the use of chronic red blood cell transfusion.

Approximately 25% of patients with SCD have cerebral arteriopathy, which is a risk factor for primary stroke, silent stroke, and recurrent stroke. In addition, SCD-associated arteriopathy often progresses despite red blood cell transfusions. Large vessel moyamoya-pattern arteriopathy vasculopathy is well described in SCD.

Elevated transcranial Doppler (TCD) velocity in the middle cerebral artery is strongly associated with stroke risk in SCD, and the incidence of first overt stroke is markedly decreased by regular red blood cell transfusions in children with increased velocities (Lee et al. 2006). Routine TCD monitoring is recommended for children age 2 to 16 years with SCD, although abnormal TCDs can be seen in children younger than 2 years. Reversion of elevated to normal TCD velocities with regular transfusions is well documented, as is subsequent reversion of normalized TCD velocities to elevated TCD velocities with cessation of transfusion.

Although chronic transfusions prevent development of stenosing arteriopathy in vessels with increased velocities, once arteriopathy is present, it can progress with resultant stroke despite use of regular transfusions. Similar to other types of moyamoya syndrome as well as moyamoya disease, once

arterial steno-occlusive disease is present, the only effective treatment for this moyamoya cerebral arteriopathy is indirect and/or direct surgical revascularization, which has been performed in patients with SCD and appears to be a safe and effective treatment.

## CERVICOCEPHALIC ARTERIAL DISSECTION

Cervicocephalic arterial dissection (CCAD) has been reported to account for 7.5% to 20% of childhood AIS. CCAD involves the anterior cerebral circulation more often than the posterior circulation, and is more common in boys than girls in both the anterior and posterior circulation. CCAD can be posttraumatic or spontaneous. Spontaneous dissection may be more common in children than adults, although the history of trauma may be difficult to obtain in children. In addition, trauma may only be a trigger in a susceptible individual. For example, dissection is more likely to occur in the setting of infection or connective tissue disorder (Table 112-2. Risk factors for cervical artery dissection in childhood are available online only). Headache and neck pain are often present at diagnosis but this is not universal. Vertebral dissection may present with ataxia and vomiting. Diagnosis of dissection is important because these children are at significant risk for recurrent stroke, subarachnoid hemorrhage due to aneurysmal dilation, and recurrent dissection.

Dissection of the cervical carotid arteries most often occurs 2 to 3 cm above the carotid bulb. Dissections of the vertebral arteries most frequently involve the V2/V3 portion of the vertebral artery as it passes around the C1-C2 lateral masses and through the transverse foramina. In the anterior circulation, intracranial dissection is more common than extracranial dissection, whereas extracranial dissection is more common in the posterior circulation. Subarachnoid hemorrhage can occur due to vessel leakage or rupture of pseudoaneurysm formation. The risk of arterial rupture is higher following dissection of intracranial than extracranial arteries.

The diagnosis of arterial dissection is now most often made on magnetic resonance imaging/magnetic resonance angiography (MRI/MRA) (Fig. 112-3). Imaging should include the head and neck extending to the aortic arch and incorporate the use of T1W fat saturation or PD sequences to allow for visualization of intramural hematomas (methemoglobin) in a false lumen, which is usually seen in cervical arterial dissections. Narrowing of the true lumen, analogous to that demonstrated on catheter angiogram (CA), is usually seen on MRA, although subtle dissections, such as the C1-C2 level of the vertebral arteries, may be missed particularly in areas of turbulent flow.

Intimal flaps and dissecting aneurysm are diagnostic for dissection, as mentioned earlier, however, subtle lesions can be missed on MRI/MRA, or mistaken for other arteriopathies such as TCA. If the MRA/MRI is negative and there is still

**TABLE 112-2** Risk Factors for Cervical Artery Dissection in Childhood

Trauma	
Infection	
Connective Tissue Disease	Ehlers–Danlos syndrome Marfan syndrome Loeys–Dietz syndrome Arterial tortuosity syndrome
Cervical abnormalities	Abnormalities of odontoid process Klippel–Fiel syndrome

significant clinical concern, cerebral catheter angiogram (CA) generally remains the most sensitive test for detecting subtle lesions. The findings on CA indicating CCAD are intimal flap and arterial stenosis and in more severe cases tapered occlusion and aneurysm formation. With advances in MR vessel wall imaging this approach may change because CA will not directly demonstrate arterial wall hematoma or inflammation.

Although computed tomography (CT) angiogram is often pursued in adults before pursuing a cerebral CA, not infrequently the cerebral CA is still required to confirm the diagnosis of a subtle dissection. In children, if there is still high suspicion for dissection after MRI, even with a normal or equivocal MRA, moving directly to cerebral CA is usually recommended as CTA requires significant radiation and may not be diagnostic. In a child with acute trauma or who is medically unstable, CTA may be the preferred study. Follow-up vascular imaging is indicated to assess for complications such as extension of dissection or formation of aneurysm. This can usually be accomplished with MRI/MRA.

The possibility of connective tissue disease, such as Ehlers-Danlos syndrome, Marfan syndrome, Loeys-Dietz syndrome, or arterial tortuosity syndrome, needs to be considered in patients presenting with dissection (Vanakker, Hemelsoet & De Paepe, 2011). In children with dissection who have hyperflexibility or other stigmata of possible connective tissue disease, evaluation including echocardiogram and genetics evaluation is indicated.

Vertebral artery dissection occurs more often in boys than girls and is often associated with head or neck trauma. Vertebral dissection most commonly involves the V2/V3 segment. Presenting symptoms often include abnormal eye movements, ataxia, nausea and emesis, and headache, although, in contrast to adults, neck pain uncommon. Vertebral artery dissection has been reported with cervical bony abnormalities in children, most commonly abnormalities of the odontoid process.

In adults, dissection is treated with antiplatelet therapy or anticoagulant therapy. Anticoagulant therapy is recommended for stroke due to dissection in childhood, with treatment duration based on follow-up imaging. Late complications after vertebral artery dissection, including pseudoaneurysm formation and recurrent stroke, have been reported. Recurrent dissection occurs in approximately 10% of patients. After cervical artery dissection, avoidance of potential triggering events such as contact sports, roller coasters, and chiropractic manipulation is recommended.

## CENTRAL NERVOUS SYSTEM VASCULITIS

Central nervous system (CNS) vasculitis is an inflammatory arteriopathy that can be primary or idiopathic or secondary to a systemic cause, most commonly systemic rheumatologic disease or infection. CNS vasculitis can have protean manifestations that make diagnosis challenging, but early diagnosis and treatment are critical to prevent progressive encephalopathy.

### Primary Central Nervous System Vasculitis

In childhood primary angiitis of the central nervous system (cPACNS), inflammation is limited to the arteries of the central nervous system (Moharir, Shroff & Benseler, 2013). cPACNS can be divided into large-medium vessel disease, in which arteriopathy can be detected on cerebral catheter angiogram, and small vessel cPACNS, in which it is not visible on a catheter angiogram. In large-medium vessel cPACNS, catheter angiogram shows irregularities, often described as beading,

most often involving the middle cerebral artery, anterior cerebral artery, and distal internal carotid arteries. In large-medium vessel cPACNS, brain parenchymal lesions involving these vascular territories may be detected on head MRI. Vessel wall thickening and inflammation may also be seen on MRI and MRA, particularly with use of vessel wall imaging.

Large-medium vessel cPACNS typically present hemiparesis, hemisensory dysfunction, or aphasia. Stuttering onset of ischemic symptoms, including TIAs, is common and may herald stroke. Inflammatory markers are frequently uninformative in large-medium angiitis. Only one third of children with large-medium vessel cPACNS will have CSF pleocytosis or elevated CSF protein. Treatment of progressive large-medium vessel cPACNS requires immunosuppression, including consideration of plasmapheresis in refractory cases. Anticoagulation or antiplatelet treatment may decrease the risk of artery to artery embolus in both progressive and nonprogressive large-medium cPACNS.

Small vessel cPACNS is particularly challenging to diagnose because the cerebral catheter angiogram is by definition unrevealing. The brain on MRI is usually abnormal, but findings are nonspecific. White- and gray-matter lesions can be seen, more often in the anterior than posterior circulation, with frequent involvement of the basal ganglia. Acute and subacute lesions may show DWI and ADC abnormalities consistent with ischemic stroke.

Patients often present with diffuse neurologic deficits and headache. Many patients have elevated inflammatory markers, including CRP, ESR, and CBC findings of leukocytosis, anemia, and thrombocytosis, but all can be normal in other patients. Analysis of the CSF may show mild predominantly lymphocytic pleocytosis and mildly elevated protein. In patients with suggestive neuroimaging and clinical findings, brain biopsy is critical to diagnose small vessel CNS vasculitis but may miss the diagnosis in a significant number of patients. High index of suspicion and prompt diagnosis is critical because treatment with immunosuppressants may prevent devastating injury.

## Secondary Vasculitis

Secondary CNS vasculitis can be associated with multiple etiologies, including underlying systemic inflammatory or infectious disease, and malignancy. The arteriopathy associated with secondary CNS vasculitis often involves multiple sized vessels. MRA and CTA arterial imaging does not have the resolution to show abnormalities in small vessel vasculitis, but in medium and large artery vasculitis, irregular lumen and vascular stenosis may be seen on MRA and CTA. Cerebral catheter angiogram has greater sensitivity for luminal abnormalities but does not directly visualize vessel walls. In some cases, gadolinium enhancement of thickened arterial walls may be seen on MRA. Inflammatory markers such as erythrocyte sedimentation rate and C-reactive protein may be elevated, but are unreliable.

Takayasu arteritis (TA) is a chronic, granulomatous arteritis involving the aorta and its branches. Twenty percent of cases of TA present in childhood. Stroke frequently occurs due to vessel wall inflammation, thickening, and segmental stenosis, with thrombus formation, as well as aneurysm (Fig. 112-4). Corticosteroids and other immunosuppressants markedly improved outcome, but recurrent stroke and death from complications are not uncommon despite treatment. Polyarteritis nodosa (PAN) can be associated with arteritis, typically involving large-medium arteries but small arteries can be involved as well.

Systemic lupus erythematosus (SLE) can be associated with cerebrovascular disease, including ischemic infarct, TIA, and

hemorrhage. Diagnosis is challenging because neuroimaging, including brain MRI, lacks sensitivity and specificity. Mechanisms of NPSLE arteriopathy include frank vasculitis, but non-inflammatory microangiopathy with vascular hyalinization, endothelial proliferation and fibrinoid necrosis is the most common pathology.

Multiple infections have been reported in association with secondary CNS vasculitis, including Epstein–Barr virus, human immunodeficiency virus, parvovirus, *Mycoplasma pneumoniae*, *Mycobacterium tuberculosis*, and acute bacterial meningitis. Heparin and aspirin have been used to prevent recurrent stroke in childhood bacterial meningitis.

Primary infection and reactivation of varicella zoster virus are both well reported associations with stroke in children and adults. Direct viral replication within the arterial wall by VZV is likely responsible for VZV vasculopathy. Confirmation of diagnosis of VZV vasculopathy requires virological confirmation either by the detection of VZV DNA by PCR in CSF or by the detection of anti-VZV IgG antibody in CSF, or both. Nagel and colleagues have shown that the diagnostic value of detecting anti-VZV antibodies in CSF is greater than that of detecting VZV (Nagel et al., 2008). Early diagnosis of VZV vasculopathy is critical because untreated it results in significant morbidity and death, and antiviral treatment can halt progression of disease or be curative. Treatment with both acyclovir and corticosteroids is recommended.

The VZV vaccine, recommended by the American Academy of Pediatrics in 1995, is not associated with childhood ischemic stroke, thus it is expected that it will result in a decrease in VZV-associated stroke in childhood as well as in adults.

The optimal use of antiplatelet and anticoagulant medication in CNS vasculitis is unknown, although most patients with secondary noninfectious CNS vasculitis are started on antithrombotic medication. Large vessel involvement or visible thrombus may be indications for anticoagulation. Although antithrombotic treatment has been used in small vessel arteriopathy, concerns about the risk of hemorrhage often outweigh concerns about thrombosis, particularly as it is not clear how effective antithrombotic medication is in preventing injury due to small vessel CNS vasculitis.

## Fibromuscular Dysplasia

Fibromuscular dysplasia (FMD) is a noninflammatory arteriopathy of unknown etiology primarily affecting women age 20 to 60, but which can occur in children, with associated ischemic and hemorrhagic stroke in childhood. Typically, irregular narrowing (“string of beads”) on angiography of the internal carotid and renal arteries is seen. The string-of-beads sign can be seen in other childhood arteriopathies, and most patients with pathologically proven FMD have less specific angiographic abnormalities including focal and segmental stenosis and occlusion, with a string-of-beads sign in only one fourth of patients. Diagnosis of FMD is important because these patients are at increased risk of stroke, TIA, dissection, and aneurysms. In addition, patients require screening for systemic arteriopathy, particularly patients with hypertension who may have renal arteriopathy.

## DIAGNOSIS OF CEREBRAL ARTERIOPATHY

Prompt diagnosis is essential in the child presenting with possible cerebral arteriopathy, so that strategies to limit injury and prevent overt stroke or recurrent stroke can be instituted. Children with cerebral arteriopathy may present with TIAs or stuttering onset of stroke symptoms. Therefore cerebral arterial imaging is indicated in children presenting with an unex-

plained history of localized neurologic dysfunction, particularly with recurrent episodes.

Head CT is often the initial imaging study because it is widely available and can be done quickly and usually without sedation. This will identify acute hemorrhage but has limited sensitivity for the detection of acute ischemia. Confirmation of AIS usually requires MRI, as will evaluation of stroke mimics; therefore MR imaging should be pursued first, unless it is contraindicated. The MRI should include DWI early in the order of sequences; this will answer the question of whether an acute stroke is present because normal DWI excludes acute infarct with rare exception. This in turn will direct the choice of subsequent imaging sequences, although TIA may not have associated DWI changes. In suspected cerebral arteriopathy, whether or not acute stroke is present, arterial imaging with TOF MRA is warranted and may alter immediate management. A dedicated MRA (with arterial vessel wall imaging if available) may not always be feasible in the acute setting, but should be pursued as soon as possible.

MRA can be insensitive to subtle vessel irregularity especially in cases of dissection in areas of poor resolution, particularly given the propensity for dissection in areas with complex flow. If the brain MRI shows multiple infarcts attributable to a single vessel, imaging of the neck for evidence of dissection should be pursued. In cases with high imaging suspicion for dissection despite normal MRA findings, catheter angiogram is indicated.

Once the presence of cerebral arteriopathy has been confirmed, etiologic investigation is crucial. The medical history may suggest etiologies for specific syndromes, particularly in the case of moyamoya arteriopathy or secondary vasculitis. Physical examination may show features of connective tissue disease or collagen vascular disease. Systemic inflammatory markers may be informative in inflammatory or infectious arteriopathies. CSF evaluation for inflammatory markers or infection should be considered in children with arteriopathy of unknown etiology.

## FOLLOW UP

Children with cerebral arteriopathy require close monitoring for progression of their arteriopathy and management of underlying associated conditions. In some cases, cerebral arteriopathy may herald systemic conditions. In addition, children with cerebral arteriopathy are at increased risk of renovascular disease with elevated blood pressures. Although blood pressure monitoring can be challenging in the very young or developmentally delayed child, it is an important aspect of the care of these children.

## CONCLUSION

Cerebral arteriopathy is the most commonly identified etiology of stroke in childhood and is associated with poor outcome including recurrent stroke. Despite its importance, the underlying mechanism in many cases is elusive. It is likely that inflammation plays a significant role, even in arteriopathies not typically classified as “inflammatory.” In this regard, the field of pediatric stroke is moving toward a model that incorporates radiographic, etiologic, and pathophysiologic features of underlying cerebral arteriopathies.

# 113 Coagulation Disorders and Cerebrovascular Disease in Children

Timothy J. Bernard, Sharon Poisson, Brian R. Branchford, and Ulrike Nowak-Göttl

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Cerebrovascular disease in pediatrics is typically divided into three separate categories (Fig. 113-1): arterial ischemic stroke (AIS; Fig. 113-2), cerebrosinovenous thrombosis (CSVT; Fig. 113-3), and hemorrhagic stroke (Fig. 113-4). Within these separate classifications, disease in neonates (age from birth to 28 days) is usually considered separately from the childhood form (age 29 days to 18 years). This distinction originates from the different risk factors seen in childhood and neonatal disease, including coagulation disorders. As previously described (Chapter 20), neonatal stroke is further subdivided into perinatal AIS (PAIS) and presumed perinatal stroke (PPS), depending on whether the presentation is acute seizures and encephalopathy in the first few days of life, as seen in PAIS, or a chronic evolving hemiparesis at 4 to 8 months of life as seen in PPS (see Fig. 113-1). Coagulation disorders play a unique role in the etiology of each subset of pediatric cerebrovascular disease—AIS, CSVT, and hemorrhagic stroke—requiring tailored evaluation and management of each disease.

The purpose of this chapter is to review disorders of both excessive thrombosis and deficient hemostasis in the context of pediatric cerebrovascular disease. In addition to describing the specific evidence supporting the role of each coagulation abnormality within pediatric cerebrovascular disease, the authors describe the application of these data in clinical practice. The identification of coagulation disorders in pediatric cerebrovascular disease is essential to proper management of the disease, and may have implications for secondary prevention of cerebrovascular disease in these children and their similarly affected family members.

Thrombophilia, or a hypercoagulable state, is a general description of several inherited (lipoprotein (a), or deficiencies of natural anticoagulants [protein C, protein S, antithrombin], prothrombin gene mutation, or factor V Leiden) or acquired (elevated factor VIII, or antiphospholipid antibodies [APAs; lupus anticoagulant [LA], anticardiolipin [aCL] antibodies, or anti- $\beta_2$  glycoprotein Ib antibodies]) prothrombotic abnormalities (Table 113-1).

## COAGULATION DISORDERS IN PEDIATRIC ARTERIAL ISCHEMIC STROKE

### Acquired Thrombophilia (Bernard et al., 2011)

#### Presentation

Acquired thrombophilia in pediatric AIS is mostly studied in childhood AIS, although acquired thrombophilia may also play a role in PAIS and PPS. APAs are the most common acquired thrombophilia investigated in clinical practice in childhood AIS. Of particular concern are those patients who develop APA syndrome, defined outside of pregnancy as

vascular thrombus and positive APA (LA, aCL, or anti- $\beta_2$  glycoprotein-I [anti- $\beta_2$  GP]) present on two or more occasions, at least 12 weeks apart (Miyakis et al., 2006). Children with AIS and APA syndrome may present with stroke as the solitary clinical feature, although a history of previous venous thrombosis, thrombocytopenia, or livedo reticularis is highly suggestive. More rare presentations in children include ischemic bone fractures, or renal and celiac artery stenosis.

In childhood AIS, the role of APAs is also uncertain. Acutely, conventional APAs (LA, anti- $\beta_2$  GP, aCL) are elevated in 7% to 14% of cases, and increase to 25% of cases when including novel APAs (anti-protein S, anti-protein C, anti-prothrombin) (Poisson S, unpublished data). The incidence of APA syndrome in childhood stroke remains uncertain. A meta-analysis performed by Kenet and colleagues determined that there is a significant association between positive APAs and childhood stroke and neonatal stroke (Table 113-2; OR 6.95; CI 3.67–13.14) (Kenet et al., 2010), but influence upon recurrent risk remains uncertain. Finally, although APA syndrome may occur in neonatal stroke, preliminary evidence about the risk of recurrent events in these children suggests that the risk may be low, although further data are clearly needed. As a result of these preliminary studies in adults, the American Heart Association (AHA) recommends evaluating adults with idiopathic stroke for APA syndrome.

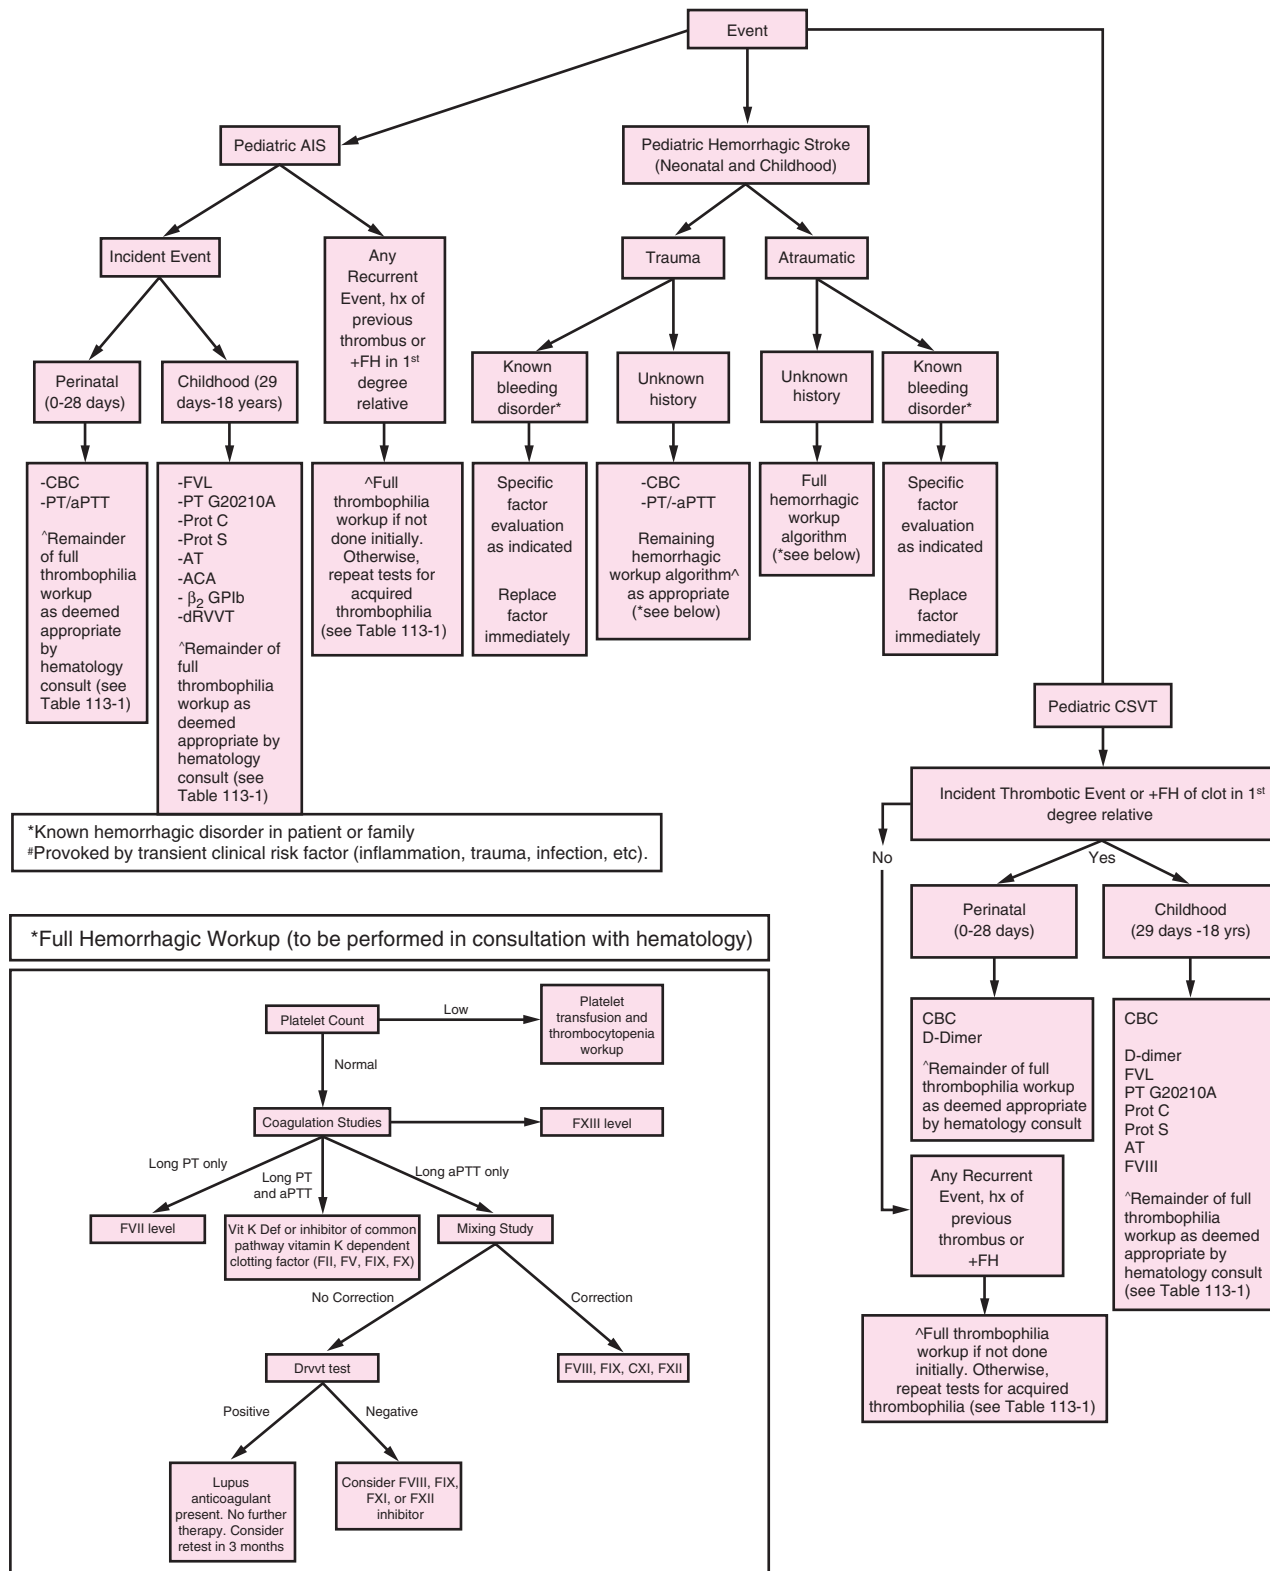

In addition to traditionally acquired thrombophilia, such as APA syndrome, other transient abnormalities of coagulation and the hematologic system have recently been investigated in childhood AIS. Iron deficiency anemia may be an independent risk factor for childhood AIS, occurring in over 50% of children (compared with 9% of controls). Transient elevations of factor VIII, D-dimer, von Willebrand factor (vWF), and PAI-1 have been observed in children with AIS, but the significance of these elevated prothrombotic factors remains uncertain. Future prospective studies in childhood and neonatal AIS are needed to evaluate the significance of these coagulation abnormalities.

#### Evaluation

In childhood AIS, the minimal evaluation for acquired thrombophilia should include conventional APA testing for anti- $\beta_2$  GP IgG/IgM, aCL antibodies IgG/IgM, and dilute Russell's viper venom time (dRVVT) (see Fig. 113-1). If these tests are positive in the acute setting, repeat testing should occur just beyond 12 weeks postischemia. Testing of neonates with isolated AIS and/or PPAIS remains controversial, as the treatment of APA syndrome in this setting is unclear. In the context of a positive family history of thrombosis or multiple thrombosis, APA testing for neonates is clearly indicated, but the extent of testing in isolated neonatal AIS remains uncertain.

In childhood and neonatal AIS, testing should also include evaluation of complete blood count (CBC) to assess for hallmarks of iron deficiency anemia (low mean cell volume and

high red cell distribution width), while testing of factor VIII, D-dimer, vWF, and PAI-1 is likely practitioner dependent.

## Treatment

Treatment of APA syndrome in neonatal and childhood AIS remains indeterminate, secondary to the lack of pertinent randomized trials. The AHA recommends treatment of adults who suffer AIS associated with transient APAs and AIS with antiplatelet therapy. Similarly, it recommends treatment of APA syndrome and stroke with antiplatelet therapy, while acknowledging the lack of consensus surrounding this recommendation. Indeed, the 13th International Congress on Antiphospholipid antibodies recommends treatment of APA syndrome in adult AIS with anticoagulation alone, or combined with aspirin in more severe cases. It is the clinical practice of these authors to treat APA syndrome in childhood AIS with anticoagulation (usually warfarin or LMWH) while

the antibodies persist, but this approach remains largely unstudied. In neonates, treatment decisions may be influenced by degree of APA positivity, family history of clotting, and additional thrombosis. Given the lack of data about acquired thrombophilia in pediatric AIS, optimal treatment will likely include a multidisciplinary team of practitioners experienced in the treatment of stroke in children.

## Genetic Thrombophilia (Bernard et al., 2011)

### Presentation

Genetic thrombophilias vary greatly in their severity, with some abnormalities such as heterozygous prothrombin gene mutations or factor V Leiden only mildly increasing thrombotic risk, whereas others such as severe protein C or S deficiency significantly increasing the lifelong risk of clotting (see Fig. 113-1). Therefore genetic counseling surrounding these traits is best performed by a hematologist and/or genetic counselor who is familiar with these traits. In pediatric stroke, the prevalence of each of these genetic abnormalities is almost uniformly increased compared with matched controls (see Table 113-2), suggesting that thrombophilia, even when mild, may play an important role in pediatric AIS of all subtypes. Indeed, inherited thrombophilias have been associated with risk of stroke in multiple subtypes.

Some inherited thrombophilias, such as severe protein S or protein C deficiency, may be the underlying cause for childhood or neonatal AIS. Protein C deficiency is a well-established risk factor for childhood and neonatal AIS (see Table 113-2) and, when present, is likely to increase recurrence risk. Similarly, protein S is a risk factor for incident AIS that is often inherited. The risk of stroke recurrence with protein S deficiency has not been studied in a large cohort of childhood stroke. Some milder thrombotic traits, such as prothrombin G20210A, factor V Leiden mutations, antithrombin deficiency, and MTHFR C677T mutation have all been associated with incident childhood AIS (see Table 113-2) but their association with recurrence risk remains uncertain. The association between lipoprotein (a), another heritable mild thrombotic trait, and recurrent childhood AIS is of particular interest. Two separate studies have demonstrated an elevated risk of recurrent AIS in children with elevated lipoprotein (a) (RR = 4.4, 95% CI = 1.9–10.5).

### Evaluation

Although the majority of genetic thrombophilia traits are established as independent risk factors for pediatric AIS, data supporting significant prognostic impact on recurrence risk exist only for a few individual traits such as elevated lipoprotein (a), protein C deficiency, and the presence of multiple risk factors. AHA pediatric stroke guidelines recommend that, “although the risk of stroke from most prothrombotic states is relatively low, the risk tends to increase when prothrombotic disorder occurs in children with other risk factors. Thus, it is reasonable to evaluate for the more common prothrombotic states even when another stroke risk factor has been identified” (Roach et al., 2008). Without an adequately powered study to detect the impact of genetic thrombophilia on recurrence risk in pediatric AIS, definite recommendations about evaluation remain challenging (Manco-Johnson et al., 2002).

### Treatment

In childhood AIS, patients should be treated with antithrombotic therapy from the onset of stroke, regardless of thrombophilia traits, unless a contraindication exists. The AHA and CHEST guidelines suggest acute treatment with aspirin (2 to

5 mg/kg) in most cases, reserving anticoagulation (typically LMWH or coumadin) in cases of dissection or cardioembolism (Monagle et al., 2012). The presence of a severe genetic thrombophilia or multitrait thrombophilia requires consideration of more aggressive treatment, such as anticoagulation in the chronic phase of secondary prevention, especially during times of increased clotting risk, such as prolonged immobility after surgery or trauma. Treatment decisions surrounding childhood stroke in the setting of multiple thrombophilia and/or genetic thrombophilia are best made by a multidisciplinary stroke team that includes a pediatric hematologist familiar with the multiple thrombophilia states and their implications across the human lifespan.

## Sickle Cell Disease

### Presentation

Sickle cell disease (SCD), particularly the hemoglobin SS variant, results in both small vessel infarctions and large vessel AIS because of moyamoya syndrome. SCD is the best studied hematological abnormality in childhood stroke, and presents one of the rare opportunities for primary prevention of stroke in children. The importance of stroke in children with SCD has been known for decades with an incidence of stroke in 285 per 100,000 per year in children with SCD. However, the great importance of silent infarcts upon cognition and outcomes has only been more recently recognized. Although children with SCD present with similar symptoms of stroke as those without AIS when infarcts are large, silent infarcts typically present with cognitive issues, including plateau and/or decline.

### Evaluation and Treatment

Typically, stroke is not the presenting symptom for children with SCD, although a screening CBC with blood smear review and hemoglobin electrophoresis should be considered in any child with new-onset AIS. For acute AIS in the setting of SCD, both AHA and American College of Chest Physicians (ACCP) guidelines recommend urgent erythrocyte exchange transfusion to reduce hemoglobin S levels to less than 30% of total hemoglobin. In addition, primary prevention of stroke in children with SCD is possible through transcranial Doppler (TCD) screening for intracranial artery stenosis (Monagle et al., 2012 and Roach et al., 2008). In the multicenter randomized controlled STOP trial, 130 children with elevated velocity (>170 to 200 cm/s) of intracranial arterial blood flow as measured by TCD were randomized to regular exchange transfusion program intended to reduce Hgb S to less than 30% of total Hgb versus no intervention. In the untreated group, the yearly stroke risk remained over 10%, whereas in the transfused group the stroke risk was reduced to 1% per year (Adams et al., 1998). Therefore RCP and ACCP guidelines also recommend that children older than 2 years who have SCD be screened yearly with TCD and placed on a chronic transfusion regimen if found to have elevated TCD velocities. Unfortunately, the real-world impact of this finding has been imperfect, as many children with SCD remain unscreened or underscreened for arterial narrowing. Chronic transfusions should also be considered in children with silent infarcts in addition to those with abnormal TCD screening.

## COAGULATION DISORDERS IN PEDIATRIC CEREBRAL SINOVENOUS THROMBOSIS

CSVT in children and neonates is a rare disorder, even compared with pediatric AIS, with an incidence of 0.67 per 100,000

children per year (DeVeber, 2001). Many risk factors outside of overt thrombophilias are associated with CSVT. In neonates, some other factors include birth trauma, delivery-related stress on the venous circulation, infection, and underdeveloped hemostatic systems. In children, trauma, dehydration, surgery, and infection are among the more common risk factors for CSVT. In addition, chronic systemic diseases, including inflammatory/rheumatologic disease, renal disease, and cardiac disease may contribute to CSVT risk. Among neonates with CSVT, prothrombotic states are found in about 20% and in children, estimates range from 24% to 64%.

Prothrombotic states may be the sole risk factor for CSVT or in combination with other risk factors. Previous studies demonstrated an elevated incidence of CSVT when a genetic or acquired hypercoagulable state is combined with a concomitant clinical risk factor for thrombosis. Interestingly, the prevalence of thrombophilias is higher in children with "idiopathic" CSVT (up to 85%) than in children with a CSVT provoked by a known clinical risk factor. In addition, the finding of multiple different genetic or acquired thrombophilias likely increases the risk of CSVT.

The role of prothrombotic factors likely differs between CSVT and AIS, as fibrin-rich thrombi are common in the low-flow system venous system, compared with platelet-rich thrombi as seen commonly in the high-flow arterial vascular system. Therefore workup and management of thrombophilias in patients with CSVT may differ from the management in children and neonates with AIS.

## Acquired Thrombophilia

### Presentation

In the neonatal and childhood period, the most common acquired thrombophilias are secondary to underlying medical illnesses. As example in children, cyanotic heart disease can lead to polycythemia, dehydration, cancer, or an endogenous hypercoagulable state. Similarly, infection is a well-known acquired cause of CSVT in neonates, with 23% to 73% of neonates and children with CSVT with a comorbid infection. Children with malignancies have a hypercoagulable state, which is most common in acute lymphoblastic leukemia (likely associated with L-asparaginase), followed by sarcoma and lymphoma. In addition, nephrotic syndrome in children is frequently associated with thromboembolism, occurring in up to 9%. Anemia is common in children with CSVT, most commonly iron deficiency anemia, although its role in the formation of thrombus is not clear.

Few studies have quantified the incidence of APA syndrome in childhood CSVT. Multicenter studies have reported the incidence or elevated RVVT is elevated in children with CSVT (4% to 11%), compared with controls. Among children with known APA syndrome, venous thrombotic events are common, occurring in up to 60%. However, only about 7% present with CSVT. In neonates, transplacental passage of maternal APAs from a mother with APA syndrome or systemic lupus is an uncommon cause of venous thrombosis. In several series of infants with perinatal thrombosis born to mothers with APA syndrome, only 10% to 20% had venous thrombosis, and all in the peripheral circulation. Neonatal APA-related CSVT has been described rarely, however. Several reports have documented APA-negative maternal testing, suggesting that there are some cases of de novo fetal production of APAs associated with CSVT.

### Evaluation

As in AIS, evaluation for APA in children and neonates with CSVT is uncertain. In children or neonates with a history of

multiple-site thrombosis or repeat CSVT, testing should include conventional APA testing for  $\beta$ 2GP IgG/IgM, ACA antibodies IgG/IgM, and a dRVVT assay for LA (see Fig. 113-2). This same evaluation should be undertaken in children with idiopathic CSVT, or in those with other symptoms of APA syndrome. As in AIS, children who are found to have APAs in the acute setting should have repeat testing at least 12 weeks later to evaluate for true APA syndrome (Miyakis et al., 2006). When to test for APAs in neonates with CSVT and no other systemic thrombi is uncertain and somewhat controversial. Guidelines recommend that all neonates and children with CSVT should have a complete blood count to evaluate for anemia.

## Treatment

Guidelines suggest treating childhood CSVT acutely with anticoagulation unless there is a contraindication, continuing for 6 weeks to 6 months regardless of the etiology. In neonates with CSVT, anticoagulation is more controversial. Variability in treatment strategies for neonates exists across geographic regions, with some areas utilizing anticoagulation in almost all patients and others only initiating anticoagulation if clot propagation is seen on a 5- to 7-day scan. In childhood CSVT, however, anticoagulation is almost uniformly suggested at onset of CSVT, unless a contraindication exists. For children with CSVT without significant hemorrhage, CHEST guidelines suggest initiating anticoagulation. For children with CSVT and significant hemorrhage, CHEST guidelines suggest initiation of anticoagulation *or* radiologic monitoring of the thrombosis at 5 to 7 days and anticoagulation for thrombus extension (Monagle et al., 2012). APA syndrome has been found among adults with first ever idiopathic DVT or pulmonary embolism to increase the risk of recurrence by 4- to 7-fold, and so adult guidelines recommend anticoagulation for the duration of APA syndrome. As previously mentioned, these authors use a similar approach. There are no clear guidelines on the long-term treatment of neonates with CSVT and APA syndrome.

## Genetic Thrombophilia

### Presentation

Many inherited procoagulant disorders have also been found to be risk factors for venous thromboembolism in adults and children. In several systematic reviews, protein C deficiency, protein S deficiency, antithrombin deficiency, factor V Leiden mutation, prothrombin G20210A mutation, and lipoprotein (a) have been found significantly associated with first venous thromboembolism in children. Fewer data are specifically available regarding inherited thrombophilias in CSVT in children, though in a meta-analysis of the existing studies, all of these factors except prothrombin G20210A mutation remained significantly associated (Table 113-3). Although the prothrombin G20210A mutation is rare, it is the only inherited thrombophilia with evidence supporting its role in CSVT recurrence (OR 5.5). The role of inherited thrombophilias is even less clear in neonates. In fact, one prospective multicenter study of children and neonates with CSVT found no recurrence of venous thromboembolism in children under the age of two at onset of CSVT.

### Diagnosis

Children with CSVT, especially those with no clear provoking factor, should have an evaluation for inherited prothrombotic conditions. The most important thrombophilias to evaluate are prothrombin G20210A mutation, factor V Leiden mutation, protein C, protein S, and antithrombin III. The utility of

evaluation of other abnormalities such as lipoprotein (a), hyperhomocysteinemia and factor VIII is less clear, and interpretation and management of results is difficult. D-dimer may be drawn as a marker of clot formation and lysis to follow during therapy. In neonates, the utility of these studies is unclear. Because most children with CSVT are treated initially with anticoagulation, it is important to note that protein C, protein S, and antithrombin III levels can be falsely depressed if checked during the acute phase. Therefore it is critical to check these studies using serum from before the start of anticoagulation or 2 to 4 weeks after anticoagulation is discontinued.

## Treatment

As discussed above, guidelines and standard practice suggest treating childhood CSVT in the acute period with anticoagulation in children and possibly neonates. As in genetic thrombophilia and pediatric AIS, the treatment team should include an experienced hematologist and/or genetic counselor who is familiar with clotting disorders in children. Given the current relative lack of data, it is reasonable to follow adult guidelines, which suggest consideration of long-term anticoagulation in patients with severe inherited thrombophilias, such as *homozygous* prothrombin G20210A or factor V Leiden mutations, or severe deficiencies of protein C, protein S, or antithrombin III. Long-term treatment should also be considered in those who have multiple genetic or acquired thrombophilias or recurrent events.

## COAGULATION DISORDERS IN PEDIATRIC HEMORRHAGIC STROKE

### Introduction

Hemophilia is the most prevalent coagulation disorder in pediatric hemorrhagic stroke. Hemophilia A and B, caused by deficiency of clotting factors VIII and IX, respectively, are X-linked bleeding disorders known for joint and soft tissue hemorrhages, but are also associated with intracranial hemorrhage (ICH) in 3% to 12% of patients with hemophilia that may cause disability and long-term neurologic sequelae. Morbidity in these cases is high, with neurologic deficit in 60% to 75% of the cases, and death in up to 20%. Patients with hemophilia are 20 to 50 times more likely to develop ICH than those without, particularly in the newborn period (4% rate compared with 0.1%), likely due in part to germinal matrix immaturity. Outside the neonatal period, the risk of ICH is approximately 300 to 800 per  $10^5$  patient years. The next sections will consider the different evaluation, management, and prevention approaches for patients with known disorders of hemostasis and those children who present with a priori ICH.

### Evaluation

In any case of known or suspected ICH, emergent imaging is imperative, but the sequence of events differs based on the underlying diagnosis. If a known coagulation factor deficiency exists, that defect must be corrected immediately even as imaging is being arranged. If, however, the child has no known bleeding disorder, then the priority becomes imaging (rapid noncontrast CT unless MRI is immediately available, in which case it is preferred) and expert consultation with neurology, hematology, and neurosurgery to determine the next steps in what may be the result of either an accident in a healthy child or the first manifestation of a congenital or acquired bleeding diathesis. In this case once the child is stabilized, the focus

should turn to the workup to rule out an undiagnosed underlying bleeding disorder or alternative cause of hemorrhage, including full history, physical examination, and a stepwise series of laboratory evaluations (see Fig. 113-1).

## Treatment

The standard treatments for general ICH are limited, consisting of close observation, standard medical management, and consideration of neurosurgical intervention. In the particular setting of hemophilia, clotting factor replacement (or inhibitor bypass strategies if necessary) is an essential first therapeutic step. Treatment for known or suspected ICH in a patient with hemophilia must include immediate clotting factor replacement to the 100% level (with goal of trough level of 50% or greater), even at the same time the clinician arranges for diagnostic imaging. Expert consultation from pediatric hematology, neurology, and neurosurgery should also be sought. High levels of factor replacement should be continued for approximately 7 days and then taper to goal of 30% to 50% factor trough to complete 2 to 3 weeks, depending on the nature of the inciting event (if any) and interim clinical progression. Additionally, the use of antifibrinolytic agents may reduce the risk of rebleeding in subarachnoid hemorrhage and has been recommended as adjunctive therapy for hemophiliacs who suffer ICH. Patients with specific clotting factor inhibitors present a special challenge and may require the use of rFVIIa or prothrombin complex concentrates. If the hemorrhage is spontaneous, strong consideration should be given to subsequent prophylactic clotting factor infusion to prevent another event, because the rate of rebleeding after initial ICH may be as high as 26%. Primary prevention strategies for patients with known bleeding disorders begin with frank discussions at initial diagnosis about the dangers of head injury (as well as the possibility of spontaneous ICH in patients with severe disease) and continued reinforcement at subsequent clinic visits.

Regarding the perinatal period specifically, it is important to avoid instrumental delivery (vacuum extraction, forceps, etc.) and fetal scalp monitors if possible. Screening of other potential hazards, such as cephalopelvic disproportion, is also recommended. It is essential to avoid complication by superimposed hemorrhagic disease of the newborn with standard newborn vitamin K supplementation.

Secondary prevention is the focus in any child who suffers an ICH, especially those with an idiopathic presentation. It is imperative that the child with idiopathic ICH be worked up appropriately to determine the underlying coagulation disorder (see Fig. 113-1) and subsequently take appropriate preventative measures to decrease the likelihood of a recurrence. In cases with a known nonhematologic etiology such as traumatic brain injury or vascular malformation, children should be screened with a PT/PTT/INR, and further evaluation considered if the hemorrhage is out of proportion to what is expected from the inciting cause.

## Other Rare Bleeding Disorders

ICH has also been described with other rare bleeding disorders, including neonates with vitamin K deficiency as well as severe deficiencies of factor II, factor V, and factor VII. ICH is also particularly common in factor X (up to 20% of affected

individuals) and factor XIII (30% of affected) deficiencies, which are often also associated with umbilical cord bleeding. Specific diagnosis is important because it may change the therapeutic approach such as using factor XIII concentrate, for example. Physiologic concentrations of vWF and the proportion of high-molecular-weight multimers are increased in the neonatal period, likely secondary to the physiologic stress of the birth process, severe/type 3 form (complete vWF deficiency) may be apparent in the newborn period. ICH in the context of vWF requires much of the same management above, but the factor replacement product must also contain vWF.

# 114 Bacterial Infections of the Nervous System

Geoffrey A. Weinberg and Robert Thompson-Stone\*

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

The brain is normally a sterile site that is protected from infection by specialized barriers, including the bony skull and the blood–brain barrier. Consequently, infections of the central nervous system (CNS) are comparatively rare, but they remain potentially devastating medical emergencies that can lead to death or severe neurologic sequelae. Injury to the brain from meningitis is a consequence of both the invasion by the particular pathogens and the host’s ensuing overwhelming inflammatory response. The impact on mortality varies greatly by patient age, global location, and the causative organism, with high-risk patients including neonates and children in lower-income countries.

## ACUTE BACTERIAL MENINGITIS

Bacterial meningitis involves inflammation of the leptomeninges, triggered by the presence of bacteria in the subarachnoid space. Prevention, prompt diagnosis, and aggressive management of acute bacterial meningitis remain the critical goals to prevent children from dying or suffering permanent neurologic sequelae (Brouwer, Thwaites, Tunkel, and van de Beek, 2012; Brouwer, Tunkel, and van de Beek, 2010; Kim, 2010).

## Epidemiology

The epidemiology of bacterial meningitis in children and adults in the United States and elsewhere has changed drastically over the last 25 years with the global spread of conjugate vaccine initiatives, first significantly affecting infection with *Haemophilus influenzae* type b and then, later, *Streptococcus pneumoniae* and *Neisseria meningitidis*. In the United States, the median age at diagnosis of bacterial meningitis is now 25 years rather than 15 months as a result of the 99% reduction of *H. influenzae* type b meningitis incidence in children after initiation of routine conjugate vaccination.

In newborns, the most common causative organism for early-onset neonatal sepsis and/or meningitis (defined as occurring within the first 7 days of life) is *Streptococcus agalactiae* (group B beta-hemolytic streptococcus), followed by *Escherichia coli* and *Listeria monocytogenes*. With the use of intrapartum maternal antimicrobial prophylaxis for women found to be carriers of group B streptococcus, the incidence of group B streptococcus early-onset disease declined from 2 in 1000 live births in 1990 to 0.3 in 1000 live births in 2004 (Thigpen et al., 2011).

\*The authors acknowledge work performed by Dr. M. Täuber and Dr. U. B. Schaad, the authors of this chapter in previous editions.

## Pathogenesis

Most cases of bacterial meningitis likely arise from bacteremia, which is caused by invasion of the bloodstream by the pathogen after colonization of the nasopharyngeal mucosa. From the nasopharyngeal surface, encapsulated organisms adhere to, colonize, and cross the epithelial cell layer and invade blood vessels. Viral coinfection of the respiratory tract also may promote invasive disease, possibly by increasing epithelial invasion. After surviving host defenses in the bloodstream, the “successful” meningeal pathogen must cross the blood–brain barrier either transcellularly or paracellularly. In neonates, however, colonization or transmission may occur vertically during birth, or from bacteremia associated with intravenous lines or mechanical ventilation. However, not all bacterial infections of the CNS are the result of bacteremia. Nonhematogenous invasion of the cerebrospinal fluid (CSF) by bacteria occurs in situations of compromised integrity of the barriers surrounding the brain (e.g., otitis media, mastoiditis, and sinusitis). Bacteria also can reach the CSF as a complication of neurosurgery, spinal anesthesia, cochlear implantation, or ventriculostomy placement.

## Clinical Manifestations

The cardinal manifestations of bacterial meningitis are fever, nuchal rigidity, toxicity, and alteration of consciousness (Box 114-1). However, the presentation differs based on age of onset and causative organism. Other focal neurologic signs sometimes can develop, including cranial nerve dysfunction. In particular, CNV III can be affected, leading to deafness and/or vestibular dysfunction. Seizures will develop in approximately one-third of patients either before or within the first few symptomatic days.

Children may demonstrate more nonspecific findings than do adults. The majority of children greater than 1 year of age (≥80%) exhibit fever, vomiting, and meningismus and toxicity on examination. Signs of meningeal irritation on examination include Kernig’s and Brudzinski’s signs. Kernig’s sign is elicited by flexing the patient’s hip and extending the knee to approximately 135 degrees in the supine position. The test is positive if the movement leads to pain in the hamstring and back (although in an ill or preverbal child, resistance of extension of the knee is considered positive). Brudzinski’s sign is elicited by flexing the patient’s neck in the supine position, and the test is positive if the patient involuntarily flexes the hips and knees. In contrast, the absence of meningeal signs does not exclude a diagnosis of bacterial meningitis, especially in infants younger than 12 months of age, who often do not exhibit nuchal rigidity with bacterial meningitis.

**BOX 114-1** Signs and Symptoms of Bacterial Meningitis

- Fever
- Nuchal rigidity
- Alteration of consciousness
- Irritability, photophobia, headache
- Vomiting, anorexia
- Kernig's sign
- Brudzinski's sign
- Seizures, focal neurologic deficits

**Clinical Presentations of Neonatal Meningitis**

In neonates and infants, the clinical features of bacterial meningitis can be quite subtle, which necessitates a higher index of suspicion. Meningitis in neonates is classified as early-onset infection (within the first 72 hours of life) and late-onset infection (from 1 week to 3 months of life). Those with early onset may be more likely to be associated with risk factors related to pregnancy and delivery, and more frequently exhibit nonneurologic, nonspecific signs, mostly related to sepsis and respiratory distress. Late-onset neonatal meningitis is more likely to present with neurologic features in addition to the nonspecific signs, including seizures (approximately 50%), focal neurologic signs (e.g., weakness), extensor rigidity, and cranial neuropathies. A bulging or full fontanel is present in one-third to one-half of cases and confers a 3.5 times greater likelihood of bacterial meningitis.

**Infection of Implantable Devices**

Infections of CNS shunts may occur in as many as 5% to 10% of patients, usually within 1 to 2 months of surgical insertion. Most of these infections are a result of coagulase-negative *Staphylococcus* or *Staphylococcus aureus*; however, a variety of other organisms, including gram-negative bacteria and other skin flora, can be causative. Clinical manifestations of CNS shunt infection usually include low-grade fever, vomiting, irritability or lethargy, and other signs of increased intracranial pressure. The onset is often insidious but can be more acute, particularly if shunt malfunction also is present. Neck stiffness is uncommon. Shunt infection should be suspected in any child with an indwelling CNS drainage system and fever. Some children with CNS shunt infection may present with abdominal pain or even peritonitis, resulting from infected CSF draining into the abdomen. Cochlear implants (neural stimulators whose electrode is placed surgically in the lumen of the cochlea) for severe to profound sensorineural hearing loss can also predispose children to develop bacterial meningitis, especially that caused by *S. pneumoniae* (~80%) and *H. influenzae* (~16%, both type b and nontypeable strains). Infectious complications from cochlear implantation are unusual, but the incidence of *S. pneumoniae* meningitis in children with cochlear implants is as much as 30-fold that of the greater U.S. pediatric population.

**Diagnostic Evaluation**

The differential diagnosis of bacterial meningitis includes viral meningitis, encephalitis, brain abscess, febrile seizure, head trauma, subarachnoid hemorrhage, and leptomenigeal neoplastic disease. In addition, unusual infectious agents, such as fungi, rickettsia, *Toxoplasma gondii*, or *Mycobacterium tuberculosis*, should be considered in selected patients. Many other conditions may cause nuchal rigidity, including

chemical meningitis (from idiopathic reactions to oral trimethoprim-sulfamethoxazole, nonsteroidal antiinflammatory drugs, intravenous immune globulin, and certain injected monoclonal antibody therapeutics), ingestion of heavy metals, infection of internal neck and throat structures, cervical lymphadenitis, and Kawasaki disease.

The diagnosis of bacterial meningitis is based on examination of CSF, together with the clinical context of the patient. Minimizing sequelae of bacterial meningitis depends on the prompt initiation of effective antibiotic therapy, which therefore demands consideration of lumbar puncture early in the evaluation and diagnosis of ill children.

Lumbar puncture for CSF examination is typically a safe procedure and should therefore be performed whenever there is even low clinical suspicion of meningitis. Four reasons for delaying lumbar puncture exist: (1) clinically important cardiorespiratory compromise; (2) signs of significantly and focally increased intracranial pressure; (3) infection in the skin, soft tissues, or epidural area at the site of lumbar puncture; or (4) suspicion or history of bleeding disorders. In these circumstances, blood cultures should be obtained, and antibiotics are provided empirically. Even 12 to 24 hours after initiation of antimicrobial therapy, the interpretation of CSF white blood cell (WBC) counts and protein and glucose concentrations is helpful in making a diagnosis. The CSF can sterilize as early as 2 to 4 hours after initiation of intravenous antibiotics, and the chance of obtaining a positive CSF culture can decline by one-third to one-half after 24 hours of therapy.

Neuroimaging studies are neither necessary nor adequate for the diagnosis of bacterial meningitis, but may be undertaken for patients when there is concern for impending herniation or intracranial mass lesions (e.g., subdural empyema, abscess, stroke). It must be noted that many patients with meningitis have some degree of increased intracranial pressure by virtue of the disease process; the level of concern among providers regarding herniation is typically out of proportion to its likelihood, which is only 1% to 4% or less. Herniation of the brain on removal of a small amount of CSF is rare in meningitis. Thus performing computed tomography (CT) scans routinely before lumbar puncture is *not* necessary in all patients with suspected meningitis. Nevertheless, lumbar puncture should be performed cautiously if significantly increased intracranial pressure is suspected, especially if the examination is difficult and the patient cannot be adequately evaluated for focal signs. Obtaining CT scans before lumbar puncture in *selected* patients is reasonable, especially for those children or adults with a history of immunosuppression, hydrocephalus, ventricular shunts, or head trauma, and in those who have focal neurologic signs or who have signs of greatly increased intracranial pressure.

**Cerebrospinal Fluid Analysis and Other Laboratory Testing**

The CSF opening pressure in children varies slightly with body mass index (BMI) and level of sedation, but should generally be less than 25 cm of water (with the 98 percentile in children of 28 cm water) (Avery et al., 2010). The CSF should be sent promptly to the laboratory for Gram stain, bacterial culture, cell count and differential, and protein and glucose concentrations. The Gram stain and bacterial culture are very useful in confirming bacterial meningitis and identifying a causative organism early in the disease course. The Gram stain is positive in approximately 70% to 90% of cases resulting from *S. pneumoniae*, *N. meningitidis*, gram-negative bacilli, and *H. influenzae* type b, but it is positive in only 33% of cases resulting from *L. monocytogenes*. Generally, bacterial cultures will be positive within 2 days if pathogens are present.

**TABLE 114-1** Characteristic Cerebrospinal Fluid (CSF) Findings in Children With and Without Meningitis

CSF Findings	Normal	Bacterial	Viral	Fungal or Tuberculous

(From Weinberg GA, Buchanan AM. Meningitis. In: McInerney TK, Adam HM, Cambell DE, Kamat DM, Kelleher KJ (eds). *American Academy of Pediatrics Textbook of Pediatric Care, 2nd Edition*. Elk Grove Village, IL: American Academy of Pediatrics; 2017. p. 2295–309).

The majority (>90%) of cases of bacterial meningitis will have a CSF WBC count greater than 500 cells/ $\mu$ L, and polymorphonuclear leukocytes (PMNs) will predominate (>80% of the total count) (see Table 114-1). The CSF protein is elevated in the vast majority of cases of bacterial meningitis, and conversely, the CSF glucose is low (Table 114-1). When considering CSF WBC counts in neonates, one needs to reference the common normative values in that population (see Table 114-2). Other diagnostic tests on the CSF, such as polymerase chain reaction (PCR) amplification tests for microbial nucleic acid detection, may be used as an adjunct diagnostic study to the CSF bacterial culture. When available, these tests are quite sensitive.

The main ancillary study that aids in the diagnosis of bacterial meningitis is blood culture, which can be especially helpful if antibiotics need to be started before lumbar puncture. Blood culture can identify the causative organism in up to 80% of cases. Various prediction models based on CSF characteristics have been developed in an attempt to help identify children at very low risk for bacterial meningitis, who might then be managed outside of the hospital. However, such models are most valuable in excluding the diagnosis of bacterial meningitis, rather than establishing it (i.e., “rules out,” but does not “rule in”).

## Neuroimaging

As discussed previously, neuroimaging studies are neither necessary nor sufficient to diagnose bacterial meningitis. However, neuroimaging may be very useful in the following

situations: (1) assessing the safety of lumbar puncture when signs of focal neurologic dysfunction and/or raised intracranial pressure are present; (2) defining unusual anatomic causes of persistent seizures, fever, or focal neurologic dysfunction after treatment has been started (e.g., infected subdural effusion, brain abscess); (3) assessing neurologic deterioration; and (4) assessing for secondary complications (e.g., hydrocephalus, venous or arterial infarctions, ventriculitis).

## Complications

### Pathophysiologic Changes

The permeability of the blood–brain barrier increases in meningitis, and this increase contributes to vasogenic brain edema. Brain edema contributes substantially to the acute fatal outcome of bacterial meningitis. The major dangers of extensive brain edema during meningitis are herniation of brain tissue and compression of the brainstem secondary to focally increased intracranial pressure, which can cause complete cessation of cerebral circulation.

Patients with acute meningitis often present with hypovolemia secondary to dehydration, and some develop hyponatremia. Syndrome of inappropriate antidiuretic hormone secretion (SIADH), with fluid retention and hypotonicity of the extracellular fluid, has been reported to be present in 29% to 88% of patients with bacterial meningitis. However, differences in definitions of whether ADH secretion is “inappropriate” for the degree of dehydration may be a factor in the wide ranges of the estimates of SIADH prevalence. It appears that

the overall risk of worsened clinical outcome as a result of SIADH is small and does not justify routine fluid restrictions in patients with meningitis and hyponatremia.

Increased intracranial pressure is present early in most patients with bacterial meningitis, yet in general, it neither contraindicates lumbar puncture nor leads to severe sequelae. The symptoms of massively increased intracranial pressure in meningitis are seizures and coma. In very advanced disease, signs of critical impairment of cerebral blood flow or impending herniation, such as unresponsive pupils, decorticate or decerebrate posturing, abnormal respiratory patterns, bradycardia, elevated blood pressure, and irregular vital signs, are observed.

In the early phase of bacterial meningitis, an increase in cerebral blood flow is observed, but as the disease progresses, cerebral blood flow reductions are observed globally and focally. Focal ischemia is the result of vascular involvement of cerebral arteries and veins caused by inflammation of the subarachnoid space, and ischemia is likely an important mediator of brain damage in meningitis.

### Seizures

Seizures complicate 20% to 30% of cases of childhood bacterial meningitis. They occur most frequently 2 to 3 days into the illness and cease 1 to 3 days later. Seizures may be focal or generalized, and the electroencephalogram (EEG) may be normal or may show generalized or focal epileptiform abnormalities, focal slowing, or only background slowing. Chronic seizures after recovery from meningitis are several-fold more common in patients than in age-matched control children.

### Deafness and Cranial Nerve Damage

Deafness is the most frequent neurologic sequela of bacterial meningitis. Of patients with pneumococcal bacterial meningitis, 31% develop hearing loss; with meningococcal meningitis, 10%; and with *Haemophilus influenzae* b meningitis, 6%. Some children exhibit fluctuating degrees of hearing impairment after meningitis, with eventual improvement, but much of the loss is severe, permanent, and may be bilateral. Hearing should be assessed in children with bacterial meningitis before discharge.

### Neuronal Damage

The neurologic sequelae after meningitis, in addition to hearing loss, include infarction, focal sensorimotor deficits, developmental delay, seizure disorders, and cortical blindness, which may occur in 15% to 25% of survivors.

### Hydrocephalus

Meningitis leads to disturbances of CSF homeostasis, with increased CSF production and reduced CSF absorption across the sagittal sinus–arachnoid villi system. In the acute phase, these disturbances can lead to transient ventriculomegaly associated with intracranial hypertension. Chronic hydrocephalus may occur as a long-term sequela of bacterial meningitis, particularly in infants but also in children. Chronic internal shunting with internal drainage is necessary in patients with persistent obstructive hydrocephalus.

### Septic Shock and Disseminated Intravascular Coagulation

Bacterial meningitis can be complicated by sepsis and septic shock, independent of the infecting organism. The

association of sepsis and extensive disseminated intravascular coagulation suggests infection caused by *N. meningitidis*, and patients present with rapidly progressive signs of severe illness, rigors, severe muscular pain, and skin lesions that progress from an early maculopapular rash to petechiae to enlarging purpuric lesions. Signs and symptoms of meningitis often are not prominent in patients with disseminated meningococcemia.

### Extraaxial Fluid Collections

The subdural space is a potential intracranial space situated between the arachnoid and dura. Fluid can collect in the subdural space and in the subarachnoid space. Because imaging often cannot distinguish between a fluid collection and a widened subarachnoid space, the fluid collection as seen on imaging is referred to as an extraaxial fluid collection. Extraaxial fluid collections are found in 20% to 50% of children with bacterial meningitis who have cranial CT performed. In general, clinical management is not influenced by the diagnosis of extraaxial fluid collections. Subdural empyema, however, is most commonly a complication of sinusitis or otitis media, and requires emergent treatment (as is discussed later in this chapter).

### Brain Abscess

The development of brain abscess is extremely rare, perhaps surprisingly so, after bacterial meningitis, given the pyogenic infection of the meninges. Brain abscess formation following bacterial meningitis is nearly exclusively seen only among neonates who have meningitis caused by *Citrobacter* or certain *Cronobacter* (formerly *Enterobacter*) species, in whom abscesses occur in approximately 80%.

### Pathology

The inflammation of the subarachnoid space in bacterial meningitis appears as a grayish yellow to green exudate covering the base and convexities of the brain (see Figure 114-4).  Histologic examination indicates that the exudate in acute bacterial meningitis consists predominantly of granulocytes; there is a mixture of lymphocytes, macrophages, and granulocytes in subacute to chronic forms of meningitis. Cerebral arteries and veins have focal infiltration of the vessel walls by the inflammatory cells. The inflammation of the vessel wall may be associated with thrombosis and vascular occlusion. Damage to the brain parenchyma in fatal cases of meningitis is manifested by signs of brain edema and by areas of cerebral infarction resulting from ischemia; neuronal loss associated with a marked reaction of astrocytes and microglia, and sometimes cerebral herniation, have been reported.

### Treatment

#### General Care

Antimicrobial therapy, fluid management, and possibly anti-inflammatory adjunctive treatments are crucial for all patients who have bacterial meningitis. Acute bacterial meningitis is always a medical emergency, and all infants and children who have an altered state of consciousness should be observed closely and the need for intensive care anticipated.

As soon as bacterial meningitis is diagnosed, intravenous access should be secured and appropriate antimicrobial agents (and possibly anti-inflammatory agents, see following discussion) provided. Management of the child who is awake and has stable cardiorespiratory vital signs consists primarily of administering antimicrobial agents and fluids and careful

**TABLE 114-3** Antimicrobial Therapy of Bacterial Meningitis

<b>Part A. Empirical Therapy Pending Culture and Susceptibility Data</b>			
Age	Likely Pathogens	Antimicrobial Agent	
0–1 mo	<i>Streptococcus agalactiae</i> , <i>Escherichia coli</i> , <i>Listeria monocytogenes</i>	Ampicillin + cefotaxime or Ampicillin + aminoglycoside	
1–3 mo	<i>S. agalactiae</i> , <i>L. monocytogenes</i> , <i>Streptococcus pneumoniae</i> , <i>Neisseria meningitidis</i> , <i>Haemophilus influenzae</i> b	Ampicillin + (cefotaxime or ceftriaxone) plus vancomycin (see text)	
3 mo–21 yr	<i>S. pneumoniae</i> , <i>N. meningitidis</i> ( <i>H. influenzae</i> b if not vaccinated)	(Ceftriaxone or cefotaxime) plus vancomycin (see text)	
<b>Part B. Specific Therapy</b>			
Pathogen	Therapy		
<i>Streptococcus agalactiae</i>	Ampicillin or penicillin G for 14–21 days; first 3 days, add gentamicin; cefotaxime also acceptable		
<i>Listeria monocytogenes</i>	Ampicillin for 14–21 days; first 3 days, add gentamicin		
<i>Streptococcus pneumoniae</i>	Penicillin MIC < 0.1 µg/ml and ceftriaxone or cefotaxime MIC ≤ 0.5 µg/ml: penicillin G or ampicillin for 10–14 days; ceftriaxone or cefotaxime also acceptable Penicillin MIC ≥ 0.1 µg/ml and ceftriaxone or cefotaxime MIC ≤ 0.5 µg/ml: ceftriaxone or cefotaxime for 10–14 days Penicillin MIC ≥ 0.1 µg/ml and ceftriaxone or cefotaxime MIC 1.0 µg/ml: (ceftriaxone or cefotaxime) + vancomycin for 10–14 days Penicillin MIC ≥ 0.1 µg/ml and ceftriaxone or cefotaxime MIC ≥ 2.0 µg/ml: (ceftriaxone or cefotaxime) + vancomycin ± rifampin for 10–14 days		
<i>Neisseria meningitidis</i>	Penicillin G for 7 days; alternatives: ampicillin, ceftriaxone, cefotaxime		
<i>Haemophilus influenzae</i> b	Ceftriaxone or cefotaxime for 10 days; alternative: ampicillin if isolate is susceptible		
<b>Part C. Antimicrobial Dosage</b>			
Agent	Dose (mg/kg Per Day)		
	Age 0–7 Days	Age 8–28 Days	Infants and Children
<b>Ampicillin</b>	150–200 divided every 8 hr	200–300 divided every 6 hr	200–300 divided every 6 hr
<b>Cefotaxime</b>	100 divided every 12 hr	200 divided every 8 hr	200–300 divided every 6 hr
<b>Ceftriaxone</b>	Not recommended	80–100 divided every 12–24 hr	80–100 divided every 12–24 hr
<b>Gentamicin</b>	5 divided every 12 hr	7.5 divided every 8 hr	7.5 divided every 8 hr
<b>Penicillin G</b>	100,000–150,000 Units divided every 12 hr	150,000–200,000 Units divided every 6 hr	300,000–400,000 Units divided every 4–6 hr
<b>Rifampin</b>	10 divided every 12 hr	20 divided every 12 hr	20 divided every 12 hr
<b>Vancomycin</b>	20 divided every 12 hr	30 divided every 8 hr	40–60 divided every 6 hr

MIC, Minimum inhibitory concentration.  
 (From Weinberg GA, Buchanan AM. Meningitis. In: McInerney TK, Adam HM, Campbell DE, Kamat DM, Kelleher KJ (eds). American Academy of Pediatrics Textbook of Pediatric Care, 2nd Edition. Elk Grove Village, IL: American Academy of Pediatrics; 2017. p. 2295–309).

monitoring for changes in level of consciousness, development of seizures, changes in vital signs, and development of SIADH. If high intracranial pressure is a major clinical concern and treatment has been initiated or is anticipated, then a neurosurgeon should be consulted and placement of an intracranial pressure monitoring device considered.

## Antibiotics

Effective eradication of the infecting pathogen generally requires antibiotics that are both bactericidal and able to penetrate well through the blood–brain barrier into the CSF. CSF concentrations of antibiotics, even with inflamed meninges, are only a fraction of the simultaneous serum concentration (~5% to 25%), such that antibiotic therapy for meningitis involves greater dosages than those used for most other infections.

Empiric therapy should be instituted rapidly in all children with suspected bacterial meningitis. In practice, the appropriate sequence of obtaining CSF and blood for cultures and other tests, instituting antibiotics, and possibly obtaining

imaging studies to exclude mass lesions and other pathologies needs to be adapted to the individual patient. The sicker the patient and the more rapidly progressive the disease, the more urgent is the start of antibiotic therapy. Antibiotic therapy should not be delayed by more than approximately 15 minutes in critically ill patients for an attempt to obtain CSF or blood. The choice of empiric antibiotics depends on the pathogens suspected to be causative, which in turn depends in part on the age and immunization status of the child, in addition to the local geographic epidemiology of pathogen frequency and antibiotic susceptibility. Recommended empiric treatment regimens adequate for patients without additional risk factors are shown in [Table 114-3](#).

Disease caused by *N. meningitidis* is treated reliably with penicillin G at high doses or, alternatively, either by ampicillin or a third-generation cephalosporin; there has been no clinically significant antibiotic resistance among meningococci in the United States or Europe. Meningitis caused by *H. influenzae* type b may be treated reliably with either ceftriaxone or cefotaxime; ampicillin may be used only if the isolate is known to be susceptible.

Currently, up to 40% of *S. pneumoniae* strains may be resistant to penicillin at some level, and many also are resistant to the third-generation cephalosporins. Therefore infants and children suspected of having bacterial meningitis caused by pneumococci (i.e., gram-positive cocci in pairs seen on a Gram stain of the CSF) should receive vancomycin in addition to either ceftriaxone or cefotaxime. Because dexamethasone (see following discussion) can decrease the CSF penetrance (and thus the activity) of vancomycin, some experts advise that either dexamethasone should be omitted or rifampin plus vancomycin plus a third-generation cephalosporin should be used when dexamethasone is provided. As soon as the antimicrobial susceptibility of an isolate is known, vancomycin should be discontinued if the isolate is susceptible to penicillin or if it is not susceptible to penicillin but still susceptible to the third-generation cephalosporins. Vancomycin is continued with ceftriaxone or cefotaxime for those isolates found not to be susceptible to both penicillin and the third-generation cephalosporins (and rifampin is added to the combination in some circumstances) (Table 114-3). Consultation with an infectious diseases subspecialist is suggested.

In areas with a low prevalence of penicillin-nonsusceptible pneumococci, especially when examination of the CSF Gram stain shows the absence of gram-positive cocci, providing a third-generation cephalosporin alone (without vancomycin) for empiric therapy is reasonable because such therapy will empirically treat *H. influenzae* type b, meningococci, and pneumococci (Table 114-3).

The principles of antimicrobial therapy for neonatal meningitis are the same as those for infants and children, but because the organisms are different, the antimicrobial selection must be adjusted. The ideal antimicrobial agent(s) would be potent against the most common organisms that cause neonatal meningitis (i.e., *E. coli* and other enteric organisms) and against group B beta-hemolytic streptococci and other gram-positive organisms. The combination of parenteral ampicillin plus gentamicin is a time-tested regimen for neonatal meningitis, although development of antimicrobial resistance has limited its utility. Cefotaxime and ceftriaxone, two third-generation cephalosporins, are extremely active against the organisms that usually cause neonatal meningitis, but they have poor activity against *L. monocytogenes* (which is best treated by ampicillin). Although ceftriaxone exhibits a much longer serum half-life than cefotaxime, ceftriaxone is highly protein bound and can displace unconjugated bilirubin from albumin, so its use in premature infants at risk for kernicterus or in term infants who have hyperbilirubinemia is restricted. Thus the combination of parenteral cefotaxime plus ampicillin (the latter to empirically treat *Listeria*) should be used to treat suspected neonatal meningitis (i.e., suspected disease plus abnormal CSF). Dosages and characteristics of the antimicrobials used most often to treat neonatal meningitis are listed in Table 114-3.

When culture results are available, modifications to treatment are made to provide definitive antibiotic therapy (Table 114-3). For susceptible pathogens, ampicillin, cefotaxime, or ceftriaxone are the usual choices. Group B beta-hemolytic streptococci and *L. monocytogenes* are thought to undergo quicker and more effective killing by beta lactam antibiotics if an aminoglycoside such as gentamicin is given concurrently for several days (Table 114-3).

Meningitis caused by *N. meningitidis* is usually treated for 7 days, that caused by *H. influenzae* type b for 10 days, and that caused by *S. pneumoniae* for 10 to 14 days, although the duration of therapy is not strictly defined by randomized trials. Neonatal meningitis caused by group B beta-hemolytic streptococci or *L. monocytogenes* is usually treated for 14 to 21 days, and that caused by Enterobacteriaceae for 21 to 28 days.

## Antiinflammatory Therapy

The use of glucocorticoids as adjunctive therapy to reduce neurologic damage in patients who have bacterial meningitis has been studied for decades, yet it continues to be controversial. There appear to be differences in benefit in studies of adults as opposed to children and in the industrialized world as opposed to the developing world. At present, it can be said that dexamethasone likely improves the hearing outcomes of children in the industrialized world who have bacterial meningitis caused by *H. influenzae* type b, but its usefulness in other forms of meningitis (pneumococcal, meningococcal, and gram-negative enteric or group B streptococcal neonatal disease) remains unproven. In addition, dexamethasone does not appear to benefit children or adults with bacterial meningitis in developing nations. In the United States, dexamethasone should be administered before or within 1 hour of the first dose of antimicrobial agents to children 6 weeks of age or older who have *H. influenzae* type b meningitis and considered for children who have pneumococcal meningitis; it has no role in cases of neonatal meningitis or aseptic meningitis. If given, dexamethasone is generally administered parenterally shortly before or simultaneously with the first antibiotic dose, at a dosage of 0.15 mg/kg every 6 hours for 4 days.

## Fluid Therapy

Maintenance fluids are necessary to perfuse, oxygenate, and deliver host defenses to the CNS, and although SIADH occurs in bacterial meningitis, no firm evidence has been found that fluid restriction prevents it. Thus obvious fluid deficits should be rapidly corrected, and serum sodium concentrations should be closely monitored several times during the first 24 hours of therapy, along with measurements of urine specific gravity. If the serum sodium concentration drops below 125 mEq/L, the test should be repeated as soon as possible. If the serum sodium is still below 125 mEq/L, fluids should be restricted to keep the vein open until the serum electrolyte concentrations have been corrected. Otherwise, for the child with bacterial meningitis, providing routine maintenance fluids (such as 0.2% saline with added potassium and dextrose) at approximately 80% of the maintenance rate after fluid repletion and advancing to full maintenance rates as the serum sodium increases beyond 135 mEq/L would appear to be appropriate. The period of fluid restriction likely only needs to be 1 day or less.

## Prognosis

Despite the appropriate use of bactericidal antibiotics, the modern mortality rate for bacterial meningitis remains at 5% to 10%. Approximately 15% to 25% of survivors will have long-term morbidity, including developmental delay and lower educational achievement, seizure disorder, spasticity, and hearing loss. Predicting long-term sequelae for an individual child is difficult at the time of discharge from the hospital because some who appear normal at discharge will have hearing or learning deficits subsequently diagnosed, and occasionally children with marked defects at discharge may improve over time.

Hearing loss is the most common sequela of bacterial meningitis; it appears to occur soon after infection. Hearing should be tested formally before discharge from the hospital because most sensorineural hearing loss can be detected at this time. The rate of persistent bilateral or unilateral sensorineural hearing loss is 31% after pneumococcal meningitis, 10.5% after meningococcal meningitis, and 6% after *H. influenzae* type b meningitis.

The complications of neonatal meningitis are similar to those seen among older infants and children, but are more frequently encountered. These include hearing loss, hydrocephalus, and blindness. The modern case-fatality rate ranges from 5% to 25%. Approximately 65% of survivors of coliform meningitis are normal 3 to 7 years after the illness, approximately 15% to 30% have mild to moderate neurologic sequelae, and 5% to 10% have major sequelae. Approximately 55% of cases of group B beta-hemolytic streptococcal meningitis survivors are normal, 25% have mild to moderate sequelae, and 20% have major sequelae (i.e., blindness, bilateral sensorineural hearing loss, cerebral palsy, profound developmental delay). As with older infants and children, all infants recovering from meningitis should have careful audiologic testing and close evaluation for attainment of developmental milestones.

## Prevention

Prevention of bacterial meningitis may be subdivided into immunization against meningeal pathogens and antibiotic chemoprophylaxis of contacts of meningitis cases.

### Immunization

As noted earlier (under "Epidemiology"), the widespread use of *H. influenzae* type b and pneumococcal conjugate vaccines has resulted in dramatic declines in the incidence of both invasive *H. influenzae* type b and pneumococcal infection. Similar changes have been noted in the United Kingdom with meningococcal serogroup C conjugates.

*H. influenzae* type b conjugate vaccines are routinely provided to U.S. infants beginning at 2 months of age. Pneumococcal conjugate vaccine (currently containing 13 serotype products, i.e., 13-valent) is recommended for routine universal administration to infants and children younger than 2 years of age, in a similar fashion to *H. influenzae* type b conjugate vaccines. The pneumococcal conjugate vaccine is also suggested for high-risk children 2 to 5 years of age, including children who have sickle-cell disease, functional or anatomic asplenia, cancer, immunosuppression, chronic renal disease, chronic cardiopulmonary disease, CSF leaks, and diabetes. At present, a tetravalent (serogroups A, C, Y, and W-135) meningococcal polysaccharide conjugate vaccine is routinely used for children and adults at higher risk of disease and for young adolescents 11 to 12 years of age (with a booster dose in late adolescence). Two new meningococcal serogroup B vaccines have recently been licensed in the United States and are available for use in interrupting epidemics and protecting children and adults at high risk of meningococcal group B disease; their role in the routine infant immunization schedule is not yet clear.

### Chemoprophylaxis

Many studies have documented an increased risk of disease in close contacts of any age of index patients with invasive disease caused by *N. meningitidis* and in unimmunized or underimmunized young children who are contacts of those with *H. influenzae* type b infection. The risk for the latter is age dependent, and disease among unvaccinated household contacts younger than 4 years old is increased. The spread of such strains is a particular concern in daycare centers.

Chemoprophylactic regimens are aimed at eradicating nasopharyngeal carriage of potentially invasive bacteria, and the preferred drug is rifampin (20 mg/kg per day, once daily, maximum daily dose 600 mg) for 4 days (*H. influenzae* b). For contacts of invasive *N. meningitidis* disease, the preferred drug also is rifampin, but in a different dosage (10 mg/kg per dose

every 12 hours, maximum daily dose 1200 mg) for 2 days. Alternatives for the elimination of nasopharyngeal carriage of *N. meningitidis* include single doses of either ciprofloxacin or ceftriaxone. Because treatment for bacterial meningitis with ampicillin or penicillin does not eradicate either meningococci or *H. influenzae* from the nasopharynx, chemoprophylaxis also is recommended for the index patient before discharge—unless the index patient was treated with cefotaxime or ceftriaxone, drugs that do eradicate colonization.

Numerous studies also have found that maternal intrapartum chemoprophylaxis can prevent maternal febrile morbidity and early-onset neonatal group B streptococcal disease, including early-onset meningitis, but, notably, not late-onset meningitis. Women who are found to be carriers of group B streptococci, based on cultures taken at 35 to 37 weeks of gestation; women who have had a previous child with group B streptococcal disease; women who have had group B streptococcal bacteriuria or urinary tract infection; and women whose group B streptococcal status is unknown at onset of labor or rupture of membranes and who have a gestation less than 37 weeks, membrane rupture greater than or equal to 18 hours, or an intrapartum temperature of greater than or equal to 38.0° C are given intravenous penicillin (or ampicillin) until delivery.

## RECURRENT ACUTE BACTERIAL MENINGITIS

Recurrent bacterial meningitis is rare and must prompt a careful evaluation for either an anatomic defect facilitating access of bacteria to the CSF space or an immunologic deficit. Anatomic defects can be acquired or developmental, and they typically lead to meningitis caused by *S. pneumoniae* or, less often, *H. influenzae* (especially nontypeable or non-b-type encapsulated isolates). Defects may involve the temporal bone or the anterior skull base and are not always associated with CSF rhinorrhea or otorrhea. Contrast-enhanced high-resolution CT, magnetic resonance imaging (MRI) cisternography, and search for CSF leakage into the nose or middle ear can help identify an anatomic defect. If such a defect is found, surgical correction usually is indicated.

Among the immunologic conditions predisposing to recurrent meningitis, deficiencies of the latter components of the complement pathway (C5 through C9) or properdin (alternative pathway) have been associated with recurrent infections caused by *N. meningitidis*. Functional or anatomic asplenia, agammaglobulinemia, and deficiencies of the early components of complement (C1 through C3) have been associated with recurrent episodes of meningitis caused by *S. pneumoniae*, *H. influenzae*, and *N. meningitidis*. Commonly, children with congenital immunodeficiencies have a history of frequent infections other than meningitis.

Nonbacterial causes of recurrent meningitis are more common in adults than in children. These include Behçet's syndrome, sarcoidosis, and Mollaret's meningitis associated with recurrent herpes simplex infection. Repeated episodes of aseptic meningitis may also result from an allergic reaction to drugs (e.g., trimethoprim-sulfamethoxazole, nonsteroidal antiinflammatory drugs, and intravenous immunoglobulin).

## CHRONIC (SUBACUTE) BACTERIAL MENINGITIS

Chronic or subacute bacterial meningitis evolves over days to weeks. Patients complain of headaches, often associated with constitutional signs of infection (fever, anorexia). Many forms of chronic meningitis involve the base of the brain and lead to cranial nerve palsies through direct inflammation or increased intracranial pressure. As the syndrome progresses, signs of brain involvement, with seizures, mental status

changes such as confusion or hallucinations, and focal neurologic deficits, may develop, along with hydrocephalus and increased intracranial pressure.

The bacterial causes of chronic or subacute meningitis include tuberculosis, Lyme borreliosis, syphilis, and leptospirosis; these are discussed in the following sections. Nonbacterial causes of chronic or subacute meningitis include fungal infections, such as *Cryptococcus neoformans*, *Histoplasma capsulatum*, or *Coccidioides immitis*, and viral infections such as cytomegalovirus and human immunodeficiency virus. Noninfectious causes of chronic or subacute meningitis include metastatic neoplastic disease and sarcoidosis.

## Tuberculous Meningitis

### Epidemiology and Pathogenesis

Tuberculosis (TB) remains one of the most common prevalent infections worldwide. *Mycobacterium tuberculosis* is transmitted by respiratory aerosols and frequently infects infants and children, particularly in developing countries. CNS involvement is a life-threatening extrapulmonary manifestation of tuberculosis, and 1% to 2% of children with untreated tuberculosis develop meningitis. The mean age at diagnosis of TB meningitis in a 20-year retrospective cohort study of 554 South African children was 37 months, with a median age of 28 months. A history of close contact with a known case of tuberculosis is often found in children with CNS tuberculosis.

The meninges are not directly invaded from the bloodstream; rather, a subcortical or meningeal caseous granuloma discharges organisms into the subarachnoid space. Multiplying organisms induce an inflammatory basilar meningitis and focal parenchymal infections (tuberculomas).

### Clinical Characteristics

Tuberculous meningitis usually evolves over several days to a few weeks, and initial symptoms include generally poor weight gain or weight loss, irritability, and apathy. In young infants, fever, cough, altered consciousness, bulging anterior fontanel, and generalized tonic-clonic seizures may be presenting symptoms. In older children, fever, nausea, vomiting, and headache are common. As the infection progresses, unilateral or bilateral cranial nerve deficits result from the basilar meningitis, along with neuro-ophthalmologic changes, impaired consciousness, and motor defects.

### Diagnosis

Head CT and MRI document findings similar to those of bacterial meningitis, especially around the base of the brain, and may reveal parenchymal lesions, infarction, and tuberculomas. Some degree of hydrocephalus is found in most children with TB meningitis. In addition, tuberculosis may affect the vertebral bodies (Pott's disease) and the spinal cord; MRI of the spine is indicated in a child with suspected tuberculosis and neurologic signs of cord involvement. Chest radiographs are commonly but not universally abnormal (~70%), with lymphadenopathy or pulmonary infiltrates; a military pattern is only seen in approximately 10%. The CSF opening pressure is often very elevated in TB meningitis. The CSF seldom contains more than 500 cells/ $\mu\text{L}$ , most of which are lymphocytes; protein content is elevated (>80 mg/dl); and CSF glucose concentration is low in relation to that of the blood glucose. Detection of the infecting organism in CSF is notoriously difficult. Large quantities of CSF (10 ml, if possible) should be collected and examined for acid-fast bacilli.

## Treatment

The increase in multidrug-resistant (MDR) TB is an increasing problem in several areas of the world. Isoniazid, rifampicin, ethambutol, pyrazinamide, ethionamide, and, to a lesser extent, streptomycin, remain the first-line drugs for the treatment of TB meningitis. Initial therapy for TB meningitis is started with four drugs for 2 months (isoniazid, rifampicin, pyrazinamide, and ethionamide or streptomycin). After 2 months, treatment is reduced to two active drugs, based on susceptibility testing, with rifampicin and isoniazid as first choices. Pyridoxine is recommended in malnourished children to prevent isoniazid-induced peripheral neuropathy. Response to antituberculous treatment usually is evident within 2 weeks. Therapy should be continued for at least 9 to 12 months. The use of corticosteroids for TB meningitis is strongly advocated (as opposed to the weaker support for typical bacterial meningitis), particularly in patients with a decreased level of consciousness, papilledema, focal deficits, or tuberculomas. A course of prednisone or dexamethasone for 6 weeks, with subsequent tapering over several weeks, is the most common regimen recommended.

The mortality rate of tuberculous meningitis remains 10% to 20%, and among survivors, 50% to 80% will have CNS sequelae, including vision or hearing loss, motor deficits, and, in children, developmental delay.

## Syphilis

### Epidemiology and Pathogenesis

Syphilis, caused by the spirochete *Treponema pallidum*, remains an important and prevalent sexually transmitted disease worldwide. In developed countries, syphilis in children is rare, but it is disproportionately frequent in underprivileged segments of the population and in the settings of HIV infection and substance abuse. In resource-poor countries, congenital syphilis remains an important health issue. Maternal syphilis acquired early in pregnancy is less often transmitted to the fetus, but if transmitted, it is more likely to result in fetal resorption in utero or spontaneous abortion. Maternal syphilis acquired later in pregnancy is more likely to be transmitted across the placenta, especially after the fifth month of gestation, and may lead to either symptomatic or asymptomatic neonatal infection.

### Clinical Characteristics

Congenital syphilis is associated with stillbirth or perinatal death in half of the cases. Early congenital syphilis manifests at birth or within the first weeks of life. Early signs include prematurity and low birth weight, skin and mucous membrane lesions, hepatosplenomegaly, and skeletal abnormalities (osteochondritis), which can be painful and prevent the child from moving affected limbs. Snuffles consist of a thick nasal discharge rich with spirochetes. The eyes (chorioretinitis, uveitis) and CNS (meningitis, meningovascular syphilis, hydrocephalus) are commonly involved, but clinical signs of neurosyphilis are rare in neonates.

In late congenital syphilis, clinical findings do not appear until several years of age. Interstitial keratitis (commonly bilateral) occurs typically in the second decade. Bone lesions result in destruction of the palate and nasal septum, with depression of the nose (saddle nose); also the tibia may become bowed (saber shins), and the knee joint can be affected with hydrarthrosis (Clutton's joints). Scars appear around the mouth from earlier fissures (rhagades). The permanent dentition is abnormal, especially the upper central incisors, which are dwarfed and notched (Hutchinson's teeth),

and the first lower molars, which have poorly developed cusps (mulberry molars).

CNS syphilis may present with various defects. Meningo-vascular syphilis leads to findings of chronic meningo-encephalitis, such as intellectual decline (juvenile paresis), which may begin by 4 to 5 years of age, headache, seizures, blindness, cranial nerve VIII deafness, other cranial nerve involvement, hemiparesis, and hydrocephalus. Sensorineural hearing loss is one part of the diagnostic Hutchinson's triad, along with the presence of Hutchinson's teeth and interstitial keratitis.

Acquired (noncongenital) syphilis can occur in children and adolescents; it resembles the disease in adults. The primary stage with chancre appears 2 to 4 weeks after exposure, followed by cutaneous eruptions of the second stage within 2 months, and can be associated with mucous membrane patches, condylomata lata, and patchy alopecia. Rarely, secondary syphilis is associated with meningitis, leading to headache, meningismus, nausea, and vomiting. If the condition is not treated, the tertiary stage of neurosyphilis (tabes dorsalis) may develop after an asymptomatic period of many years (thus it is extremely rare in pediatric patients).

## Diagnosis

The diagnosis of syphilis relies mainly on clinical suspicion and serologic testing, rather than stains or culture. Serologic testing relies on two different categories of assays: nontreponemal (i.e., the rapid plasma reagin [RPR] antibody test and Venereal Disease Research Laboratory [VDRL] antibody test) and treponemal tests (*T. pallidum* particle agglutination, microhemagglutination, and fluorescent treponemal antibody absorption tests [TPPA, TP-MHA, and FTA-ABS, respectively]). Traditionally, nontreponemal tests have been used as the first diagnostic test to yield relatively high sensitivity screening for syphilis; positive tests are then confirmed with the more specific treponemal test (e.g., RPR screening, confirmed by FTA-ABS or TPPA). Recently this order of testing has been inverted by the "reverse algorithm" of syphilis testing, made possible by the development of even more sensitive (and easily automated by mechanized laboratory equipment) treponemal enzyme-linked immunosorbent assay (EIA) antibody tests. In reverse algorithm testing, a positive treponemal antibody screen is followed by both a nontreponemal test (to stage the infection and provide a baseline for possible treatment) and by a different, confirmatory, treponemal test. This algorithm appears to have boosted both sensitivity and specificity for the diagnosis of syphilis, and it is expected to become the diagnostic gold standard in the near future. Possible congenital syphilis should be investigated by serologic testing of both the mother and child; acquired syphilis is diagnosed using serologic testing of the child, and if positive, the possibility of sexual abuse must be investigated.

Laboratory diagnosis of CNS syphilis depends on examination of the CSF. CNS involvement is assumed if CSF pleocytosis or elevated protein is present; CSF should also be submitted for testing by the VDRL assay (which is the only assay standardized on CSF; unlike the situation in blood, in which the RPR is superior to the VDRL as a nontreponemal test).

## Treatment

Penicillin remains the treatment of choice for all clinical forms of syphilis. For early stages of acquired syphilis, one injection of benzathine penicillin is sufficient. For neurosyphilis and congenital syphilis, high-dose treatment with intravenous penicillin G is recommended.

## Lyme Disease (Lyme Neuroborreliosis)

### Clinical Characteristics

Lyme disease is caused by the spirochete *Borrelia burgdorferi* (sensu lato), which includes *B. burgdorferi* (sensu stricto) in the United States and *B. afzelii* and *B. garinii* in Europe and Asia. The major manifestations of Lyme borreliosis are very similar, but not identical, in disease caused by the three species, with *B. burgdorferi* being more arthritogenic, *B. afzelii* causing chronic cutaneous disease, and *B. garinii* being neurotropic. Lyme borreliosis is transmitted in endemic areas by the bite of *Ixodes* ticks during the warm season, and children frequently are affected. The disease occurs in three stages: early localized disease, characterized by the rash of erythema migrans; early disseminated disease, characterized by extracutaneous CNS or cardiac signs and symptoms; and late disease, as manifested by Lyme arthritis.

Neurologic manifestations of Lyme disease are observed in 10% of infected patients and become apparent during the early disseminated phase. These manifestations include lymphocytic meningitis, radiculitis, neuritis, and, in rare cases, encephalomyelitis and subtle encephalopathic syndromes with memory and cognitive dysfunction. Neurologic symptoms develop within weeks to months after onset of erythema migrans and tend to be more frequent and severe in Europe than in the United States, likely as a result of the increased neurotropism of *B. garinii*. Infection with *B. garinii* is associated with a painful meningoradiculitis known as Bannwarth's syndrome; this is rare with U.S. Lyme disease caused by *B. burgdorferi* (Mygland et al., 2010). In children, fatigue, peripheral palsy of cranial nerve VII, loss of appetite, and fever are all common manifestations of CNS early disseminated Lyme disease.

### Diagnosis

The diagnosis of erythema migrans (i.e., early Lyme disease) is based solely on epidemiologic and clinical grounds and does not require laboratory confirmation. Serologic tests are used to diagnose early and late disseminated Lyme disease. EIAs with high sensitivity serve as screening tests in patients with symptoms compatible with Lyme disease; positive or equivocal tests must be confirmed by more specific Western blot tests (for both IgM and IgG antibodies) or, more recently, by a different EIA directed at the C6 peptide epitope of the variable surface protein of the *Borrelia* spirochete. Neurologic involvement is diagnosed based on suggestive symptoms combined with CSF signs of inflammation (lymphocytic pleocytosis, increased protein concentrations) (Halperin et al., 2008; Shapiro, 2014). Antibodies (IgM, IgG, and IgA) can be detected in the CSF as a result of intrathecal antibody production. Direct demonstration of spirochetes in the CSF is not feasible in most cases, even by PCR amplification.

### Treatment and Outcome

In early stages of the disease, doxycycline or amoxicillin is recommended. The latter is preferred in children younger than 8 years old. Doxycycline and ceftriaxone are equally effective for CNS disease in adults, and are both used in children with CNS symptoms; recent experience favors outpatient therapy with doxycycline in Lyme neuroborreliosis unless symptoms are severe. The prognosis is generally excellent for children and adults with CNS Lyme disease who are treated with appropriate antimicrobial agents, but in up to 10% of children with facial nerve palsy, recovery is not full after 6 months.

## Leptospirosis

Leptospirosis, caused by spirochetes of the *Leptospira* spp., is an uncommonly diagnosed cause of meningitis; it is typically

acquired through abraded skin or the conjunctivae coming into contact with water contaminated by rodent (rat) urine, but it also can be transmitted to children by contact with dog urine (rats and dogs commonly have leptospirosis). A typical case scenario would be a child with high fever and constitutional symptoms, headaches, gastrointestinal symptoms, myalgia, and conjunctival suffusion who appears to recover, only to have a second, immunologically mediated phase of illness occur, with liver, kidney, and nervous system involvement. Nervous system involvement typically takes the form of aseptic meningitis and may be more common in children than in adults. Severe leptospirosis may present as Weil's disease, with jaundice, renal failure, and hemorrhage; this manifestation of leptospirosis appears to be more common in adults. The diagnosis of leptospirosis is difficult to definitively establish; serologic techniques are most common but are not widely available outside of reference laboratories. Visualization of the organism in urine is difficult and requires dark-field microscopy; culture is slow and insensitive and is rarely available. In the future, PCR amplification tests may facilitate diagnosis, but they are not yet standardized. Penicillin, ceftriaxone, and doxycycline are among the antibiotics effective for the treatment of leptospirosis, although most disease is self-limiting, and there is controversy about which patients require antibiotic therapy.

## ASEPTIC MENINGITIS

Aseptic meningitis is most strictly defined as meningitis in which the gram-stained CSF does not reveal organisms. The term is often used to indicate enteroviral meningitis, which is the most common cause of aseptic meningitis; however, many pathogens, including bacteria, may cause aseptic meningitis (see Table 114-4). Discussion of all of the causes of aseptic meningitis is beyond the scope of this chapter.

## OTHER BACTERIAL INFECTIONS OF THE NERVOUS SYSTEM

### Bartonella

*Bartonella* spp. are small, fastidiously growing, gram-negative bacteria that are the major cause of cat scratch disease (CSD), a regional lymphadenopathy/lymphadenitis that is uncommonly associated with CNS disease. CSD is a mildly febrile or afebrile illness, typically transmitted to children by the scratch or bite of an infected kitten or young adult cat or, more rarely, through infected cat fleas. CNS involvement from *B. henselae* infection is found in about 2% to 5% of infected healthy hosts, with the major manifestations being encephalopathy and neuroretinitis.

CSD encephalopathy typically presents as acute generalized tonic-clonic seizures, combativeness, and even coma approximately 1 to 6 weeks following the development of the skin papule (which itself may not have been noticed or may have been long forgotten). The encephalopathy may be accompanied by regional lymphadenopathy, a finding that should increase the diagnostic consideration of CSD encephalopathy in a child with acute onset of encephalopathy or seizures. The CSF profile is most commonly normal, but a slight lymphocytic pleocytosis is sometimes observed; neuroimaging studies are often unremarkable. Recovery from CSD encephalopathy tends to be rapid, over days to weeks, with few sequelae. Diagnosis of CSD is typically made serologically, by demonstrating IgM and IgG antibodies in the blood. Antibiotic therapy of uncomplicated CSD lymphadenitis is generally not undertaken because the infection is self-limiting, and antibiot-

ics have not been demonstrated to have more than a minimal clinical effect on its resolution.

CSD neuroretinitis occurs in children and young adults. It typically includes anterior optic neuropathy with papillitis, short-segment retrobulbar inflammation of the optic nerve (as demonstrated by MRI), and, often, development of a macular star—a stellate exudate in the macular region caused by neuroglial ingestion of lipids. Clinically, the disease presents as a subacute to acute progressive loss of vision, which slowly resolves over weeks to months. CNS neuroretinitis and macular star formation from CSD neuroretinitis appear to be the cause of the stellate maculopathy of Leber, described in 1916 and previously thought to be idiopathic.

### *Mycoplasma pneumoniae*

*Mycoplasma pneumoniae* has been implicated in diseases affecting the CNS (either by neurotropic invasion or immune-mediated disease). It is estimated that up to 5% to 10% of cases of pediatric encephalitis are attributable to *M. pneumoniae* infection. However, the diagnosis of CNS involvement secondary to *M. pneumoniae* is difficult, and its exact role in causing CNS disease is unclear because serologic tests for *M. pneumoniae* are fraught with false positives, and they remain positive long after unrelated episodes of infection preceding the presumed CNS illness. CNS disease attributed to *M. pneumoniae* includes a variety of neurologic syndromes, including meningoencephalitis, acute disseminated encephalomyelitis, and an ascending paralysis similar to Guillain-Barré syndrome. PCR amplification of respiratory secretions (or if available, CSF) is likely a more accurate diagnostic method and is useful in confirming *M. pneumoniae* serologic studies in children with CNS disease, alongside concurrent evaluation of other potential pathogens (e.g., enterovirus, arbovirus, or herpes simplex virus). In suspected cases of *M. pneumoniae* CNS disease, antimicrobial therapy with drugs that penetrate into the CNS and have in vitro activity against *M. pneumoniae* (e.g., doxycycline, quinolones, azithromycin) should be instituted, despite the lack of firm evidence of a beneficial effect.

### Leprosy (Hansen's Disease)

Despite increasing efforts to control leprosy (Hansen's disease), it is still prevalent in some countries of Asia, Africa, and South America, and it is one of the most common treatable causes of peripheral neuropathy. The disease should be considered in patients with persistent skin lesions and peripheral neuropathy who have lived in countries with warm climates and limited resources. The most common neurologic manifestations of leprosy are peripheral mononeuritis, mononeuritis multiplex, polyneuropathy, and cranial neuropathy (trigeminal and facial nerves). The disease often affects peripheral nerve trunks in fibro-osseous tunnels (e.g., ulnar, median, lateral popliteal, and posterior tibial nerves) and small dermal nerves. This results in sensory and motor loss, hypesthesia, and anhidrosis. The diagnosis of leprosy is made clinically, based on the presence of hypopigmented or reddish patches of skin with reduced sensation, thickening of peripheral nerves, or infiltrative skin lesions with the presence of acid-fast bacilli on skin smears or biopsy material. *M. leprae* may be cultured from skin biopsies, or the nucleic acid may be amplified by PCR methods. Treatment depends on the form of disease and uses multidrug approaches, consisting of combinations of dapsone, clofazimine, rifampicin, ofloxacin, and minocycline. Guidelines from the U.S. National Hansen's Disease Center should be consulted, and consultation with

**Figure 114-5.** Magnetic resonance sagittal T1-weighted images with gadolinium contrast, from two different patients with cerebral abscess (red arrows). Each abscess has a hypointense core with a rim of contrast enhancement. In addition, each patient exhibits an epidural empyema (green arrow), developing from a contiguous area between the abscess and epidural space.

infectious diseases specialists with experience treating leprosy is advised.

## CENTRAL NERVOUS SYSTEM ABSCESS

Abscesses are focal infections consisting of an encapsulated collection of pus, pyogenic bacteria, and, less commonly, mycobacteria, fungi, protozoa, or helminths. Abscesses may be found in various sites of the nervous system, including the brain parenchyma, cranial epidural space, and spinal epidural space. All are rare in children.

### Brain Abscess

#### Epidemiology and Pathogenesis

The incidence of bacterial brain abscesses in the general population is 0.5 to 0.9 per 100,000 population, although the number is likely significantly lower in children (Brouwer, Tunkel, McKhann, and van de Beek, 2014). Predisposing factors are found in the majority (~80%) of cases; these include contiguous focus of infection (50%; including otitis media, mastoiditis, sinusitis), conditions associated with bacteremia (30%; including cyanotic congenital heart disease and odontogenic or pulmonary infection), or the presence of an immunosuppressive condition or a disruption of the body's natural barriers (e.g., neurosurgical procedure or head trauma). The most common causative organisms in patients with trauma or surgical procedures are *S. aureus*, coagulase-negative staphylococci, or gram-negative bacilli. The most common causative organisms from contiguous spread from the middle ear or sinuses are *Streptococcus* spp., including *S. pneumoniae*. Anaerobic and microaerophilic bacteria (e.g., *Bacteroides fragilis*, *Eikenella corrodens*, *Abiotrophia* and *Granulicatella* spp.) are found in many brain abscesses, and over 25% of such abscesses are polymicrobial. Bacterial meningitis in the older child or adult is very rarely associated with brain abscess. However, neonatal meningitis is more often associated with development of one or more abscesses, especially if the meningitis is caused by *Citrobacter* spp. (which leads to the development of  $\geq 1$  brain abscess in 85% of infected babies) or *Cronobacter* (formerly *Enterobacter*) *sakazakii*.

#### Clinical Manifestations and Diagnosis

Only ~20% of patients with brain abscess will present with the "classic triad" of fever, headache, and focal neurologic deficits. The most common symptom of a brain abscess is headache (70%), with fever and focal neurologic deficits occurring in about half of patients. About 25% of individuals will develop seizures. Papilledema, a distinctly uncommon finding with bacterial meningitis, occurs with brain abscesses in older children and adults.

The most important study for initial diagnosis of brain abscess is cranial imaging, with either MRI or CT with contrast. Early cerebritis will be suggested by hypodense areas on CT and focal edema on MRI. With a more mature abscess, classic ring-enhancing lesions with a necrotic center and surrounding edema can be documented with intravenous contrast (Figure 114-5; see also Figure 114-6).

Lumbar puncture should not be performed in patients with a suspected brain abscess because of the risk of herniation secondary to elevated intracranial pressure; in addition, it is uncommon to have a positive CSF culture in this situation. Identification of the causative organism is best attempted by obtaining Gram stain and culture information on material obtained through stereotactic aspiration of the abscess. Blood cultures can identify the causative organism in one-third of cases.

#### Neurosurgical Management and Antimicrobial Therapy

Neurosurgical intervention is generally undertaken in the majority of cases, with stereotactic aspiration, for both etiologic diagnosis and reduction of lesion size, being the most common indication. In stable patients with multiple abscesses, none of which are greater than 2.5 cm in diameter, nonsurgical management with antibiotic therapy has had success in some reports. Intravenous antimicrobial therapy should be given without delay to patients with brain abscess. For cases likely to be caused by contiguous spread from the middle ear or sinuses, a third- or fourth-generation cephalosporin plus metronidazole is used (with the addition of vancomycin if methicillin-resistant *S. aureus* [MRSA] is suspected). If head

trauma or a neurosurgical procedure is thought to be a factor, vancomycin plus metronidazole plus a third- or fourth-generation cephalosporin may be indicated. The duration of intravenous antibiotic therapy is typically 6 to 8 weeks, although some experts advocate shorter intravenous courses (e.g., 2 weeks) followed by oral therapy for several weeks in selected patients. Serial CT or MRI should be used to determine when medical therapy is failing. Corticosteroids may be useful to reduce edema in symptomatic patients, but they are only used in about 50% of cases because the effect of this therapy on antimicrobial penetration is unclear. Both case-fatality and morbidity rates have declined substantially over the last 6 decades as a result of improvements in cranial imaging, neurosurgical techniques, and antimicrobial therapy.

## EPIDURAL ABSCESSSES

### Spinal Epidural Abscess

Spinal epidural abscess is a rare diagnosis, but it is one that requires emergent identification and management for optimal outcome. The abscess typically is attributable to a hematogenous source in healthy children (as opposed to adults, who generally have predisposing conditions). Spinal epidural abscesses tend to extend over three to four vertebral segments, and they are most common posteriorly (where the epidural space is largest, with a fat pad containing a venous plexus) and in the thoracolumbar segments. *S. aureus* (including MRSA) is the most common organism recovered (60% to 70%). Presentation is typically back pain (75%) and fever (50% to 66%) accompanied by neurologic symptoms (30%) referable to the spinal cord. The “classic triad” of pain, fever, and spinal cord neurologic symptoms is seen only in the minority of children at the onset of infection (Darouiche, 2006).

With a suspicion of spinal epidural abscess, emergent MRI with gadolinium contrast is indicated, whereas lumbar puncture is contraindicated. Surgical treatment involves either incision and drainage with laminectomy or CT-guided needle drainage. Patients also require appropriate intravenous antibiotic coverage for *S. aureus*, including MRSA, and other bacteria (e.g., vancomycin and a third- or fourth-generation cephalosporin); treatment is often given parenterally for 6 to 8 weeks. In cases known to be caused by methicillin-sensitive *S. aureus*, nafcillin or cefazolin is preferred. The factors that most significantly affect outcome include length of time before initiation of treatment and severity of neurologic deficits at presentation.

# 115 Viral Infections of the Nervous System

Daniel J. Bonthius and James F. Bale, Jr.

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

More than 100 virus species have been associated directly or indirectly with disorders of the human central or peripheral nervous system (Box 115-1) (Johnson, 1998). Although infections with several viruses have become infrequent because of immunization programs or less severe because of antiviral therapies, many others remain potential threats to children worldwide (Pickering et al., 2012). This chapter describes virus-induced neurologic disorders, emphasizing the epidemiology, clinical manifestations, treatment, and prevention.

## GENERAL CONSIDERATIONS

The pathogenesis of a virus-induced neurologic disorder reflects the complex interactions of the viral pathogen and the host (Reiss, 2008). Because the majority of viral neurologic disorders begin with virus entry and replication in the skin or cells lining the respiratory or gastrointestinal tracts, several host factors, including the integrity of skin or mucosal barriers and the innate immune response of the host, determine whether viruses successfully invade human tissues and cause neurologic disease. Most viruses reach the central nervous system (CNS) hematogenously and enter the brain via the choroid plexus or directly through the vascular endothelium (Johnson, 1998). Rabies virus and a few others reach the CNS via neural routes. Rabies virus, a negative-strand RNA virus, infects neuromuscular junctions, enters motor nerve endings, travels via retrograde transport to the neurons of the spinal cord, and then ascends to the brain. Neural pathways can also participate during infections with the herpes simplex virus (HSV) and the varicella zoster virus.

Viruses can cause neurologic disease directly by infecting and damaging neural cells or indirectly by stimulating immune responses that alter host cell function (Johnson, 1998). Several factors, including neuroinvasiveness (the ability of viruses to enter the nervous system), neurotropism (the capacity of viruses to infect certain neural cell types), neurovirulence (the capacity of viruses to induce neurologic disease), and the immune responses of the infected host, determine the spectrum and severity of virus-induced neurologic signs and symptoms. Certain viruses, such as the herpes simplex viruses, produce lytic infection of neural cells and induce necrosis of infected cells, whereas other viruses, such as La Crosse encephalitis, produce minimal neural cell damage despite direct infection. Other viruses, such as the childhood respiratory viruses, may not infect neural cells directly, but may induce neurologic disease through secondary, immune-mediated mechanisms, such as the events that lead to acute disseminated encephalomyelitis, a disorder that accounts for a substantial proportion of “viral” encephalitis in young children.

Cellular and humoral immune responses, including those mediated by small molecules such as interferons and inflammatory cytokines, have major roles in inhibiting viral CNS infections. Toll or toll-like receptors participate in host responses to viruses, and in certain instances, mutations in the

human genes encoding such proteins can determine the risk of acquiring herpes simplex virus (HSV) encephalitis. Mutations in RANBP2, a gene encoding a nuclear pore protein, can influence whether children have acute necrotizing encephalomyelitis, a potentially life-threatening disorder triggered by several common viral infections. Host immune responses can provoke several neurologic disorders, including Guillain-Barré syndrome (GBS), Bell palsy, transverse myelitis, or acute disseminated encephalomyelitis (ADEM). The latter disorders can complicate infections with several viruses that commonly infect young children.

## EPIDEMIOLOGY OF VIRAL INFECTIONS

During the past fifty years, the epidemiology of virus-induced neurologic disease has changed dramatically due to the development of vaccines and the implementation of vaccination programs. Poliomyelitis, the consequence of infection with polioviruses types 1 to 3, has been eliminated in nearly all regions of the world, and subacute sclerosing panencephalitis (SSPE), the consequence of latent measles virus infection, is exceptionally rare in nations with widespread measles-mumps-rubella (MMR) vaccination coverage (Johnson, 1998).

Many neurologic disorders, including meningitis or encephalitis caused by several different viruses, cannot be prevented by vaccination. The herpesviruses (especially herpes simplex viruses), tick- or mosquito-borne viruses (arboviruses), and nonpolio enteroviruses account for the majority of encephalitis cases among children in many regions of the world. Some of these, especially the nonpolio enteroviruses, cause many cases of viral, or aseptic, meningitis in young children. The incidence rates of viral encephalitis in the pediatric population range from 3 to 30 or more per 100,000 persons of all ages annually. However, rates of viral CNS infections are likely higher, because current surveillance systems fail to capture all cases of viral encephalitis and meningitis.

Major outbreaks of viral infections appear periodically in human populations. In 1999, West Nile virus (WNV) emerged in the United States, and by the end of 2003, the Centers for Disease Control and Prevention (CDC) had recorded approximately 14,000 cases of human WNV infections in the United States and 6000 cases of WNV neuroinvasive disease. Approximately 260,000 hospitalizations due to all causes of encephalitis occurred between 1998 and 2010 in the United States, corresponding to slightly more than 20,000 children and adults with encephalitis annually or approximately 6 cases of encephalitis per 100,000 persons/year. Herpes simplex encephalitis affects approximately 1 in every 250,000 to 500,000 persons. Human rabies affects 1 in 100,000 to 1 million inhabitants annually in Africa and India, causing several thousand deaths annually in Africa.

Neurologic disorders caused by environmentally derived pathogens, such as the tick- or mosquito-borne encephalitis viruses, occur when vectors are active, typically late spring through fall, and display characteristic epidemiologic patterns

(Fig. 115-2). La Crosse encephalitis, a common arthropod-borne disorder in the United States, typically affects children who reside in the Eastern and Midwestern United States, prime habitat for the *Aedes triseriatus*, the principal mosquito vector. Cases occur from June to October, reflecting peak activity of the vector, and frequently involve boys 5 to 15 years of age who live near or enter wooded areas.

Transmission of several viruses, including the herpesviruses and nonpolio enteroviruses, requires direct contact with infected humans or with fomites harboring virus-infected human secretions. Infections with these viruses can occur throughout the year, although some, such as measles and chickenpox, peak in the late winter or early spring, whereas others, such as the nonpolio enteroviruses, peak during the summer and fall.

## CLINICAL FEATURES OF VIRUS-INDUCED NEUROLOGIC DISORDERS

### Meningitis

Viral, or aseptic, meningitis, the most frequent virus-induced neurologic disorder, produces malaise, headache, vomiting, irritability, stiff neck, and neck or back pain (Bonthius

and Karacay, 2002). Children and adolescents with viral meningitis appear moderately ill with signs of meningeal irritation, including the Kernig sign (involuntary spasm of the hamstring muscle evoked by knee extension in a supine patient) or Brudzinski sign (flexion of the knees provoked by forced flexion of the patient's neck). However, meningeal signs may be subtle or absent in young infants, indicating that the clinician must maintain a high index of suspicion when considering CNS viral infections in the neonate.

Systemic features in pediatric patients with aseptic meningitis sometimes provide useful etiologic clues. The nonpolio enteroviruses, agents frequently associated with aseptic meningitis, commonly produce gastrointestinal symptoms and an evanescent, erythematous rash or oral lesions of the hand-foot-mouth syndrome. Diarrhea and an erythematous, truncal exanthem can also accompany or precede neuroinvasive disease due to WNV. Hepatomegaly or prominent lymphadenopathy can suggest infection with the Epstein-Barr virus (EBV), cytomegalovirus or, possibly, human immunodeficiency virus (HIV).

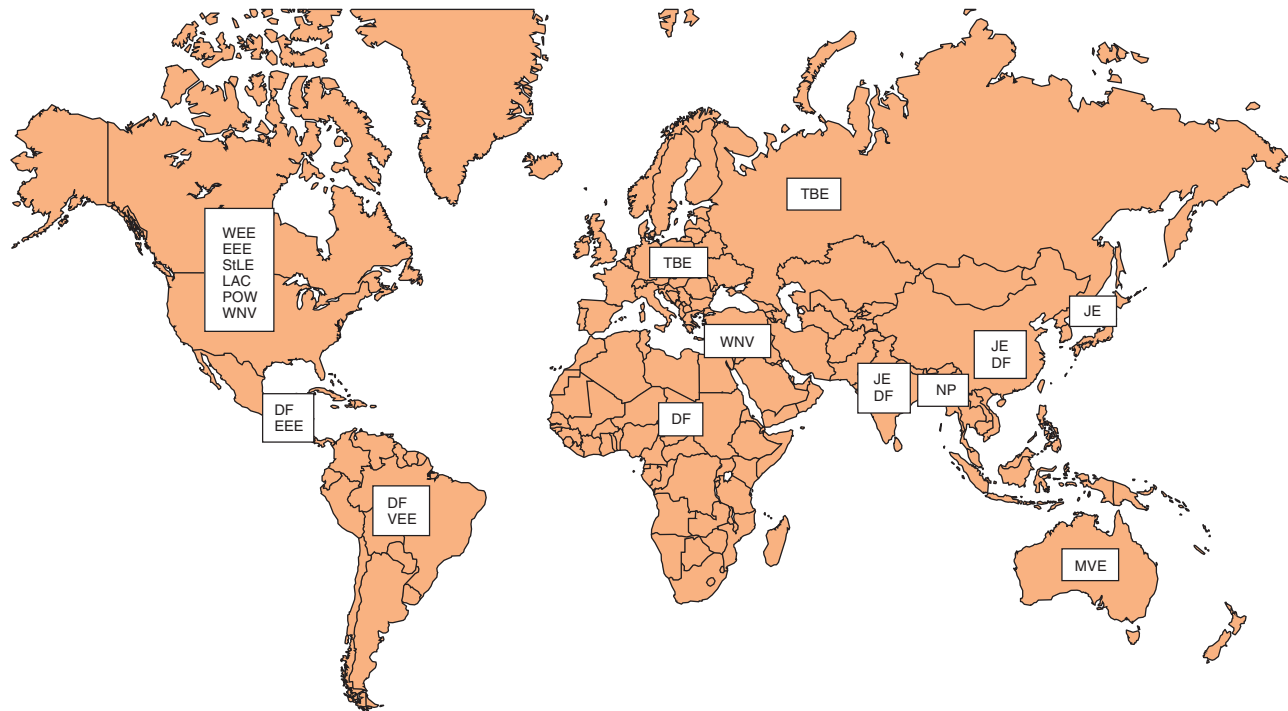

### Encephalitis

In addition to headache, fever, and vomiting, important features of viral meningitis, viral encephalitis produces symptoms or signs of cerebral dysfunction, including seizures, focal neurologic dysfunction, and altered alertness, ranging from somnolence to deep coma (Johnson, 1998). Because the clinical features of meningitis often accompany those of encephalitis, the term *meningoencephalitis* is sometimes used to describe encephalitis. Seizures, focal or generalized, affect 10% to 50% or more of patients with encephalitis, and when focal, can suggest serious conditions, such as HSV encephalitis, or relatively benign conditions, such as La Crosse virus encephalitis. The neurologic examination of pediatric patients with encephalitis can reveal cognitive dysfunction, ataxia, hyperreflexia, diffuse weakness, movement disorders, and focal deficits, such as aphasia or hemiparesis. Severe encephalitis can be associated with coma and signs of cerebral edema and central or uncus herniation.

### Other Disorders

Guillain-Barré syndrome (GBS), myelitis, Bell palsy, acute cerebellar ataxia, and poliomyelitis-like disorders are additional neurologic conditions that can result from viral infections. GBS and myelitis, frequently called transverse myelitis, commonly begin with weakness or vague sensory symptoms that can evolve rapidly to severe, flaccid paralysis. Marked sensory dysfunction, such as sensory loss corresponding to a spinal level, indicates myelitis, whereas facial paralysis, either unilateral or bilateral, suggests GBS. Autonomic nervous system dysfunction, a potential feature of the latter disorder, can produce hypertension, hypotension, or life-threatening cardiac arrhythmias. Myelitis or GBS can result from infections with numerous viruses, including the nonpolio enteroviruses, EBV, varicella zoster virus, and cytomegalovirus (CMV). Several viruses, including WNV and the nonpolio enteroviruses (EV) 70 and 71, can damage anterior horn cells and produce a poliomyelitis-like disorder with flaccid paralysis and areflexia in the affected extremities.

Acute cerebellar ataxia, a potential complication of several viral infections, can produce vomiting, headache, behavioral dysfunction, and truncal or appendicular ataxia. Chickenpox-associated ataxia, a disorder that has become uncommon in regions with widespread varicella vaccine coverage, typically begins 5 to 14 days after the onset of the varicella rash, although occasional cases can begin during the preruleptic

phase of chickenpox. Virus-induced ataxia and the associated behavioral dysfunction peak by 1 to 2 weeks and gradually resolve, usually completely, in 4 to 8 weeks.

## Intrauterine Viral Infections

Intrauterine or congenital infections with a small number of viruses, as well as nonviral pathogens, can cause microcephaly, hydrocephalus, intracranial calcifications, schizencephaly, porencephaly, lissencephaly, and other brain malformations (Bale 2009). Linked conceptually by the acronym TORCH (Toxoplasmosis, Rubella, Cytomegalovirus, Herpes simplex virus), these infectious pathogens produce similar systemic manifestations, including intrauterine growth retardation, hepatomegaly, splenomegaly, jaundice, and skin lesions. Neurologic manifestations include microcephaly, macrocephaly, seizures, sensorineural hearing loss, chorioretinitis, cataracts, and hypotonia. Although the TORCH acronym reminds clinicians that these agents produce similar clinical features in infected infants, some TORCH agents produce unique, distinguishing abnormalities. Rubella virus can produce congenital

heart lesions, whereas varicella-zoster virus can cause a cicatrix, a dermatomal pattern of skin scarring. Lymphocytic choriomeningitis virus (LCMV), a rodent-borne arenavirus, can induce postnatal hydrocephalus through infection of ependymal cells and aqueductal obstruction.

Because congenital infections begin with maternal viral infection, the outcome relates to the maternal immune status and the timing of infection. Vaccination with the MMR vaccine protects women and their fetuses from rubella virus infection; women who are seropositive for CMV are less likely than seronegative women to deliver infants with congenital CMV disease. Maternal infections during the first half of pregnancy tend to be associated with more severe fetal consequences (Bale, 2009). During the first 8 to 12 weeks of gestation, maternal rubella may lead to cataracts or optic atrophy and congenital heart lesions, such as patent ductus arteriosus or atrial septal defect. By contrast, maternal rubella after week 20 of gestation, although producing sensorineural hearing loss in some infants, rarely causes neurologic sequelae. Similarly, the outcome of LCMV is closely linked to the timing of maternal infection, a conclusion supported by animal studies.

## DIAGNOSIS

### Cerebrospinal Fluid

The cerebrospinal fluid (CSF) in viral meningitis or encephalitis typically has a lymphocytic pleocytosis (5 to 500 cells/mL), mildly elevated protein content (50 to 200 mg/dL), and normal or slightly low glucose content. Normal CSF examination does not eliminate the possibility of a serious viral CNS infection. As many as 15% of patients with HSV encephalitis have an entirely normal initial CSF profile, and 10% or more of children with La Crosse virus encephalitis have normal CSF findings throughout their infection.

Early in the course of many viral CNS infections, neutrophils predominate in the CSF thus suggesting bacterial disease, but the profile typically shifts to a lymphocytic predominance over time. CSF protein in viral meningitis and encephalitis tends to be mildly abnormal, and the glucose content, although modestly depressed to levels of 30 to 50 mg/dL in some instances, rarely reaches the low levels (10 mg/dL or lower) associated with bacterial disease. However, occasional viral infections, such as eastern equine encephalitis, a rare but serious disorder, are associated with CSF profiles that appear more bacterial than viral.

The CSF profiles in other virus-induced neurologic disorders vary widely. The CSF in viral myelitis can be normal or similar to that of aseptic meningitis (lymphocytic or mixed pleocytosis, mildly elevated protein content, and normal glucose content), and the CSF in ADEM, a condition that accounts for at least 15% of cases of viral encephalitis in children, often mimics that of viral encephalitis or meningitis. Children with GBS can have normal CSF during the early course of the disorder, but by 7 to 14 days, most display the characteristic albuminocytologic dissociation (elevated protein with few or no leukocytes).

### Neuroimaging

Computed tomography (CT) and magnetic resonance imaging (MRI) have considerable utility in evaluating pediatric patients with suspected CNS viral infections, especially when encephalitis is being considered. The sensitivity of brain MRI exceeds that of CT, especially in patients with HSV encephalitis or ADEM. The brain MRI in nonneonatal HSV encephalitis usually identifies T2 hyperintensities in the medial temporal lobe, orbitofrontal region, or cingulate gyrus; cortical enhancement in these regions, especially in the insular cortex (Fig. 115-3), supports the diagnosis of HSV encephalitis. However, atypical features can be observed in HSV encephalitis in young children, including abnormal diffusion-weighted imaging and diffuse or parietooccipital localization of T2 hyperintensities. The MRI in ADEM characteristically demonstrates multiple areas of T2 hyperintensity involving the white matter of the cerebrum, cerebellum, or brainstem. The CT or MRI in neonatal HSV encephalitis commonly shows diffuse abnormalities, consisting of brain edema, cortical enhancement and neuronal necrosis.

The brain MRI in other forms of virus encephalitis can be normal or characteristically abnormal. Children with Japanese or EBV virus encephalitis, for example, often have focal abnormalities of the thalamus and/or basal ganglia, seen best on T2-weighted or fluid-attenuated inversion recovery (FLAIR) sequences, and patients with neuroinvasive WNV infection can have MRI abnormalities of the thalamus, basal ganglia, brainstem, or spinal cord. Nipah virus produces focal lesions of the gray matter and subcortical white matter. Mild encephalitis with reversible lesions of the splenium of the corpus callosum (mild encephalitis) has been associated with several common viral and nonviral infections of childhood. In severe

**Figure 115-3.** Gadolinium-enhanced, T1-weighted brain magnetic resonance imaging in a teenager with herpes simplex virus encephalitis. The scan shows gadolinium enhancement in the right insular cortex (arrows).

cases of encephalitis, CT or MRI can reveal cerebral edema with uncus or central herniation.

Children with viral myelitis frequently have MRI abnormalities of the spinal cord, especially on T2-weighted or fluid-attenuated inversion recovery sequences, consisting of signal hyperintensities, spinal cord edema or gadolinium-enhancing lesions. These lesions may extend for several cord segments and can occasionally be hemorrhagic. The syndrome of acute flaccid paralysis, once the characteristic feature of childhood poliomyelitis, can be associated with lesions of the central cord. Patients with GBS commonly have evidence of nerve root inflammation, seen best on T1-weighted, gadolinium-enhanced sagittal MRI of the spinal cord. Pediatric patients with viral meningitis, on the other hand, typically have normal neuroimaging studies.

Cranial ultrasound, a useful, bedside study in unstable infants, detects hydrocephalus, periventricular calcifications or cystic lesions in infants with congenital viral infections. The CT effectively detects small intracranial calcifications (Fig. 115-5), although calcifications can also be detected by newer, more sensitive MRI sequences, such as susceptibility-weighted imaging. MRI has greater sensitivity than either CT or cranial ultrasonography in detecting cortical abnormalities, such as lissencephaly, polymicrogyria (Fig. 115-6), or cortical clefting, that can be present in infants with intrauterine viral infections.

### Microbiological Evaluation

Serology, cell culture, immunohistochemistry, and nucleic acid amplification techniques, such as the polymerase chain reaction (PCR), are available to detect specific etiologic pathogens in cases of suspected viral neurologic infections (Glaser et al., 2003) (Table 115-1). Serologic studies remain the principal means of diagnosing infections with the Epstein-Barr virus, LCMV, and WNV. Immunoglobulin M (IgM) capture antibody assays remain the standard diagnostic methods for children with suspected infections with several

**Figure 115-5.** Unenhanced computed tomography scan of an infant with symptomatic congenital cytomegalovirus infection. The scan shows multiple calcifications (circles) and a smooth appearance to the cerebral cortex (arrow).

**Figure 115-6.** A coronal T2-weighted magnetic resonance image in a child with congenital cytomegalovirus infection. The image shows ventriculomegaly, cerebellar hypoplasia, and cortical dysplasia (arrows).

**Table 115-1** Cerebrospinal Fluid Profiles in Central Nervous System Infections

Parameter	Organism			
	Virus	Bacterium	Mycobacterium	Fungus
Cell number*	n to ↑↑	↑ to ↑↑↑	↑ to ↑↑	n to ↑↑
Cell type†	Lymph	PMN	Lymph	Mixed
Protein content‡	n to ↑	↑ to ↑↑↑	n to ↑↑	n to ↑↑
Glucose content§	n to ↓	↓ to ↓↓↓	n to ↓	n to ↓

\*Cell number: n, <5; ↑, 10–100/mm<sup>3</sup>; ↑↑, 100–1000/mm<sup>3</sup>; ↑↑↑, >1000/mm<sup>3</sup>.

†Dominant cell type: Lymph, lymphocyte; PMN, polymorphonuclear leukocyte; Mixed, variable mix of PMNs and lymphocytes, depending on the organism. PMNs can be the dominant cerebrospinal fluid leukocyte during the early phase of viral CNS infections, and meningitis with certain bacteria, notably *Listeria monocytogenes*, can be associated with a predominance of lymphocytes. Eosinophils occasionally can be observed in viral, fungal, or parasitic CNS infections.

‡Protein content: n, <50 mg/dL; ↑, 50–100 mg/dL; ↑↑, 100–500 mg/dL; ↑↑↑, >500 mg/dL.

§Glucose content: n, cerebrospinal fluid to serum ratio of >0.6; ↓, cerebrospinal fluid to serum ratio of <0.4; ↓↓↓, 0. Virus-associated reductions in the cerebrospinal fluid glucose content are usually modest, with levels ranging from 25 to 50 mg/dL in herpes simplex, lymphocytic choriomeningitis, and mumps viruses.

arthropod-borne viruses, including La Crosse, eastern equine, western equine, and Japanese encephalitis viruses (Baron et al., 2013).

Because of enhanced sensitivity compared with cell culture, PCR has become the preferred method (“Gold Standard”) for the diagnosis of HSV encephalitis at all ages. PCR also

facilitates the diagnosis of neurologic infections with CMV, varicella-zoster virus, human herpesvirus (HHV)-6 and HHV-7, rabies virus, and the nonpolio EVs (Baron, 2013). The specificity of PCR approaches 100% for most viral pathogens, although the clinical sensitivity of PCR may vary considerably depending on the virus and the clinical setting. PCR analysis of CSF in suspected HSV encephalitis has approximately 75% sensitivity in the newborn and approximately 95% in children and adolescents. Coupling PCR with brain MRI enhances the predictive value of both studies in cases of suspected HSV encephalitis; a negative CSF HSV PCR and a normal brain MRI, for example, make HSV encephalitis exceedingly unlikely at any age. Because the clinical sensitivity of PCR in other neurologic infections of presumed viral etiology has not been determined completely, clinicians must use sound clinical judgment when managing patients with negative PCR results. In some instances, repeating the CSF examination and PCR analysis may be necessary to establish or exclude viral infections, particularly in cases of HSV encephalitis.

## Treatment

### Supportive Care

Therapy for CNS viral infections must be tailored to the severity of the illness and the availability of specific antiviral therapy (Johnson, 1998). Although numerous viruses cause neurologic disease, relatively few can be treated effectively with antiviral medications. Consequently, clinicians must carefully monitor pediatric patients for seizures, increased intracranial pressure, or respiratory compromise. Pediatric patients with severe infection-related neurologic disorders require hospitalization in nursing units, such as pediatric or neonatal intensive care units, that are experienced in managing such patients. The outcome of viral infections varies according to the pathogen, the availability of specific antiviral therapy, and the management of potential complications.

## Specific Medications

HSV encephalitis, varicella zoster virus encephalitis or myelitis, systemic or CNS HIV infections, and congenital or invasive cytomegalovirus infections can be treated with specific antiviral drugs. Although the mechanisms of action vary according to the drugs, the goal of drug therapy is to inhibit effective viral replication and reduce or prevent virus-induced neural cell damage. Survival from symptomatic human rabies has been associated in two cases in the United States with pharmacologically induced coma and antiviral therapy (Willoughby et al., 2005). Corticosteroids, intravenous immunoglobulin, and immunomodulators, such as rituximab or cyclophosphamide, can be effective in selected conditions, including GBS and myelitis, as well as ADEM and anti-N-methyl-D-aspartate receptor antibody encephalitis, conditions that mimic viral encephalitis and account for a substantial proportion of encephalitis of nonviral etiology.

## SELECTED VIRAL INFECTIONS

### Herpesviruses

The human herpesviruses, a family of large DNA viruses, can produce neurologic disorders during intrauterine, perinatal, or postnatal infections. Important members of this family are HSV-1, a major cause of focal encephalitis in children and adults; HSV-2, an important cause of neonatal infection, CMV, the most common cause of congenital infection; Epstein-Barr virus (EBV), a cause of the GBS; human HHV-6 and HHV-7, the agents of roseola and frequent causes of febrile seizures; and varicella zoster virus (VZV), a pathogen often associated with acute cerebellar ataxia in unimmunized children. Other neurologic disorders associated with the HHVs include aseptic meningitis, myelitis, optic neuritis, Bell palsy and postinfectious neuritis.

### Herpes Simplex Viruses Types 1 and 2

#### Clinical Manifestations

Most humans acquire HSV-1 by oral transmission during childhood. Some children experience gingivostomatitis, a condition associated with fever, diminished oral intake, drooling, and herpetic lesions of the throat, oral mucosa, and face. Primary infection with HSV-2, usually acquired during sexual contact, is frequently asymptomatic; genital lesions associated with HSV-2 can appear during primary or reactivated infections. HSV-associated neurologic disorders in children can be the results of either primary or reactivated infections.

Neonatal HSV infections, more often due to HSV-2, are categorized as: (1) skin, eyes, mouth disease, affecting 43% of HSV-infected neonates; (2) disseminated disease, affecting 23% of HSV-infected neonates; or (3) encephalitis, affecting 34% of HSV-infected neonates. Neonatal HSV disease begins nonspecifically with poor oral intake, somnolence, irritability, or low-grade fever as early as the first day of life, but more often during the second or third week. Neonatal HSV encephalitis, due to HSV-1 or HSV-2, can produce focal or generalized seizures, apnea, lethargy, or coma and can be accompanied by hepatitis, pneumonia, or disseminated intravascular coagulopathy. Approximately two thirds of infants with HSV encephalitis have vesicular rashes. Neonatal HSV encephalitis can be rapidly fatal due to multiorgan system failure or be indolent with apnea, bulbar dysfunction, and frequent seizures. Approximately 5% of HSV-infected infants acquire HSV in utero and display a relatively characteristic congenital syndrome with microcephaly, cataracts, intrauterine growth retardation and intracranial calcifications.

HSV encephalitis in children or adolescents, typically due to HSV-1, begins nonspecifically with headache, fever, malaise, vomiting, and somnolence. Focal or generalized seizures and focal neurologic signs, such as aphasia, visual field defects, or paralysis, appear subsequently in most infected patients (Whitley and Kimberlin, 2005). Focal abnormalities reflect the predilection of HSV to infect the frontotemporal brain regions, but other areas can be affected, especially in young children. The course of HSV encephalitis can be rapidly progressive, with intractable seizures, coma, and increased intracranial pressure, or be indolent with behavioral disturbances, memory loss, and focal seizures. HSV infections in pediatric populations have also been linked to Bell palsy, primary or recurrent aseptic meningitis (Mollaret meningitis), and myelitis.

### Diagnosis

Neonates with HSV-1 or HSV-2 can have elevated serum transaminases, direct hyperbilirubinemia, or features of disseminated intravascular coagulopathy. The CSF in neonatal HSV encephalitis contains a lymphocytic pleocytosis and elevations of the protein content; CSF glucose can be normal or mildly low. An MRI and CT usually reveal diffuse cerebral edema and cortical enhancement in the acute stages of infection, and atrophy, cystic encephalomalacia, or passive ventriculomegaly later. EEGs frequently show diffuse slowing or epileptiform discharges that can be periodic. HSV infection of the newborn can be confirmed by detecting HSV DNA in serum, CSF, or vesicular lesions using the nucleic acid amplification techniques, particularly PCR (Baron, 2013). In infants with confirmed HSV infection, PCR detected HSV DNA in the CSF of 93% of the infants with disseminated infections, 76% of the infants with encephalitis, and 24% of the infants with skin-eye-mouth disease.

In older children and adolescents with suspected HSV-1 encephalitis, MRI frequently demonstrates signal abnormalities of the temporal lobe(s) or insular cortex and gadolinium enhancement of the same areas (Fig. 115-3). Focal abnormalities can be detected in other cortical regions, including the occipital and parietal lobes, particularly during atypical infections in young children. Electroencephalograms (EEGs), abnormal in approximately 80% or more of pediatric patients with HSV encephalitis, show focal or diffuse slowing and focal epileptiform features that can be lateralized and periodic. The sensitivity and specificity of current PCR methods for detecting HSV DNA in the CSF of pediatric patients with HSV encephalitis is approximately 95% (Baron, 2013). Some of the negative results can be attributed to the timing of CSF analysis; CSF analysis in children or adolescents with suspected HSV encephalitis is most sensitive 3 to 5 days after the onset of CNS symptoms. Consequently, clinicians must interpret negative CSF PCR results for HSV cautiously. However, a negative CSF HSV-1 PCR and normal brain MRI in a patient with signs of encephalitis make HSV-1 encephalitis very unlikely.

### Treatment and Outcome

Neonates with skin-eye-mouth infections should receive acyclovir for 14 days; those with disseminated infections or encephalitis should receive the drug for 21 days (Pickering et al., 2012). Infants with neonatal encephalitis, disseminated disease, or skin-eye-mouth infections should receive suppressive therapy for 6 months thereafter. Children with HSV-1 encephalitis should also receive acyclovir every 8 hours for 21 days; because of potential nephrotoxicity, children 12 years of age and older should receive a reduced dose of acyclovir.

All acyclovir-treated infants with skin-eye-mouth HSV infections survive with no long-term sequelae, other than the

propensity to have recurrent herpetic skin lesions. Cutaneous recurrences and potential systemic dissemination of HSV during recurrences can be reduced by suppressive therapy with acyclovir. Prolonged courses of acyclovir can be associated with neutropenia and occasionally with the emergence of acyclovir-resistant HSV strains, although the risk of inducing resistance appears to be low. As many as 30% of infants with disseminated HSV infections die despite therapy, and approximately 30% of the survivors have neurologic sequelae, ranging from mild (speech or motor delay) to severe (cerebral palsy, global developmental delay, or epilepsy). Approximately 10% of neonates with HSV encephalitis die despite therapy, and 20% to 30% or more have severe neurodevelopmental sequelae, including cerebral palsy, bulbar palsy, and epilepsy. A prolonged course of acyclovir is associated with improved developmental outcome. Infants with congenital HSV infections generally have poor prognoses. The vast majority of children and adolescents with HSV-1 encephalitis survive when treated with acyclovir (Whitley, 2005). However, 40% or more have permanent sequelae with developmental delay/cognitive impairment, behavioral abnormalities, memory deficits, motor dysfunction, and epilepsy (Whitley, 2005).

Signs or symptoms of HSV encephalitis, manifesting as fever, headache, lethargy, and movement disorders, can recur in infants, children, or adolescents who have received acyclovir and appropriate supportive care. Children with suspected relapse should undergo repeat CSF analysis and MRI. If CSF PCR is positive for HSV, a repeat course of acyclovir for 21 days should be provided. If MRI suggests ADEM, high-dose methylprednisolone should be given intravenously. Some cases of relapse may be the result of the emergence of anti-N-methyl-D-aspartate (NMDA) receptor antibodies, indicating that serum and CSF should be analyzed for these antibodies (Peery et al., 2013). When anti-NMDA receptor antibodies are detected, methylprednisolone should be administered; intravenous immunoglobulin (IVIg) and/or rituximab may be required in such patients should methylprednisolone not provide benefit. Recovery from anti-NMDA receptor encephalitis can be protracted (Peery, 2013).

## CYTOMEGALOVIRUS

### Clinical Manifestations

CMV infections have been associated with several neurologic conditions, including congenital infection, infantile spasms, GBS, myelitis, and encephalitis. Some conditions, such as infantile spasms and GBS, occur in immune competent hosts, whereas others, such as encephalitis and myelitis, occur more often in immunocompromised hosts, especially those with HIV/AIDS. Approximately 1% of infants shed CMV at birth, indicating congenital infection. Humans acquire CMV steadily thereafter throughout life such that, by late adulthood, the majority of persons have been infected with CMV, most often without recognizable symptoms.

Approximately 10% of CMV-infected newborns have signs of congenital infection, including intrauterine growth retardation, microcephaly, hepatomegaly, splenomegaly, jaundice, petechiae, purpura, or chorioretinitis. CMV has been linked to infantile spasms, predominantly in infants with symptomatic congenital CMV infections. CMV-infected, immunocompetent children or adolescents may have GBS or a mild, self-limited encephalitis, associated with seizures and altered consciousness. Patients immunocompromised by HIV/AIDS, malignancy, transplantation, or immunosuppressive therapy are at risk of severe, invasive CMV-induced disease, including hepatitis, colitis, retinitis, encephalitis, myelitis, and GBS-like disorders.

## Diagnosis

Intrauterine CMV infections can be confirmed by assaying saliva or urine using cell culture or PCR methods. Newborn blood spot analysis can be used to establish the diagnosis of congenital CMV infection retrospectively. CMV infection in older children or adults can be established by detecting CMV in urine, saliva, serum, or CSF using PCR. Head CT detects intracranial calcifications in 25% to 50% of symptomatic infants with congenital CMV infection. Many other abnormalities seen in congenitally infected infants, such as hydranencephaly, lissencephaly, schizencephaly, white matter lesions, and cerebral or cerebellar atrophy, can be identified better by MRI (Fig. 115-6). CT or MRI in children with acquired CMV infections can detect abnormalities of the brain or spinal cord including demyelination, edema or inflammation.

## Treatment and Outcome

Infants and children who survive symptomatic congenital CMV infection have high rates of permanent neurodevelopmental disorders including cognitive impairment, cerebral palsy, visual impairment, sensorineural hearing loss, and epilepsy. Approximately 35% to 50% of infants with symptomatic congenital CMV infections have sensorineural hearing loss. Infants with asymptomatic congenital CMV infections have an 8% to 10% risk of sensorineural hearing loss that can be evident at birth or appear later in childhood, usually by age 8 years. Infants with abnormal head CT or MRI studies have higher rates of adverse neurodevelopmental outcomes.

Prolonged treatment with ganciclovir can improve hearing and neurodevelopmental outcomes in infants with symptomatic congenital CMV infections. Bone marrow suppression and nephrotoxicity are potential side effects. Although studies of a human vaccine based on glycoprotein B, the major immunogenic protein of CMV, were encouraging, no vaccine is currently available to prevent congenital CMV infection. Immunocompromised children with invasive CMV disease, especially retinitis or CNS infections, should also receive ganciclovir. Children or adolescents with CMV-associated GBS require therapy with intravenous immunoglobulin using standard doses.

## EPSTEIN-BARR VIRUS

### Clinical Manifestations

Encephalitis caused by the EBV accounts for approximately 5% of encephalitis cases in childhood and produces fever, headache, altered consciousness, and seizures, including acute status epilepticus. The Alice-in-Wonderland syndrome, which can accompany mild cases of EBV encephalitis, causes personality changes and illusions or hallucinations of distorted size, shape, or distance ("metamorphopsia").

### Diagnosis, Treatment, and Outcome

Acute or recent infection is suggested by the presence of EBV viral capsid antigen (VCA) IgM or IgG and the absence of EBV nuclear antigen (EBNA) IgG. The presence of EBNA IgG indicates past infection. A positive serum heterophile antibody response supports acute or recent EBV infection, although young children frequently have false negative results. An EBV infection also can be established by using PCR to detect EBV DNA in CSF, although this assay can be negative in EBV encephalitis (Baron et al., 2013). Pediatric patients with EBV infection also frequently have elevated serum transaminases or hematological abnormalities consisting of thrombocytopenia, leukopenia and atypical lymphocytosis.

During acute EBV encephalitis or the Alice-in-Wonderland syndrome, EEGs may show slowing or epileptiform discharges. Neuroimaging studies can occasionally be abnormal, showing features similar to acute disseminated encephalomyelitis. Although most children with EBV encephalitis recover completely with supportive care, some have permanent neurologic sequelae. Anecdotal reports suggest that therapy with acyclovir or ganciclovir may be beneficial in severe, invasive EBV infections, although no controlled studies have been conducted to assess efficacy. The prognosis for other EBV-associated neurologic conditions, such as GBS, Bell palsy, ataxia, or chorea, is generally favorable.

## FLAVIVIRUSES

### West Nile Virus

In 1999, WNV encephalitis, linked to a virus strain closely related to a strain identified in Israel in 1998, caused seven deaths among adults in the New York City metropolitan area, marking the first appearance of WNV in the Western Hemisphere. By 2000, WNV was detected in 12 states surrounding New York (210). WNV spread rapidly among North American birds and mosquitoes thereafter, leading to a massive human outbreak in 2003 that affected nearly 10,000 persons from New York to California. WNV activity has persisted, making WNV the most common neuroinvasive arboviral disease in the United States.

WNV is maintained in a bird–mosquito cycle, involving rural and urban wild birds and *Culex* and *Aedes* mosquitoes in several areas of the world (Fig. 115-2). Humans typically acquire WNV from mosquito bites, although human-to-human transmission by organ transplantation and blood transfusion can occur. Neuroinvasive disease, including meningitis, encephalitis, myelitis, and polio-like illness, affects approximately 1 of every 150 infected persons, and adults comprise the majority of cases.

### Clinical Features

After an incubation period of 2 to 14 days, systemic symptoms of fever, malaise, headache, nausea, and vomiting occur in symptomatic infections. Of symptomatic patients, 50% have a maculopapular rash and lymphadenopathy. Encephalitis, affecting approximately 60% of persons with WNV neuroinvasive disease, manifests as altered mental status, coma, diffuse muscle weakness (proximal greater than distal), respiratory paralysis, and hyporeflexia. Tremor, myoclonus, and parkinsonian features are additional components of the acute illness. Less common neurologic manifestations of WNV infection include aseptic meningitis, myelitis, optic neuritis, and GBS. Involvement of the anterior horn cells can lead to a poliomyelitis-like disorder with asymmetric paralysis of the upper or lower extremities. A single report suggests that WNV can cause intrauterine CNS infection.

### Diagnosis, Treatment, and Outcome

The CSF of WNV encephalitis has a mild, lymphocytic pleocytosis (30 to 100 cells/ $\mu$ L), elevated protein content (80 to 100 mg/dL), and normal glucose content. Cranial CT is normal, whereas MRI can reveal leptomeningeal enhancement, periventricular inflammation, or abnormalities of the spinal cord. The diagnosis of WNV infection can be confirmed by detecting neutralizing antibodies to the virus in acute or convalescent serum samples or WNV-specific IgM in serum or CSF. WNV-specific IgM persists in serum for at least 16 months in more than half of infected persons. Infected patients experience brief periods of viremia, but infectious virus is rarely

isolated from serum or CSF; reverse transcription PCR can sometimes detect WNV in clinical samples. A CDC protocol guides the evaluation of infants with potential intrauterine WNV infection.

Therapy for the neurologic complications of WNV infection currently consists of supportive care, with close observation for respiratory decompensation. The mortality rate for WNV neuroinvasive disease is approximately 5%, and most deaths occur among the elderly. Approximately one third of survivors of neuroinvasive disease have permanent sequelae affecting cognition, behavior, or motor function. Patients with limb paralysis usually have permanent deficits.

## PARAMYXOVIRUSES

### Measles and Subacute Sclerosing Panencephalitis

Before vaccine availability, measles typically caused disease in infants and young children during the winter and spring. Symptoms of measles include fever, cough, coryza, and conjunctivitis, beginning approximately 12 days after exposure in susceptible persons. The characteristic morbilliform, maculopapular exanthem appears on the face and spreads centrifugally to involve the trunk and extremities.

### Clinical Features

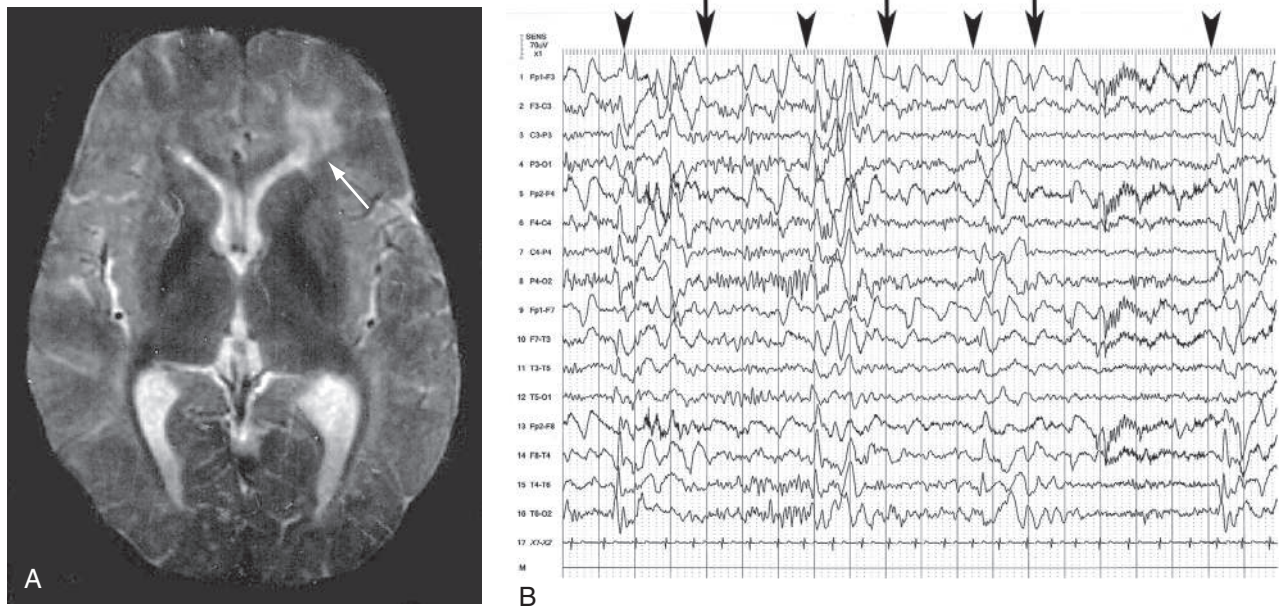

Approximately 1 of every 1000 measles virus-infected children experienced measles encephalitis, either from direct brain infection or immune-mediated mechanisms. SSPE, a neurodegenerative disease caused by persistent infection of the brain by a mutated form of the measles virus, results from a complex and poorly understood interaction between the host's immune system and the measles virus. The risk of SSPE correlates with age; the prevalence of SSPE is nearly 20 per 100,000 when measles occurs under 1 year of age versus 1 per 100,000 for infections after 5 years of age. The disorder displays relatively stereotyped clinical stages, beginning with insidious declines in behavior and cognition mimicking a psychiatric disorder. Myoclonus, a prominent component of the next phase of disease, involves the extremities, trunk, or head. Generalized or focal seizures may begin concurrently. As the disorder progresses, speech and intellectual function deteriorate; myoclonus intensifies; and other neurologic abnormalities, such as choreoathetosis, bradykinesia, or rigidity, appear. Approximately half of patients have chorioretinitis and visual impairment. The disorder typically ends in debility, coma, and death. SSPE is rare in the United States and other regions with mandatory vaccination programs.

### Diagnosis

Children with measles encephalitis can have CSF pleocytosis and elevated protein content. Patients with SSPE have elevated CSF immunoglobulin levels, oligoclonal bands, and increased IgG synthesis rates, indicating dramatic production of measles-specific IgG. High CSF titers of measles-specific IgG establish the diagnosis of SSPE, and measles virus RNA can be detected in CSF or plasma by reverse transcription PCR. EEGs show bilaterally synchronous spike-wave or slow-wave bursts with regular periodicity that eventually assume a suppression-burst pattern, and MRI commonly exhibits T2 prolongation of subcortical and periventricular white matter and eventually cortical atrophy (Fig. 115-14).

### Treatment and Outcome

Unfortunately, SSPE cannot be effectively treated. Antiviral agents, including isoprinosine and ribavirin, immunoglobulin

**Figure 115-14.** Magnetic resonance imaging (MRI) scan and electroencephalogram from a 13-year-old boy with subacute sclerosing panencephalitis (SSPE). **A**, T2-weighted MRI scan demonstrates a hyperintense signal abnormality in the white matter of the left frontal lobe (*arrow*). **B**, EEG shows periodic bursts of high amplitude slow wave complexes (*onset marked by arrowheads; offset marked by arrows*), a pattern characteristic of SSPE.

therapy, interferons, and H2 receptor blockers, have been tried, alone and in combination, with little or no effect on the disease course. Divalproex sodium, clonazepam, or levetiracetam may provide some relief for SSPE-associated myoclonus.

## RHABDOVIRUSES

### Rabies Virus

#### Clinical Features

Rabies poses a threat to individuals in many regions of the world, especially in the developing countries of Africa and Asia, where the incidence of 1 in 100,000 to 1 million inhabitants corresponds to 25,000 to 50,000 deaths annually. In these regions, unvaccinated domestic dogs transmit rabies virus to humans, and children constitute most human rabies cases. By contrast, human rabies is rare in the US and has been eradicated in a few regions as a result of quarantine and vaccination of domestic animals (Johnson, 1998). Most recently, domestically acquired human rabies cases in the US have been linked to strains carried by bats, often the insectivorous silver-haired and Brazilian free-tailed bats.

After a variable incubation period, averaging 20 to 60 days, human rabies begins with chills, fever, headache, sore throat, malaise, nausea, or abdominal pain (Johnson, 1998; Willoughby, 2005). Pain or itching corresponding to the site of inoculation is common. Neurologic symptoms and signs begin thereafter; symptoms and signs are cerebral in 80% and GBS-like in the remainder. Patients with cerebral symptoms have agitation, hypersalivation, delirium, opisthotonic posturing, and seizures. Hydrophobia, present in 20% to 50%, produces spasms of the laryngeal muscles, diaphragm, and accessory respiratory muscles, and leads to respiratory arrest and death. Patients with rabies encephalitis eventually lapse into a fatal coma. Paralytic rabies induces a GBS-like disorder with muscle paralysis, bulbar dysfunction, cardiac arrhythmias, coma, respiratory arrest, and death (Johnson, 1998).

#### Diagnosis

Human rabies, often unsuspected during the early, nonspecific phase, is identified most often at postmortem examination. Premortem diagnosis can be established by immunofluorescence examination of skin from the nape of the neck, detection of rabies virus antibody in CSF or serum (assuming the patient was not vaccinated previously), or isolation of rabies virus from saliva or CSF (Johnson, 1998). Reverse transcription PCR can be used to detect rabies virus and determine the molecular profile and origin of the virus strain. The CSF may be normal or reveal a mixed or lymphocytic pleocytosis and mild protein elevation (Johnson, 1998). The CT is normal; MRI can demonstrate signal abnormalities of the basal ganglia or thalami.

#### Treatment and Outcome

In the United States, where almost all domestic cats and dogs are vaccinated, people must avoid contact with wild animals, especially bats. However, caution must also be exerted around unfamiliar cats and dogs, as unvaccinated free-roaming cats and dogs remain sources of rabies in the United States. In many developing countries, rabies remains prevalent among wild and domesticated dogs. Consequently, rabies is a major concern for travelers to India, the Philippines, Mexico, Morocco, and Algeria. Risk factors include young age and tourism. Therefore travelers should avoid animals and immediately cleanse and disinfect any animal-related injuries.

Virtually 100% of humans with symptomatic rabies die despite supportive care, and only a handful of survivors have been reported in the medical literature over the past four decades (Willoughby, 2005). Children with suspected or possible rabies exposures, including anyone with exposure to live or dead bats, should receive postexposure prophylaxis in accordance with public health guidelines, taking into account the animal species and the nature of the exposure. All postexposure treatment should begin with immediate and thorough cleansing of the wound with soap and water (Johnson, 1998).

Human-to-human transmission of rabies virus has been reported after corneal and organ transplantation, but transmission by body fluids has not been described. Nonetheless, persons with suspected rabies should be maintained in strict isolation to minimize contact with rabies virus-contaminated fluids and to reduce the number of health-care workers who require postexposure prophylaxis.

## ARENAVIRUSES

### Lymphocytic Choriomeningitis Virus

Most human infections with LCMV are transmitted by the common house mouse, *Mus musculus*, but human disease has also been linked to hamsters and laboratory mice. Postnatal infections are relatively minor, although those of prenatal infections are usually severe. Acquired LCMV infection can produce a nonspecific, influenza-like disorder, with fever, headache, myalgia, nausea, vomiting, backache, and cough. Virtually all infants with congenital LCMV infections have chorioretinitis, and most also have microcephaly and periventricular calcifications. Other infants have porencephaly, neuronal migration defects, hydrocephalus, or cerebellar hypoplasia. LCMV rarely damages the systemic organs of congenitally infected infants. The diagnosis of congenital LCMV infection can be established by detecting LCMV-specific antibodies in CSF or serum, and potentially by detecting LCMV RNA in CSF with reverse transcription PCR. Current antiviral drugs do not possess clinically useful anti-LCMV activity. Cognitive impairment, vision loss, epilepsy, cerebral palsy, and ataxia are commonly present in congenitally infected infants.

## INFLUENZA VIRUSES

Although primarily causing disease of the respiratory system, influenza viruses can occasionally induce CNS disease. Encephalitis lethargica, associated with the influenza A pandemic of 1918, caused ophthalmoplegia, vomiting, vertigo, stupor, and coma. In the 1960s, Reye syndrome, a disorder of the liver and brain most frequently associated with influenza B infections, produced intractable vomiting, lethargy, coma, hyperammonemia, and other signs of liver dysfunction. Pernicious cerebral edema led to coma, decorticate posturing, and death. After peaking in the 1970s, the prevalence of Reye syndrome declined dramatically, largely due to the avoidance of aspirin in children with influenza-like symptoms or varicella, another triggering infection.

Influenza encephalopathy, currently the most common neurologic complication of influenza virus infection, begins within a few days of the onset of respiratory symptoms and produces confusion, delirium, and sometimes seizures, including status epilepticus refractory to anticonvulsant therapy. Children under the age of 6 years are at highest risk. The CSF usually contains no leukocytes and has normal glucose and protein concentrations, and although the brain MRI is often normal, diffuse cerebral edema can be identified. Most patients with uncomplicated influenza encephalopathy have favorable outcomes.

Children with acute necrotizing encephalopathy (ANE), a more severe CNS condition associated with the influenza viruses, are critically ill with coma and markedly abnormal neuroimaging; death occurs in more than 30%. Children under the age of 6 years are at highest risk, but older children and adults have been affected, as well. The CSF usually has an elevated opening pressure, lacks pleocytosis, and usually has normal glucose and protein concentrations. MRI often demonstrates areas of T2-weighted hyperintensity in the thalami,

basal ganglia, brainstem, and cerebral white matter. No effective therapy has been identified, and approximately 50% of the survivors have permanent neurodevelopmental sequelae. Although the pathogenesis of sporadic ANE is poorly understood, mutations in the nuclear pore gene *RANBP2* contribute to familial and recurrent cases of ANE.

## RETROVIRUSES

The HIV type 1 (HIV-1), HIV type 2 (HIV-2), and human T-cell lymphotropic virus type 1 (HTLV-1) are human retroviruses that were linked in the 1980s to HIV/AIDS and progressive myelopathy, respectively. Maintained in human reservoirs and transmitted via virus-contaminated human fluids or blood products, the retroviruses produce neurologic disease during primary infection or virus reactivation. Cures or vaccines to prevent these infections have not yet been identified.

### Human Immunodeficiency Virus

#### Clinical Features

Early cases of AIDS in children were linked to blood transfusions, hemophilia requiring factor replacement, or having a parent with AIDS or an AIDS-related condition. Most HIV-1 infections in infants and children are now the result of vertically transmitted HIV-1 via the placenta, during delivery, or via breast milk. The offspring of untreated, HIV-1-infected women have a 20% to 45% risk of infection. With current combination antiretroviral treatment and management strategies, the risk of vertical transmission of HIV can be reduced to 2% or less. HIV-1 infection remains a major threat to the world's population; approximately 35 million people are living with HIV/AIDS worldwide and approximately 3.4 million of these are children. More than 1.5 million people die of AIDS each year, and nearly 40 million people have died from AIDS since the first cases were identified.

Infants infected vertically with HIV-1 can become symptomatic after the third month of life, manifesting hepatomegaly, lymphadenopathy, failure to thrive, interstitial pneumonitis, opportunistic infections (especially with *Pneumocystis jiroveci* [formerly, *Pneumocystis carinii*] or cytomegalovirus), or neurologic disease. In some children HIV-1 infection can remain dormant, however, and 10 or more years may lapse before the symptoms of HIV-1 infection appear. Before current combination antiretroviral therapies, a child infected vertically with HIV-1 had a 50% probability of HIV/AIDS-related disease by age 5 years.

Before the initiation of antiretroviral therapy, infants and children with HIV-1 can display global developmental delay, seizures, attention-deficit/hyperactivity disorder, behavioral problems, or school failure. Neurologic findings attributable to the direct CNS effects of HIV-1 include microcephaly and spastic diplegia. HIV-1 invades the CNS early after intrauterine or postnatal infection and displays tropism for microglia/macrophages and astrocytes; microglia and macrophages are the principal reservoirs of HIV-1 infection within the CNS.

#### Diagnosis

Passive transfer of maternal antibody complicates the diagnosis of HIV-1 infection during the first 18 months of life. Consequently, detection of HIV-1 nucleic acids (DNA or RNA) by the PCR is necessary to identify HIV-1 infections in young infants. HIV-1 infection in exposed infants (i.e., infants with positive antibody tests shortly after birth or infants born to HIV-1-seropositive mothers) can be confirmed by serial serum PCR assays, with the first test in the immediate newborn

period, a second test during the first or second month of life, and a third test at 4 to 6 months of age. If two samples are positive for HIV-1, the infant is considered infected; two successive negative tests indicate that infection is unlikely. In children and adolescents, serologic studies using enzyme-linked immunosorbent assay and Western blotting can identify HIV-1 infection.

The CSF is usually normal in HIV-1-associated progressive encephalopathy, whereas the EEG may exhibit diffuse slowing. Neuroimaging studies reveal cortical atrophy in vertically or horizontally acquired infections. Calcifications of the basal ganglia or frontal white matter—best detected by CT—and nonspecific abnormalities of white or gray matter—most evident by MRI—occur in vertically acquired HIV infections.

### Treatment and Outcome

With currently available medications, the risk of death from AIDS has declined dramatically. Current strategies use combinations of at least three different antiretroviral drugs from the classes of nucleoside analog reverse transcriptase inhibitors, protease inhibitors, and nonnucleoside reverse transcriptase inhibitors. Because treatment of HIV/AIDS continues to evolve, individuals and centers experienced in HIV/AIDS treatment should be consulted regarding current therapeutic approaches. For updated, downloadable information regarding the available antiretroviral therapies and current evaluation and treatment guidelines for pediatric HIV/AIDS, see [www.aidsinfo.nih.gov](http://www.aidsinfo.nih.gov).

## EMERGING VIRAL INFECTIONS

### Nipah Virus

In the fall of 1998, an outbreak of severe encephalitis appeared in Malaysia due to a paramyxovirus, named Nipah virus after the Malaysian village in which the virus was first detected. The clinical features included fever, headache, vomiting, cough, cerebellar signs, pupillary abnormalities, seizures, autonomic dysfunction, and coma. The initial outbreak of Nipah encephalitis resulted from contact with pigs or with pig excrement, and after slaughter and disposal of pigs, the initial outbreak ended. Fruit bats (genus *Pteropus*) serve as a natural reservoir of the virus, and during recent outbreaks, person-to-person spread, as well as foodborne transmission, has been documented. The disease remains highly fatal; cognitive impairment is common among survivors.

### Dengue Virus

Dengue virus, spread by the bites of *Aedes aegypti* or *Aedes albopictus* mosquitoes, commonly causes “breakbone fever,” a self-limited disorder associated with high fever, headache, myalgia, bone pain, rash, and easy bruising. The more severe form of infection, dengue hemorrhagic fever, produces severe abdominal pain, dyspnea, and persistent vomiting, and deaths can result from shock or congestive heart failure. Dengue virus infections in adults and children have been associated rarely with encephalitis manifesting with fever, seizures, weakness, or alterations in consciousness. Neurodiagnostic features consist of CSF pleocytosis, EEG slowing, and cerebral edema or focal areas of T2 hyperintensity on MRI. The diagnosis is established by detecting virus in clinical samples, serologic responses using IgM antibody capture enzyme-linked immunosorbent assay (MAC-ELISA), or viral nucleic acids in serum or CSF using real time, reverse transcription PCR. At present, treatment consists of fluid replacement, supportive care, and avoidance of medications, such as aspirin, that potentiate the hemorrhagic complications.

### Parechoviruses

The human parechoviruses (HPeVs), members of the picornavirus family, have been linked to neonatal encephalitis and injury to cerebral white matter. Infected infants have sepsis-like illnesses, accompanied by rash, irritability, and seizures. Although CSF should be obtained to exclude other conditions, including neonatal HSV infections, CSF pleocytosis is uncommon. Parechovirus infection can be confirmed by reverse transcription PCR analysis of blood or CSF, or by culturing the virus from CSF, stool, or nasopharyngeal secretions. Given the propensity of HPeVs to damage the white matter, infants with confirmed infections should undergo serial examination by MRI. There is no effective antiviral treatment for infection with HPeVs.

### Chikungunya Virus

Chikungunya virus, an alphavirus of the *Togaviridae* family, is transmitted to humans and other amplifying hosts by *Aedes* mosquitoes. In December 2013, chikungunya virus first appeared in the Western Hemisphere and within 7 months, the virus caused more than 400,000 cases of disease in more than 20 countries in the Caribbean and in Central and South America. The term *chikungunya* translates as “disease that bends up the joints,” reflecting the severe pains affecting the wrists, hands, knees, and ankles. In some patients, chikungunya virus causes encephalitis with altered mental status, seizures, coma, and, occasionally, death. Newborns who acquire chikungunya virus perinatally can develop a severe encephalopathy, with high rates of morbidity and mortality. Children who survive perinatal chikungunya infection frequently have microcephaly, global developmental delay, and cerebral palsy. Thus far, few cases of chikungunya virus have been acquired in the continental United States.

### Zika Virus

First isolated from a rhesus monkey infected with a previously unknown virus in the Zika Forest of Uganda in the late 1940s, Zika virus belongs to the *flaviviridae*, a family of RNA viruses transmitted to humans by arthropod vectors (Hayes, 2009). Zika virus, related to St. Louis encephalitis and yellow fever viruses, naturally circulates among primates and *Aedes* species mosquitoes, particularly *Aedes africanus*, in endemic regions of Africa and Asia. Until recently, Zika virus infrequently caused human disease.

In 2007, Zika virus appeared in Micronesia, and in the fall of 2013 the virus caused a massive human outbreak in French Polynesia, eventually affecting nearly 30,000 persons or more than 10% of the population (Musso et al., 2014). Most infected persons had a mild viral syndrome with low-grade fever, conjunctivitis, arthralgias, and a maculopapular rash, but some experienced Guillain-Barré syndrome approximately 1 week after Zika virus infection (Oehler et al., 2013). The virus continued its eastward trajectory and in early 2015, cases of Zika virus began to appear in Brazil, most likely transmitted to humans by *Aedes aegypti*, a mosquito species prevalent throughout the Americas.

As with prior outbreaks, the majority of human infections (~80%) in Brazil occurred asymptotically; when symptoms occurred, they mirrored those of the French Polynesia outbreak. In contrast to the Polynesian outbreak, however, the Brazilian epidemic was associated with a marked increase in the numbers of infants born with microcephaly and intracranial calcifications, suggesting intrauterine transmission of Zika virus and damage to the developing central nervous system (Mlakar et al., 2016). Zika virus infection of the fetus

was confirmed by isolation of the virus from placenta, amniotic fluid and brain tissue. In addition to the apparent effects of Zika virus on the brain, congenital Zika virus infections have been associated with optic nerve hypoplasia and abnormalities of the retinal pigment (Ventura et al., 2016).

Zika virus infection should be suspected in infants with microcephaly, intracranial calcifications and ophthalmological abnormalities in the absence of microbiological evidence for the agents typically associated with congenital infection, including CMV, lymphocytic choriomeningitis virus, rubella virus, *Toxoplasma gondii*, *Treponema pallidum*, herpes simplex virus, herpes zoster virus, and *Trypanosoma cruzi*. The diagnosis of Zika virus infection can be established by serologic testing of mothers and infants for Zika virus-specific IgM or neutralizing antibodies and RT-PCR testing of the infant's serum and CSF for Zika virus RNA (Staples et al., 2016). At time of this writing many questions regarding maternal-fetal transmission, the clinical spectrum, and the neuropathogenesis of congenital Zika virus infection remain unanswered. The virus represents an ominous, potential threat to pregnant women visiting or residing within the host range of *Aedes aegypti* mosquitoes, including the United States.

**Table 115-3** Outcome of Selected Viral Central Nervous System Disorders

# 116 Fungal, Rickettsial, and Parasitic Diseases of the Nervous System

Alexander L. Greninger and Carol A. Glaser

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## FUNGAL DISEASES

The importance of invasive fungal infections, including those of the central nervous system (CNS), has risen as the population of immunologically compromised patients, including preterm infants, has grown. Patients with congenital immunological deficiencies, aplastic anemia, poorly controlled human immunodeficiency virus (HIV) infection, patients receiving chemotherapy as well as transplant recipients are susceptible. The normal host can also develop invasive fungal infection but does so less often and to a smaller spectrum of organisms.

Fungal diseases involving the brain are usually spread via the bloodstream after a systemic or pulmonary focus is established. Alternatively, these pathogens invade the CNS via direct extension from adjacent sinuses, the cranial vault, orbits, or the spine. With exceptions such as *Candida* spp. meningitis in premature neonates and *Aspergillus* spp. brain abscess in the highly compromised host, CNS fungal infections in children are rare. Table 116-1 provides a more extensive list of risk factors, syndromes, and treatments for fungal infections of the nervous system. Because clinical manifestations of CNS fungal infections can be subtle and not specific to individual pathogens, errors and delays in diagnosis occur. Fungi may cause a variety of clinical syndromes, including meningitis, brain abscesses, granulomas, and invasion of the vasculature, further complicating clinical presentation and treatment.

### Cryptococcosis

Cryptococcosis is globally distributed and is most commonly seen in patients with acquired immunodeficiency syndrome (AIDS) and in those receiving systemic corticosteroids; infection also occurs in those without apparent predisposition but at a lower frequency. Infants have contracted the disease, and vertical transmission has been reported from a mother with advanced AIDS. The mode of entry in humans is probably through inhalation or ingestion, and dissemination to the nervous system can follow. The most common cause, *Cryptococcus neoformans*, is encapsulated yeast found widely in the environment, particularly in bird feces and soil (Fig. 116-1). Infection with *Cryptococcus gattii* is emerging in humans in British Columbia and the northwestern United States. Notably, *C. gattii* most often affects immunocompetent individuals.

*Cryptococcus* most often causes a meningoencephalitis but can also cause brain abscess and cryptococcomas. Typical meningitis features such as nausea, vomiting, headache, and fever are often present. Caution is urged in ruling out the diagnosis based on history and physical examination alone because presenting symptoms may be nonspecific and a substantial number of patients are afebrile and lack meningeal signs. In AIDS patients, CNS *Cryptococcus* tends to be acute, with fever and headache in 70%; meningismus, photophobia,

or mental status changes in 20% to 25%; and focal deficits in a small percentage. A substantial minority of these patients may have initially normal CSF cell counts, glucose, and protein.

When *C. neoformans* causes mass lesions, it can result in papilledema, cranial neuropathies, and hemiparesis. Brain abscess and cryptococcomas may begin with an indolent course, but hydrocephalus occurs and often necessitates shunting; if untreated, the mortality is high. *Cryptococcus* can be identified by culturing CSF on Sabouraud agar, but large volume culture on more than one occasion may be needed. Latex agglutination detection of cryptococcal antigen is a rapid and useful adjunct test for both serum and CSF specimens. The Infectious Disease Society of America (IDSA) recently published treatment guidelines and recommends an initial combination of amphotericin B and flucytosine for cryptococcal CNS disease in all age groups, regardless of HIV status (Perfect et al., 2010).

### Coccidioidomycosis

Coccidioidomycosis is caused by the fungus *Coccidioides immitis*. Disease caused by *C. immitis* most commonly occurs in the southwestern United States, northern Mexico, and portions of Central and South America. Coccidioidomycosis is acquired by inhalation of spore-laden dust or transcutaneously after skin abrasion. Only 40% of acutely infected normal hosts experience acute respiratory symptoms, typically within 3 weeks after exposure and accompanied by fever, chills, night sweats, cough, anorexia, and weight loss. Dissemination of the infection from the pulmonary focus to distant sites usually occurs 1 to 6 months after primary infection in approximately 0.5% of cases; half of these are meningitis. Other sites of dissemination include skin, lymph nodes, bones, and joints. The risk of dissemination is highest in patients of Filipino, African American, and Hispanic backgrounds and in immunocompromised individuals.

The clinical characteristics of coccidioidal meningitis are nonspecific and prompt diagnosis can be difficult. The most prevalent manifestations are headache, fever, malaise, and weight loss; meningismus may be absent (Saitoh et al., 2000). Findings can include confusion, personality changes, focal neurologic deficits, ataxia, obtundation, and coma. Brain and spinal cord abscesses can occur with or without concurrent meningitis. Spinal cord symptoms may also occur in conjunction with coccidioidal osteomyelitis of the cervical vertebrae. CSF abnormalities include mononuclear pleocytosis, increased protein content, increased chloride concentration, and normal or decreased glucose concentration. Diagnosis can be confirmed by either direct microscopy or culture of the CSF (Fig. 116-2). Unfortunately, CSF cultures and microscopy are often negative in *C. immitis* meningitis, requiring other testing. Complement fixation and precipitin tests provide accurate

diagnosis in more than 99% of patients with disseminated infection.

The 2008 IDSA guidelines for treatment of coccidioidal meningitis recommend oral fluconazole or itraconazole for all patients; intrathecal amphotericin was recommended by some clinicians but was graded C-III (poor evidence) by the IDSA.

### North American Blastomycosis

Blastomycosis is caused by inhalation of airborne spores from *Blastomycosis dermatitidis*, a dimorphic fungus found in soil. The endemic area includes the midwestern, southeastern, and south central United States, and the Canadian provinces near the Great Lakes and the St. Lawrence Seaway. The spectrum of clinical manifestations in adults includes pulmonary disease, acute and chronic skin disease, and disseminated disease involving the bones, the genitourinary tract, or the CNS. The three major CNS clinical manifestations are meningitis, intracranial mass, and spinal mass. Children are infrequently affected but suffer a similar spectrum of illness as adults.

In pulmonary disease, the organism can be identified on microscopy and culture of respiratory tract specimens. For CNS disease, ventricular and cisternal fluid may have a higher yield than lumbar CSF, which is rarely positive. Amphotericin B for 4 to 6 weeks is recommended for moderate to severe disease, followed by prolonged treatment with oral fluconazole, itraconazole, or voriconazole.

### South American Blastomycosis

South American blastomycosis is caused by the fungus *Paracoccidioides brasiliensis*. Acquisition of disease is restricted to people living in latitudes between Mexico and Argentina, with most patients reported from Brazil. CNS involvement may follow disseminated infection. The most common findings of CNS infections included seizures, hemiparesis, cerebellar signs, and hydrocephalus. CNS infection usually causes single or multiple mass lesions that appear hypodense and enhance on CT scan; MRI may show contrast-enhancing brain lesions with occasional meningeal involvement.

CSF findings are typically normal, except for slightly elevated protein, and CSF cultures are often negative. The diagnosis of South American blastomycosis is best suggested by simultaneous involvement of several organs or by characteristic oral and skin lesions in patients who reside in endemic areas. Brazilian guidelines on treatment are available in Portuguese and recommend that CNS infection be treated with trimethoprim-sulfamethoxazole for prolonged periods.

### Histoplasmosis

Histoplasmosis is globally distributed; *Histoplasma capsulatum* is found in the Americas (the Mississippi River basin, Mexico, and Central and South America), and *Histoplasma duboisii* is found in Africa. In most cases, infection is self-limited, but an estimated 10% of those infected with *Histoplasma capsulatum* develop pulmonary symptoms to a degree prompting medical evaluation; those younger than 2 years, the elderly, and those with immunocompromising conditions are more likely to be symptomatic. Only a small subset of individuals with primary histoplasmosis develops disseminated disease, and an even smaller group develops a CNS infection. *Histoplasma* can remain quiescent in the lungs or the adrenal glands for more than 40 years before dissemination.

Most children with respiratory infection are asymptomatic. Fever, chills, and a productive cough can occur, and initial chest radiographs may document a nodular or diffuse infiltrate. Years later, chest radiographs demonstrate characteristic

calcification in the central lymph nodes and peripheral lung fields.

Signs and symptoms associated with CNS involvement in children include memory impairment, confusion, seizures, ataxia, cranial nerve palsies, and urinary incontinence. Neuroimaging may show evidence of hydrocephalus. Diagnosis is made via a four-fold rise in complement fixation titers between acute and convalescent specimens; a single elevated titer in the correct clinical setting is diagnostic. The organism can be directly detected through culture of CSF, blood, and bone marrow, and through biopsy of liver, bone marrow, and lymph nodes.

CNS infection in children should be treated with amphotericin B followed by itraconazole, according to the 2007 IDSA guidelines.

### Nocardia

*Nocardia* spp., gram-positive, branching, filamentous bacteria, are ubiquitous in the environment; *Nocardia asteroides*, *Nocardia farcinica*, and *Nocardia brasiliensis* are the species most often responsible for clinical disease. Risk factors for pediatric CNS infections include malignancy, chronic granulomatous disease, lupus, HIV infection, organ transplantation, and surgery.

Brain abscess is the most frequently reported CNS manifestation of nocardial infection, but meningitis can occur, typically after rupture of an abscess or, more rarely, as the primary presentation.

Diagnosis of *Nocardia* brain abscess may require a drainage procedure to obtain an adequate specimen for prolonged laboratory incubation to ensure growth on culture. Treatment and management of nocardial CNS infection requires multiple agents for prolonged periods and susceptibility testing should be done at a reference laboratory.

### Actinomycosis

*Actinomyces* spp. are anaerobic or microaerophilic, gram-positive, nonspore forming, branching bacilli that normally colonize the mouth, intestine, and female genital tract. CNS disease in young children has not been reported, but risk factors for CNS disease in older children and adults include untreated focal infections, immunosuppression, and congenital heart disease with right-to-left shunts.

Actinomycosis is a chronic, slow-growing, inflammatory mass, most frequently affecting the lungs, cervicofacial region, abdomen, and pelvis (in association with intrauterine devices). Cerebral involvement is rare and manifested as an abscess (solitary or multiple) and, less commonly, meningitis. CNS *Actinomyces* may be difficult to recover on culture. The etiology of CNS disease may be inferred if *Actinomyces* spp. are isolated at another site. Standard recommended treatment for CNS disease is penicillin for at least 6 months. Recently, successful shorter courses of treatment with drugs other than penicillin for CNS disease have been reported. Surgical drainage may also be needed.

### Aspergillosis

*Aspergillus* spp. comprise a variety of highly aerobic, asexual molds that initially gain entrance to the lung by inhalation. Aspergillosis of the CNS was rare until the population of immunocompromised hosts increased during the past two decades. Among compromised hosts, the highest frequency of invasive aspergillosis is in heart and lung transplant recipients (19% to 26%), followed by those with chronic granulomatous disease (24% to 40%), acute leukemia (5% to 24%), bone marrow or hematopoietic stem cell recipients (0.5%

to 9%), AIDS (0 to 12%), and solid organ transplant recipients (0.5% to 10%). CNS disease complicates 10% to 20% of invasive disease.

### Clinical Characteristics, Clinical Laboratory Tests, and Diagnosis

Three types of clinical presentation have been reported with CNS aspergillosis:

1. An intracranial form, the most common, presenting like a space-occupying lesion
2. A rhinocerebral form, with primary involvement of the sinuses and secondary involvement of the skull base, cranial nerves, and brain
3. A vascular form with stroke-like symptoms

Other less common manifestations include meningitis, meningoencephalitis, hemorrhagic or ischemic necrosis, solitary granulomas, and invasive fungal arteritis. Neuroimaging may reveal sinus invasion, enhancing or nonenhancing hypodense brain lesions indicative of abscess, or prominent ischemic lesions in the basal ganglia; concurrent chest radiography or CT scan usually shows multiple nodular lesions.

Definitive diagnosis of invasive *Aspergillus* is made by smear and culture of biopsy material. A presumptive diagnosis of CNS infection can be made if *Aspergillus* is identified from another site at the same time that neuroimaging shows multiple mass lesions. A positive serum galactomannan test supports the diagnosis. The 2009 IDSA guidelines for *Aspergillus* spp. infection of the CNS recommend voriconazole as the primary medical therapy, with itraconazole, posaconazole, and liposomal formulations of amphotericin B as alternatives in cases of intolerance.

### Candidiasis

*Candida* spp. are the most common invasive fungal infections in infants and children. Cerebral candidiasis is a rare sequela of disseminated disease in debilitated patients. Risk factors include prematurity, prolonged broad-spectrum antibiotics, total parenteral nutrition, central venous catheterization, immunosuppression, immunodeficiency (congenital or acquired), chronic renal disease, diabetes, neutropenia, and ventriculoperitoneal shunts. Meningitis is the most common manifestation of candidal CNS disease, but abscesses and granulomas occur independently and in combination with meningitis. When brain abscesses occur, they are typically multiple in number, illustrating the consequence of hematogenous dissemination. Arterial and venous involvement can lead to the development of intracranial mycotic aneurysms.

Diagnosis can be confirmed by identification of the organism in spinal fluid or infected neural tissue. Pleocytosis or reduced CSF glucose occurs in only about half of the patients who are culture-positive. Recent IDSA guidelines for adults for *C. albicans* infection in the CNS recommend amphotericin, with or without 5-flucytosine followed by fluconazole.

### Zygomycosis

Zygomycetes are ubiquitous, broad, irregularly branched fungi found in soil and decaying matter. The classic progression to the syndrome known as rhinocerebral zygomycosis begins with a nasopharyngeal or sinus focus, followed by direct invasion into the CNS. This invasive infection rarely, if ever, occurs in the normal host. Risk factors include diabetes mellitus, intravenous drug use, solid organ or bone marrow transplantation, and other immunocompromising conditions. Fever, facial and ocular pain, or CNS symptoms may herald the

onset, and a black eschar-like plaque may be seen in the oropharynx or nasopharynx. Etiology of CNS disease seen on neuroimaging can be inferred from biopsy of nasopharyngeal or sinus specimens. Hyphae can be found in biopsy material. Amphotericin and posaconazole are the most commonly used therapies.

### *Scedosporium* spp. Infection

Two species of *Scedosporium* environmental molds, *prolificans* and *apiospermum* (sexual state known as *Pseudallescheria boydii*), can cause a wide variety of human disease, including CNS infection. Risk groups include compromised hosts and survivors of near drowning.

*Scedosporium* spp. can cause skin, lung, bone, joint, ocular, and bloodstream and CNS infections. Brain abscess is the typical CNS manifestation and can be solitary or multiple. Definitive diagnosis is through brain biopsy, although culture from a nonsterile site can support the diagnosis. The principles of therapy are similar to those for aspergillosis and zygomycosis, and include surgical resection of accessible brain abscesses, reduction or reversal of immunosuppression, and the use of antifungal agents.

## RICKETTSIAL DISEASES

Rickettsiae are pleomorphic coccobacilli that are obligate intracellular bacteria whose arthropod vectors include ticks, mites, fleas, or lice. Rickettsial diseases include the spotted fevers, typhus fevers, scrub typhus, Q fever, and ehrlichioses. Rickettsial infections often have an accompanying skin eruption. *Coxiella burnetii*, the rickettsia causing Q fever, differs from the other organisms because it does not require a vector and rarely causes a skin rash.

The clinical and pathologic response of the CNS to different infections caused by *Rickettsia* spp. is generally similar and differs only in severity. Headache is often the earliest and most frequent symptom in all rickettsial infections.

Diagnostic testing is also similar for most rickettsial infections. Serology is the most generally available and widely used method. The indirect fluorescent antibody assay is considered the gold standard. However, because most patients with rickettsial diseases do not develop antibodies reactive in the first week of illness, serologic tests are often negative early in illness. Evaluation of paired serum specimens collected during the acute and convalescent phases of the illness for a four-fold or greater change in antibody titer confirms the diagnosis. Extensive crossreactivity exists among antigens of the spotted fever group rickettsiae (e.g., *Rickettsia rickettsii*, *Rickettsia akari*, and *Rickettsia conorii*), and among antigens in the typhus group (*Rickettsia prowazekii* and *Rickettsia typhi*). In this context, most indirect fluorescent antibody assays are group-specific rather than species-specific tests for rickettsial infection.

Doxycycline is the drug of choice for Rocky Mountain spotted fever and other rickettsia in all age groups (except for pregnant women). Empiric treatment with doxycycline should be initiated early in the course if clinical and epidemiologic findings are suggestive of a rickettsial infection because delays in treatment can lead to adverse outcomes.

Rocky Mountain spotted fever is the prototypic condition for these infections and is discussed in the next section. The epidemiology, clinical, and laboratory features of other Rickettsia infection are outlined in Table 116-2.

### Rocky Mountain Spotted Fever

Rocky Mountain spotted fever (RMSF) is caused by *Rickettsia rickettsii* and is the most common fatal tick-borne illness in the United States.

RMSF has been reported throughout the United States, with the exception of Hawaii and Vermont. The states with the highest incidence of RMSF are Oklahoma and North Carolina. In the United States the number of RMSF cases has increased in recent years, averaging over 2000 cases a year reported between 2005 and 2010—the highest recorded levels in more than 80 years (Walker et al., 2008). Children are at a higher risk of infection (half of the cases are under 19 years of age) as are Native Americans (Buckingham et al., 2007). The incubation period ranges from 2 to 14 days (mean 7 days) after a tick bite. Symptoms of RMSF vary in severity from mild to severe; the course may rapidly lead to death. RMSF is characterized by the classic triad of fever, headache, and rash particularly in the setting of a recent tick bite. Most patients with RMSF, however, do not present with the classic triad. Additionally, many patients are unaware of tick bite. Initial symptoms are nonspecific and include fever, malaise, lethargy, and headache. The headache is usually intense and refractory to most analgesics. Progressive restlessness, irritability, confusion, and delirium may also occur. By day 5 of the illness, 85% of patients develop a rash. The rash often begins with a maculopapular appearance and becomes more defined as petechiae as the rash evolves. The rash often begins around the ankles or wrists and then spreads to other parts of the body. Acute renal failure, coagulopathy, and cerebral edema are well-recognized complications. Edema, usually periorbital at first and then generalized, is characteristic of and may suggest the diagnosis. Hepatosplenomegaly and liver dysfunction, including coagulation defects, may also be present. Skin necrosis and gangrene can be a late complication. Ophthalmic features in all rickettsial disorders are virtually identical, and may include photophobia, conjunctivitis, petechiae on the bulbar conjunctiva, exudates and retinal venous engorgement, papilledema, and ocular palsies.

The differential diagnosis of RMSF includes meningococemia, enteroviral infection, scarlet fever, toxic shock syndrome, Kawasaki disease, Epstein-Barr virus, syphilis, typhoid, rat-bite fever, and other tick-borne diseases. Spinal fluid may demonstrate a lymphocytic pleocytosis, and the protein is elevated in about 30% to 50% of patients. Direct immunofluorescence antibody studies can be performed on skin biopsy, and PCR for *R. rickettsii* DNA can be done on serum, whole blood, or tissue specimens but is available only at specialized research laboratories.

## PARASITIC DISEASES

Human parasitic infestation occurs worldwide in tropical, temperate, and cold climates. Parasitic infections impair the CNS by a variety of mechanisms, including the following:

1. Direct invasion from the circulation or lymphatic system may cause local changes, such as inflammation and edema.
2. Granuloma development may result in disturbances associated with mass lesions.
3. Remote effects associated with nutrient deprivation of the CNS may cause diffuse or focal CNS symptomatology.
4. Immunologic or hypersensitivity effects may develop.

Changes in society have spread what were once exotic diseases largely restricted to developing countries into the developed world. Ease and frequency of travel require that all clinicians have general familiarity with these infections when considering differential diagnoses. Population shifts, whether due to immigration or social unrest, have brought unfamiliar parasitic infections into urban and other areas of the world.

Please see Table 116-3 for a complete list of parasites that can affect the CNS.

## PROTOZOAL INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

### Amebic Infections of the Central Nervous System

For information on *Entamoeba histolytica* and *Microsporidia* sp., see Table 116-3 and the online version of this chapter.

#### Primary Amebic Meningoencephalitis:

##### *Naegleria fowleri*

Primary amebic meningoencephalitis (PAM) is a fulminant disease occurring in children and young adults caused by *Naegleria fowleri*. *N. fowleri* is a free-living, facultative parasite that can be found in water, soil, sewage, or other decaying organic material where there is a bacterial food source. Of an estimated 200 cases since the first descriptions of PAM, more than 90% of the patients have died. The disease has been reported primarily from the United States, Australia and Europe but cases occur worldwide.

Typically, infection with *N. fowleri* occurs when swimming, or washing in warm, fresh water containing the amebas such as ponds, man-made lakes, hot springs, wading pools, irrigation canals, thermally polluted streams, and inadequately chlorinated swimming pools. Those affected are previously healthy children or young adults. Most infections have been associated with diving and underwater swimming, but sinus irrigation has been recently associated with PAM.

The onset of PAM is usually within 2 to 3 days after exposure. Amebas enter the nasal passages and gain access to the nervous system by penetrating the olfactory mucosa, entering the submucosal nervous plexus, migrating along the olfactory nerves, and traversing the cribriform plate.

The most common manifestations of PAM are severe headache, stiff neck, nausea, vomiting, fever, behavioral changes, change in smell, seizures, diplopia, and coma. Spinal fluid typically has a decreased glucose concentration, increased protein content (75 to 970 mg/dl), and innumerable white blood cells (300 to 24,600/mm<sup>3</sup>) with a predominance of polymorphonuclear cells and erythrocytes.

A CSF wet mount can aid in the diagnosis—the amebas can be recognized by their relatively swift movement with an anterior, eruptive pseudopod. A multiplex, real-time polymerase chain reaction has recently been developed with the ability to detect *Naegleria*, *Balamuthia*, and *Acanthamoeba* simultaneously (Qvarnstrom et al., 2006). There is a high mortality associated with PAM; however, occasional favorable outcomes have been achieved with a combination of various therapies (Linam et al., 2015). Miletfosine has recently been recommended for PAM and is available as an investigational drug from the CDC.

#### Granulomatous Amebic Encephalitis: *Acanthamoeba* spp. and *Balamuthia mandrillaris*

Two different, closely related amebas cause granulomatous encephalitis: *Acanthamoeba* spp. and *Balamuthia mandrillaris*. *Acanthamoeba* granulomatous encephalitis is an opportunistic, chronic disease that may have a prodromal period of weeks to months, with most patients being immunocompromised. A small number of *Acanthamoeba* granulomatous encephalitis cases have been described in immunocompetent children.

*Acanthamoeba* is commonly found in soil. *Acanthamoeba* is also found in the home in aquariums, flower pot soil, humidifiers, sink taps, and drains and has been isolated from

hot tubs, hydrotherapy baths, dental irrigation equipment, and laboratory eye wash stations. Infection may take place through breaks in the skin that are contaminated with soil, or by inhalation of airborne amoeba cysts originating from soil.

In addition to encephalitis, *Acanthamoeba* can cause nasopharyngeal, cutaneous, and disseminated infections. Nasopharyngeal and cutaneous infections can be precursors to disseminated amoebiasis or encephalitis, as amoebas spread from their initial portal of entry. The CNS becomes infected by hematogenous transport of amoebas, either from the lungs or from cutaneous lesions.

Clinical features typically have a subacute to chronic presentation, with fever, headache, seizures, personality change, lethargy, or confusion. Children with *Acanthamoeba* exhibit headache, stiff neck, vomiting, abnormal behavior, fever, ataxia, and tonic-clonic seizures. CSF protein is elevated (range 31 to 500 mg/dl), as is the white blood cell count (14 to 750 cells/ $\mu$ L) and glucose level (17 to 240 mg/dl); among the white blood cells are lymphocytes (19% to 100%) and polymorphonuclear leukocytes (2% to 70%). Neuroimaging may show punctate focal lesions in the cerebellar hemispheres or in the corpus callosum or hydrocephalus. Sequential MRIs may resemble a rapidly expanding brain mass. *Acanthamoeba* can sometimes be seen on CSF wet-mount slide preparations. A multiplex, real-time polymerase chain reaction has recently been developed with the ability to detect *Balamuthia*, *Acanthamoeba*, and *Naegleria* simultaneously (Qvarnstrom et al., 2006).

*Acanthamoeba* infections of the CNS are usually fatal, although some reports of successful antimicrobial treatment are described. Most recoveries result from successful treatment with combinations of different antimicrobials as outlined in online version of this chapter. In vitro studies suggest that miltefosine and voriconazole have activity against *Acanthamoeba*.

### Granulomatous Amebic Encephalitis: *Balamuthia mandrillaris*

*Balamuthia* granulomatous encephalitis was initially described in immunocompromised humans, but more recent cases have occurred in immunocompetent adults and children. The importance of *Balamuthia* as a CNS pathogen is increasingly recognized (Schuster et al., 2009). Most cases are reported in the United States and South America but cases are now recognized across the globe. Like *Acanthamoeba*, it is likely to enter the body by inhalation of cysts in windblown soil or through breaks in the skin contaminated by soil, followed by hematogenous spread. Signs and symptoms of *Balamuthia* granulomatous encephalitis include fever, headache, vomiting, ataxia, hemiparesis, tonic-clonic seizures, cranial nerve palsies (particularly third and sixth cranial nerves), and consequent diplopia. Areas of the brain that are typically infected are the basal ganglia, midbrain, brainstem, and cerebral hemispheres. CSF may have mild to markedly elevated protein and leukocyte levels, and normal or slightly decreased glucose.

Neuroimaging reveals single or multiple space-occupying or ring-enhancing lesions, enlarged ventricles, atypical demyelinating lesions, or ring-enhancing lesions with surrounding edema or hydrocephalus. A multiplex, real-time polymerase chain reaction has recently been developed with the ability to detect *Balamuthia*, *Acanthamoeba*, and *Naegleria* simultaneously (Qvarnstrom et al., 2006).

Of the approximately 200 recognized *Balamuthia* cases, successful outcomes have been reported in 10 individuals, including four pediatric patients, using various combinations of antimicrobials. Miltefosine is currently available through

the CDC as an investigational new drug and available for treatment of the free-living amoeba.

### Toxoplasmosis

*Toxoplasma gondii* is found worldwide in a variety of mammals and birds and is a public health problem in both developed and developing countries. Approximately 20% to 40% of the adult population in the United States is seropositive. The cat is the definitive host of the parasite and excretes oocysts in the feces. Ingestion of the oocyst by animals and humans continues the life cycle of the parasite.

Humans are infected by ingestion of raw or inadequately cooked meat containing tissue or by ingestion of oocysts shed in cat feces. Reactivation of a latent infection can be triggered by the host becoming immunodeficient or immunocompromised.

Intrauterine or congenital toxoplasmosis may develop in the fetus when the mother is infected during pregnancy. The incidences of maternal and fetal infection in the United States are 6 and 2 per 1000, respectively. The risk of fetal infection increases as the pregnancy progresses: 25% in the first trimester, 54% in the second trimester, and 65% in the third trimester. Severity of infection is inversely related to when infection occurs during pregnancy. When disseminated, acquired toxoplasmosis produces systemic manifestations consisting of multiple organ infection, including the brain.

Clinical manifestations of congenital infection are extremely variable. The well-known clinical constellation of hydrocephalus, cerebral calcifications, and chorioretinitis is variably present in affected infants. The approximate incidence of abnormalities in 180 cases of intrauterine toxoplasmosis included microcephaly (20%), hydrocephalus (25%), microphthalmia (35%), seizures (40%), psychomotor retardation (45%), cerebral calcification (60%), and chorioretinitis (95%). Although the manifestations of some cases have been similar to those of congenital cytomegalic inclusion disease, CNS involvement is usually more common and extensive in toxoplasmosis. Skull radiographs and ultrasound demonstrate punctate, scattered calcifications and separated cranial sutures. Delayed onset of seizures, chorioretinitis, and cognitive impairment can also occur. Even in those infants with toxoplasmosis who are asymptomatic at birth, up to 85% may develop chorioretinitis or serious neurologic disability by 8.3 years.

Outside the newborn period, the infection is often asymptomatic in the immunocompetent host. In contrast, immunosuppressed individuals can develop a life-threatening illness either from acute infection or through reactivation. The acquired form of toxoplasmosis causes meningoencephalitis, and long-term sequelae are common.

Immunologic diagnosis of toxoplasmosis relies on the Sabin-Feldman dye test (which detects live parasites), the direct hemagglutination test, the double-sandwich enzyme-linked immunosorbent assay, the immunosorbent agglutination assay, the complement fixation test, the evaluation of immunoglobulin M levels, and the indirect fluorescent antibody test. Diagnosis of congenital toxoplasmosis can be especially challenging—consultation and testing with a laboratory experienced with toxoplasmosis diagnostics is warranted.

Early treatment with spiramycin for the mother and sulfadiazine, pyrimethamine, and folinic acid for the infant is beneficial and 70% effective (Montoya and Liesenfeld, 2004). Outside the newborn period, treatment is usually not required, except in immunocompromised hosts. There are recommended treatment protocols for children infected with HIV and CNS toxoplasmosis.

## Malaria

Malaria is one of the most common tropical infectious diseases. In 2013 the WHO estimated that there were 198 million cases worldwide. Malaria is caused by the protozoal parasites of the genus *Plasmodium*, with life cycle stages alternating between the mosquito and a variety of mammals and birds. The definitive host and vector for malaria is the female *Anopheles* mosquito. Several species of *Plasmodium* cause disease in humans—*Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium malariae*, and the recently discovered *Plasmodium knowlesi*. However, *P. falciparum* and *P. vivax* are the only members of the genus that have been well documented as affecting the CNS in humans.

In endemic areas, neonates are protected from infection by maternal (transplacental) antibody, in part, from the vestigial presence of fetal hemoglobin. This protection lasts for about 1 year, after which the infant becomes susceptible to disease. The child of 1 to 4 years of age is the most vulnerable to infection and the development of severe malaria, with a mortality of about 5%. Malaria acquired by recipients of blood transfusions from infected but asymptomatic carriers is also a major problem in endemic regions of the world. Because of more frequent international travel, increasing numbers of cases in adults and children are being recognized in the United States.

The clinical features of malaria are notoriously nonspecific, especially in children. Initial symptoms can include influenza-like illness with fever, chills, rigors, headache, and myalgia. These vague prodromal symptoms precede the development of acute paroxysms of high fever and chills, with the classically described periodic fever patterns observed after several days of untreated illness. Gastrointestinal and respiratory symptoms are also common.

Cerebral malaria is most often heralded by mental deterioration, particularly confusion or delirium, followed by progression to stupor and coma that transpires over the next 1 to 3 days. In children, cerebral involvement can be more fulminant, with most patients becoming comatose within 2 days. New-onset seizures may be confused with febrile seizures in young children. Extensor plantar responses, cerebellar impairment, abnormal movements, and psychosis may also occur. Children with severe illness exhibit evidence of transtentorial herniation. Papilledema and extramacular retinal edema are markers of a poor prognosis.

In patients with impaired consciousness, a lumbar puncture should be performed to assess for concurrent meningitis. Caution, however, should be exercised due to the potential for focal gradients of elevated intracranial pressure. Acutely, MRIs may demonstrate multifocal T2-enhancing lesions indicative of capillary occlusion and cerebral edema or increased brain volume.

The current gold standard for diagnosis of *P. falciparum* infection remains the study of thick and thin peripheral Giemsa-stained blood films. If antimalarial therapy was started before preparation of blood smears, the smears may be negative. Although examination of Giemsa-stained blood films remains the gold standard, rapid diagnostic tests also play an important role in diagnostics.

In 2010, the World Health Organization published updated guidelines for the treatment of malaria (WHO, 2010). The new guidelines emphasize the importance of parasitologic confirmation of diagnosis before initiation of antimalarial treatment. Artemisinin derivatives are the most rapidly acting of all antimalarial drugs and have transformed current treatment strategies. In the United States artemisinin-based drugs are available under investigational use only, and can be obtained

by contacting the CDC directly at the CDC Malaria Hotline [(770) 488-7788 or (770) 488-7100].

## Trypanosomal Infections of the Nervous System

The trypanosomes are a group of flagellated protozoa that infect a variety of vertebrates, but the clinically important species for humans are *Trypanosoma cruzi* (Chagas disease or American trypanosomiasis) and *Trypanosoma brucei* (African sleeping sickness). Both species are transmitted to humans by insect vectors.

### Chagas Disease

Chagas disease (American trypanosomiasis) affects 15 to 16 million people in Latin America and extends from Argentina to the Mexican border with the United States (mostly in southern tier). The vector, the triatomine bug or “kissing bug” (*Triatoma* spp.), lives in thatched walls and roofs of houses and primarily affects those living in poor housing conditions. At the time the triatomine bug bites a human, it defecates on the skin surface, leaving a drop containing parasites. The parasite penetrates the broken skin when the presumptive host scratches or rubs the deposited fecal matter into the site of the insect bite or when fecal matter is transferred by fingers on to the corneal surface of the eye or mucous membranes.

The disease can also be passed by transplacental infection, breastfeeding, and blood transfusions. Intrauterine Chagas disease occurs in 2% to 4% of infants born to mothers who have acute or chronic infection with *T. cruzi*. Such infants are usually born prematurely and are small for gestational age. When meningoencephalitis occurs, seizures, hypotonia, and a weak suck are characteristically present. Almost half the infants who acquire infection in utero die by age 4 months.

When Chagas disease is acquired from an insect vector, it can manifest in two phases: acute and chronic. The acute phase begins about a week after infection, and is often asymptomatic, subclinical, and undiagnosed in 66% to 99% of cases, most of whom are babies or young children (Pittella, 2009). The acute phase is characterized by mild, nonspecific symptoms and signs (e.g., fever, vomiting, diarrhea, and hepatosplenomegaly). Inflammation develops at the portal of entry of the trypanosomes, producing a nodule (chagoma) and causing swelling of proximal lymph nodes. The Romaña sign (unilateral palpebral and periocular swelling) may occur as a result of conjunctiva contamination with the vector’s feces. A small percentage of acutely infected patients develop cardiac symptoms suggestive of myocarditis or signs of meningoencephalitis.

After the latent asymptomatic phase of 10 to 25 years, chronic Chagas disease may represent in young adulthood. Most symptoms are due to severe cardiac or gastrointestinal involvement. Reactivated chronic Chagas disease is also observed in immunosuppressed patients, most commonly those with AIDS (75% to 80% of cases) and less frequently in patients after organ transplant or with chronic use of immunosuppressive medications.

In children with acute meningoencephalitis due to Chagas disease, CSF reveals a mild to moderate pleocytosis (less than 100 cells/mm<sup>3</sup>), predominantly of lymphocytes, and protein elevation. Neuroimaging studies may reveal nonspecific ring-enhancing lesions. The diagnosis of CNS Chagas disease is often made by direct examination of the CSF, which will reveal *T. cruzi* trypomastigotes.

Nifurtimox and benznidazole are the only approved drugs with trypanocidal activity and are only available in the United States by contacting the CDC.

### African Sleeping Sickness

Human African trypanosomiasis, or sleeping sickness, is prevalent in many sub-Saharan countries and is transmitted by the bite of an insect vector, the tsetse fly. Tryptophol, the 3-indole ethanol formed by the parasite, produces the characteristic sleep. Only two subspecies of the parasite are infectious to humans: *Trypanosoma brucei gambiense* in West and Central Africa, and *Trypanosoma brucei rhodesiense* in East and Southern Africa (Fig. 116-18).

Approximately 60 million people are at risk for infection; disease transmission occurs during activities such as farming, hunting, fishing, or washing clothes in remote rural areas.

Between 5 and 15 days after the bite, a painful skin lesion (chancere) may develop at the site of the bite. The parasites spread in the bloodstream 1 to 3 weeks after the initial bite, invading lymph nodes, liver, spleen, heart, endocrine system, and eye (hemolymphatic stage).

The typical symptoms and signs can be divided into two stages, although with *T. b. rhodesiense* infection there may be no clear distinction between the first and second stages. The early, first stage, symptoms include chronic and intermittent fever, regional lymphadenitis around the bite site, malaise, headache, arthralgia, erythematous and edematous cutaneous eruption, hepatosplenomegaly, and generalized lymphadenopathy, particularly in the posterior cervical nodes (Winterbottom sign).

The second stage is characterized by parasite invasion of the CNS. In *T. b. rhodesiense* disease, CNS involvement occurs early after infection, usually within 3 to 4 weeks of the bite. In contrast, in *T. b. gambiense* disease, CNS invasion can be delayed until many months or even years after infection. Signs of neurologic involvement include irritability, lack of concentration, personality changes, seizures, muscle fasciculation, and, in some cases, paralysis, hyperesthesia, anesthesia, or intense itching, and a variety of sleep disturbances such as daytime somnolence accompanied by night-time insomnia. As the disease progresses to the final stage, untreated patients become difficult to rouse and eventually progress to coma and death (Brun et al., 2009).

The clinical presentation is very different in travelers compared with African patients and is similar for both *T. b. gambiense* and *T. b. rhodesiense* infections. Patients frequently present with acute febrile illness, a chancere at the inoculation site, and a trypanosomal rash. These cases may manifest severe hematological disorders, impaired kidney function, electrolyte disturbances, and elevated liver enzymes.

The diagnosis and staging of disease rely on laboratory examination, given the nonspecific symptoms and signs. Correct staging is critical because the treatment is dependent on the stage of illness. Criteria for diagnosis of trypanosomiasis are the presence of flagellates in the CSF, elevated CSF leukocyte levels and the presence of intrathecal immunoglobulin M, as shown by the card agglutination trypanosomiasis test.

Suramin is recommended for patients with *T. b. rhodesiense* disease in early stages but avoided in western and central Africa because, where *Onchocerca* spp. are also present, its high activity against these parasites can cause severe allergic reactions. Pentamidine is the treatment of choice for first-stage disease caused by *T. b. gambiense*. In contrast, pentamidine treatment in intermediate-stage disease does not appear to be

effective, and is not generally recommended. In late stages of the disease, melarsoprol is recommended.

## HELMINTHS

For information on *Toxocara* and *Trichinella* species, see Table 116-3 and the online version of this chapter.

### Baylisascaris Procyonis Infection

*Baylisascaris procyonis* is a roundworm of raccoons and causes rapidly fatal eosinophilic encephalitis in humans. Racoon are the definitive host, and humans are considered an accidental intermediate host. *B. procyonis* infection in raccoons is usually asymptomatic and occurs in North America, Europe, and parts of Asia (Gavin et al., 2005). Infected humans may have classical visceral larva migrans with fever, leukocytosis, eosinophilia, hepatomegaly, and pneumonitis. If larvae reach the CNS, they produce damage and inflammation, resulting in progressive CNS disease, and the severity is often dose-related. Presenting CNS symptoms include lethargy, irritability, loss of muscle coordination, ataxia, nystagmus, loss of spontaneous movement, and extensor rigidity, and ultimately, the illness culminates in coma and death.

Ocular larva migrans usually involves children 7 years of age and older, with no history of pica and without marked eosinophilia. Laboratory findings of persistent eosinophilia in the blood and spinal fluid are typical findings. Early in the course of illness, neuroradiologic studies may demonstrate periventricular white-matter disease. Atrophy occurs in later stages of illness. Larvae can sometimes be visualized in histopathology or biopsy of brain tissue. In ocular larva migrans, migration tracks or live larvae are sometimes observed by funduscopic examination. Serologic testing is available in a limited number of laboratories throughout the world.

Treatment with antiparasitic agents and steroids has been attempted with variable success (Pai et al., 2007).

### Angiostrongylus Infection

*Angiostrongylus cantonensis*, the rat lungworm, is the principal cause of human eosinophilic meningitis worldwide. Rodents are the definitive host of the parasite and mollusks are the intermediate host. Humans are an incidental host and become infected by ingestion of the third-stage larvae in the molluscan intermediate host (e.g., snails, crabs, freshwater prawns) or contaminated vegetables. The larvae penetrate the intestinal wall and reach the CNS via the bloodstream after ingestion.

The infection is most common in tropical climates, especially in Southeast Asia, the South Pacific, and Taiwan. Cases have also been reported in Africa, Polynesia, and eastern Australia. In the United States *Angiostrongylus* is endemic to Hawaii. Other countries in the Western Hemisphere where cases have occurred include Puerto Rico, Cuba, Jamaica, and the Dominican Republic.

The onset of CNS symptoms occurs 1 to 35 days after ingestion of the infective larvae. *A. cantonensis* larvae often invade leptomeninges and brain parenchyma, although a minority of larvae may invade the lungs and cause eosinophilic pneumonitis. When the larvae reach the CNS, the worms die in the meninges, brain, or eyes. Upon death of the worm, intense inflammation occurs. The resultant clinical forms, sometimes overlapping, include meningitis, encephalitis, or ocular forms. Severe headache, photophobia, meningeal signs, hyperesthesia, and paresthesia are common. Migratory sensory symptoms are sometimes described as "pain under the surface" or "like a sunburn," and affected individuals

often experience discomfort wearing clothes. Individuals with the encephalitis form are severely ill, with paralysis of extremities or coma. Neuroimaging findings include meningeal enhancement, abnormalities in the brainstem, spinal cord, and basal ganglia. Crescent-shaped or stick-shaped linear enhancements in the parenchyma are particularly suggestive of neuroangiostrongylus.

Conjunctivitis, periorbital swelling, retinal hemorrhage, retinal detachment, or blindness may occur if the eye is infected. In most cases, recovery occurs approximately 4 weeks after onset but may take several months. In some cases involving very young children, progressive deterioration of CNS function has been described. Severity is likely related to the number of larvae ingested.

Eosinophilic pleocytosis, peripheral eosinophilia and elevated immunoglobulin E levels may be seen. The eosinophilia may persist for months. The diagnostic gold standard is identification of larvae in the CSF but is only found in 2% to 12% of cases (Ramirez-Avila et al., 2009). Serologic and molecular tests are available in a few specialized laboratories. Treatment with antihelmintics has been attempted, but efficacy is questionable. Sequential lumbar punctures, steroids, and analgesics may improve symptoms.

### Gnathostomiasis

Gnathostomiasis, most commonly caused by the nematode *Gnathostoma spinigerum*, is the cause of eosinophilic myeloencephalitis. Most cases are associated with the ingestion of raw or undercooked fish, frogs, snakes, chickens, or ducks. The disease is well-established in Southeast Asia, particularly Thailand and Japan, and is emerging as a public health problem in Peru, Ecuador, and Mexico (Moore et al., 2003). The median time from ingestion of infected food to onset of symptoms may be several months.

Infection can be grouped into cutaneous, visceral, and CNS forms. Common symptoms include intermittent episodes of cutaneous larva migrans (“creeping eruption”) with localized pain and pruritus. These lesions may recur for several years. Visceral symptoms occur if larvae migrate to deep tissues.

CNS involvement is rare and occurs more frequently in adults, but occasional cases occur in older children. CNS findings include the sudden onset of radicular pain or headache. Paralysis of the extremities and loss of bladder control typically follow. Acute eosinophilic meningitis, encephalitis, and cranial nerve abnormalities are also described. Neuroimaging of the spinal cord may reveal enlargement and diffuse high-signal intensity of the gray and white matter. Hemorrhagic tracts and scattered deep intracerebral hemorrhages are seen in the brain parenchyma. CT scans may demonstrate subarachnoid or intracerebral hemorrhage. Occasionally, parasite tracts can be visualized and appear as diffuse, fuzzy, high-intensity signals in the white matter.

Intermittent symptoms can occur for 10 to 15 years because the larvae are long-lived. Deaths are usually due to direct involvement of the brainstem or to secondary complications of pneumonia or sepsis. Ocular involvement can result in iris holes, anterior uveitis, and subretinal hemorrhages. Serologic (enzyme-linked immunosorbent assay and Western blot) tests have been developed but are not widely available.

Patients with gnathostomiasis will often have pronounced eosinophilia. In cases with CNS involvement, spinal fluid analysis shows eosinophilic pleocytosis. If there is ocular involvement, worms can sometimes be visualized by an eye examination.

Treatment recommendations include albendazole or ivermectin for dermal and subcutaneous gnathostomiasis. The

role of steroids and antihelmintics for CNS involvement is undefined. Surgical removal is often needed if larvae are identified in the eye.

### Cestodes

For information on *Diphyllobothrium latum*, see Table 116-3 and the online version of this chapter. 

### Sparganosis

Sparganosis is caused by a larval cestode of the genus *Spirometra sparganum*, which can invade the CNS. Humans typically acquire the infection via ingestion of raw frogs, snakes, or freshwater fish that are infected with *Spirometra sparganum*. Most cases have been reported in Southeast Asia, China, Japan, and Korea. Larvae migrate to the subcutaneous tissue or muscle but can also migrate to the genitourinary tract, pleural or abdominal cavity, scrotum, spinal cord, or brain. The clinical and radiologic presentation of cerebral sparganosis can resemble a tumor or tuberculoma. Neurologic manifestations may occur as many as 20 years after infection and include headache, seizure, or hemiparesis. Abnormalities seen on neuroimaging include unilateral ventricular dilation, cortical atrophy, irregular or nodular enhancing lesions, and punctate calcifications. Migratory lesions (also known as “wandering lesions”), the “tunnel sign” and “string-knots” sign are particularly suggestive of this infection. Surgical excision may be both diagnostic and curative. Praziquantel and steroids have been successful in some individuals.

### Echinococcosis

Echinococcosis, commonly referred to as hydatid disease, has a worldwide distribution. The two major species of *Echinococcus* that are of public health and medical importance are *Echinococcus granulosus* and *Echinococcus multilocularis*. *E. granulosus* disease is characterized by cystic lesions found primarily in the liver and lungs and is known as cystic hydatid disease. *E. multilocularis* disease is less common but is a more malignant form than that caused by *E. granulosus*. *E. multilocularis* infection is characterized by tumor-like collections of vesicular parasites found primarily in the liver and is known as alveolar hydatid disease.

Certain activities, such as the widespread rural practice of feeding dogs the viscera of home-butchered sheep, facilitate transmission to dogs and, consequently, raise the risk of humans becoming infected for *E. granulosus*. The disease is often acquired in childhood, with latency periods lasting as long as 20 years. During the initial stage of the infection, humans are asymptomatic. In cases of *E. granulosus*, cysts grow slowly and may ultimately contain several liters of fluid. Symptoms are frequently caused by pressure induced by the expanding cysts in adults; only 10% to 20% of cases are diagnosed in patients younger than 16 years (Moro and Schantz, 2009). The majority of hydatid cysts occur in the liver (75%) or lungs (15%). Less common sites include the bone, pelvis, spleen, and CNS.

*E. granulosus* infection of the CNS occurs in 2% to 5% of cases and may be primary or secondary when lesions occur in the CNS. CNS disease is more common in children than in adults. Most cysts are singular, intraparenchymal, and in the region of the middle cerebral artery. Patients with *E. granulosus* lesions in the CNS typically present with signs of increased intracranial pressure. Symptoms of *E. multilocularis* infection are almost always limited to adults and characterized by invasive growth of larvae in the liver, with occasional metastasis. When metastasis to the brain occurs, the patient often presents with a mass lesion.

Neuroimaging is extremely helpful in the diagnosis of CNS hydatid disease. In cases of *E. granulosus*, neuroimaging often demonstrates oval or spherical, homogeneous, sharply demarcated cystic lesions with smooth borders. If the protoscolex, referred to as “hydatid sand,” is seen in the image, it is considered diagnostic. In CNS *E. multilocularis* infections, cysts may appear as an ill-defined mass. A cauliflower-like contrast enhancement pattern on MRI is sometimes described. Eosinophilia is present in less than 25% of cases. Liver involvement is almost always present in these cases and ultrasound or other imaging of the abdomen may be helpful.

Serology can be helpful in cases that have unclear neuroimaging studies. Enzyme-linked immunosorbent assay or indirect hemagglutination is available for screening, and immunoblot assay can help confirm the diagnosis.

Surgical removal and an antiparasitic drug are usually the recommended treatments for CNS disease. In cases of *E. granulosus*, meticulous care must be taken during surgery to prevent spillage of the contents of the cysts. For *E. multilocularis*, CNS involvement is usually a consequence of advanced disease. Surgery and prolonged antiparasitic medications are generally recommended.

### Cysticercosis

Cysticercosis, an infection caused by the larval form of the pork tapeworm *Taenia solium*, is the most common parasitic infection of the CNS worldwide. The WHO estimates that over 50,000 deaths due to cysticercosis occur annually. Cysticercosis is found in areas with poor sanitation, especially in places in which pigs have access to human feces. It is especially prevalent in Central and South America, sub-Saharan Africa, and Southeast Asia.

Neurocysticercosis is characterized by pleomorphic clinical manifestations and depends on location of parasites (brain parenchyma, subarachnoid space, ventricular system or spinal cord), number of lesions, and the intensity of the host's immune response. Spinal fluid analysis is abnormal in 50% of cases and may show moderate pleocytosis, a normal glucose level (although hypoglycorrhachia is seen in 12% to 18%), and a moderately increased CSF protein (range 50 to 300 mg/dl). CSF eosinophilia is variably present. In severe forms of neurocysticercosis (e.g., location of cysts in the subarachnoid space at the base of the brain or in the ventricular system), CSF cell counts may exceed 1000 cells/mm<sup>3</sup>. Neuroimaging typically shows cystic lesions, single or multiple ringlike or nodular enhancing lesions, and parenchymal brain calcifications. If a cystic lesion with an associated scolex is seen, this is considered pathognomonic for cysticercosis.

The immunoelectrotransfer blot (EITB) assay generally has both high sensitivity and specificity; however, approximately 30% of cases with a single brain lesion may test negative. In the United States the EITB assay is available at the CDC.

Treatment of the adult tapeworm is routinely recommended. Praziquantel and niclosamide are highly effective for the eradication of the adult tapeworm. Niclosamide is not absorbed from the intestine. Considerable controversy exists about the role of antiparasitic treatment of neurocysticercosis and reviewed in the online version of this chapter.

### Coenurosis

For information on Coenurosis, see Table 116-3 and the online version of this chapter.

### Schistosomiasis

Schistosomiasis is a neglected tropic disease that ranks second only to malaria as the most devastating parasitic disease

worldwide in terms of human suffering and economic influence. It is caused by the blood-dwelling fluke worms of the genus *Schistosoma*; snails are the intermediate hosts. Many species of *Schistosoma* exist, but only a few are responsible for human infection—primarily *Schistosoma haematobium*, *Schistosoma mansoni*, and *Schistosoma japonicum*.

Over the past few decades man-made reservoirs and irrigation systems have contributed to the spread with stagnant or slow-flowing water bodies enhancing the survival of the intermediate hosts, snails. Children and adolescents are most commonly infected particularly because they are more likely to play in contaminated water. *S. mansoni* is endemic in Africa, South America, and the Caribbean Islands. *S. haematobium*, the organism that causes classic urinary tract bilharziasis, is found in Asia, from Bombay to the Suez Canal, and in Africa. *S. japonicum* causes illness in the Far East, including China, Japan, Indochina, the Philippines, and Indonesia.

Two types of CNS lesions occur. One consists of isolated granulomatous masses that contain ova and can be surgically excised. The other type consists of diffuse small lesions that are located in both white and gray matter, and are often asymptomatic. Space-occupying lesions, known as bilharzias, are apparent on MRI and CT scans. Adult worms, which can remain viable for 10 to 25 years, have also been reported in ectopic locations such as brain tissue.

*S. japonicum* infections are more likely to involve the brain and meninges, whereas *S. mansoni* and *S. haematobium* usually affect the spinal cord. Lesions from *S. mansoni* are usually located at the level of T6 or lower, coinciding with the more frequent anastomosis of the Batson venous plexus with the portal venous system at this region.

Clinical symptoms occur in three phases, the first being associated with cutaneous penetration and migration of the *Schistosoma* that result in an active dermatitis (“swimmer's itch”). The second phase (Katayama fever) occurs 6 to 8 weeks later and consists of a wide variety of symptoms, including chills, headache, fever, fatigue, hepatosplenomegaly, lymphadenopathy, eosinophilia, urticaria, and gastrointestinal distress. For *S. haematobium*, the beginning of egg output in the urine may be accompanied by dysuria and nocturia. Hematuria is the most important finding. In *S. mansoni* infection, patients may be asymptomatic, or they may present with chronic or intermittent abdominal pain, loss of appetite, and diarrhea alternating with slimy, blood-tinged stools; these symptoms and signs indicate the beginning of egg excretion in the descending colon, sigmoid, and rectum. About 10% of children in endemic areas progress to the third stage, with hepatosplenic involvement and liver fibrosis, usually 5 to 15 years after acute infection. The hallmark presentation is a healthy-looking child with preferential enlargement of the left liver lobe and an enlarged spleen. The progression to liver fibrosis can be more rapid in *S. japonicum* infection, in some cases with little or no interval between acute and chronic disease. In these cases, hematemesis from gastroesophageal varices, anemia, cachexia, and growth retardation may be seen.

Symptoms of neuroschistosomiasis are directly caused by inflammation around ectopic worms or eggs in the cerebral spinal venous plexus, which can progress to fibrotic scars.

*S. japonicum*, and rarely *S. haematobium* and *S. mansoni*, can be associated with cerebral granulomatous lesions. Headache, seizures, nausea, vomiting, visual abnormalities, speech disturbances, ataxia, vertigo, sensory impairment, and hemiparesis have all been reported, depending on location of the lesion. Growth retardation in children, associated with depressed function of the pars anterior of the pituitary gland, can occur. Cognitive and memory impairment have also been reported. Duration of the symptoms varies from a few weeks to more than a year, but most present within 3 months.

Ectopic *S. mansoni* and *S. haematobium* infections are associated mainly with spinal pathology with myelitis, myelodysplasia, or a granulomatous form. The most frequent initial complaint is lower back pain radiating to lower limbs or nonspecific pain in the lower limbs. Spinal neuroschistosomiasis can mimic a neoplastic process. Lower limb weakness, progressing to paraplegia, urinary retention, and paresthesia of the limbs, is a common presentation in pediatric patients.

CSF examination may reveal pleocytosis, eosinophilia, and elevated protein with oligoclonal bands. Brain neuroimaging studies may reveal edema, multifocal lucencies, and atrophy in later stages of the disease, whereas investigation of spinal cord schistosomiasis may reveal myelitis, swelling at the base of the cord (conus medullaris), or cord compression. A characteristic MRI pattern can be seen in cerebral schistosomiasis and consists of multiple intensely enhancing nodules with areas of linear enhancement. Spinal cord involvement is characterized by swelling of the cord with ill-defined regions of hyper intensity on T-2 weighted images. The conus medullaris and cauda equine are the most common sites of involvement.

Ova have not been found in CSF but can be found in urine, feces, and tissue and are diagnostic; concentration of the specimen may be necessary (Kato technique). In chronic schistosomiasis, however, eggs may not be passed, and serial stool examinations may be negative; in this situation, rectal biopsy can increase sensitivity to 95% to 100%. Several other tests are available, including an intradermal skin test, a complement fixation test, a cholesterol-lecithin cercarial slide flocculation test, and a bentonite flocculation test.

Praziquantel is the drug of choice for *S. haematobium*, *S. mansoni*, and *S. intercalatum* infections. Most experts recommend that CNS disease merits treatment with praziquantel in conjunction with steroids.

## Paragonimiasis

Paragonimiasis, a neurologic and neurosurgical condition, has a high incidence in certain areas of Asia (China, Korea, Japan, and Taiwan), and occurs less frequently in some regions of Africa and South America. Human paragonimiasis results from the ingestion of freshwater crayfish or crabs containing the metacercarial form of the parasite. After humans ingest infected raw or poorly cooked crab or crayfish, the metacercariae excyst in the small intestine and pierce the intestinal wall as larvae, embedding in the abdominal wall. After several days, the larvae reenter the abdominal cavity and migrate to the diaphragm, pleural cavity, and lungs to mature into adult flukes. The lungs are the primary habitat in the human host, and adult worms are reported to live for 10 to 20 years. Lung disease, including pleurisy, pneumothorax, and hemoptysis, constitutes the cardinal clinical feature of human paragonimiasis.

Cerebral infection occurs in approximately 0.8% of patients; spinal cord involvement is even less common. Headache, nausea, vomiting, visual impairment, hemiplegia, and mental deterioration often occur early in the course of the illness. Neurologic evaluation frequently reveals dementia, homonymous hemianopia, optic atrophy, diminished visual acuity, hemiparesis, hemihypesthesia, and meningismus. The most common location of spinal involvement is in the lower thoracic area. An extradural mass may cause spastic paraplegia. Individuals with cerebral paragonimiasis may have history of a seizure disorder with onset during childhood, but the diagnosis may not be made until several decades later. Cerebral

paragonimiasis has been reported to lie dormant for 30 years before becoming symptomatic.

Characteristic neuroimaging during the acute phase includes multiple, ring-enhancing lesions referred to as “grape clusters,” whereas the chronic phase reveals multiple, round or oval-shaped calcification. In the pediatric age group, irregular hemorrhages are common findings, although multiple and conglomerated enhanced lesions and migratory tracks of adult worms are sometimes seen.

Peripheral blood eosinophilia is often present. Pleocytosis (approximately equal numbers of polymorphonuclear cells and mononuclear cells), decreased glucose concentration, and increased protein content are frequent spinal fluid findings. The definitive diagnosis of paragonimiasis requires finding the operculated eggs in sputum or feces. Serologic assays are available and both are sensitive and specific. Praziquantel is the drug of choice for paragonimiasis, although surgical removal of the parasite may also be necessary in some cases.

# 117 Neurologic Complications of Immunization

Claudia A. Chiriboga

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Immunization programs are undoubtedly cost-effective public health measures that protect against infectious disease. Recommendations on immunization schedules are made by the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC) to the Surgeon General. New recommendations of the ACIP are published in *Morbidity and Mortality Weekly Report*, and they are the standard of care for immunization practices (Table 117-1). Vaccination programs have proved successful in eradicating diseases worldwide, best exemplified by smallpox, which was eradicated in 1980.

Despite these early successes in the United States and other industrialized nations, such programs are currently threatened. As more parents choose vaccine exemptions for their children, an erosion of herd immunity has ensued. This has resulted in a 3-fold increased rate of pertussis and a 10-fold increased rate of measles in the United States. The reason for the increase in antivaccine sentiments in industrialized countries is not known but would appear to be fueled by ignorance, celebrity endorsement, lack of scientific scrutiny of the Internet, anecdotal reports, and frustration among parents relating to the lack of well-defined causes to explain neurologic or developmental disorders (e.g., autism) that may coincide temporally with vaccination.

## ASSESSING CAUSALITY

Events that are associated temporally are not necessarily linked causally. Determining causal relationships between vaccinations and specific disorders with certainty is difficult. Among existing methods, the least helpful in assessing causality are the anecdotal and case report, which rely on simple temporal associations that may easily have occurred by coincidence. Such chance associations can be expected to occur and often do when the outcomes are common (e.g., developmental disorders) and do not denote causality.

Clinical trials and epidemiologic population-based studies are more robust in assessing links between vaccines and adverse outcomes. Clinical trials are valid, but they are limited by their relatively small sample size, which precludes the identification of associations with rare outcomes. Population-based studies are useful, especially if large, because they can assess even rare outcomes. However, causality cannot be determined with certainty, only suspected, unless there is a biologic marker. Further complicating the assigning of causality is the administration of several vaccines at one time.

The U.S. Institute of Medicine (IOM) was charged with undertaking the first reviews of vaccine-related complications, and it continues to review vaccine safety. Because absence of proof is not proof of absence, the IOM takes into account level of proof and does not make determinations based on lack of evidence. In 2011 the IOM committee revised its methodology and established a new framework by which two lines of evidence (epidemiologic weight of evidence and mechanistic factors) influence determinations of causality based on a revised classification (Institute of Medicine, 2011):

- Evidence convincingly supports a causal relationship.
- Evidence favors acceptance of a causal relationship.
- Evidence is inadequate to accept or reject a causal relationship.
- Evidence favors rejection of a causal relationship.

The weight of epidemiologic data was classified as high, moderate, limited, or insufficient based on the number of studies with negligible methodological limitations. In determining causality, biologic mechanisms were also taken into account. The committee considered whether the vaccine had been linked to a specific condition in one or more individuals (high or moderate weight of evidence), whether there was an appropriate latency of the exposure, and whether there was a plausible mechanism by which the vaccine could cause the complication or disease in question based on human, animal, or in vitro studies.

## VACCINE INJURY COMPENSATION PROGRAM

The U.S. Vaccine Injury Compensation Program (VICP), effective since 1988, is a federal no-fault system designed to compensate individuals or families of individuals who have been injured by childhood vaccines. The list of vaccines and covered complications are shown in Table 117-2. Vaccines are covered, whether administered individually or in combination. VICP further includes a provision to cover any new vaccine recommended by the CDC for routine administration to children, after publication by the Secretary of the Department of Health and Human Services of a notice of coverage.

## TYPES OF VACCINES

### Vaccines Composed of Whole-Killed Organisms

Vaccines composed of whole-killed organisms were the first laboratory-produced vaccines. They provoke an antibody response that provides temporary immunity. Some vaccines made from whole-killed organisms may cause immune-mediated disorders.

#### Inactivated Polio Vaccine

Sabin's oral poliovirus vaccine (OPV) was replaced in the United States in 2000 by an enhanced-potency trivalent polio vaccine (eIPV) that is not associated with vaccine-associated poliomyelitis (see section [Vaccines composed of live-attenuated viruses](#)).

#### Influenza Virus Vaccine

Epidemic human influenza illness is caused by influenza A and B. Influenza A viruses are categorized into subtypes, based on two surface antigens: hemagglutinin (H) and neuraminidase (N). These two surface antigens of the influenza A viruses vary over time through the process of drift and shift. Influenza B viruses are separated into two distinct genetic lineages (Yamagata and Victoria). Antigenic drift is caused by point mutations arising during viral replication in hemagglutinin

**TABLE 117-1** Schedule of Routine Immunization of Healthy Infants and Children

Recommended Age	Immunizations
Birth	HBV
2 months	HBV, DTaP, Hib, eIPV, PCV, RV
4 months	DTaP, Hib, eIPV, PCV, RV
6 months	HBV, DTaP, Hib, PCV, RV
12–15 months	DTaP, Hib, MMR, eIPV, Var, PCV, influenza (yearly), HepA (2 doses)
4–6 years	DTaP, eIPV, MMR, Var
11–12 years	DT, MMR, MCV4, HPV (3 doses), and Var if not given at or after 12 months

DT, diphtheria–tetanus; DTaP, pertussis vaccine combined with diphtheria and tetanus toxoids; eIPV, enhanced-potency trivalent inactivated polio vaccine; HBV, hepatitis B virus; HepA, hepatitis A virus; Hib, *Haemophilus influenzae* type b; HPV, human papillomavirus; MCV4, meningococcal conjugate vaccine; MMR, measles, mumps, and rubella vaccine; OPV, oral polio vaccine; PCV, pneumococcal conjugated vaccine; Var, live-attenuated varicella vaccine; RV, rotavirus.

(HA) and neuraminidase (NA), whereas antigenic shift involves major changes in RNA caused by replacement of the gene segment. New influenza virus variants result from antigenic drift, whereas antigenic shift may facilitate cross-species infection and fuel pandemics.

Every year, a new influenza vaccine is developed to protect against the prevalent virus strains that are expected to appear in the United States the following winter. Each vaccine contains three influenza viruses: one A (H3N2) virus, another A (H1N1) virus, and one B. Two types of flu vaccines are available: the inactivated flu vaccine (discussed later) and the nasal-spray flu vaccine (i.e., live-attenuated influenza vaccine [LAIV]). The LAIV is prepared from live-attenuated flu viruses that do not cause disease in humans and is approved for use in healthy people 5 to 49 years of age who are not pregnant. The CDC recommends treating with LAIV within 48 hours of symptoms onset in high-risk individuals. A recent Cochrane review (2014) suggests that LAIV does not reduce the risk of serious influenza complications (pneumonia, hospitalization, or death).

The “flu shot” vaccine is prepared from inactivated flu virus and is approved for use yearly in all high-risk groups (young children, the elderly, and people with chronic diseases). There are two types of inactive vaccine: the trivalent flu vaccine that contains three influenza viruses (one A [H3N2] virus, one A [H1N1] virus, and one B virus), and the new quadrivalent flu vaccine that includes four different flu viruses (two influenza A viruses and two influenza B viruses). The CDC does not endorse any specific inactive flu vaccine.

**Guillain–Barré Syndrome.** Increased rates of Guillain–Barré syndrome (GBS) ranging from 8 to 13 per million were reported to be associated with the swine vaccine of 1976 [Institute of Medicine, 2003]. After 1976, no influenza season has shown a significant increase risk of GBS after influenza vaccination, including the 2009 H1N1 vaccine (Baxter et al., 2013). Rates of GBS are elevated 16-fold within 30 days of an influenza-like illness, compared with influenza vaccination.

**Multiple Sclerosis.** Although early studies suggested an association with multiple sclerosis relapse, numerous studies show no evidence of increases in the risk of multiple sclerosis (MS) relapse after influenza vaccination (Langer-Gould et al., 2014). As with GBS, the rate of MS relapse after an influenza-like

illness was significantly higher (33%) than after vaccination (5%). There is consensus that influenza vaccination does not induce MS relapse and should be used in affected individuals when indicated, based on risk factors (Institute of Medicine, 2003).

**Acute Disseminated Encephalomyelitis.** Influenza infection is a known risk factor for acute disseminated encephalomyelitis (ADEM) occurring at a rate of about 0.4 cases per 100,000 children. Case reports and passive surveillance studies have described a temporal, though not causal, link between influenza vaccinations and ADEM (Institute of Medicine, 2011). In population studies, such associations are very rare, about 1 case per 10 million vaccines.

**Bell’s Palsy.** Higher rates of Bell’s palsy were reported after intranasal vaccination with inactivated influenza virus in a case–control study in Switzerland. Such reports have not been replicated elsewhere.

**Narcolepsy.** An increased risk of narcolepsy, including a 10-fold elevated risk in children, was noted in Europe after vaccination with a monovalent 2009 H1N1 influenza vaccine during the H1N1 influenza pandemic (Miller et al., 2013). This vaccine uses an adjuvant, ASO3, that likely contributed to findings. No adjuvanted influenza vaccines have been used in the United States during any influenza season. A recent detailed study found no association between influenza vaccinations in the United States and narcolepsy (Duffy et al., 2014).

## Rabies Vaccine

The early rabies vaccine was developed in the central nervous system of animals and contained myelin basic protein. These vaccines (Semple vaccine), still in use in developing countries, were linked to high rates of ADEM (0.15%), polyradiculitis, and polyneuritis. The rabies vaccine licensed for use in the United States is prepared from rabies virus grown on human diploid cells, and it has an excellent safety record. Rare cases of demyelinating reactions have been reported, usually during the administration of the vaccine series or 1 week after completion, including atypical GBS and ADEM.

## Whole-Cell Pertussis Vaccine

Whole-cell pertussis vaccine, routinely combined with diphtheria and tetanus toxoids (DwPT), was replaced in 1992 by the acellular pertussis vaccine (see section **Component vaccines** below). The endotoxin contained in the whole-cell vaccine causes fever and pain at the injection site. DwPT was associated with febrile seizures within a day of vaccination and hypotonic hyporesponsiveness in about 1 case per 1750 doses, and with a rare (0–10.5 cases per 1 million doses administered) acute encephalopathy, characterized by persistent crying. The IOM review in 1994 concluded that the evidence was consistent with a causal relationship between DwPT and an acute encephalopathy in the children who experience a serious acute neurologic illness within 7 days after receiving DwPT vaccine. There is no evidence to support a causal relationship between DwPT and chronic nervous dysfunction.

## Hepatitis A Vaccine

Hepatitis A vaccine, licensed for use in 1995, is composed of an inactivated whole-virus vaccine that is derived from an attenuated strain of hepatitis A virus grown in human diploid cell lines. It has been recommended since 2006 for use in all children aged 1 year or older. No adverse neurologic events have been attributed to hepatitis A vaccine.

TABLE 117-2 Vaccine Injury\*

Vaccine	Adverse Event	Time of First Onset
I. Tetanus toxoid-containing vaccines (DTaP, Tdap, DTP-Hib, DT, Td, TT)	A. Anaphylaxis or anaphylactic shock B. Brachial neuritis C. Any acute complication or sequela (including death) of above events within time period prescribed	4 hours 2–28 days Not applicable
II. Pertussis antigen-containing vaccines (DTaP, Tdap, DTP, P, DTP-Hib)	A. Anaphylaxis or anaphylactic shock B. Encephalopathy (or encephalitis) C. Any acute complication or sequela (including death) of above events within time period prescribed	4 hours 72 hours Not applicable
III. Measles, mumps, and rubella virus-containing vaccines in any combination (MMR, MR, M, R)	A. Anaphylaxis or anaphylactic shock B. Encephalopathy (or encephalitis) C. Any acute complication or sequela (including death) of above events within time period prescribed	4 hours 5–15 days No <5 or >15 days Not applicable
IV. Rubella virus-containing vaccines (MMR, MR, R)	A. Chronic arthritis B. Any acute complication or sequela (including death) of above event	7–42 days Not applicable
V. Measles virus-containing vaccines (MMR, MR, M)	A. Thrombocytopenic purpura B. Vaccine-strain measles viral infection in an immunodeficient recipient C. Any acute complication or sequela (including death) of above events within time period prescribed	7–30 days 6 months Not applicable
VI. Polio live virus-containing vaccines (OPV)	A. Paralytic polio In a nonimmunodeficient recipient In an immunodeficient recipient In a vaccine-associated community case B. Vaccine-strain polio viral infection In a nonimmunodeficient recipient In an immunodeficient recipient In a vaccine-associated community case C. Any acute complication or sequela (including death) of above events within time period prescribed	30 days 6 months Not applicable 30 days 6 months Not applicable Not applicable
VII. Polio inactivated-virus-containing vaccines (e.g., IPV)	A. Anaphylaxis or anaphylactic shock B. Any acute complication or sequela (including death) of above event	4 hours Not applicable
VIII. Hepatitis B antigen-containing vaccines	A. Anaphylaxis or anaphylactic shock B. Any acute complication or sequela (including death) of above event within time period prescribed	4 hours Not applicable

Information effective as of March 6, 2015.

\*Based on data from <http://www.hrsa.gov/vaccinecompensation/vaccinetable.html> (see original table for full definition of each adverse event). No condition specified for compensation for the following vaccines: *Haemophilus influenzae* type b, varicella, rotavirus, pneumococcal, hepatitis A, trivalent and tetravalent influenza, meningococcal tetravalent, and human papillomavirus.

DT, diphtheria–tetanus vaccine; DTaP, acellular pertussis vaccine combined with diphtheria and tetanus toxoids; DTP-Hib, diphtheria, tetanus pertussis, and hemophilus influenza type b; Hib, *Haemophilus influenzae* type b; IPV, inactivated polio vaccine; MMR, measles, mumps, and rubella vaccine; MR, mumps and rubella vaccine; OPV, oral polio vaccine; P, pertussis; Td, tetanus and diphtheria toxoid; Tdap, tetanus and reduced dose of diphtheria and pertussis (for older children aged >11 years); TT, tetanus toxoid.

## Vaccines Composed of Live-Attenuated Viruses

Live-attenuated virus vaccines are intended to cause an asymptomatic infection. However, properly constituted vaccines can cause symptomatic infection and the expected complications of the natural disease. The immunity provided by live-attenuated virus vaccines is similar to that from natural diseases, and it may persist for life.

### Measles: Rubeola

Measles vaccinations have been in use since 1963. As of 2000, measles is no longer endemic in the United States. The measles epidemic of 2014 saw a 10-fold increase in rates in the United States. Measles cases in the United States are imported from Europe and Asia and spread readily because of the increasing number of unvaccinated children in the community and concomitant loss of herd immunity. Infants who are not vaccinated until after age 12 months are most vulnerable to infection because of other children's vaccine exemptions.

The licensed measles vaccine uses the Edmonton B measles virus, attenuated by prolonged passage in chick embryo cell culture, and is combined with mumps and rubella vaccines (MMR). Children who receive live-attenuated measles vaccines are expected to develop an asymptomatic case of measles. Children with vaccine-induced measles can develop any of the known complications of natural infection, except for subacute sclerosing panencephalitis (SSPE). Some children develop fever, rash, and conjunctivitis in the second week after immunization (i.e., the incubation period is at least 5 days). The main neurologic complication of measles immunization is a 2- to 6-fold elevated risk of febrile seizures, often complex, in the second week after immunization (Ward et al., 2007). Measles vaccine is not associated with increased risk of afebrile seizures or epilepsy, even among high-risk children. Cases of SSPE among measles-vaccinated children, when studied, are found to be caused by wild-type measles infection. Rare cases of measles encephalitis have been linked temporally, but not causally, to the vaccine. Measles inclusion body encephalitis

has been causally linked ([Institute of Medicine, 2011](#)) to MMR in immunocompromised children.

## Mumps

The mumps vaccine is administered with MMR vaccination. It is prepared by passage of the Jeryl Lynn strain of mumps virus in chick embryo cell culture. No adverse neurologic events are associated with the mumps vaccine used in the United States. Aseptic meningitis has been linked to the mumps vaccine used in other countries that use a different viral strain, but not the Jeryl Lynn strain. Unilateral sensorineural deafness has been linked temporally, but not causally, to immunization with MMR on passive surveillance, for an estimated rate of 1 case for each of 4 to 6 million vaccines. The rate of hearing loss linked to mumps is 1 in 20,000 cases.

## Rubella

The rubella vaccine used in the United States has been prepared since 1979 from human diploid cells. The immunologic response it produces parallels that of the natural infection. Up to 25% of people receiving the current rubella vaccine may develop transient arthralgias and paresthesias. In children, a controlled study found a 3.6 elevated risk of arthralgias between 6 to 14 days after MMR vaccination. In 2011 the IOM review concluded that the evidence supported a causal relationship between MMR and transient arthralgias, but not chronic arthralgias. Rubella virus vaccine has been highly successful in eradicating endemic rubella and congenital rubella in the United States. Inadvertent rubella vaccination of pregnant women has not resulted in any case of congenital rubella syndrome.

## Oral Polio Vaccine

Sabin's OPV, introduced in 1963, was successful in eradicating polio in the United States. However, because the greatest risk of contracting polio in the United States was vaccine associated (i.e., the risk of wild polio is nil), OPV was replaced by eIPV. The overall risk for vaccine-associated paralytic poliomyelitis (VAPP) after OPV administration was 1 case per 2.4 million doses distributed, with 82% of cases occurring after the first vaccination. Risk of VAPP is greatest among immunodeficient patients: 3200- to 6800-fold greater than the risk for immunocompetent OPV recipients. There is no evidence that administration of OPV or IPV increases the risk for GBS.

## Varicella

A live-attenuated varicella virus (Oka strain) vaccine was licensed in 1995 in the United States, and is currently recommended for routine immunization of children between 12 and 24 months of age. It is safe and effective in normal and mild to moderately immunocompromised children (e.g. with leukemia and HIV infection), but not recommended in severely immunocompromised children. The vaccine produces a mild case of chickenpox, resulting in any of the neurologic complications linked to the wild-type varicella infection, but at lower rates. For acute cerebellar ataxia (ACA), the vaccine-associated rate is 33-fold lower than ACA linked to varicella; for herpes zoster (HZ), rates are 4.7-fold lower than among unvaccinated children ([van der Maas et al., 2009](#)). About half of HZ cases among vaccine recipients are attributable to wild-type reactivation. Zoster complications with Oka virus, compared with wild-type VZV, tend to occur in younger children (about 2 years of age) and have a shorter onset after vaccination (318 vs. 588 days) ([Wen and Liu, 2015](#)). The zoster eruption correlated with the site of the vaccination in 46% of cases. The rate of zoster among varicella vaccinees aged 10 to

23 years and followed for 10 years was 1 case per 1000 person-years, which is comparable to zoster rates described after wild-type VZV infection. The IOM identifies an association between meningitis or encephalitis and reactivated Oka strain months to years after varicella vaccination with causal implications. Varicella vaccine-associated stroke from Oka virus vasculopathy has not been reported in a study that reviewed over 3 million vaccinees. No major neurologic adverse effects were reported as being associated with Oka virus 42 or more days after varicella vaccination.

## Smallpox

The smallpox vaccine eradicated the disease in 1980. Smallpox reemerged as a potential risk in the wake of terrorist events because of its potential use as a biologic weapon. Smallpox is prepared from vaccinia, a live poxvirus that causes mild disease, including rash, fever, and aches. The main neurologic complication of smallpox vaccination is postvaccinal encephalomyelitis. Among the 1.2 million U.S. operational forces and health care workers vaccinated with smallpox after a 2002 U.S. Presidential directive, the rate of encephalitis was about 2 cases per million and there were 40 cases of myopericarditis that showed good recovery. In data collected before 1970, the mortality rate among patients with postvaccinal encephalomyelitis was 29%; the highest risk for developing postvaccinal encephalomyelitis was among infants younger than 1 year (risk ratio = 2.80, compared with vaccinees 1 year or older). These risks were significantly reduced among revaccinees.

The smallpox vaccine currently is recommended only for high-risk personnel (i.e., laboratory workers and at-risk military personnel), and is contraindicated for children and individuals with cutaneous disorders and immune suppression. In case of an outbreak, individuals of all ages would be vaccinated. Clinical trials with a recombinant smallpox vaccine, designed to be safer, are being carried out. Compensation for smallpox vaccination complications is part of the vaccine compensation program.

## Rotavirus

Rotavirus (RV) vaccine is composed of a live, attenuated human G1P RV. No adverse neurologic side effects have been attributed to RV vaccine.

## Component Vaccines

Acellular pertussis vaccine, *Haemophilus influenzae* type b vaccine, and meningococcal conjugate tetravalent vaccine are made from components of the bacteria. Human papillomavirus is made of noninfectious virus-like particles (VLPs). Toxoids are composed of denatured bacterial toxins. Toxoids prevent disease but not infection.

## Acellular Pertussis Vaccine

Since 1997, acellular pertussis vaccines have been recommended for initial vaccination of children, beginning at 6 weeks of age. Acellular pertussis vaccines contain substantially fewer proteins (five) and less endotoxin than whole-cell pertussis vaccines. Acellular pertussis vaccination is associated with fewer local adverse events and systemic adverse events compared with DwPT, including lower rates of febrile seizures and hypotonic unresponsive events. No cases of encephalopathy have been identified that could be attributable to acellular pertussis after the administration of millions of doses of vaccines. A handful of vaccine-associated encephalopathy patients were found to have an SCN1A mutation thought to explain the encephalopathy.

## Meningococcal Conjugate Vaccine

Meningococcal conjugate vaccine (MCV4) is a tetravalent vaccine constituted by capsular polysaccharide of serotype A, C, Y, or W135. It was licensed for use in January 2005 and is recommended for routine administration in adolescents 11 to 18 years of age. In October 2005, five cases of GBS among recipients of MCV4 reported to VAERS, first raising the possibility of an increased risk of GBS in association with MCV4 (within 42 days of vaccination). Subsequently, 2 population-based studies and a multicenter, retrospective cohort study assessed the occurrence of GBS in more than 10 million adolescents between 11 to 19 years of age. No study has found a relationship between MCV4 and GBS.

## Haemophilus Influenzae Type b

*Haemophilus influenzae* type b (Hib) vaccines in use in the United States are based on Hib polysaccharide (PRP) conjugated to a protein carrier. The conjugation of PRP to the protein induces a T-cell-dependent immune response to the Hib polysaccharide. The vaccine is administered in the United States during infancy concomitantly with diphtheria-tetanus-acellular pertussis vaccine (DTaP) as repeated doses. Hypersensitivity to the vaccine components is the only contraindication to its administration. No neurologic adverse events have been attributed to the vaccine in the United States.

## Pneumococcal Conjugated Vaccine

The first conjugate pneumococcal vaccine was licensed in the United States in 2000. It is composed of purified capsular polysaccharide of seven serotypes of streptococcal pneumonia, conjugated to a nontoxic strain of diphtheria toxoid. Pneumococcal conjugated vaccine is indicated for routine vaccination of children younger than 2 years. The vaccine produces local side effects, fever, and myalgias. No serious neurologic side effects have been attributed to pneumococcal conjugated vaccine.

## Human Papillomavirus Vaccine

Human papillomavirus vaccine (HPV) is recommended for routine vaccination of children aged 11–12 years. It is composed of VLPs of the major capsid L1 protein of HPV types 6, 11, 16, and 18. It has been found to be effective in preventing cervical, vulvar, and vaginal dysplasia, genital warts, and cervical cancer caused by these specific HPV types. In the United States, HPV vaccine-associated adverse effects reported to VAERS were nonserious. Ninety-three percent of side effects related to arm pain at the injection site and syncope, including convulsive syncope. Increased risk of venous thrombotic disease has been temporally linked to HPV, but the IOM has concluded that these cases had other thromboembolic risk factors. Rates of GBS and CNS demyelination after HPV vaccination are no greater than those encountered in the general population. Vaccination is contraindicated in individuals with yeast allergies.

## Tetanus and Diphtheria

Tetanus and diphtheria are toxoids that are produced by formalin inactivation of the toxins elaborated by the two organisms. Both have low rates of complications. Tetanus toxoid is given alone to children and adults after injury or burn exposure. The only contraindication for either toxoid is a history of a neurologic or severe hypersensitivity reaction after a previous dose.

GBS has been temporally, though not causally, associated with tetanus toxoid in two children and one adult. Controlled

studies have noted no association between diphtheria-tetanus vaccine (DT) and GBS. Two cases of brachial neuritis were reported temporally associated with DTP immunization, and in such cases, the tetanus toxoid has been implicated. The IOM concluded that a causal relationship exists between tetanus toxoid and brachial neuritis ([Institute of Medicine, 2011](#)).

## Recombinant Vaccines

Recombinant vaccines are genetically engineered vaccines. Hepatitis B is the only recombinant vaccine in use.

## Hepatitis B Vaccine

Hepatitis B vaccine is prepared by introducing DNA coding for the hepatitis B surface antigen into yeasts for cloning. The original plasma-derived vaccine is also safe and effective, and it is still used elsewhere in the world. Multiple sclerosis initially was associated temporally with hepatitis B vaccine in France after hepatitis B immunization became mandatory for health-care workers in that country. Controlled studies, however, have not noted an association between hepatitis B vaccine with new-onset multiple sclerosis in adults or adolescents. The IOM has determined that the evidence is insufficient to support a cause-and-effect association.

## COMBINATION VACCINES AND ADDITIVES

Most vaccination preparations involve combination vaccines. Concerns have been raised that combination vaccines (e.g., MMR) or vaccine additives (e.g., thimerosal) could elicit specific developmental disorders of childhood.

## Mumps, Measles, and Rubella Vaccine and Autism

A major debate arose after Wakefield's publication of a small gastroenterology study in 1998 in Britain claiming a causal link between the MMR vaccine and autism. The study was subsequently retracted, deemed fraudulent, and Wakefield disciplined by the U.K. General Medical Council, but not before causing broad repercussions throughout Britain and the United States. Subsequently, numerous studies around the globe have found no association between MMR and pervasive developmental delay or autistic regression. The IOM has concluded, after a careful review of existing studies, that data do not support a causal relationship between MMR and autism ([Institute of Medicine, 2004](#)).

## Thimerosal-Containing Vaccines and Developmental Disorders of Childhood

Thimerosal is an organic mercury compound preservative that has been in use since the 1930s. It was contained in more than 30 vaccines licensed and marketed in the United States, including some of the vaccines administered to infants (DTP, Hib, hepatitis B). Theoretical concerns were raised that cumulative exposure to ethylmercury, a metabolite of thimerosal and known neurotoxin, could have developmental side effects. In 1999 thimerosal was removed from vaccines to trace amounts (<3 µg). Several studies have found no association between thimerosal-containing vaccines and autism. Ecologic studies reported that, after discontinuation of thimerosal-containing vaccines, rates of autism remained unchanged or increased. Other studies targeting development and cognition have failed to identify thimerosal-associated impairments. The IOM has

concluded that thimerosal-containing vaccines are not associated with neurodevelopmental disorders, including autism, attention deficit hyperactivity disorder, and developmental delay.

## VACCINE INJECTION-RELATED OUTCOMES

Bursitis and syncope are vaccine-associated outcomes that can occur independently of vaccine type.

### Deltoid Bursitis

Deltoid bursitis can develop after vaccine injection, not only from inadvertent introduction into the bursa, but also by the injection itself. The IOM has concluded that the evidence convincingly supports a causal association between injection of a vaccine and deltoid bursitis.

### Syncope

Increased rates of syncope are reported to be temporally linked to vaccination and about 50% occur within 15 minutes of administration. The IOM concluded that the evidence convincingly supports a causal relationship between the injection of a vaccine and syncope. Vaccine recipients should be observed for 15 minutes after vaccination to prevent syncope.

# 118 Paraneoplastic Neurologic Syndromes

Adrienne Boire and Yasmin Khakoo

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Paraneoplastic neurologic syndromes (PNS) are the result of indirect effects of malignancy on the nervous system. These syndromes represent a diagnostic challenge because of both their rarity and protean neurologic presentations. Indeed, these syndromes may present at any time during the course of malignancy and may occur virtually anywhere along the neuraxis. Furthermore, select PNS may masquerade as direct effects of the primary tumor and/or metastases, or even as treatment-related complications. Importantly, in the setting of appropriate and timely therapy, PNS may respond to therapy, with regain of neurologic function. The aim of this chapter, therefore, is to provide the neurologist with an understanding of the scope of the most common PNS and their diagnosis and management.

## HISTORY OF PARANEOPLASTIC SYNDROMES

Broadly defined, paraneoplastic syndromes encompass any indirect effect of cancer on the organism. Identifying the relationship between cancer and thrombosis, Armand Trousseau described the first paraneoplastic syndrome in 1865. From a neurologic perspective, Derek Denny-Brown identified two patients with sensory neuronopathy and lung cancer in 1948; the first case of encephalomyelitis and carcinoma was described in 1965.

The term “paraneoplastic syndrome” was first employed in 1956 by Cabanne and colleagues, who described three patients with paraneoplastic polyneuritis in the setting of cancer. The first antibody associated with paraneoplastic syndrome was formally identified in 1985 by Graus and colleagues. Since then, 16 identifiable syndromes and more than 20 paraneoplastic antibodies have been described. Neuroblastoma-associated opsoclonus-myoclonus-ataxia (OMA) syndrome was the first paraneoplastic syndrome identified in children in 1968 by Solomon and Chutorian. More recently, anti-N-methyl-D-aspartate antibodies have been associated with an encephalomyelitis that may be paraneoplastic in adults but is only rarely associated with an identifiable neoplasm in pediatric patients. Overall, PNS affect fewer than 0.01% of cancer patients.

## DEFINITION

PNS are antibody-associated disorders of the nervous system in which antibody directed against a tumor antigen cross-reacts with antigen in the nervous system. These “onconeural antibodies” mediate autoimmune neuronal damage and resulting neurologic dysfunction. PNS may be divided into three major categories: classical PNS, which strongly suggest

an associated malignancy; nonclassical PNS, which are only occasionally associated with malignancy; and autoimmune encephalitis, which is strongly associated with malignancy in adults, but rarely in children (Table 118-1). These divisions reflect known pathophysiologic mechanisms and provide insight into therapeutic options and prognosis. The antibodies responsible for classical PNS target intracellular neuronal antigens, and the associated tissue damage is mediated by cytotoxic T-cell responses. Following from this, classical PNS have a limited response to treatment. They are exemplified by Lambert–Eaton myasthenic syndrome (LEMS), OMA syndrome, and sensory neuronopathy. The neurologic symptoms of classical PNS typically, but not always, present before the tumor is diagnosed.

In contrast, the nonclassical PNS are associated with antibodies against intracellular synaptic proteins cyclically expressed on the cell surface through synaptic recycling. These antibodies may or may not be associated with malignancy. Unlike classical PNS, tissue damage may occur as a result of both B- and T-cell responses, and these syndromes display a heterogeneous response to treatment. These syndromes include cerebellar ataxia and the stiff-person syndrome.

Finally, the autoimmune encephalitides, including NMDA receptor encephalitis associated with antibodies against neuronal cell surface or synaptic receptors, are mediated by B-cell responses, and may respond to treatment with substantial neurologic recovery. These syndromes have been the subject of intense investigation in the recent past, and occur more frequently in the pediatric population.

## DIAGNOSIS

Perhaps the most critical component in the diagnosis of PNS is clinical suspicion on the part of the medical team. PNS may cause injury anywhere along the neuraxis: autoimmune encephalitis can affect the supratentorial compartment of the brain, whereas the cerebellum is involved in paraneoplastic cerebellar degeneration (PCD) and OMA syndrome. The visual pathway is affected in cancer-associated retinopathy (CAR), whereas the spinal cord can be injured in subacute motor neuronopathy. Sensory neuronopathy involves the sensory nerves and, in LEMS, the neuromuscular junction is the target. Finally, inflammatory myopathies, including dermatomyositis, polymyositis, and inclusion body myositis, are PNS that affect the muscle. Once the neurologic targets of autoimmune attack are identified, laboratory-based screening of the relevant neuroanatomic compartment for autoantibodies should follow (Table 118-2). Paraneoplastic antibodies may be detected in serum and spinal fluid (Table 118-3). An array of paraneoplastic antibodies may be obtained. However, the judicious clinician should bear in mind that these

**TABLE 118-1** Paraneoplastic Syndromes of the Nervous System

<b>CLASSICAL</b>
Limbic encephalitis
Encephalomyelitis
Cerebellar degeneration
Opsoclonus-myoclonus
Sensory neuronopathy
Gastrointestinal pseudoobstruction/autonomic neuropathy
Lambert–Eaton myasthenic syndrome
Inflammatory myopathy
<b>NONCLASSICAL</b>
Brainstem encephalitis
Stiff-person syndrome
Motor neuron disease
Necrotizing myelopathy
Optic neuropathy/retinopathy
Acute sensorimotor neuropathy
Chronic sensorimotor neuropathy
Myasthenia gravis
<b>AUTOIMMUNE ENCEPHALITIDES</b>
NMDAR encephalitis
AMPA encephalitis
AMPA, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor; NMDAR, anti-N-methyl-D-aspartate receptor.

**TABLE 118-2** Diagnostic Criteria for Paraneoplastic Neurologic Syndromes

<b>DEFINITE PARANEOPLASTIC NEUROLOGIC SYNDROMES</b>
1. A classical syndrome and cancer that develops within 5 years of the diagnosis of the neurologic disorder
2. A nonclassical syndrome that resolves significantly after cancer treatment without concomitant immunotherapy provided that the syndrome is not susceptible to spontaneous remission
3. A nonclassical syndrome with onconeural antibodies (well characterized or not) and cancer that develops within 5 years of the diagnosis of the neurologic disorder
4. A neurologic syndrome (classical or not) with well-characterized onconeural antibodies (anti-Hu, Yo, CV2, Ri, Ma2, or amphiphysin) and no cancer
<b>POSSIBLE PARANEOPLASTIC NEUROLOGIC SYNDROMES</b>
1. A classical syndrome, no onconeural antibodies, no cancer, but at high risk to have an underlying tumor
2. A neurologic syndrome (classical or not) with partially characterized onconeural antibodies and no cancer
3. A nonclassical syndrome, no onconeural antibodies, and cancer present within 2 years of diagnosis

**TABLE 118-3** Paraneoplastic Syndromes and Associated Tumors and Antibodies

Clinical Syndrome	Associated Tumors	Associated Antibodies
Limbic encephalitis	SCLC, testicular cancer, thymoma, teratoma, Hodgkin disease, non-SCLC	<b>Anti-Hu</b> (ANNA-1), <b>anti-Yo</b> (PCA-1), <b>anti-Ri</b> (ANNA-2), ANNA-3, anti-Ma1, <b>anti-Ma2</b> (Ta), <b>anti-amphiphysin</b> , <b>anti-CRMP5</b> (CV2), PCA-2, anti-CRMP3,4, anti-NR2B,* NR2A,* neuropil antibodies,* <b>GABA<sub>B</sub></b> , <b>AMPA</b>
Cerebellar degeneration	Breast cancer, ovarian cancer, SCLC, Hodgkin disease	<b>Anti-Yo</b> (PCA-1), <b>anti-Hu</b> (ANNA-1), anti-Tr, <b>anti-Ri</b> (ANNA-2), antimGluR1, anti-VGCC, anti-Ma1, anti- <b>RMP5</b> (CV2), anti-Zic4
Opsoclonus-myoclonus	Neuroblastoma, SCLC, breast	<b>Anti-Ri</b> (ANNA-2), <b>anti-Yo</b> (PCA-1), <b>anti-Hu</b> (ANNA-1),* anti-Ma1, <b>anti-Ma2</b> (Ta), <b>anti-amphiphysin</b> , <b>anti-CRMP5</b> (CV2)
Stiff-person syndrome	Breast cancer, SCLC, Hodgkin disease	<b>Anti-amphiphysin</b> , <b>anti-GAD</b> , <b>anti-Ri</b> (ANNA-2), antigepryrin
Retinopathies	SCLC, melanoma, breast cancer	<b>Antirecoverin</b> , antienolase, anti-TULP1, anti-PTB-like protein, antiphotorceptor cell-specific nuclear receptor, <b>anti-CRMP5</b> (CV2)
Motor neuron disease	Lymphoproliferative disorders, SCLC, breast cancer, ovarian cancer	<b>Anti-Hu</b> (ANNA-1), <b>anti-Yo</b> (PCA-1), anti-MAG, anti-SGPS, antigangliosides GM1, GM2, GD1a, GD1b
Peripheral neuropathy	SCLC, thymoma, lymphoproliferative disorders	<b>Anti-Hu</b> (ANNA-1), <b>anti-CRMP5</b> (CV2), anti-MAG, anti-SGPS, antigangliosides GM1, GM2, GD1a, GD1b
Neuromyotonia	Thymoma, Hodgkin disease, SCLC	Anti-VGKC, <b>anti-Hu</b> (ANNA-1)
Lambert–Eaton syndrome	SCLC	Anti-P/Q VGCC
Myasthenia gravis	Thymoma	Anti-AChR, <b>antititin</b> , antiryanodine
Inflammatory myopathies	Non-Hodgkin lymphoma, ovarian cancer, lung cancer, gastric cancer, pancreatic cancer, bladder cancer	Anti-Jo-1, anti-JO, anti-Mi-2, antip155

Well-characterized onconeural antibodies are in bold.  
 AMPAR, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor; ANNA, antineuronal nuclear antibody; CRMP, collapsin response mediator protein; GABA<sub>B</sub>, γ-aminobutyric acid type B receptors; GAD, glutamic acid decarboxylase; MAG, myelin-associated glycoprotein; NR, NMDA(N-methyl-D-aspartate) receptor; PCA, Purkinje cell autoantibody; PTB, polypyrimidine-tract binding; SCLC, small-cell lung cancer; SGPS, sulfated glucuronic acid paragloboside; TULP1, tubby-like protein 1; VGCC, voltage-gated calcium channels; VGKP, voltage-gated potassium channel; voltage-gated calcium channels.  
 \*Pediatric cases reported.  
 (Adapted with permission from *Toothaker and Rubin, 2009*.)

“paraneoplastic panels” represent only the most commonly encountered paraneoplastic antibodies, and do not encompass the full range of possible onconeural antibodies. In the patient with a well-described PNS such as PCD and elevated anti-Yo paraneoplastic antibody titer, a diligent search for malignancy, including body PET and abdominal and chest imaging, is appropriate. In patients for whom the paraneoplastic panel is unrevealing, demonstration of intrathecal clonal antibody production and/or the presence of a clonal population of antibodies provides supportive evidence. If the serum is reactive against both the patient’s own tumor and the relevant neuroanatomic compartment, that is, the dorsal root ganglia in sensory neuronopathy, a paraneoplastic process may be diagnosed despite the absence of a previously described onconeural antibody. These formal principles of PNS diagnosis are of particular use to the clinician presented with a neurologic syndrome not previously described (see Table 118-2).

## TREATMENT

The general principles of treatment in PNS reflect the current pathophysiologic understanding of these syndromes. Generation of onconeural antibodies must be suppressed if not arrested by treatment (surgical, radiotherapeutic, or chemotherapeutic) of the underlying malignancy. Antibody load must be reduced to reduce insult to the nervous system. The pace of this treatment process is dictated by the pace of the illness itself, and by the particular nervous structures involved: a slowly progressive LEMS may be initially managed on an outpatient basis with intravenous immunoglobulin (IVIg) infusions, with screening for malignancy. In contrast, a patient with rapidly progressive encephalitis, such as NMDA-receptor encephalitis, may require ICU-level neuromonitoring, airway management, and aggressive immunosuppression concurrent with surgical resection of suspected tumor mass.

There are few trials focused on PNS treatment strategies. Treatments are therefore largely empiric and based on extension of observations from other autoimmune diseases. In practice, initial treatments with corticosteroids, IVIg, plasma exchange, and/or rituximab may be followed by more aggressive immunosuppression with cyclophosphamide, tacrolimus, or cyclosporine in the setting of precipitous neurologic decline. There are no standard dosing regimens for PNS; the interested reader is directed to a recent excellent review on this topic (Rosenfeld and Dalmau, 2013).

These general principles of diagnosis and treatment will be applied to several PNS and will serve to illustrate the wide range of clinical presentations, relevant diagnostic and treatment strategies, as well as outcomes in these fascinating autoimmune syndromes.

## CLASSICAL PNDS

### Lambert–Eaton Myasthenic Syndrome

Several neurologic paraneoplastic disorders may affect the neuromuscular junction: LEMS, myasthenia gravis (MG), and neuromyotonia. MG and neuromyotonia are well-covered elsewhere in this volume (Chapters 136 and 137). LEMS is a disorder of presynaptic neuromuscular transmission, in contradistinction to the postsynaptic disorder MG.

**Clinical features:** Diffuse weakness and fatigue are the typical initial complaints, followed by sleepiness, evidence of autonomic dysfunction, muscle weakness on confrontational testing, and diminished deep tendon reflexes. Consistent with their distinct neuroanatomical localization, LEMS and MG display distinct electromyographic responses: patients with LEMS have an incremental response to repetitive muscle

stimulation, whereas those with MG have a decremental response. Forty percent to 60% of patients with LEMS harbor a malignancy and neurologic symptoms often precede tumor diagnosis.

**Antibodies:** The onconeural antibodies associated with LEMS are antivoltage-gated calcium channel antibodies (VGCC, V/Q type). The most common malignancy associated with LEMS is small-cell lung cancer (SCLC). However, this relationship is complex: Payne and colleagues examined 63 patients with the diagnosis of SCLC and found that 5 (8%) had high titers of anti-VGCC antibodies present in the serum, with only 2 (3%) exhibiting clinical and electrophysiologic evidence of LEMS (Payne et al., 2010). Moreover, though classically associated with SCLC, LEMS may occur in other malignancies: there have been several reports of neuroblastoma-associated LEMS in pediatric patients.

**Prognosis:** The disease course is exceedingly variable; outcome prediction is made more complex by concurrent malignancy. In a retrospective analysis of LEMS associated *without* SCLC, mean antibody titers declined after prolonged immunosuppression, and most patients improved clinically and electromyographically. However, long-term disability was high with over 25% of patients requiring the use of a wheelchair at final follow-up (on average 3 to 4 years after diagnosis).

**Treatment:** Corticosteroids, IVIg, plasmapheresis, and azathioprine are all commonly employed in the management of this PNS. Although less common, dysphagia and attendant aspiration risk are important sources of morbidity and mortality in this neuromuscular syndrome. Therefore non-pharmacologic measures, including speech and swallow therapies, are also key treatments in the management of these patients.

## OPSOCLONUS MYOCLONUS ATAXIA SYNDROME

OMA syndrome (also called “dancing eyes, dancing feet syndrome,” myoclonic encephalopathy of infancy, or Kinsbourne syndrome) is a paraneoplastic syndrome associated with neuroblastoma in children and breast cancer in adults.

**Case 1:** MS is a previously healthy 18-month-old girl who developed sudden onset of ataxia, chaotic rapid eye movements and irritability. MRI of the brain was normal and metaiodo-benzyl-guanidine (MIBG) revealed uptake in the left adrenal gland (Fig. 118-1). Thin-cut contrast-enhanced CT of the chest/abdomen/pelvis confirmed a homogeneously enhancing mass in the left adrenal gland. Tumor was resected and found to be consistent with favorable histology, non-MYC*N*-amplified neuroblastoma. The patient did not require further therapy for neuroblastoma; however, for treatment of refractory OMA syndrome, she received monthly IVIg for 2 years, intramuscular ACTH for 14 months, and a 4-week course of rituximab. Motor symptoms of OMA completely resolved after 24 months of therapy. The patient is now 6 years old and “mainstreamed” for education; gross motor symptoms have resolved and she receives weekly occupational and speech therapy. Her neuroblastoma has been in remission since surgery.

**History:** Orzechowski first coined the term in 1913 based on the Greek term “opso” meaning eye and “clonus” meaning violent, nonpurposive motion. “... the ocular globes are in a state of continuous agitation, being shaken and increasingly displaced by very rapid unequal movements, which generally take place in the horizontal plane.” In 1927, he noted the association between opsoclonus and myoclonus. Kinsbourne described a syndrome of myoclonic encephalopathy in 1962 and finally in 1968, Solomon and Chutorian described the association between neuroblastoma and OMA syndrome.

**Figure 118-1.** Images of the patient in case 1. Metaiodo-benzyl-guanidine (MIBG) showing uptake in the left adrenal gland. Thin-cut contrast-enhanced CT scan of the abdomen confirmed a homogeneously enhancing mass in the left adrenal gland.

**Incidence:** The incidence of OMA syndrome is estimated at 1 in 10 million, occurring in 2% to 3% of all neuroblastoma patients. Up to 50% of children with OMA harbor a neuroblastoma; some researchers speculate that the incidence of neuroblastoma in children with OMA is actually higher but a cellular and/or antibody-mediated response destroys the tumor before detection. OMA in children has been reported in infections, including EBV, mumps, West Nile virus, salmonellosis, and *Mycoplasma pneumoniae*. OMA is paraneoplastic in 20% of adults. Typically, patients have breast or gynecologic cancers.

**Clinical features:** Patients with OMA typically have rapid, involuntary, irregular but conjugate eye movements; myoclonic jerking of the limbs, trunk, and head; truncal ataxia; and irritability with rage attacks and other behavioral disturbances. Patients tend to keep their eyes closed, as they experience oscillopsia.

**Antibodies:** The most common antibody associated with OMA in adults is the anti-Ri antibody that binds to Nova, an RNA-binding protein important in regulating inhibitory neurotransmitters in the brainstem. Despite multiple attempts to isolate a specific antibody in pediatric patients with OMA, to date one has not been identified. Approximately 75% of neuroblastomas express anti-Hu antigen, but only 5% to 15% of serum samples contain the anti-Hu antibody. Classically, the OMA precedes the diagnosis of neuroblastoma. Kurian and colleagues described a 23-year-old woman with OMA syndrome plus other neurologic abnormalities (facial palsy, frontal lobe-type disinhibition behavior). Extensive evaluation for malignancy was negative but the patient did have anti-NMDA receptor antibodies present in the CSF. Morales-Briceno reported a case of OMA that developed in a patient 5 days after an upper respiratory infection. GQ1b antibodies were detected in CSF and patient improved shortly after IVIg.

**Evaluation and treatment:** MRI of the brain is typically normal at the onset of OMA although it may reveal cerebellar

atrophy at a later time. Lumbar puncture early in the course of the illness may reveal normal to slightly elevated protein with no cells or predominantly B-cell lymphocytes. If the patient has already been diagnosed with neuroblastoma, LP should be avoided in patients with known bone marrow disease, as there are data to suggest that LP in these patients may potentially seed the CNS.

Children with OMA should have an MIBG scan in an effort to identify the neuroblastoma. Thin-cut CT through the area of increased uptake will help identify the tumor. Patients usually have lower stage/grade neuroblastoma with favorable histology and unamplified *MYCN*. Treatment of the OMA begins with surgical resection of the tumor and is typically followed by immunomodulation. For 2 days perioperatively, IVIg is administered at a dose of 1 g/kg, as surgery may transiently increase symptoms. There are numerous protocols for immune suppression thereafter, but clearly immunomodulation is the next treatment of choice. In 1997 Russo and colleagues suggested that children with OMA-associated neuroblastoma had better neurologic outcome if they received cyclophosphamide chemotherapy as part of the treatment for neuroblastoma. Pranzatelli and colleagues at the National Pediatric Myoclonus Center have advocated the use of ACTH as follows: within 1 week of surgery, patients are started on ACTH 75 IU/m<sup>2</sup>/day intramuscularly twice daily. The ACTH is tapered quickly in the first month and then more slowly over the next 11 months. If OMA recurs, the previous dose of ACTH is reinstated. High-dose pulse dexamethasone has been successfully used with lower cost of treatment and fewer long-term side effects of ACTH. Pranzatelli and colleagues identified B-cell expansions in the CSF of many of these patients and found that a short course of rituximab (375 mg/m<sup>2</sup>/week for 4 consecutive weeks) improves symptoms. If a prominent T-cell population is noted in the CSF of refractory patients, then cyclophosphamide is recommended at a dose of 750 mg/m<sup>2</sup>/day monthly for 3 to 6 months. Ofatumumab has also

been successfully used: in one patient who developed an allergy to rituximab and in a patient in combination with methotrexate (Ketterl et al., 2013). Patients with OMA should not receive immunizations as any stimulus to the immune system may exacerbate the symptoms.

**Prognosis:** Patients with neuroblastoma-associated OMA typically have a better overall survival than patients without OMA (Rudnick et al., 2001). Their neurologic and cognitive outcomes, however, are generally not as good. I Catsman-Berrepoets identified 9 children with OMA (4 with neuroblastoma) who were followed for a median of 11 years. Despite severe motor deficits initially, patients actually recovered these functions quite well; in 7/9 patients, however, severe cognitive and behavioral impairments persisted. Hasegawa and colleagues identified 23 patients with OMA from 2005 to 2010 in Japan. They reported 44% with identified neuroblastoma, 40% with infection, and 9% related to immunizations. They also reported a high rate of intellectual impairment (74%) and the most severely affected patients were those whose treatment was delayed (Hasegawa et al., 2014).

**Pathophysiology:** As yet, the pathophysiology of OMA is poorly understood. In 2003 Helmchen and colleagues performed fMRI in two adults with OMA syndrome and demonstrated disinhibition of the fastigial nucleus in the cerebellum. As mentioned above, unlike adults, children with OMA do not have a specific antibody present in the CSF and serum. The initial suggestion that the syndrome is humorally mediated is being challenged as more evidence supports a cellular etiology. Though the neuroblasts of OMA-associated neuroblastomas appear histologically identical to those tumors in patients without OMA, the tumors themselves are quite distinctive. Patients with OMA-associated neuroblastoma have large lymphocytic infiltrates present in the tumor specimens. In a study by Cooper and colleagues, the pathologist could identify which patients had OMA simply by looking at the tumors in 92% of cases.

Saccades are normally prevented by inhibitory pontine pause cells. Inappropriate timing of pause cell inhibition or excessive firing of burst cells may lead to "saccadomania" (e.g., opsoclonus).

## SUBACUTE SENSORY NEURONOPATHY

PNS can affect peripheral nerves, neuromuscular junction, or muscle. In one series, 9% of patients referred to a center for evaluation of a peripheral neuropathy had cancer as the underlying cause. The neuropathy may be axonal or demyelinating, or in the case of a pure sensory neuropathy, a dorsal root ganglionopathy. In patients older than 50 years, particularly smokers and those with acutely developing purely sensory neuropathy, a PNS is likely.

**History:** In 1948, Denny-Brown described two patients with a rapidly developing and debilitating sensory neuronopathy. Pathologic evaluation revealed inflammatory infiltrates within the dorsal root ganglia and degeneration of the posterior columns of the spinal cord. In 1985 Graus and colleagues identified an antibody called anti-Hu associated with patients who have SCLC and SSN.

**Clinical features:** Anti-Hu patients typically have sensory loss and paresthesias, which may affect the extremities initially, but may also include the neck and trunk and can occasionally be asymmetric. All sensory modalities are involved, but proprioceptive loss can severely impair gait and use of the hands. In 1992 Dalmau and colleagues identified 71 patients with paraneoplastic encephalomyelitis syndrome/SSN in association with the presence of anti-Hu antibodies. Seventy-eight percent had SCLC. In 9 patients no tumor was detected. In the others, tumors included prostate cancer (2), adenocarcinoma of the lung (1), chondromyxosarcoma (1), and, interestingly, neuroblastoma (1).

**Antibody:** Anti-Hu antibody is a 35 to 40 kDa protein that immunoreacts with the nuclei of neurons. The antigen is expressed in the nuclei of most neurons in the CNS, including those in the dorsal root ganglia, explaining why the anti-Hu neurologic paraneoplastic syndrome may cause encephalomyelitis and/or SSN in the same patient. In addition, most SCLCs express the antigen as well.

**Treatment and prognosis:** Detection of the anti-Hu antibody in patients with SCLC is associated with response to cancer treatment and improved survival. However, a retrospective review of 71 patients with anti-Hu syndromes (59% of whom demonstrated sensory neuropathy) revealed that treatment of the primary tumor with surgery, chemotherapy, or radiation did not improve the neurologic symptoms in any patient.

## NONCLASSICAL PNS

### Paraneoplastic Cerebellar Degeneration

PCD is a paraneoplastic syndrome of pan-cerebellar dysfunction most commonly associated with SCLC, ovarian, and breast malignancies.

**History:** PCD was actually the first paraneoplastic syndrome to be described and as such is the most well described and easily recognized. In 1919 Brouwer described a patient with rapid onset of a cerebellar syndrome. At autopsy the patient had Purkinje cell loss in the cerebellum and a pelvic tumor, most likely ovarian carcinoma. In 1938 Brouwer postulated the association between PCD and cancer. PCD may occur in isolation but may be associated with other PNS, including limbic encephalitis (LE) and LEMS.

**Clinical features:** PCD is most commonly associated with SCLC, gynecologic cancers, and Hodgkin lymphoma. Symptoms often begin precipitously with dizziness, nausea, and vomiting. Patients may develop diplopia and subsequently both truncal and appendicular ataxia, and dysarthria and dysphagia: a veritable pan-cerebellar syndrome. Though not necessary to make the diagnosis, the CSF may display mild pleocytosis and MRI may reveal cerebellar edema. There is evidence of clonal antibody production in the CSF, classically anti-Yo. About 50% of patients with SCLC and PCD do not harbor currently identified onconeural antibodies.

PCD clinical manifestations are diverse: patients with SCLC and PCD may also develop LEMS because of the presence of antibodies to VGCC that may cause both syndromes. Sabater and colleagues described a PCD ZIC variant (associated with zinc fingers in the cerebellum) in which MRI is initially normal, but as the disease progresses, cerebellar atrophy may become more prominent. The diversity of PCD clinical presentation suggests that PCD does not represent a single syndrome, but rather a collection of several, similar nonclassical PNS with onconeural antibodies directed against Purkinje cell antigen.

**Antibodies:** Onconeural antibodies in PCD, such as anti-Yo, are directed against a cytosolic Purkinje cell antigen, cDR2 (cerebellar degeneration-related protein). The resulting cytotoxic T-cell response results in massive Purkinje cell destruction visible on histopathology at autopsy. The anti-Yo antibody is the most frequently detected antibody in patients with PCD and ovarian or breast cancer. Patients with gynecologic cancers who develop PCD invariably harbor anti-Yo antibodies. Interestingly, approximately 60% of patients with ovarian cancer who do not have PCD express cDR2 on their tumor cells. All patients with PCD-associated breast and ovarian cancer express cDR2 antigens on their tumor cells.

**Treatment and prognosis:** Treatment of PCD has generally consisted of corticosteroid, plasmapheresis, or IVIg; there is scant evidence to support one of these regimens over another. Prognostication response to treatment is challenging,

particularly in the setting of active malignancy. However, a small retrospective analysis suggests that modest to substantial functional improvement can occur with inpatient rehabilitation after initial treatment for PCD. In addition, though anti-Yo PCD was formally diagnosed in 34 women, only 63% of these women were eventually diagnosed with malignancy after more than 4 years of follow up.

## STIFF-PERSON SYNDROME

**History:** Moersch and Woltman first described the “stiff-man syndrome” (SMS) in a series of 14 patients with fluctuating truncal and limb rigidity in 1956. This syndrome became notable for distinctive hyperexcitability of spinal motor neurons, as well as marked therapeutic benefit with diazepam treatment. In 1988 Solimena and colleagues demonstrated the autoimmune nature of the disease and first linked glutamic acid decarboxylase antibodies to the syndrome, providing a pathophysiologic mechanism to account for decreased GABAergic tone in these patients.

**Clinical manifestations:** There are three recognized phenotypes of SMS: classic, variant, and progressive encephalomyelitis with rigidity and myoclonus (PERM). Classic SMS presents with stiffness and spasms of the lumbar region and lower extremities. Variant SMS is characterized by stiffness limited to a single limb or the trunk. Entire-body stiffness in conjunction with encephalomyelitis is the hallmark of PERM syndrome. In all phenotypes, examination of the symptomatic region is notable for rigidity with continuous muscle activity despite attempted relaxation.

Although more common in women than in men, in the pediatric population SMS is evenly distributed between boys and girls (Clardy et al., 2013). A recent retrospective review over a 29-year period at the Mayo clinic found that 5% of SMS cases were diagnosed in patients less than 18 years of age. Importantly, all pediatric cases had positive antiglutamic acid decarboxylase (GAD) serology, 5/8 of the patients had a coexisting immune disorder, and cancer was not identified in any of the pediatric patients.

Brainstem and spinal hyperexcitability are hallmarks of SMS. These are demonstrated by exaggerated and poorly habituating acoustic startle reflex, exaggerated exteroceptive reflexes (tactile, thermal, visual, acoustic, and pain reflexes), and/or continuous paraspinous motor unit activity. In a recent retrospective review, 61% of patients with classic and 45% of patients with variant SMS demonstrated spinal hyperexcitability. Consistent with the poor GABAergic tone in these patients, psychiatric comorbidities, including anxiety and specific phobias, may complicate diagnosis in SMS. The differential diagnosis of these patients includes hereditary spastic paraplegia, hereditary hyperekplexia, and spastic dystonias.

**Antibodies:** 80% of SMS will have positive serology for GAD65 (glutamic acid decarboxylase, the rate-limiting enzyme for the production of GABA<sub>A</sub>). Other antibodies associated with SMS include glycine receptor alpha 1 subunit (GlyR $\alpha$ 1), accounting for about 10% of SMS. Antiampiphysin antibodies are also implicated in SMS, most commonly associated with breast adenocarcinoma and SCLC in adults.

**Treatment and prognosis:** Treatment attempts to increase GABAergic tone, both pharmacologically and immunotherapeutically. Diazepam and baclofen are both commonly employed to improve stiffness and spasms. IVIg, plasmapheresis, prednisone, and rituximab have all been shown to improve symptoms as well. The bulk of clinical improvement was apparent after the first year of treatment, and though stiffness and spasms were improved with immunotherapy, mobility changes because of therapy were infrequent.

## LIMBIC ENCEPHALITIS

Limbic encephalitis (LE) is a paraneoplastic syndrome characterized by onconeural antibodies reactive against the limbic regions of the brain. In LE, the presentation is generally abrupt (days to weeks) with onset of personality/behavior changes, seizures, and alteration of consciousness.

**History:** Paraneoplastic LE was first described in 1968 by Corsellis and colleagues, who published a clinicopathologic series of patients with carcinoma and neurologic symptoms consisting of seizures and memory loss. Since then, two distinct clinical syndromes have emerged: those that result from antibodies directed against cell surface antigens (the autoimmune encephalitides; discussed below), and those like LE that result from antibodies directed against intracellular antigens.

**Clinical features:** Acute and persistent memory loss with behavioral changes may be the first presenting symptom of malignancies such as SCLC. When these symptoms occur in a previously well person, LE, either paraneoplastic or nonparaneoplastic (autoimmune), must be considered.

Brain MRI may show FLAIR and T2-weighted hyperintensity; imaging changes in the medial temporal lobes are frequently mistaken for herpes simplex. However, the inflammatory process may involve the hippocampi, amygdalae, and, less frequently, frontobasal and insular regions. CSF may reveal lymphocytic pleocytosis, oligoclonal bands, and elevated protein. EEG may show generalized slowing and epileptiform activity primarily in the temporal lobes. LE is associated with SCLC in 50% to 60% of patients, with testicular germ cell tumors in 20% of patients, and breast cancer approximately 8% of patients. If no paraneoplastic antibodies are found and PCR rules out herpes simplex encephalitis, one must search for cancer, usually by body PET imaging.

In addition to symptoms from LE, patients with antibodies directed against intracytoplasmic targets also present with other neurologic symptoms. For example, sensory neuronopathy or encephalomyelitis is frequently present in LE with anti-Hu antibodies.

**Antibodies:** The anti-Hu antibody is present in 60% of cases in which an antibody is detected; presence of anti-Hu antibody in patients with paraneoplastic LE confers a 94% chance of having SCLC. More than 95% of patients with antibodies against intracytoplasmic targets have cancer, and the outcome is poor with limited response to treatment.

## CANCER-ASSOCIATED RETINOPATHY

Paraneoplastic visual disorders are rare. Among these, CAR and melanoma-associated retinopathy are the most common syndromes. CAR was first reported in 1976 by Sawyer and colleagues who evaluated three women with visual loss before or after the diagnosis of cancer was made. In 50% of patients, CAR precedes the diagnosis of cancer, typically SCLC and gynecologic cancers.

Patients complain of painless visual loss that may begin with night blindness. On physical examination the retina may initially appear normal but later is mottled with optic disc pallor and retinal artery narrowing. CAR affects rods and cones and histologically shows loss of both inner and outer layers with occasional inflammation. Vitreous and CSF may contain inflammatory cells. Several antibodies have been identified, but most commonly, antirecoverin is found.

Recoverin is a member of a family of calcium-binding proteins involved in the transduction of light by photoreceptors. Recoverin has been found to be expressed in the lung tumor of a CAR patient but not in similar tumors obtained from individuals without the associated retinopathy.

## AUTOIMMUNE ENCEPHALITIDES

The paraneoplastic encephalitides are defined by onconeural antibodies to neuronal cell-surface or synaptic receptors (Dalmou and Rosenfeld, 2014). These encephalitides are the result of onconeural antibodies directed against the AMPA receptor, GABAB receptor, LGI1, Caspr2, GABAA receptor, DPPX, glycine receptor, mGluR1, mGluR5, dopamine-2 receptor, and, most commonly, the NMDA receptor.

### ANTI-N-METHYL-D-ASPARTATE RECEPTOR ENCEPHALITIS

**Case 2:** D.F. is a 6-year-old boy who developed a change in behavior followed by focal seizures and gait disturbance. EEG revealed nonconvulsive status epilepticus requiring induction of burst suppression with phenobarbital and levetiracetam. Contrast-enhanced MRI of the brain, lumbar puncture, and CNS PET scan were normal. CSF, however, revealed the presence of anti-N-methyl-D-aspartate receptor (NMDAR) antibodies. He was treated with IV steroids and IVIg. Further oncologic evaluation included a total body PET scan, a CT scan of the chest/abdomen/pelvis, and scrotal ultrasound, all of which were normal. He was weaned off all medications over several months and achieved a complete recovery.

**History:** In 1997, Nokura and colleagues reported a case of a 19-year-old woman with psychosis and confusion who was found to have an ovarian teratoma. Once the teratoma was removed the patient made a partial recovery. At that time, no clear paraneoplastic antibody was identified. Other similar cases were subsequently described but the first antibody was not identified until 2005 when Vitaliani and colleagues reported four young women with ovarian teratoma with acute behavioral and psychiatric changes, neurologic deterioration, seizures, orofacial dyskinesias, and central hypoventilation. CSF and serum revealed a novel antibody against EFA6A, a protein expressed in the cytoplasm of hippocampal neurons. In 2007 Dalmou and colleagues further characterized these antibodies as being against the NR1 subunit of the NR1/NR2 heteromers of the NMDAR, also expressed on the tumors.

**Clinical features:** In 2008, the same group analyzed 100 cases of patients with anti-NMDAR encephalitis. Ninety-one percent of patients were women; 59% had tumors (primarily ovarian teratomas), although one man had SCLC. Twenty-two aged 18 years or less, and 55% of these patients had an underlying tumor. Severe neurologic deficits, including poor responsiveness, catatonia, abnormal movements, and central hypoventilation, were present in 93 patients. Ninety-two percent of patients had abnormal EEGs; 95% had abnormal CSF profiles and 55% had FLAIR or T2 signal abnormalities on MRI. Adang and colleagues reviewed 29 cases of nononcologic anti-NMDAR encephalitis and noted that in 78% of cases symptoms began in warm weather months, suggesting a seasonal trigger. Nosadini and colleagues identified four pediatric patients with anti-NMDAR encephalitis and reported 4 distinct phases of EEG findings: 1) early phase, during the behavioral and orofacial/limb dyskinesias where the EEG is essentially normal; 2) florid phase, when consciousness is impaired, stereotyped movements occur, and the EEG shows rhythmic delta/theta that is not responsive to stimuli or anti-epileptic medications; 3) recovery phase, when rhythmic sequences decrease; and 4) normalization phase, when EEG is back to baseline usually 2 to 5 months after onset of the disease.

The current view in the pediatric population is that if no tumor is detected during the initial evaluation, further oncologic evaluation is not warranted unless symptoms recur (Dalmou, personal communication, 2010).

**Prognosis:** Despite severe neurologic deficits, 75% of patients made a complete recovery whereas 25% had severe deficits or died. In 2009 Florance and colleagues reported 81 patients with NMDAR encephalitis from several institutions (Florance et al., 2009). Thirty-two patients were 18 years old or younger. Seventy-seven percent of pediatric patients had seizures; 84% had movement disorders and 60% had personality or behavioral changes. Teratomas were identified in 25% of patients, all of whom were adults. As mentioned above, Kurian et al. reported about a 23-year-old woman with OMA syndrome plus features of LE who was diagnosed with NMDAR encephalitis. A tumor was not identified in this patient and although she made a significant recovery with immunotherapy, she had persistent frontal lobe behavioral abnormalities 5 months after diagnosis. In 2009 at the European Paediatric Neurologic Society meeting, multiple groups reported about individual children with and pediatric patient case series of NMDAR encephalitis, none of whom had evidence of malignancy and most of them had favorable neurologic outcome.

## CHAPTER SUMMARY AND FUTURE PERSPECTIVE

Among neurologic complications of cancer, PNS represent a significant challenge in both diagnosis and treatment. These problems loom larger as systemic cancers respond better to treatment leading to longer survival. Discovery of new paraneoplastic antibodies and other diagnostic techniques, particularly advances in imaging (MRI and PET), have allowed for earlier cancer diagnosis. Further work is necessary to understand the exact role of different antibodies in PNS. Many new antibodies against neuronal cell-surface antigens will probably be described in the future. Factors hampering clinical research include methodological difficulties in study design and patient accrual in uncommon entities. A regularly updated classification of PNS and its subtypes, according to autoantibodies and the roles these antibodies have, is needed. It is hoped that understanding pathophysiology, identifying subtypes, and development of newer immunosuppressive agents will lead to improved prognoses in PNS.

## INTRODUCTION

### Background

Definitions: Immune Activation, Immune Mediation, Autoimmune

Immunologic activity in the central nervous system (CNS) can take many forms. There is a low rate of immune surveillance of the CNS under normal resting conditions. However, if the acquired immune system is activated peripherally, activated lymphocytes or autoantibodies can access the CNS, which may recognize autoantigens and cause secondary activation of the immune system. A number of other variables are also likely to be important, such as disruption of the blood–brain barrier secondary to infection. There is also no doubt that some people are predisposed to autoimmunity; different populations appear vulnerable to certain autoimmune CNS disorders. Therefore autoimmune CNS disorders are undoubtedly complex, involving genetic vulnerability, environmental factors (e.g., infection), and the acquired and innate immune systems. However, the immune system and its role in the CNS is complex, and for this reason we start with some simple definitions:

**Autoimmune:** Autoimmune disorders usually result from a loss of immune tolerance or abnormal activation of the acquired immune system. Autoimmunity is typically dominated either by T-cell mechanisms or humoral mechanisms (B cells and autoantibody), or often both. Autoimmune disorders often respond to immune-suppressive therapies.

**Immune mediation:** This is a more ambiguous term that is typically used when the immune system is clearly driving the inflammatory response in the CNS, although the exact mechanism by which this is occurring is unclear. For example, this term is used in disorders such as acute disseminated encephalomyelitis, which is clearly an inflammatory brain condition, but the exact immune mechanisms are likely complex and incompletely understood.

**Immune activation:** This term is more typically used when there is activation of the immune system secondary to neurologic damage, such as in stroke, neurodegeneration, metabolic processes, or trauma. This immune response could theoretically be damaging or protective. The benefit of immune suppression in this context is less clear.

### Autoantibody: The Cell-Surface Paradigm

Antibodies are part of the body's defense system against infection. Autoantibodies are antibodies that attack the host and are associated with a broad spectrum of acquired autoimmune disorders. Some of these autoantibodies are diagnostic biomarkers but probably do not play a pathogenic role in disease. However, other autoantibodies are both diagnostic biomarkers and pathogenic in the disease process. Even in disorders

that are clearly mediated by autoantibodies, the autoantibody rarely acts in isolation, and the autoimmune process is complex, involving autoantibodies, T cells, and sometimes other immune cells or immune molecules.

Paraneoplastic autoantibodies, such as anti-Hu and anti-Yo antibodies, are autoantibodies that are strongly associated with tumors and almost exclusively described in adults. These autoantibodies are important biomarkers of disease but are not pathogenic autoantibodies, because they bind to intracellular proteins. These autoantibodies will not be described further in this chapter, and their relevance to pediatric neurology is minimal.

In the last decade, increasing examples of cell-surface autoantibodies that are involved in autoimmune CNS disease have been found. This cell-surface paradigm involves the principle that autoantibodies that are pathogenic bind to cell-surface epitopes of neurologic proteins involved in neurotransmission or cell function (Irani et al., 2014). The best examples of this paradigm are antibodies that bind to important neuronal receptors such as the N-methyl-D-aspartate (NMDA) receptor, the gamma-aminobutyric acid (GABA) receptors, or the glycine receptor. Other cell-surface proteins include synaptic proteins such as LGI-1 and CASPR2, which are part of the voltage-gated potassium channel complex. These autoantibodies typically bind to the extracellular domains of these receptors or proteins. For example, the dominant epitope involved in NMDA receptor autoantibody binding is the extracellular amino terminus domain of the NR1 subunit of the NMDA receptor.

### Autoantibody Methodology

There are many different methods to detect autoantibodies. However, each of these methodologies can affect the way the protein is presented to the autoantibody. For example, tissue homogenization results in destruction of cells and consequent release of intracellular and membrane proteins. The use of this method will therefore result in detection of autoantibodies against proteins that may not be physiologically relevant. For this reason, to measure cell-surface autoantibodies, it is necessary to present the protein of interest (such as a receptor) in its conformational state on the surface of a representative cell. These cell-based assays have become the classic method to define autoantibodies against cell-surface antigens.

### Autoantibody Pathogenic Mechanisms

An autoantibody can have multiple mechanisms of action. For example, an autoantibody can bind to a protein, triggering complement or natural-killer binding with resultant secondary cytotoxicity and cell death. As described earlier, some autoantibody-associated diseases are now recognized to

involve additional T-cell mechanisms and engagement of neutrophils and eosinophils, such as in neuromyelitis optica. However, sometimes the autoantibody binding alone results in direct alteration of the antigen. For example, autoantibodies that bind to the NMDA receptor result in alteration of the receptor function, followed by internalization of the receptor away from the cell surface, ultimately resulting in NMDAR receptor hypofunction. A similar mechanism of action has been described for many of the cell-surface autoantibodies. This direct pathogenic process is generally considered to be reversible if the autoantibody is removed.

## IMMUNE-MEDIATED EPILEPSY

### Autoimmune Encephalitis Syndromes

Before we discuss the different causes of autoimmune epilepsy or movement disorders, we will first consider the different diagnostic categories, which are as follows:

**Encephalitis:** Encephalitis is inflammation of the brain. Pathologically, there is typically inflammatory infiltrate of the brain parenchyma surrounding the blood vessels. Encephalitis can result from infections, including those caused by viruses and bacteria, but also autoimmune and immune-mediated mechanisms. Encephalitis is a clinical syndrome, and to improve diagnostic classifications, international criteria have been proposed. In brief, encephalitis is diagnosed when there is acute or subacute neurologic dysfunction in association with encephalopathy, plus evidence of brain inflammation evidence on magnetic resonance imaging (MRI) or cerebrospinal fluid (CSF) examination. Although many of the autoimmune CNS disorders result in encephalitis, some of the autoimmune processes result in a focal neurologic deficit without overt encephalopathy, examples being autoimmune cerebellar ataxia and Sydenham chorea.

**Limbic encephalitis (autoimmune or paraneoplastic):** Limbic encephalitis is encephalitis affecting the limbic region, which classically includes the mesial temporal lobe, the hippocampus, and the amygdala. Typically this results in cognitive dysfunction, personality change, confusion, and temporal lobe seizures, although more diffuse signs are sometimes evident. Limbic encephalitis can result from an autoimmune process, a paraneoplastic process, or, alternatively, infections with certain pathogens, such as HHV-6 infection in immune-suppressed individuals.

**Pan-encephalitis:** The best example of a pan-encephalitis is anti-NMDA receptor encephalitis. Since its original descriptions, it has been clear that this autoimmune encephalitis particularly affects young people from infancy to middle age. Females are more commonly affected in adulthood, but males and females are nearly equally affected in children under 10 years of age. A diagnosis is made by finding the presence of autoantibodies against NMDA receptor in the CSF and/or sera. CSF NMDA receptor antibodies are more specific than serum antibodies (Dalmau et al., 2011). The syndrome is paraneoplastic and associated with ovarian teratoma in a minority of female adolescents. More commonly the encephalitis is unexplained, or occasionally may follow a well-defined infection. Recently, some cases of anti-NMDAR encephalitis following confirmed herpes simplex encephalitis have been described, providing an example of post-viral autoimmune encephalitis. The clinical syndrome in its full form is very recognizable, with psychosis, agitation, and dyskinesias being typical and characteristic. Encephalopathy, aphasia, seizures, and dysautonomia may also occur, but these features are less helpful in the differentiation from other encephalitis syndromes. MRI results are normal in approximately half of patients, although MRI may show limbic encephalitis or nonspecific white-matter or

cortical changes. CSF pleocytosis occurs in two-thirds of children affected by anti-NMDAR encephalitis, and oligoclonal bands may be present in established disease. There is increasing evidence that immune therapy improves outcomes, reduces relapses, and reduces the risk of mortality. First-line immune therapy is with corticosteroids, intravenous immunoglobulin, or plasma exchange, and if this is inadequate, second-line therapy with rituximab or cyclophosphamide, or both, can be used for rescue therapy. Relapses occur in less than 10%, tend to be less severe, and have decreased in incidence since the original descriptions, possibly in relation to the increased use of early immune therapies (Titulaer et al., 2013).

### Autoantibody Associations with Epilepsy

The recognition of autoimmune encephalitis has resulted in increased interest in autoimmune and inflammatory causes of seizures and epilepsy (Suleiman and Dale, 2015). Table 119-1 describes autoantibodies associated with seizures and epilepsy in the context of autoimmune encephalitis. The table describes the seizure association and the other features associated with the respective autoantibodies. Many of the syndromes are characterized by movement disorders or other localizing features. Indeed, a recent large study of all types of encephalitis in children noted that the presence of movement disorders was significantly associated with the chance of the encephalitis being autoantibody associated (Pillai et al., 2015). For example, dyskinesias are common in anti-NMDAR encephalitis, and subcortical myoclonus or rigidity occurs in glycine receptor antibody-associated encephalitis.

Autoimmune encephalitis associated with autoantibodies present with acute or subacute change in neurologic function, including encephalopathy, cognitive alteration, and psychiatric features. Seizures occur in a significant proportion and can be refractory, particularly in anti-GABA-A receptor autoimmune encephalitis.

These descriptions have resulted in the hypothesis that some patients with unexplained new-onset epilepsy may have an autoimmune etiology. There are now a number of research cohorts demonstrating autoantibodies in a minority of epilepsy patients (5%–10%). The patients who were positive for autoantibodies tended to have otherwise “unexplained” epilepsy (i.e., no clear genetic or structural causes of epilepsy), were more likely to have focal epilepsy, and often had normal MRI neuroimaging.

### Guidelines for Identification of Autoimmune Epilepsy

The recognition of autoimmune causes of seizures and epilepsy has resulted in the generation of guidelines to help identify these patients (Suleiman et al., 2013). In general, the level of evidence for an autoimmune etiology has been grouped into the three categories of *confirmed*, in which autoantibodies are found in the CSF; *probable*, in which the autoantibody is found in serum; and *possible*, in which the autoantibody is absent or not tested, but the patient has a beneficial response to immune therapy and has other features of an autoimmune etiology. This hierarchical approach to diagnosis of autoimmune encephalitis and autoimmune epilepsy needs to be assessed in larger cohorts.

As is true for encephalitis in general, features of an autoimmune epilepsy include the presence of acute or subacute onset of seizures, typically in the context of other features of encephalopathy or neurologic disturbance, plus evidence of inflammation using neuroimaging, CSF examination, or

**TABLE 119-1** Neuronal Antibodies Associated with Encephalitis Complicated by Seizures That Have Been Reported in Children\*

Antibody Type	Encephalitis Association in Adults	Encephalitis Association in Children	Seizure Types (Adults and Children)	Typical Associated Features	MRI Features
<b>VGKC-complex</b>	Limbic encephalitis Morvan's syndrome	Limbic encephalitis Encephalitis with status epilepticus	Focal (or multifocal) seizures (mostly temporal lobe) Mixed seizure types Faciobrachial dystonic seizures (LGI-1 antibodies)	Fever Encephalopathy Behavioral changes Memory and cognitive impairment	Normal High signal in medial temporal lobes White-matter signal abnormalities, high signal in basal ganglia
<b>NMDAR</b>	Encephalitis with movement disorder, psychiatric disturbances, aphasia, autonomic dysfunction, seizures	Encephalitis with movement disorder, psychiatric disturbances, aphasia, autonomic dysfunction, seizures	Focal seizures (motor and dyscognitive), mostly extratemporal Mixed seizure types Status epilepticus/EPC	Encephalopathy Movement disorder Psychiatric disturbance Autonomic instability	Normal High signal in medial temporal lobes and other regions
<b>GABA<sub>B</sub>R</b>	Limbic encephalitis	Limbic encephalitis	Focal seizures (temporal lobe) Generalized seizures (primary and secondary) Status epilepticus	Memory disturbance Movement disorder (dystonia, chorea), opsoclonus, ataxia	Normal High signal in medial temporal lobes and other regions
<b>GABA<sub>A</sub>R</b>	Encephalitis with seizures or status epilepticus (multifocal encephalitis)	Encephalitis with seizures or status epilepticus (multifocal encephalitis)	Focal seizures (temporal and extratemporal) Mixed seizure types Status epilepticus/EPC	Memory and cognitive impairment Behavioral changes, psychosis Movement disorder (dystonia chorea) Other autoimmune disorders	Cortical-subcortical lesions (multifocal) High signal in temporal lobes
<b>GlyR</b>	Other spinal and brainstem disorders (stiff person syndrome, PERM) Limbic encephalitis	PERM Focal encephalitis with seizures	Myoclonic jerks (cortical or subcortical) Hyperekplexia Temporal lobe seizures and status epilepticus	Rigidity (startle induced) Cognitive impairments	Normal
<b>GAD</b>	Limbic encephalitis Stiff person syndrome	Limbic encephalitis	Focal seizures (mostly temporal) Secondary generalized seizures EPC (multifocal)	Memory, cognitive impairment, ataxia Autoimmune disorders or immune deficiency	Normal Lesions in hippocampus, cortex, or cerebellum

EPC, *epilepsia partialis continua*; GABA, gamma-aminobutyric acid; GAD, glutamic acid decarboxylase; GlyR, glycine receptor; NMDAR, N-methyl D-aspartate receptor; PERM, progressive encephalomyelitis with rigidity and myoclonus; VGKC, voltage-gated potassium channel.

\*Although tumors are reported in association with some of these antibodies in adults, these syndromes are rarely paraneoplastic in children. LGI-1, CASPR2, and AMPA-R antibodies associated with epilepsy in children have not been described and so are not presented here.

(Adapted from Suleiman J, Dale RC. *Dev Med Child Neurol*. May 2015;57[5]:431-440.)

electroencephalogram (EEG) (Box 119-1). Although further studies are required to test these guidelines, it is important for clinicians to be aware of inflammatory causes of epilepsy, because early immune therapy may improve outcomes. For this reason, it is reassuring that an inflammatory subgroup has now been added to the causes of epilepsy in the International League Against Epilepsy (ILAE) classification.

## AUTOIMMUNE MOVEMENT DISORDERS

### Background

Movement disorders are classically considered to be generated secondary to dysfunction of the basal ganglia, although any disruption of the corticostriatal circuits can produce abnormal or involuntary movements. The classic autoimmune movement disorder is Sydenham chorea, which has been described since the seventeenth century, although more recently the

discovery of autoantibodies has helped define other autoimmune movement-disorder syndromes (Mohammad et al., 2013).

### Autoimmune Encephalitis Associated with Movement Disorders (Table 119-2)

**Anti-NMDAR encephalitis:** As described earlier, autoimmune encephalitis associated with NMDA receptor antibodies results in a diffuse pan-encephalitis. Abnormal movements are a common feature in children with this disorder. The movement disorders are very variable but typically are hyperkinetic, with flailing stereotypical movements, often with perseverative characteristics. Perseverative stereotypical movements may include self-injurious movements, repetitive purposeless movements, cycling movements, or catatonic postures of the

### BOX 119-1 Clinical and Investigative Features Suggestive of Autoimmune Encephalitis in Patients with Seizures

#### 1. Clinical features

Focal seizures, particularly focal motor and focal dyscognitive, secondary generalized seizures  
 Seizure clusters—status epilepticus  
 Seizures and epilepsy of “unknown” cause  
 Refractory seizures  
 Associated features: encephalopathy, movement disorders, neuropsychiatric symptoms, cognitive or memory impairment  
 History of other autoimmune diseases (personal or family history)

#### 2. Imaging and other investigations

Positive CSF findings suggestive of inflammation (pleocytosis, elevated neopterin, oligoclonal bands)  
 Inflammatory MRI changes of high T2 or FLAIR signal in medial temporal structures, cortical or subcortical areas, and cerebellum and basal ganglia  
 Focal (or multifocal) electrographic changes including slowing and/or epileptiform activity, particularly involving temporal lobe (s)  
 Histopathologic findings compatible with inflammation (such as lymphocytic infiltrates) on biopsy  
 Positive cell-surface neuronal autoantibodies (serum or CSF)

#### 3. Treatment response

Resistance to conventional AEDs  
 Response to immunotherapy (including steroids, immunoglobulin and immunosuppressive agents)

#### 4. No other explanation

AEDs, antiepileptic drugs; CSF, cerebrospinal fluid; FLAIR, fluid-attenuated inversion recovery; MRI, magnetic resonance imaging.  
 (Adapted from Suleiman J, Dale RC. *Dev Med Child Neurol. May 2015;57[5]:431–440.*)

limbs. Children can also exhibit dystonia, chorea, and other hyperkinetic movements. In the latter phase the child can become akinetic. Typically, the movement disorder is accompanied by agitation, psychiatric features, encephalopathy, and aphasia. The movement disorders are typically refractory to conventional treatment, and the child often requires sedation for treatment of the symptoms.

**Basal ganglia encephalitis:** Basal ganglia encephalitis is rarer than anti-NMDAR encephalitis, has been described in young children, and is characterized by selective inflammatory changes involving the basal ganglia structures, specifically the caudate putamen, globus pallidus, and substantia nigra. The child typically presents with an extrapyramidal movement disorder, particularly parkinsonism and dystonia, often with emotional psychiatric features such as anxiety or depression. Often there are inflammatory changes selectively involving the basal ganglia, but CSF pleocytosis is less likely than in anti-NMDA receptor encephalitis, although there may be oligoclonal bands or other markers of CSF inflammation. Autoantibodies against dopamine-2 receptor have been found in the serum of patients, although the pathogenic properties of these antibodies have yet to be demonstrated. If the diagnosis is recognized early, patients often respond to corticosteroids or intravenous immunoglobulins and can make a complete recovery, although striatal gliosis or atrophy is recognized as an outcome in some children with residual dystonia or cognitive features (Dale et al., 2012).

**Glycine receptor antibody encephalitis:** Glycine receptor antibody encephalitis is more commonly described in adults but also can affect children. The disease process is considered to dominantly involve the brainstem and spine, and the classic movement disorder phenotype is myoclonus, or hyperkplexia with a stimulus-induced startle response. Patients often additionally have rigidity, and in the full form, the syndrome is referred to as progressive encephalomyelitis with rigidity and myoclonus (PERM). As with other autoimmune encephalitis syndromes, immune therapy appears to improve outcomes (Carvajal-Gonzalez et al., 2014).

**Other autoimmune encephalitis:** Movement disorders have been associated with other autoantibodies in a few patients, such as opsoclonus in patients with GABA-B receptor encephalitis and dyskinesias in patients with GABA-A receptor encephalitis.

## Sydenham Chorea

Sydenham chorea (SC) is the classic postinfectious autoimmune movement disorder and is the commonest cause of acute chorea worldwide. Occurring after beta-hemolytic streptococcal infections, SC is the neurologic manifestation of rheumatic fever. SC typically occurs in adolescent females, although it can occur in males and younger children. Certain populations appear to be particularly vulnerable, such as indigenous populations of Australia or Brazil. SC typically causes a pure chorea and is typically generalized, although it can result in hemi-chorea. There may be associated emotional symptoms, such as anxiety, obsessive-compulsive symptoms, or depression. Other major changes in neurologic function, such as seizures or pyramidal signs, are rare, other than dysarthria. Magnetic resonance neuroimaging is typically normal. Investigation should focus on proving the presence of previous streptococcal infection with the use of throat swabs and serology, in addition to investigation for associated rheumatic fever involvement such as carditis. Treatment should focus on preventing further heart involvement with the use of antibiotic prophylaxis until 21 years of age; monthly penicillin injections are probably more effective than oral penicillin administration. There is increasing evidence to suggest that SC can result in residual and permanent neurologic or psychiatric problems. For example, 50% of patients may have some residual mild chorea 2 years after illness, and there is an increased rate of neuropsychiatric symptoms after recovery of SC. For this reason, some experts have advocated more aggressive treatment of SC during the acute phase with immune therapy such as steroids or intravenous immunoglobulins (IVIg). A recent study from South Africa found that patients treated with IVIg had better outcomes than those given symptomatic treatment only. Symptomatic management of SC includes the use of sodium valproate, carbamazepine, or antipsychotics.

## PANDAS, PANS, and Tourette Syndrome

In the 1990s, a number of investigators noted some similarities between Sydenham chorea and other acute-onset neuropsychiatric syndromes that followed infectious illnesses. Some of these illnesses were termed *pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection* (PANDAS). Patients with PANDAS typically present after a sore throat with acute-onset anxiety, separation anxiety, obsessive-compulsive symptoms, and sometimes tics. Although these symptoms were initially associated with streptococcal infections, more recently observers have noted that these acute neuropsychiatric symptoms can occur after a number of other infections, but still with an acute explosive onset, which has been termed *pediatric acute onset neuropsychiatric syndrome* (PANS). Although

**TABLE 119-2** Autoimmune Movement Disorders

Group	Syndrome	Movement Disorder	Other Features	Diagnostic Features
Autoimmune encephalitis with movement disorders	NMDAR antibody encephalitis	Stereotypical hyperkinetic movements, perseverative movements, chorea, dystonia, rigidity	Encephalopathy, agitation and psychosis, aphasia, seizures, dysautonomia, sleep dysregulation	CSF and serum NMDAR antibodies
	Basal ganglia encephalitis	Dystonia, akinesia, chorea	Emotional disorders	MRI basal ganglia lesions, serum D2R antibodies
	Glycine receptor antibody encephalitis (PERM)	Myoclonus, rigidity, hyperekplexia	Encephalopathy, seizures	Serum (and CSF) glycine receptor antibodies
Autoimmune movement disorders	Sydenham chorea	Chorea	Emotional disorder	Recent streptococcal infection, rheumatic carditis
	Opsoclonus myoclonus ataxia	Opsoclonus, myoclonus, ataxia	Sleep disturbance, irritability	Clinical syndrome, neural crest tumor
Infection-associated movement disorders	PANDAS and PANS	Infection-associated relapsing remitting tics	Emotional lability, obsessive-compulsive disorder	Clinical syndrome
Movement disorders associated with systemic autoimmune disease	Neuropsychiatric systemic lupus erythematosus	Chorea, parkinsonism	Emotional disorder, psychosis, cognitive deficits, seizures	Lupus autoantibodies, antiphospholipid antibodies
	Antiphospholipid syndrome	Chorea	Emotional disorder, psychosis, cognitive deficits, seizures	Antiphospholipid antibodies
	Hashimoto encephalopathy	Chorea, dystonia, ataxia	Encephalopathy, psychiatric features, seizures	Antithyroid antibodies, likely cell-surface antibodies (NMDAR antibodies)

CSF, cerebrospinal fluid; MRI, magnetic resonance imaging; NMDAR, N-methyl D-aspartate receptor; PANDAS, pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection; PANS, pediatric acute neuropsychiatric syndrome; PERM, progressive encephalomyelitis with rigidity and myoclonus; VGKC, voltage-gated potassium channel.

(Adapted from Mohammad SS, Ramanathan S, Brilot F, Dale RC. *Neuropediatrics*. Dec 2013;44[6]:336–345.)

tics remain a key component of this entity, the dominant features tend to be emotional alteration, particularly anxiety and obsessive-compulsive symptoms, and some patients also appear to develop changes in cognitive function, enuresis, and altered eating behavior. Unfortunately, there is no robust biomarker of this entity, and for this reason diagnosis is dependent on the clinical phenomenology. A number of different autoantibodies have been proposed to be important in these patients, but these findings have not been confidently reproduced. It is indeed possible that PANS is not an autoimmune disorder but some other immune-mediated phenomenon. For this reason, the treatment of PANS lacks a convincing evidence base, although antibiotics can be helpful in the acute phase, and other investigators have used steroids or intravenous immunoglobulin.

There is an expanding literature on the role of the immune system in neuropsychiatric disorders such as Tourette's syndrome, and it is probable that the immune system is involved either in a primary causal fashion or, alternatively, in a modifying secondary fashion in genetically predisposed individuals. Large-scale longitudinal studies are required to unravel the complexity of immune involvement in Tourette syndrome.

## HASHIMOTO ENCEPHALOPATHY OR SREAT

### Background

Hashimoto encephalopathy is a rare entity of acute neurologic dysfunction in patients with confirmed autoimmune thyroid disease. This neurologic syndrome occurs classically in patients with antithyroid antibodies, particularly antithyroid peroxidase antibodies, although it also may occur in patients with Graves' disease. Despite the presence of antithyroid antibodies,

patients are often clinically and biochemically hypothyroid. Hashimoto encephalopathy has also been termed *steroid responsive encephalopathy associated with thyroid autoantibodies (SREAT)*, and many investigators prefer this descriptive term (Castillo et al., 2006). The discovery of cell-surface autoantibodies in the last decade has led to a reconsideration of the etiology of Hashimoto encephalopathy.

### Clinical Syndrome

Most of the literature regarding Hashimoto encephalopathy consists of single case reports or small case series. The clinical phenomenology is relatively broad, possibly related to the fact that Hashimoto encephalopathy is not a single entity but a heterogeneous group of conditions associated with autoimmune thyroid disease. Children and adults are affected, and females are more commonly affected. All patients have in common an acute or subacute neurologic syndrome, typically with encephalopathy and behavioral change such as psychosis or emotional dysregulation. Seizures are also common, affecting ~60%. Aphasia and movement disorders (myoclonus and tremor) are also commonly described. Magnetic resonance neuroimaging is typically normal, and CSF may show pleocytosis or other markers of inflammation. The presence of thyroid autoantibodies is a requirement of the diagnosis, particularly antithyroid peroxidase antibodies. Part of the challenge with the diagnosis is the fact that a significant proportion of the general population can have antithyroid antibodies, and thyroid autoantibodies may sometimes represent a familial predisposition to autoimmunity, without the presence of biochemical or clinical hypothyroidism. For this reason, isolated antithyroid antibodies can result in false positive issues in the context of acute neurologic disturbance.

## Etiology

It had been originally proposed that the thyroid autoantibodies directly affected the brain, resulting in neurologic dysfunction. However, recently, most observers have suggested that the antithyroid antibodies are simply a manifestation of an autoimmune predisposition, and in fact patients with Hashimoto encephalopathy are more likely to harbor cell-surface antibodies, but the antithyroid antibodies themselves are not causing the neurologic disease. There are a number of recent reports demonstrating a higher rate of antithyroid antibodies in patients with anti-NMDA receptor encephalitis. Indeed, the clinical features of historical cohorts of Hashimoto encephalopathy (SREAT) have many similarities with those of anti-NMDAR encephalitis and other autoimmune encephalitis syndromes (as described earlier). There are also many examples in the medical literature of overlapping autoimmune disorders. For example, patients with systemic lupus erythematosus or Sjögren's disease are more likely to develop neuromyelitis optica. Therefore, testing for a broad panel of cell-surface autoantibodies is recommended when the diagnosis of Hashimoto encephalopathy is considered. As the alternative name SREAT suggests, Hashimoto encephalopathy is an immune-responsive condition, and patients typically respond well to steroids or additional immune therapies, and only a minority of patients will experience relapse.

## TREATMENT OF AUTOIMMUNE CNS DISEASE AND THERAPEUTIC DECISION MAKING

Therapeutic decision making for patients with autoimmune CNS disease is complex. The discovery of autoantibody biomarkers has empowered the clinician to treat patients with inflammatory brain diseases; however, the therapies have side effects, and the drugs pose potential risk to the patient. Therefore it is essential for the clinician to balance the potential benefit of the therapies with the potential risk. Anti-NMDA receptor encephalitis is a severe disorder, with a 7% risk of mortality and a 50% risk of morbidity. Thus it is possible to rationalize the use of stronger immune therapies in this condition. However, other conditions such as Sydenham chorea, have less risk of permanent disability; in these milder conditions it would be much harder to rationalize potent immune suppression with agents such as rituximab or cyclophosphamide.

First-line immune therapy generally consists of intravenous corticosteroids, sometimes followed by an oral corticosteroid taper. Alternative or additional first-line immune therapies include intravenous immunoglobulins, typically at a dose of 2 g per kilogram over 2 to 5 days. Plasma exchange can be used and is preferred by some centers. There is no clear evidence to suggest which of these first-line therapies is more efficacious; however, corticosteroids are usually used by most physicians. When first-line immune therapies do not produce adequate response, second-line immune therapies can be considered. It is easier to rationalize the use of second-line immune therapies when the diagnosis is clear and undoubted. There are many instances when the diagnosis is less clear, such as for suspected seronegative autoimmune encephalitis; however, these seronegative patients may also respond to immune therapy.

For patients who do not respond to first-line therapy, rescue therapy with rituximab (which depletes B cells for 6 months) or cyclophosphamide is considered. Both rituximab and cyclophosphamide produce immune effects within 1 to 2 weeks, and therefore represent useful rescue therapies.

However, both agents carry the risk of infections induced by immune suppression, such as viral reactivation syndromes or progressive multifocal leukoencephalopathy.

In disorders that are steroid responsive and prone to relapse, such as neuromyelitis optica, steroid-sparing immunosuppressants, such as mycophenolate mofetil or azathioprine, can be considered. However, both of these agents take a few months before they produce adequate immune suppression, and therefore prolonged corticosteroid taper is often required.

# 120 Opsoclonus Myoclonus Syndrome

Michael R. Pranzatelli and Elizabeth D. Tate

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Opsoclonus-myoclonus syndrome (OMS) affects an estimated one in a million children worldwide. Although it also occurs in adults, reference only to pediatric OMS is made herein. Recent advances in the neuroimmunology of OMS, prefigured by transformational developments in understanding human autoimmune disorders of the nervous system, have revived the field. This chapter aims to guide clinical decision making through the authors' 25-year clinical experience from operating the National Pediatric Myoclonus Center (NPMC), now an international specialist center for OMS; a review of the medical literature and practices from the past decade; and recent translational research in the field. Citations to the earlier literature can be found in the authors' previous reviews of the topic (Pranzatelli and Tate, 2010), and the reviews and perspectives of other authors also are available. The broad categories covered are as follows:

1. Clinical aspects
2. Immunopathogenesis
3. Treatment
4. Management of relapse and progression
5. Future directions

## CLINICAL ASPECTS

### Presentation and Course

Both the clinical presentation and course of OMS are multifarious (Figure 120-1). In typical OMS, the symptom cluster appears acutely and intensifies over days to weeks. After teetering for weeks, OMS may appear to improve or worsen. Motor aspects of OMS include the triad of opsoclonus, myoclonus, and ataxia (see Video 120-1). Opsoclonus must have a random or chaotic multidirectional element in contradistinction from nystagmus (Wong, 2007). Because eye movement disorders can be complex, video-documentation for later consulting should be standard. The subcortical myoclonus is exacerbated by action and contravenes fine motor activity. In the beginning, there is gait ataxia; later, limb dysmetria may emerge. The level of dysfunction ranges from an ambulatory child who is a little shaky or wobbly to a hospitalized, nonverbal, non-ambulatory child on a feeding tube, with copious drooling, choking, limpness, and loss of purposeful function. Presence of a Horner syndrome or signs of spinal cord compression signals nonparaneoplastic manifestations of neuroblastic tumors.

Nonmotor comorbidities of OMS affect the quality of life both of children and their parents. Irritability is an early and disruptive characteristic. The OMS sleep disorder comprises prolonged sleep-latency, fragmented sleep, reduced total sleep time, and nonrestorative sleep with excessive daytime fatigue. Wakefulness compromises learning and behavior. Rage "meltdowns" or intermittent explosive disorder may occur several times a day. The child's aggression often targets the mother, who may be bitten or slapped. The "velcro child" is another common phenomenon, clinging to one parent or both

throughout the day. Normal siblings sometimes become angry and depressed at being assailed by the affected child or marginalized by parental focus on the affected child's sick role. Eroded by sleep loss, stress, depression, and anxiety, the family dynamic suffers. In chronic OMS, children display prominent deficits in executive, attentional, and behavioral regulatory skill development. Affective dysregulation, disruptive behavior, impulsivity, and inattention are among the psychiatric symptoms, as are obsessions/compulsions and oppositional defiant behavior.

## Differential Diagnosis

Establishing an accurate diagnosis is requisite for treatment. Presence of opsoclonus excludes the diagnosis of acute cerebellar ataxia, with which early OMS is so often confused, when gait ataxia is the presenting or predominant feature (Desai and Mitchell, 2012). Ataxia may be the only neurologic sign in neuroblastoma. Hence, OMS should be considered in all cases of nonexanthematous acute cerebellar ataxia, especially when spontaneous improvement has not occurred within a few weeks.

The term "atypical OMS" or "OMS variant" applies when either the amount of opsoclonus, myoclonus, and ataxia is greatly disproportionate, or when opsoclonus is absent but the rest of the history and examination are compatible with OMS. Isolated opsoclonus or mixed ocular movement abnormalities with predominant nystagmus in infants younger than 6 months of age seldom presage OMS. Although children with OMS may develop strabismus, OMS is not associated with loss of vision or acquired microcephaly. Bone fide seizures (not severe myoclonic jerks imitating seizures), especially if pharmacotherapy resistant, and epileptiform EEG abnormalities should redirect the differential diagnosis. If neuroblastoma is present, consider anti-Hu (ANNA-1) and anti-Ma2 and anti-CV2/CRM5 paraneoplastic syndrome.

## Genetics

There are no reported cases of twins in one family both having OMS or more than one family member having OMS across generations. A higher incidence of autoimmune disorders in the parents suggests shared genetic susceptibility to other autoimmune conditions. Infrequently, children with OMS or their parents develop another autoimmune disorder years later; a second paraneoplastic syndrome is rare.

## Etiology

In 105 children with OMS, neural crest tumors, such as neuroblastoma, ganglioneuroblastoma, and ganglioneuroma, were found in about 50%, though OMS occurs in only a few percent of patients with neuroblastoma (Tate et al., 2005). Neuroblastoma is an embryonal malignancy of the sympathetic nervous system arising from pluripotent sympathetic cells (neuroblasts). Tumor location frequency is mostly abdominal and thoracic, less often pelvic or cervical. Patients

with tumor are not distinguishable by prodromal symptoms, OMS age of onset or severity, relapse rate, or geographic distribution. The relationship of incidence of OMS to patient age does not differ depending on whether neuroblastoma is present or absent. A uniform paraneoplastic classification of OMS etiology has been proposed, but is currently untestable.

When a tumor is not detected, the question arises: Are there two distinct etiologic paths to OMS or two different proximal approaches that converge on the same final common pathway? "Viral," "para-infectious," or "postinfectious" etiologies have been posited. Various microbiologically documented infections are reported, but cause and effect has not been established. Confusion arises because the OMS viral-like prodrome, which can include vomiting, differs little between children with or without a tumor. OMS related to Epstein–Barr virus does not preclude an occult neuroblastic tumor. Designation as "idiopathic" is probably more prudent.

## Epidemiology

The OMS onset age spectrum is a bell-shaped curve from 0.5 to 5 years, with outliers in younger infants and elementary-school-aged children (Tate et al., 2005). Whereas neuroblastoma can present in neonates, OMS does not. There is a slight female preponderance. All races and ethnicities are affected. Cases are geographically distributed in keeping with population densities in the United States. The mean OMS onset age is  $1.6 \pm 0.7$  years, with a 3-month average delay to correct diagnosis. Similar observations based on smaller surveys have been made in other countries (Brunklau et al., 2011). OMS sometimes follows vaccination.

## Diagnostic Testing

The main purpose of diagnostic testing is fourfold: 1) find the tumor if there is one; 2) reveal neuroinflammation through state-of-the-art commercially available immunologic tools; 3) rule out other plausible neurologic etiologies; and 4) establish the pretreatment health of the immune system (Figure 120-2).

### Tumor Detection

Neuroblastoma may be more difficult to detect in children with than without OMS because of the relative maturity and low metabolic activity of their tumors. A 24-hour collection for urinary catecholamines (VMA, HVA) is a suggestive indicator that is helpful only if positive; false negatives are common in OMS. CT/MRI imaging was found superior to metaiodobenzyl guanidine (MIBG) and urine catecholamines for neuroblastoma detection. The newer MIBG tracer ( $^{131}\text{I}$  replaced by  $^{123}\text{I}$ ) is the main functional imaging tracer for neuroblastoma detection. [ $^{18}\text{F}$ ] FDG PET/CT is an alternative for tumors with little or no MIBG uptake. Because neuroblastoma may be discovered several years after OMS onset, patients require continued surveillance in tumor-negative cases.

### Neuroinflammation Detection

Neuroinflammation in OMS cannot be detected through blood testing; lumbar puncture is necessary. Improved methods of detecting neuroinflammation should be applied. Cerebrospinal fluid (CSF) *oligoclonal* bands that are not found in a parallel serum sample by isoelectric focusing with immunofixation are indicative of an intrathecal humoral immune response. Lymphocyte subset analysis is practicable at the hospital clinical flow cytometry laboratory. Paraneoplastic autoantibody trawling by commercial laboratories is not

cost-effective for typical OMS and best reserved for atypical cases. When sedation is required for children with acute OMS undergoing procedures, the usual sedatives do not work, cause paradoxical excitation, or exacerbate OMS for hours to days. The anesthetics propofol and sevoflurane are tolerated.

### Ancillary Testing

To exclude neuroinfectious diseases, an encephalitis panel is routine. Head MRI scanning rules out cerebellitis or a posterior fossa mass. EEG slowing can be seen in OMS, but epileptiform EEGs should raise suspicion.

### Pretreatment Immune Health

The pretreatment health of the immune system should be verified by serum quantitative immunoglobulins, blood lymphocyte subset analysis, and serum 25-hydroxyvitamin D levels. IgA deficiency is more frequent in the presence of autoimmune diseases. Vitamin D insufficiency, even deficiency, is not uncommon in OMS, and should be corrected.

### ACTH or Dexamethasone Challenge Test

In pursuing the diagnosis of OMS variant, further ancillary tests may clarify the issue, but sometimes a 1-month therapeutic challenge of high-dose ACTH or dexamethasone is necessary when faced with a diagnostic dilemma (Figure 120-3). The unparalleled initial response rate of OMS to ACTH makes the 1-month "ACTH challenge test" clinically useful.

## Standard of Care and Quality of Life

The acceptable standard of care for OMS is to rapidly put the child into a durable neurologic remission, and to reverse or prevent relapse and secondary progression. In human terms, it is nothing less than to return children to their lives with the future capability of living independently, holding jobs, and having friends and loved ones. Best practice should be applied in a timely and uniform fashion for all children with OMS. The standard of care at centers seeing larger numbers of children with OMS has improved, and there have been positive changes in practice styles in the United States, but the standard is not uniform and varies across the globe. Denied access to care and inadequate health-care resources are significant barriers.

## IMMUNOPATHOGENESIS

Although an autoimmune causation for OMS has not been proven, the evidence for the theory is becoming quite compelling (Pranzatelli and Tate, 2010). The culprit may be ectopic expression of a neuronal antigen in the periphery, engaging the adaptive immune subsystem and transmigration of activated lymphocytes into the CNS. However, despite much searching, the antigen or antigens remain at large. The theater of operations includes the posterior fossa (cerebellum and brainstem), especially the cerebellar vermis, and possibly supratentorial structures (cerebral cortex) (Anand et al., 2015). There are both brainstem and cerebellar hypotheses of opsoclonus (Wong, 2007). A simplistic schema of possible pathophysiologic events in OMS is shown in Figure 120-4.

## Tumor Immunology

Neuroblastoma in OMS is more highly infiltrated with lymphocytes than in the absence of OMS. Tumor survival is much greater in the presence of OMS. In the absence of OMS, the

frequency of neuroblastoma in the youngest children is higher. Neuroblastomas in OMS exhibit lymphoneogenesis, a feature of chronic inflammatory brain disease as well.

## CNS Inflammatory Mediators

**Immune Dysregulation.** The first putative biomarker of disease activity in untreated OMS was the increased frequency of mature B cells in CSF; the second was CSF oligoclonal bands (OCB). Multiple types of activated B and T cells are involved in abnormal trafficking into the CNS. After encountering self-antigen, dysregulated B-cell signaling can drive autoimmunity.

**Inflammatory Proteins.** *Chemokines* are chemoattractant cytokines and the predominant human cytokines and inflammatory mediators. Recent evidence indicates upregulated production of various inflammatory chemokines in four different chemokine/receptor systems. Of these, CSF CXCL13, a major B-cell chemoattractant acting at the CXCR5 receptor, is a putative biomarker of disease activity and treatment biomarker in OMS (Pranzatelli et al., 2012). The net effect of these abnormalities is to allow autoaggressive B and T cells to permeate the CNS.

The CSF concentration of the cytokine B-cell-activating factor (BAFF) is elevated in untreated OMS. It is lower in patients treated with corticosteroids or ACTH, but not with IVIg, and correlates with the concentration of antibodies to cerebellar granule cells and OMS severity category. Higher CSF BAFF correlates with CSF oligoclonal bands and a higher concentration of inflammatory chemokines in CSF. BAFF may be a bridge between neuroblastoma and OMS (Raffaghello et al., 2013).

**Brain-Related Proteins.** Recent biochemical data suggest neuronal/axonal injury in a subpopulation of children with OMS. From a panel of seven established markers of neuronal/axonal and astroglial injury, only CSF neurofilament light chain was elevated in untreated OMS versus controls. No significant differences were found for glial fibrillary acidic acid protein or S-100 beta, which are primarily glial markers.

**The Effect of Immunotherapy on Brain Inflammation.** Some, but not all, immunotherapies decrease concentrations of inflammatory mediators in OMS. The argument can be made that corticotropin and corticosteroids shut down production of inflammatory cell products with clinical benefit. However, the cells, unless reregulated or killed, are ready to start producing again once steroids are tapered (hence relapse).

**Autoantibodies.** Activated B cells may produce antibodies, but memory B cells, plasmablasts, and plasma cells do so at a faster rate. Using flow cytometry, surface-binding subclass autoantibodies to cerebellar granule neurons were discovered. Mostly of the IgG3 subclass, they possessed antiproliferative and apoptosis effects on neuroblastoma cell lines. No antigen was identified. The results await independent confirmation. Detection of other antibodies in OMS has been discussed elsewhere.

## TREATMENT

### Treatment Strategy

To facilitate the reestablishment of tolerance, neuroinflammation must be expunged. The challenge is how to best deploy the available therapeutics. Unlike relentlessly progressive multiple sclerosis or neuropsychiatric lupus, the brain usually needs protection in OMS for just the few years it is beset with this disorder, and so it will not be left damaged after neuroinflammation's dénouement. The argument hinges not on

whether to use "aggressive" versus "nonaggressive" therapy, but rather on using *sufficient* therapy to achieve full recovery, implementing disease-modifying agents, continually reassessing adequate treatment response, and being mindful of the changeable risk/benefit ratio. Likewise, the contrast of "conventional" versus "unconventional" agents is also fading with the changing practice patterns in OMS. Our semantic lexicon needs to be expanded to include *disease-modifying targeted biotherapies*, use of *biomarker-assisted therapy*, and *personalized medicine* instead. These remarks are prefatory to a discussion of a trenchant division in the initial approach to OMS (Table 120-1).

**The Front-Loaded Approach.** In the "front-loaded" or "front-end" approach, multiple immunotherapeutic modalities are initiated together for *neuroprotection* as a *medical emergency*. Rituximab or cyclophosphamide is utilized early. Increased immunosuppression with ACTH, IVIg, and rituximab or cyclophosphamide has been associated with improved cognitive and other outcomes. Also, the pathologic B-cell-related chain of events in the CNS occurs early in OMS and cannot be broken by steroids/ACTH or IVIg alone. Early anti-B-cell therapy may prevent autoreactive B cells from differentiating into long-lasting plasma cells and the formation of ectopic lymphoid follicles in the brain. The front-loaded approach is exemplified by *FLAIR* therapy, an acronym for front-loaded ACTH, IVIg, and rituximab. *DEXIR*, also coined by the NPMC, refers to the combination of high-dose pulse dexamethasone, IVIg, and rituximab.

**The Staggered Approach.** In the "staggered" approach, also termed "escalation treatment" and "treatment intensification," steroids or IVIg are used first, but chemotherapy and anti-B-cell agents are held in reserve. Proponents of this approach disagree about the urgency of OMS and the timing of therapy, and also subscribe to different views as to when to shift strategy from reduplication of initial efforts to *nouveau* therapies. The choice of preferred steroids has shifted from prednisone, prednisolone, and methylprednisolone to pulse dose dexamethasone. The concern is that unchecked disease activity early in the course of OMS may prevent remission and propagate disease progression. Because of brain developmental vulnerabilities, it is not possible to recapture lost time once the critical window for intervention has closed. Though opinions are polarized, the long-running clinical debate can only be informed by more immunologic and outcome data.

**Integrating Neuroinflammation with Clinical Assessment.** Biofluid testing for neuroinflammation can be used to inform treatment decisions, which focus on OMS severity and duration (Box 120-1). It is a particularly powerful tool not only for initial evaluation, but also in assessing partial or complete treatment failures, in which concurrent drugs may be masking clinical signs of underlying neuroinflammation. The use of the percentage and numbers of B cells and oligoclonal bands is a step toward biomarker-assisted individualized medicine and a step away from determining the level of treatment on purely clinical grounds. It prevents the delay inherent in the "wait-and-see" approach because the impact of the level of neuroinflammation can be anticipated and helps prevent patient misclassification. The more informed the treatment decision is, the greater the likelihood it will be effective.

### Antitumor Therapy

Successful treatment of the tumor usually does not improve OMS. The treatment for neuroblastoma in infants less than 6 months of age is transitioning to expectant observation. With spontaneous tumor regression, many are spared surgery.

**BOX 120-1** Factoring Clinical and Neuroinflammatory Severity in Patient Assessments\***SEVERE****Clinical Criteria (Score 25 to 36)**

The patient is unable to get to a standing position independently; is unstable with feet apart; cannot stand with feet together; cannot sit without falling forward; cannot target or grasp objects with hands, no finger pincer; eyes cannot track because of frequent opsoclonic intrusions; and dysarthria/anarthria. The nonmotor aspects often include rage, sleeplessness, and encephalopathic appearance.

**Immunologic Criteria**

Cerebrospinal fluid (CSF) B-cell frequency is >2% and may be as high as 10% to 20%. CD4/CD8 ratio is usually low at <1. Highest frequency of CSF oligoclonal bands. May be mild CSF leukocytosis, 4 to 100 cells.

**Treatment Considerations**

The consensus among several opsoclonus-myoclonus syndrome (OMS) experts is that three-agent multimodal combination immunotherapy is advised in severe OMS. Which is the best combination of agents can be debated. ACTH (ACTH option 1), the most potent induction agent, is usually given with IVIg, and the third agent is either rituximab or cyclophosphamide. Sole reliance on steroids/ACTH or IVIg in the face of partial response, relapse, or progression is now considered below the standard of care.

**MODERATE****Clinical Criteria (Score 13 to 24)**

Patient may be ambulatory, but gait is wide-based with front-to-back and side-to-side imbalance; achieves standing with self-support; able to sit; reaches target with moderate to severe jerks; grasps object with two hands, but has difficulty holding it; eyes have frequent/large-amplitude jerks with tracking; and moderate dysarthria. When a patient exhibits mixed levels of severities for OMS components, they may be designated as “moderate-to-severe” or “mild-to-moderate,” as the case may be.

**Immunologic Criteria**

CSF B-cell frequency is >2%. CD4/CD8 T-cell ratio is variable, often 1 to 1.5. CSF oligoclonal bands are often elevated but may be normal.

**Treatment Considerations**

Moderate-severity OMS carries the same potential risks as severe OMS for neurologic sequelae and long-term prognosis. It is not currently possible to predict which of the moderate cases will have a poor outcome. Therefore the authors recommend three-agent multimodal combination immunotherapy, but may use a shorter course of ACTH (ACTH option 2 or 3), or substitute dexamethasone for ACTH on a case-by-case basis. Treatment delay, an important risk factor for poor outcome, ratchets the level of immunotherapy one notch.

**MILD****Clinical Criteria (Score 1 to 12)**

Can stand without support, but may exhibit side- or back-stepping; walks with slight wide base and instability; sits with no or minimal support; targets with minimal tremulousness; able to grasp objects with thumb and digit, but hold may be unstable; infrequent or small-amplitude eye jerks may not be present both on fixation and at random; and mild dysarthria.

**Immunologic Criteria**

CSF B-cell frequency may be 1% to 2% (intermediate range). CD4/CD8 ratio is usually 1.5 to 2.5. CSF oligoclonal bands are often negative.

**Treatment Considerations**

The management of mild OMS is controversial for lack of long-term data as to whether steroids and IVIg immunotherapies are sufficiently protective. The authors typically combine IVIg and pulse-dose dexamethasone and carefully monitor response, but if B-cell expansion is present, they add rituximab. Others may choose oral glucocorticoids instead of dexamethasone. Mild cases are more often monophasic, but can escalate in severity and relapse.

\*The authors base this categorization on their clinical experience and literature review. The clinical and immunologic designations are evidence-based; the therapeutic recommendations are not. Motor severity levels in OMS can be defined by the OMS Evaluation Scale, which was designed and validated as a method to score videotapes of patient response. It is a 12-item scale, scored 0 to 3 in severity, generating a summated total score, which indicates clinical severity. The patient's age may affect these criteria.

Thereafter, the treatment of stage I and stage IIA neuroblastoma is usually surgical excision alone. Neuroblastoma surgery may increase the hematogenous antigenic load in OMS, and so, as not to delay treatment for OMS, giving IVIg *before* (and perhaps *after*) tumor resection is advisable. For higher stage tumors, oncologists apply chemotherapeutic regimens.

**Immunotherapy**

There are many agents in the OMS armamentarium to optimize therapy (Table 120-2). Oncologists recommend IV ports in infants and toddlers who will receive ongoing IV agents and blood testing for compassionate reasons and poor venous access. The following are practical guidelines on administration.

**IVIg.** Intravenous immunoglobulin (IVIg or IgV) consists of polyclonal IgG pooled from the serum of thousands of blood donors. Possessing both antiinflammatory and immunomodulatory properties, it has been used to treat children with autoimmune diseases for 30 or more years. Administration of a higher dose for induction is based on better clinical response

and scientific evidence of greater suppressive effect on the provocative dendritic immune cell. In an unpublished NPMC-sponsored open-label trial of IVIg in OMS (BB-IND #5389), the 1 to 2 g/kg dose now used had the best efficacy, with fewer side effects than higher doses.

**Corticosteroids.** Glucocorticoids act through a multiplicity of mechanisms and targets. They differ in relative antiinflammatory potency: dexamethasone (20 to 30×), methylprednisolone (5×), prednisolone = prednisone (4×), hydrocortisone (1×). High-dose dexamethasone pulse therapy is an attractive alternative to prednisone/prednisolone/methylprednisolone because of its longer duration of action, short-term course, and greater relative antiinflammatory potency (Ertle et al., 2008).

**ACTH 1-39.** ACTH 1-39 is an agonist at each of the melanocortin receptors 1 to 5, and releases cortisol, which acts through adrenal glucocorticoid receptors. It remains the most potent induction agent for OMS. Clinical response to ACTH is the litmus test for determining steroid responsiveness. One-half of patients with nonprogressive OMS who fail or partially

TABLE 120-2 Immunotherapeutics and Prophylactic Safety Medications

Agent	Dose and Administration
<b>Immunotherapeutics</b>	
IVIg <sup>a</sup>	<i>Induction:</i> 2 g/kg (1 g/kg/day × 2 consecutive days), then 1 g/kg single monthly infusion for course of therapy. <i>Tapering:</i> sequentially lengthen intervals between infusions from 5, 6, 7, then 8 weeks.
Dexamethasone <sup>b</sup>	<i>Induction:</i> 20 mg/m <sup>2</sup> /day divided TID. Give for 3 to 4 consecutive days/month. <i>Tapering:</i> sequentially lengthen intervals between pulse doses.
ACTH ACTH1-39 <sup>c</sup> Option 1 (for severe onset) <sup>d</sup>	<i>Induction:</i> 75 mg/m <sup>2</sup> IM or SC BID × 1 week, then daily × 3 weeks. If child not in remission, continue daily 2 to 4 more weeks if tolerated. <i>Tapering:</i> QOD dosing × 1 month at the same dose, then taper over 7 to 9 months. Monitor blood pressure, weight, CBC, BMP, U/A, ECG, and ECHO. Check for adrenal insufficiency when concluded.
Option 2 (for moderate onset) <sup>d</sup>	<i>Induction:</i> 75 mg/m <sup>2</sup> IM or SC BID × 1 week, daily for 1 week, then QOD for 2 weeks. <i>Tapering:</i> If child in remission, go to every other day dosing at 70 mg/m <sup>2</sup> for 1 month, then taper over 4 to 7 months.
Option 3 (for relapsers)	Add monthly 3-day dexamethasone pulses about two-thirds of the way through the ACTH tapering schedule for either option 1 or 2. Continue pulses for 3 to 6 months after ACTH discontinuation.
ACTH1-24 <sup>e</sup>	<i>Induction:</i> IM M-W-F × 1 week. Usually about 25 IU in infants/toddlers, 50 IU in preschool ages, and 100 IU in school-aged children. <i>Tapering:</i> M-Th over several months based on response. Can widen intervals between doses if Cushingoid. Monitor as for ACTH1-39.
Rituximab <sup>f</sup>	300 to 375 mg/m <sup>2</sup> /infusion once weekly × 4 consecutive weeks for induction. Monitor for allergic reactions during infusions. Follow serum q Ig and blood LSA.
Cyclophosphamide <sup>g</sup>	750 mg/m <sup>2</sup> IV once monthly × 3 to 6 cycles. Monitor for neutropenia at 21 days and per oncologist.
Methotrexate <sup>h</sup>	Oral, once a week, 5 to 10 mg/m <sup>2</sup> induction, titrate slowly to 15 to 20 mg/m <sup>2</sup> as needed and tolerated. Monitor CBC, LFTs, annual CXR.
<b>Prophylactic Indications, Agents, and Measures</b>	
Trimethoprim/sulfamethoxazole ( <i>Pneumocystis jirovecii</i> , formerly called <i>Pneumocystis carinii</i> )	150 mg/m <sup>2</sup> /day // 750 mg/m <sup>2</sup> /day twice a day on 3 days/week
Ranitidine HCl (or omeprazole) (GERD/GI bleeding)	2 to 4 mg/kg/day
Calcium with vitamin D supplement (osteopenia/osteoporosis)	800 to 1000 mg/day // 400 IU/day. Obtain annual DEXA scan
Low-sodium diet; no salty treats (Cushingoid syndrome)	Restrict to 1 to 2 g/day
<sup>a,b,c,e</sup> Supported by case series and reports.	
<sup>b</sup> A dose of 21 mg/m <sup>2</sup> /day can be used instead: 7 mg/m <sup>2</sup> T.I.D. × 3 consecutive days.	
<sup>c</sup> Acthar Gel, 80 IU/mL.	
<sup>d</sup> See Box 120-1 for differentiation of severe versus moderate opsoclonus-myoclonus syndrome (OMS). Regardless of ACTH option used, tapering should not begin unless the patient is remitting. Children with severe acute OMS may not tolerate tapering (“brittle”).	
<sup>e</sup> Tetracosactin (Synacthen, Cosyntropin), 100 IU/mL.	
<sup>f</sup> Supported by phase I clinical trial, case series, and reports.	
<sup>g</sup> Pretreatment for IVIg or rituximab: acetaminophen (15 mg/kg), diphenhydramine (1.5 mg/kg, maximum dose 25 mg), and dexamethasone (1 mg). Ceterizine may be substituted for diphenhydramine in case of paradoxical reactions.	
<sup>h</sup> Supported by case series and reports (used in unpublished COG phase III clinical trial since 2004).	
<sup>i</sup> Based on the experience of the authors, not on evidence-based medicine.	
<sup>j</sup> If not tolerated, IV pentamidine can be given at time of IVIg infusions per oncologist.	
BMP, basic metabolic panel; CBC, complete blood count; CXR, chest-ray; ECHO, echocardiogram; ECG, electrocardiogram; LFTs, liver function tests; LSA, lymphocyte subset analysis; q Ig, quantitative immunoglobulins; U/A, urinalysis.	
<i>Disclaimer:</i> There are no FDA-approved treatments for OMS. All the above agents are used off-label. Although every attempt has been made to verify doses and dosing schedules, the authors cannot assume any responsibility for the accuracy. All treatment decisions need to be made together by treating physicians and the parents.	

respond to steroids will respond to ACTH. There are several options when using ACTH (Table 120-2). ACTH 1-24 was available in Europe until recently.

**Monoclonal Antibody Therapy.** Rituximab was the first targeted immunotherapy for OMS. It is prototypical for first-generation anti-B-cell monoclonal antibodies directed to the B-cell-specific antigen CD20. Besides a clinical trial, there are several small case series or reports on the beneficial clinical response to adding rituximab to steroids or IVIg in OMS (Mitchell et al., 2015). Ofatumumab, a second-generation fully human anti-CD20 monoclonal antibody, has been used successfully to treat two rituximab-allergic children with OMS.

**Cyclophosphamide.** Cyclophosphamide plus steroids with or without IVIg is used by some oncologists for paraneoplastic OMS since 2004, based on an unpublished clinical trial (COG-ANBL00P3, NCT00033293). Its potential bladder and infertility side effects are well known, but the antiimmune dosage is well below antitumor dosage. Cyclophosphamide and dexamethasone have also been combined as “salvage therapy” in OMS.

**Steroid Sparing.** Various agents, such as azathioprine, 6-mercaptopurine (6-MP), and mycophenolate mofetil (MMF), have been administered adjunctively to reduce steroid dose in OMS based on utility in various other pediatric inflammatory

diseases. Their open-label use in OMS is empiric, not evidence-based. The agents do not appear to normalize CSF B-cell percentage. Two no-responders to cyclosporine were reported.

**Methotrexate.** In the authors' experience, weekly oral methotrexate has a role in the treatment of chronic relapsing OMS that has not responded to rituximab and cyclophosphamide. The application to OMS is not evidence based, but derives from its longstanding use in pediatric rheumatological disorders. It takes several weeks to safely titrate the dose, and so the clinical effect will be delayed and will persist for weeks after the drug is discontinued.

**Plasmapheresis.** The therapeutic use of plasma exchange in combination with steroids for OMS remains anecdotal. In very young children, the large-bore catheter placed in the neck is infeasible, especially if there is cognitive impairment. In older symptomatic children, it is an option. There has been no clinical study.

### Inadequate Response

"Inadequate response" is defined as failure to achieve a full neurologic remission within a reasonable timeframe. A child who is nonambulatory because of OMS should be able to walk by 4 to 6 weeks after starting multimodal immunotherapy. Three months after beginning treatment, improvements in development should be apparent. By 6 months, the clinical picture should look quite good. Identifying inadequate response is essential to making midcourse corrections to the trajectory of improvement (Figure 120-5).

### Potential Side Effects and Safety Monitoring

Most deleterious effects of immunotherapy can be anticipated. Safety monitoring is essential for a favorable treatment risk/benefit ratio (Table 120-2). Prophylactic medications and measures should be scrupulously applied to prevent Cushingoid syndrome, opportunistic infections, osteopenia or osteoporosis, gastroesophageal inflammation, and hemorrhage. Rituximab can cause prolonged or permanent B-cell lymphopenia and hypo/agammaglobulinemia. In an effort to reduce the risk, the NPMC has lowered the rituximab dose to  $300 \text{ mg/m}^2 \times 4$ . Patients who develop this complication should receive "rescue" IVIg and should not be exposed to any further B-cell-depleting drugs. Fatal reactions to any of these agents are rare but can occur. Given the gravity of OMS and lack of equally effective agents with fewer side effects, the use of these immunotherapies seems justified.

### Supportive Therapy

Evaluation and intervention by a behavioral therapist can be crucial for family well-being through modification of maladaptive responses. Children with dysarthria require years of therapy for speech articulation and language development. A child psychiatrist should manage rage, depression, and mood disorder. Attention-deficit disorder is so common in chronic OMS that the threshold for testing should be low. Finding or creating a fitting academic environment requires cooperation of the schools and an individualized education plan.

## MANAGEMENT OF RELAPSE AND PROGRESSION

### Relapse

Central nervous system relapse is the single biggest clinical stumbling block in OMS (Box 120-2). It may occur at any time in the course of OMS. The first principle of relapse is to treat

### BOX 120-2 Management of OMS Relapse

#### TREAT UNDERLYING TRIGGER

##### Infection Induced

The intercurrent illness may be blatant or occult, and need not be febrile; relapse may precede its appearance. In an immunosuppressed child, opportunistic as well as common infections may be at play, requiring appropriate screening.

##### Steroid/ACTH Tapering Induced

Relapse occurring during drug tapering requires dose escalation and/or more frequent dosing. It is seldom reversed merely by going back to the dose just before the relapse. A return to  $25 \text{ IU/m}^2$  (sometimes  $40 \text{ IU/m}^2$ ) and to daily rather than alternate-day dosing may be required for ACTH. If the ACTH dose at relapse was very low, monthly high-dose pulse dose dexamethasone may obviate the need to restart ACTH.

#### ADJUST IMMUNOTHERAPY PLAN

If the above measures are insufficient or more than one relapse has occurred, flexibility and empiricism are required. In changing to combination multimechanistic and multitargeted therapy, a disease-modifying agent should be added.

#### REEVALUATE FOR NEUROINFLAMMATION

Initial cerebrospinal fluid lymphocyte subset analysis (LSA) and oligoclonal bands (OCB) testing are highly recommended to inform clinical decision making. Reevaluation in chronic opsoclonus-myoclonus syndrome (OMS) can also help differentiate active inflammatory disease from "burned out" OMS with permanent sequelae. It is essential to interpret immunologic results in the clinical context.

#### LOOK FOR NEUROBLASTOMA

Imaging studies for neuroblastoma in so-called tumor-negative cases should be repeated in the setting of incomplete response to immunotherapy or relapses. Multiple types of tests, if done originally, may not be necessary.

the underlying trigger when possible. "Corticosteroid- or ACTH-dependency" indicates ongoing autoimmune disease. No patient should be allowed to repeatedly relapse on IVIg and steroids/ACTH alone. In chronic relapsing OMS, the risk of eventual cognitive impairment escalates, and previously used immunotherapeutics are no longer as effective. After multiple medications have failed, empirical approaches are necessary to prevent conversion to progressive OMS.

### Progression

OMS sometimes progresses to an implacable chronic state with reduced sensitivity or unresponsiveness to immunotherapy ("treatment resistance") and irreversible cognitive regression. This eventuality can blindside treating physicians and come as a heartbreak to parents, who should be counseled about the possibility. Disease progression occurs more often in children who fail to go into neurologic remission or have multiple relapses despite prolonged immunosuppressive regimens. At some point, the treatment risk/benefit ratio becomes unfavorable. For now, the best treatment for progressive OMS is to prevent it.

### Immunization Issues

During the acute phase of OMS, immunizations may trigger disease exacerbation or relapse. The conservative recommendation of the NPMC has been to withhold immunizations for 2 years after cessation of immunotherapy and relapse, and

then cautiously reintroduce as singlet vaccinations of killed virus at 6-month intervals. Antibody titer testing can help by checking for immunity to various viruses. For patients on high, immunosuppressive doses of steroids or ACTH, no live-virus vaccines should be given. Live-virus vaccines are generally contraindicated when there is B-cell suppression. Immunization is unlikely to be successful while a child is receiving IVIg and for up to a year after discontinuation. Immunization with attenuated live virus in the aftermath of OMS should be considered on a case-by-case basis.

## Future Directions

A cure for OMS might also reveal one for neuroblastoma, the flip side of the same coin. Once the OMS antigen is identified, an animal model can be created, autoimmune causation can be proven, and hindrances caused by disease rarity and lack of brain tissue can be offset. Exploring new therapeutic targets and strategies is essential to improve OMS treatment. Meanwhile, one can expect incremental improvements in multimodal therapy and neuroprotective strategies. The rarity of OMS and ethics issues undermine the standard randomized, controlled trial study design and encourage use of available alternate designs. Based on what is known about neuroinflammation in OMS, all clinical trials in OMS should include biomarker measurement protocols. As new biomarkers are discovered, biomarker-assisted therapy is the emerging treatment paradigm. The past 10 years have brought many exciting developments, but there are still wide gaps in our knowledge. Much work remains to be done.

The rheumatic disorders of childhood include conditions ranging from isolated arthritis to complex multisystem autoimmune diseases. The presence and the degree of nervous system impairment varies, and manifestations may precede the onset of other symptoms. The current classification of the chronic rheumatic disorders is shown in [Box 121-1](#) ([Dannecker and Quartier, 2009](#)). Examples of autoantibodies found in rheumatic diseases are given in [Table 121-1](#).

Neurologic manifestations arise in primary and secondary fashion ([Benseler and Schneider, 2004](#)). Antibodies or cellular immune elements can directly affect nerves, muscle, brain, spinal cord, and sensory organs. Alternatively, innocent bystander (e.g., vascular inflammation and immune complex deposition) or medication effects can impair the nervous system. Rheumatic disease should be considered in evaluating unexplained childhood neurologic syndromes such as persistent fever, weight loss, myalgias, arthralgias, meningeal signs, or multiple nonanatomically contiguous neurologic deficits.

## JUVENILE IDIOPATHIC ARTHRITIS (CHRONIC ARTHROPATHIES)

The key neurologic and laboratory findings in chronic arthropathies are summarized in [Table 121-2\(A\)](#). Neurologic manifestations of juvenile idiopathic arthritis (JIA; previously described as juvenile rheumatoid arthritis) vary with the arthritis subtype. Children with pauciarticular or polyarticular JIA rarely have central nervous system (CNS) disease, but approximately 6% with systemic-onset JIA develop CNS involvement.

### Neurologic Manifestations

#### Systemic Juvenile Idiopathic Arthritis

**Acute Encephalopathy.** The most common form of acute encephalopathy is macrophage activation syndrome (MAS), a complex syndrome with similarities to hemophagocytic lymphohistiocytosis. Symptoms include unremitting fever, rash, hepatic dysfunction, metabolic alterations, lymphadenopathy, as well as cardiac, pulmonary, and renal failure. Neurologic symptoms include seizures, acute encephalopathy, and intracranial hemorrhage.

Laboratory studies demonstrate cytopenia, low albumin, and elevated D-dimer, ferritin, and lactate dehydrogenase, liver enzymes, serum triglycerides as well as cerebrospinal fluid protein and cell counts. Generalized electroencephalographic (EEG) slowing is seen. MAS can occur after use of acetylsalicylic acid, indomethacin, gold, nonsteroidal antiinflammatory drugs (including sulfasalazine), or spontaneously. Immediate corticosteroid treatment is associated with resolution. In resistant disease, cyclosporine A and biologic agents are effective.

**Neuropathies.** Peripheral motor and sensory neuropathies are associated with epineural vasculitis and axonal neuropathy with demyelination due to occlusion of the vasa nervorum.

**Mood Disturbances.** Anxiety, a decreased sense of well-being, and depression occur in children with JIA. Premorbid family dynamics, maternal depression, and drug interactions may contribute to psychological disorders.

**Myositis.** One third of children have mild elevations of creatine kinase without weakness. Proximal weakness and biopsy-confirmed myositis are rare; intermittent myalgias are common.

#### Polyarticular Juvenile Idiopathic Arthritis (Poly JIA)

**Myelopathy.** Many children with polyarticular or systemic-onset JIA develop neck stiffness secondary to cervical arthritis. Cervical myelopathy associated with atlantoaxial dislocation is highly unusual.

#### Pauciarticular Juvenile Idiopathic Arthritis (Pauci JIA)

**Iridocyclitis and Uveitis.** The incidence of iridocyclitis and uveitis is now similar in children with pauci JIA and poly JIA. In girls, the incidence increases with age and disease duration.

#### Psoriatic, Enthesitis-Related, and Undifferentiated Syndromes

Approximately 3% of children with inflammatory bowel disease (IBD) have neurologic involvement including myasthenia gravis, myopathy, peripheral or cranial neuropathy, cerebral sinovenous thrombosis, recurrent strokes, myelopathy, seizures, headache, confusional states, meningitis, and syncope. About 5% of patients with enthesitis-related arthritides develop uveitis with eye redness, pain, photophobia, and blurred vision.

### Neuropathology

Neuropathologic studies are discussed in the online chapter.

### Management

Treatment of JIA has been transformed by the development of biologic agents and varies by disease subtype. Pauci JIA is managed with nonsteroidal antiinflammatory drugs such as naproxen and tolmetin sodium or with intraarticular steroid injection. Iridocyclitis responds to topical ophthalmic corticosteroids. Polyarticular JIA is treated with nonsteroidal antiinflammatory drugs; however, agents such as methotrexate and tumor necrosis factor (TNF)- $\alpha$  inhibitors, such as etanercept or infliximab may be required. Systemic JIA is managed with

**TABLE 121-1** Autoantibodies in Pediatric Rheumatic Diseases

Antibody	Clinical Finding
ANA	97% SLE, but also positive in MCTD, SSc, 10–85% JDMS, 20–88% JRA, SS, and 2%–5% of controls
Antids-DNA	30%–70% SLE, rarely in other CTDs
Anti-Sm	30% SLE
Anti-RNP	MCTD, also in SLE
Anti-SSA/Ro	25% SLE, 75% SS
Anti-SSB/La	10% SLE, 40% SS
Antihistone	50% SLE, >90% DILS
Anticentromere	44%–98% CREST syndrome
Anti-Scl-70	27% SSc
Anti-ANCA	>90% Granulomatosis with polyangiitis
Anti-p-ANCA	10% Granulomatosis with polyangiitis, 70% CSS, 75% UC, 20% Crohn's disease, 30% SLE
Anti-NR2 NMDAR	10% SLE
RF A	20% polyarticular JRA, 50% SS; 10%–30% SLE, MCTD
LAC	Correlates with thromboembolic risk in SLE
aCL	Correlates with thromboembolic risk in SLE, malignancy; variable in many other diseases

aCL, anticardiolipin antibody; ANA, antinuclear antibody; c-ANCA, cytoplasmic staining antineutrophil cytoplasmic antibody; CREST, calcinosis, Raynaud's, esophageal dysmotility, sclerodactyly, telangiectasia; CSS, Churg–Strauss syndrome; CTD, connective tissue disease; DILS, drug-induced lupus syndrome; ds-DNA, double-stranded (native) DNA; JDMS, juvenile dermatomyositis; JRA, juvenile rheumatoid arthritis; LAC, lupus anticoagulant; MCTD, mixed connective tissue disease; NMDAR, *N*-methyl-D-aspartate receptor; p-ANCA, perinuclear staining antineutrophil cytoplasmic antibody; RF A, rheumatoid factor A; RNP, ribonucleoprotein; SLE, systemic lupus erythematosus; Sm, Smith; SS, Sjögren's syndrome; SSc, systemic scleroderma; UC, ulcerative colitis. (Adapted from: Okano, Y., 1996. *Antinuclear antibody in systemic sclerosis [scleroderma]*. *Rheum Dis Clin North Am* 22, 709; Moder, K.G., 1996. *Use and interpretation of rheumatologic tests: A guide for clinicians*. *Mayo Clin Proc* 71, 391; Bylund, D.J., McCallum, R.M.. *Vasculitis*. In: Henry JB, editor: *Clinical diagnosis and management by laboratory methods*. Philadelphia, WB Saunders; 1996.)

nonsteroidal antiinflammatory drugs but often requires steroids, methotrexate, or biologic agents. Etanercept or infliximab is used in resistant cases. High-dose methylprednisolone, intravenous immunoglobulin, and cyclophosphamide are helpful; newer agents that block IL-1 and IL-6 have shown benefit. Some children develop psychological problems; counseling and physical and occupational therapy are beneficial.

**PERIODIC FEVER SYNDROMES****Neonatal-Onset Multisystem Inflammatory Disease or Chronic Infantile Neurologic Cutaneous and Articular Syndrome**

Neonatal-onset multisystem inflammatory disease (NOMID) or chronic infantile neurologic cutaneous and articular (CINCA) syndrome is an unusual autosomal dominant disorder (NLRP3 gene mutation) that mimics systemic JIA. It occurs

**TABLE 121-2** Key Neurologic and Laboratory Findings in the Rheumatic Disorders

<b>A. CHRONIC AND REACTIVE ARTHROPATHIES</b>		
<b>Disease</b>	<b>Neurologic Findings</b>	<b>Laboratory Findings</b>
Systemic juvenile idiopathic arthritis	Encephalopathy, seizures, macrophage activation syndrome (Reye-like syndrome), neuropathies	Elevated WBC and ESR, anemia, DIC, elevated CSF protein and cell count, marked increase in ferritin and LDH
Inflammatory bowel disease	Myasthenia gravis, myopathy, neuropathy, seizures, cognitive changes	Elevated ESR, microcytic anemia, melena
Acute rheumatic fever	Chorea, personality changes, seizures	Positive ASO titers, elevated ESR and CRP, abnormal ECG
Lyme disease	Early infection: aseptic meningitis, headache, chorea, cranial nerve palsies, late neuroborreliosis myelitis, MS-like symptoms, subtle encephalopathy, radiculopathy, mononeuritis multiplex	Positive IgG Lyme titer by ELISA, protein by Western blot in serum, positive PCR in CSF
ASO, antistreptolysin O; CRP, C-reactive protein; CSF, cerebrospinal fluid; DIC, disseminated intravascular coagulation; ECG, electrocardiogram; ELISA, enzyme-linked immunosorbent assay; ESR, erythrocyte sedimentation rate; IgG, immunoglobulin G; LDH, lactate dehydrogenase; MS, multiple sclerosis; PCR, polymerase chain reaction; WBC, white blood cell count.		
<b>B. CONNECTIVE TISSUE DISEASES</b>		
<b>Disease</b>	<b>Neurologic Findings</b>	<b>Laboratory Findings</b>
SLE	Encephalopathy, chorea, seizures, aseptic meningitis, psychosis, behavioral or cognitive dysfunction, headaches, strokes, neuropathy, myelitis	Elevated ANA, low C3 and C4, pancytopenia, hematuria, proteinuria, autoantibodies, LAC, elevated aCL
Scleroderma: coup-de-sabre deformity	Seizures, blurred vision, bulbar palsy, optic neuritis, trigeminal neuropathy	Elevated ANA and rheumatoid factor
Mixed connective tissue disease	Same as SLE	Same as SLE plus elevated anti-RNP, elevated CK
Sjögren's syndrome	Encephalopathy, optic neuritis, aseptic meningitis, recurrent paresis, myelopathy, neuropathy, autonomic dysfunction	Positive ANA, rheumatoid factor, antibodies to SSA/Ro and SSB/La
aCL, anticardiolipin antibody; ANA, antinuclear antibody; C3, third component of complement; C4, fourth component of complement; CK, creatine kinase; LAC, lupus anticoagulant; RNP, ribonucleoprotein; SLE, systemic lupus erythematosus.		
<b>C. CHILDHOOD VASCULITIDES</b>		
<b>Disease</b>	<b>Neurologic Findings</b>	<b>Laboratory Findings</b>
Polyarteritis nodosa	Headache, encephalopathy, stroke, seizures, neuropathies	Elevated WBC, ESR, positive HBsAg and c-ANCA
Kawasaki disease	Aseptic meningitis, focal neurologic findings	Coronary aneurysms, thrombocytosis
Cogan syndrome	Neurosensory hearing loss	None
Henoch-Schönlein purpura	Encephalopathy	Elevated IgA in 50%, hematuria, melena
Churg-Strauss syndrome	Headache, encephalopathy, stroke, seizures, various peripheral neuropathies, coma, intracranial hemorrhage	Eosinophilia, eosinophils on skin biopsy, p-ANCA
Granulomatosis with polyangiitis	Encephalopathy, intracranial hemorrhage, meningitis	c-ANCA
Primary angiitis of the CNS	Headache, encephalopathy, seizures, stroke, myelopathy	Elevated ESR
Sarcoidosis	Obstructive hydrocephalus, seventh nerve palsy, meningitis, seizures, peripheral neuropathies	Noncaseating granuloma
Temporal arteritis	Blindness, encephalopathy, headache	Elevated ESR
Takayasu arteritis	Headache, stroke, syncope, visual loss	Elevated ESR and factor VIII-related antigen
Behçet disease	Headache, meningitis, psychiatric disorders, encephalopathy, pseudotumor cerebri, brainstem signs	Elevated ESR
c-ANCA, cytoplasmic staining antineutrophil cytoplasmic antibody; CNS, central nervous system; ESR, erythrocyte sedimentation rate; HBsAg, hepatitis B surface antigen; IgA, immunoglobulin A; p-ANCA, perinuclear staining antineutrophil cytoplasmic antibody; WBC, white blood cell count.		

during the first year of life. Manifestations include hectic fever, intermittent rash, lymphadenopathy, hepatosplenomegaly, uveitis, cognitive and developmental delay, chronic meningitis, hydrocephalus, seizures, hemiplegia, papilledema, optic neuritis, uveitis, and deforming arthropathy with periosteal changes and bony overgrowth. Seventy-five percent of patients develop progressive sensorineural deafness. Long-term prognosis is poor.

### Familial Mediterranean Fever

Familial Mediterranean fever is an autosomal-recessive disorder due to mutations in the MEFV gene. Symptoms include fever, abdominal pain, peritonitis, pleuritis, and

arthritis. Myalgias after exertion are common. Headache, febrile seizures, aseptic meningitis, and posterior reversible leukoencephalopathy occur, as has progressive sensorineural deafness.

### Periodic Fever, Aphthous Stomatitis, Pharyngitis, and Adenitis Syndrome

Periodic fever, aphthous stomatitis, pharyngitis, and adenitis (PFAPA) syndrome has an unclear etiology. It is characterized by febrile episodes persisting for 4 to 6 days, separated by afebrile periods lasting 4 weeks to 4 months. Headaches occur during febrile episodes. Recurrent aseptic meningitis accompanied by seizures has been described.

## Hyper-IgG (Autoimmune Lymphoproliferative) Syndrome

This genetic syndrome presents with splenomegaly, skin rashes, enlarged lymph nodes, and autoimmune hemolytic anemia. Neurologic symptoms are associated with other autoimmune phenomena, including Guillain-Barré syndrome.

## ARTHRITIS ASSOCIATED WITH INFECTIOUS AGENTS

### Acute Rheumatic Fever

Acute rheumatic fever (ARF) is an inflammatory illness that follows a group A beta-hemolytic streptococcal pharyngitis. Manifestations include migratory polyarthritis, fever, carditis, and, less frequently, Sydenham chorea, subcutaneous nodules, and erythema marginatum. The modified 1992 Jones criteria are used to confirm the diagnosis (two major and one minor criteria; or one major and two minor criteria), as well as antibody evidence of preceding streptococcal infection (Box 121-2). In the case of isolated Sydenham chorea, demonstration of streptococcal infection may not be possible and is not a requirement for diagnosis (Dajani, et al., 1992).

### Neurologic Manifestations

#### Sydenham Chorea

**Clinical Manifestations.** Sydenham chorea is characterized by involuntary, distal, purposeless, rapid movements; hypotonia; and emotional lability. It may be associated with other ARF manifestations or as the sole manifestation. Isolated chorea represents 20% to 30% of acute rheumatic fever cases and occurs long after the pharyngitis has resolved. Laboratory evidence of preceding streptococcal infection may not be demonstrable in up to 35% of children. Onset may be explosive or insidious. Chorea may be misdiagnosed as an emotional disorder, tics, decreased attention span, or a degenerative process.

Choreiform movements involve the face, hands, and feet. Facial movements include grimacing, frowning, grinning, and pouting. Children commonly are unable to sustain prolonged hand contraction ("milkmaid" sign). Emotional lability, personality changes, restlessness, and irritability may herald the onset of chorea. Occasionally, "spooning" with hyperextension of the hands is observed. In adolescents, chorea occurs almost exclusively in females and may be associated with hemichorea or hemiparesis. Choreiform movements subside in 2 to 4 months but can persist. Chorea and arthritis usually do not accompany each other; however, carditis frequently develops as the chorea is improving.

**Laboratory Findings.** Laboratory studies include documentation of antecedent streptococcal infection with an antistreptolysin-O titer, demonstration of a prolonged PR interval on electrocardiogram, elevated C-reactive protein or erythrocyte sedimentation rate, and leukocytosis. Although throat culture may show group A beta-hemolytic streptococci, an elevated or increasing antistreptolysin-O titer is required. An elevated anti-DNase-B increases the sensitivity of an antistreptolysin-O titer alone. To exclude other choreiform conditions, patients may need additional studies (serum ceruloplasmin, thyroxine, calcium, and antinuclear antibody titers). EEGs may demonstrate diffuse paroxysmal features and generalized slowing. Cerebrospinal fluid (CSF) examination and neuroimaging are rarely necessary. Of interest is the finding of antineuronal antibodies in the CSF of patients with chorea. The specificity of these antibodies is unknown, and they are frequently documented in patients with CNS lupus.

### BOX 121-2 Jones Criteria for Diagnosis of Acute Rheumatic Fever (Revised 1992)

#### MAJOR\*

##### Carditis

Murmur consistent with aortic regurgitation or mitral insufficiency; echocardiogram findings without significant auscultatory findings are not adequate

##### Chorea

May be the only manifestation; proof of prior streptococcal infection in only 80%

##### Erythema Marginatum

Rare manifestation; never on the face; transient and migratory

##### Migratory Polyarthritis

Almost always migratory, involving larger joints, responds within 48 hours to aspirin and usually resolves in 1 month

##### Subcutaneous Nodules

Rare manifestation; nontender, on extensor surfaces, usually over elbows, wrists, knees, occipital region, or spinous processes

#### MINOR

##### Fever

Usually greater than 39°C

##### Arthralgia

Consider if arthritis not present

##### Prolonged PR Interval

Does not correlate with the development of carditis

##### Elevated Erythrocyte Sedimentation Rate or C-Reactive Protein

Acute phase reactants

\*Prior episodes of acute rheumatic fever are not criteria; if a patient has had a prior attack of acute rheumatic fever, a new attack may be difficult to diagnose on the basis of changing carditis. In this setting, proof of recent streptococcal infection and either one major or one minor criterion may allow a presumptive diagnosis. Proof of recent streptococcal infection is necessary, except for isolated chorea. (Adapted from: Dajani, et al. and The Special Writing Group, 1992. Guidelines for the diagnosis of rheumatic fever. Jones Criteria, 1992 update. JAMA 268, 2069.)

MRI abnormalities include cystic changes, restricted diffusion in the caudate and putamen, and multiple subcortical and peripheral white matter signal intensity abnormalities.

### Neuropathology

Findings in ARF are rare and include small cortical and meningeal endarteritis with spotty patches of gray-matter degeneration.

### Treatment

All patients, including those only with chorea, should receive a 10-day course of penicillin or erythromycin. Prophylaxis with penicillin or sulfadiazine should be started immediately and continued until adulthood because of the risk of reinfection and of rheumatic heart disease. When residual valvular disease exists, prophylaxis should continue for at least 10 years after the last episode and at least until age 40. If there is no residual valvular disease, the duration of treatment beyond 10 years or into adulthood is uncertain. When Sydenham chorea is diagnosed and there is no valvular disease, the duration of

prophylaxis should be at least 5 years or until age 21, whichever is longer. Children who develop chorea as the sole manifestation of ARF have a 50% risk of developing rheumatic heart disease.

Sydenham chorea has been treated with chlorpromazine, haloperidol, phenobarbital, diazepam, valproic acid, cyproheptadine, and prednisone. Clonidine, pimozide, and pulsed intravenous methylprednisolone followed by an oral taper, intravenous immunoglobulin, or plasma exchange may be beneficial in refractory cases. Recovery can be expected within 2 to 6 months, although some children have residual manifestations.

### Postinfectious Tourette Syndrome and PANDAS

Chorea, obsessive-compulsive disorder, tic disorder, and Tourette syndrome may all have a common autoimmune pathway. Some children with chorea have obsessive-compulsive disorder that resolves before or simultaneously with the resolution of the chorea. An increased prevalence of obsessive-compulsive disorder occurs in children with tics and Tourette syndrome; an increased prevalence of antineuronal antibodies, as well as increased levels of antistreptococcal antibodies, occurs in all four of these conditions. The acronym PANDAS (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections) has been suggested when there is a combination of behavioral problems, obsessive-compulsive behavior, and tics when associated with a group A beta-hemolytic streptococcal infection.

### Other Central Nervous System Manifestations

About 3% to 5% of patients with ARF develop other neurologic problems including meningoencephalitis, encephalitis, seizures, pseudotumor cerebri, papilledema, diplopia, central retinal occlusion, transient intellectual loss, and acute psychosis.

### Lyme Disease

Lyme disease is an important cause of neurologic symptoms in children (Bingham, et al., 1995). The illness follows a tick bite and occurs in endemic areas during the summer. The early stage begins with a flu-like illness and the appearance of an oval, expanding rash. Systemic infection with *Borrelia burgdorferi* may be documented by culture. Within several weeks, the patient develops neurologic manifestations, with facial nerve palsy, aseptic meningitis, other cranial neuropathies transverse myelitis, and sometimes direct invasion of the organism into CSF. Acute sinovenous thrombosis with consequent pseudotumor cerebri can occur. The illness resolves spontaneously but may be hastened by antibiotic treatment (amoxicillin or erythromycin in children younger than 9 years old; tetracycline in children age 9 years or older, either for 10 to 30 days).

Weeks to months later, untreated patients may develop episodic arthritis of the large joints. The knee becomes acutely effused but not particularly tender or hot. Joint swelling lasts for several days and resolves but returns repeatedly if treatment with antibiotics is not started. Diagnosis may be confirmed after the first few weeks with a positive serum IgG titer against *B. burgdorferi*. Western blotting from blood or polymerase chain reaction (PCR) amplification of the *B. burgdorferi* genome in the CSF is available.

Some patients develop neuroborreliosis years later. This rare complication manifests as a subtle encephalopathy with stuttering and memory disturbances. The diagnosis is confirmed by demonstration of an elevated intrathecal IgG titer compared with serum titers. Treatment with intravenous

ceftriaxone for 1 month is indicated, but the response is variable.

### Reactive Arthritis (formerly called Reiter Syndrome)

Reactive arthritis is characterized by arthritis, uveitis, and urethritis. Progressive myelopathy, cerebral vasculitis, axonal polyneuropathy, and seizures have been reported as rare neurologic complications in adults.

### CONNECTIVE TISSUE DISORDERS

The key neurologic and laboratory findings in connective tissue disorders are summarized in [Table 121-2\(B\)](#).

### Systemic Lupus Erythematosus

Revised criteria for diagnosing SLE (2012) ([Box 121-3](#)) call for having at least 4 of 17 criteria (at least 1 clinical and 1

#### BOX 121-3 Revised Criteria for the Classification of Systemic Lupus Erythematosus (2012)

Diagnosis requires at least 4 criteria (at least 1 clinical and 1 immunologic) OR biopsy-proven lupus nephritis with positive antinuclear or anti-DNA antibodies.

##### CLINICAL CRITERIA

- Acute cutaneous lupus: lupus malar rash (not discoid), bullous lupus, toxic epidermal necrolysis variant of lupus, maculopapular lupus rash, photosensitive lupus rash (in the absence of dermatomyositis), nonindurated psoriaform and/or annular polycyclic lesions that resolve without scarring
- Chronic cutaneous lupus: classic discoid rash, hypertrophic (verrucous) lupus, lupus panniculitis (profundus), mucosal lupus, lupus erythematosus tumidus, chilblains lupus, discoid lupus/lichen planus overlap
- Oral or nasal ulcers: in the absence of a cause other than lupus
- Non-scarring alopecia: diffuse thinning or fragility of hair with visible broken hairs in the absence of a cause other than lupus
- Arthritis: synovitis involving 2 or more joints
- Serositis: pleural or pericardial inflammation, effusions, or rub in the absence of a cause other than lupus
- Renal: urine protein-to-creatinine ratio (or 24 h urine protein) representing 500 mg protein/24 h or red blood cell casts
- Neurologic: seizures, psychosis, mononeuritis multiplex, myelitis, peripheral or cranial neuropathy, or acute confusional state in the absence of a cause other than lupus
- Hemolytic anemia
- Leukopenia: leukopenia  $<4000/\text{mm}^3$  or lymphopenia  $<1000/\text{mm}^3$
- Thrombocytopenia:  $<100,000/\text{mm}^3$

##### IMMUNOLOGIC CRITERIA

- Antinuclear antibody
- Anti-DNA antibody
- Anti-Smith antibody
- Antiphospholipid antibody
- Low serum complement (C3, C4, CH50)
- Direct Coombs' test positive in the absence of hemolytic anemia

(Modified from: Petri M, Orbai AM, Alarcón GS, et al. Derivation and validation of the Systemic Lupus International Collaborating Clinics classification criteria for systemic lupus erythematosus. *Arthritis Rheum* 2012;64:2677-2686.)

immunologic) or biopsy-proven nephritis and a positive anti-nuclear or anti-DNA antibody. Arthritis, arthralgia, fever, and photosensitive rash are the most common initial complaints, with renal, cardiac, and neurologic involvement responsible for chronic disability. Lymphadenopathy, hepatosplenomegaly, pleural and pericardial effusions, pulmonary infiltrates, pericarditis, abdominal pain, and peritonitis may be present at presentation. Renal disease (nephrotic syndrome, acute or chronic glomerulonephritis) occurs in 60% to 80% of children. Laboratory findings include an abnormal urinalysis, low serum complement levels, high antibodies to double-stranded DNA, a decreased glomerular filtration rate, and abnormal renal biopsy. Management is highly individualized. The prognosis for children with SLE has improved dramatically, with 10-year survival of 85%.

### Neurologic Manifestations

Nervous system involvement is common in children, and now the outcome is more favorable, with most recovering (Muscal and Brey, 2010).

**Seizures.** Up to 50% of children develop seizures, usually during the first year of illness. Interictal EEGs show multifocal paroxysmal sharp-wave or slow-wave activity. Seizures can be secondary to hypertension, uremia, electrolyte disturbances, immunosuppressive treatment, opportunistic CNS infections, or cerebral edema (Appenzeller, et al., 2004).

**Neuropsychiatric Lupus.** Neuropsychiatric complications range from 22% to 95%. Nineteen neuropsychiatric SLE (NPSLE) syndromes have been defined for adults. Neurologic manifestations in children include headache (72%), mood disorders (57%), cognitive dysfunction (55%), seizures (51%), acute confusional state (35%), peripheral nervous system dysfunction (15%), psychosis (12%), and stroke (12%). Neuropsychiatric manifestations are classified as primary (direct SLE brain involvement) or secondary (related to disease/treatment complications). About 70% of children manifest neuropsychiatric symptoms within the first year; in the remaining 30%, symptoms may be latent. The majority of affected children have more than one neuropsychiatric symptom. Onset may be acute or indolent and may appear as the only presenting symptom. Numerous autoantibodies are associated with NPSLE, including antineuronal antibodies, antiphospholipid antibodies, anti-NR2 N-methyl-D-aspartate (NMDA) receptor antibody, and antiribosomal P antibody. The wide availability of newer MRI sequences is improving the likelihood of identifying brain abnormalities. These abnormalities are not specific for NPSLE; they can also reflect postictal or postschemic phenomena. Some patients with NPSLE have TREX1 mutations that code for the DNA repair enzyme, DNase III.

**Headache.** Headaches are common, usually occurring during disease exacerbation and in association with other neurologic symptoms. The diagnostic workup may yield few abnormalities; evaluation for a hypertensive encephalopathy or posterior reversible encephalopathy syndrome should be considered. Most patients respond to increasing corticosteroids.

**Chorea.** Chorea occurs in approximately 5% of children and is the initial nervous system symptom in 25% to 30% of patients. SLE symptoms occur within 1 year of chorea onset; rarely, a prolonged latent interval may ensue. Approximately 50% of children with chorea develop other CNS manifestations. Chorea also is associated with thromboembolic disease and elevated anticardiolipin antibody.

**Reye-like Syndrome.** A Reye-like syndrome associated with acetylsalicylic acid treatment of SLE has been recognized. This

syndrome has not been seen with other nonsteroidal antiinflammatory agents.

**Cerebrovascular Disease.** Approximately 3% of children develop cerebrovascular occlusive disease usually with serious renal, cardiac, pulmonary, hematologic disease, hypertension or thrombocytopenia. Antiphospholipid antibody has been associated with thrombosis, especially when lupus anticoagulant is present. Microemboli, thrombotic, or thromboembolic disease due to a vasculopathy with or without atheromatous disease, valvular disease, or vasculitis may contribute to stroke occurrence.

Patchy areas of altered MRI signal intensity have been interpreted as acute vascular lesions associated with pulse steroid therapy in patients with SLE. This syndrome responds well to substitution of cyclophosphamide for pulse methylprednisolone.

**Hypertensive Encephalopathy.** Headache, seizures, coma, and focal ischemic injury can be manifestations of hypertensive encephalopathy with or without posterior reversible leukoencephalopathy in patients with nephritis. Controlling blood pressure and treatment with intravenous corticosteroids improves outcome.

**Cranial Nerve, Brainstem, and Spinal Cord Dysfunction.** Ophthalmoplegia, ptosis, diplopia, facial numbness, vertigo, sensorineural hearing loss, vocal cord paralysis, and ataxia occur. Approximately 6% of children manifest visual symptoms (e.g., blurred vision, sudden blindness, visual field loss). Retinal hemorrhages, cotton wool exudates, papilledema, optic neuritis, cytoid bodies, and retinal artery occlusion have been reported. Papilledema is associated with pseudotumor cerebri caused by the disease or corticosteroid therapy. Patients with retinal artery occlusion or papilledema should be treated with high dose intravenous corticosteroids after diagnostic elimination of structural or occlusive cerebrovascular disease. Transverse myelopathy and Devic disease with neuromyelitis optica (NMO) antibody seropositivity can occur. High doses of intravenous corticosteroids, alone or in combination with cyclophosphamide or rituximab, show variable improvement.

**Central Nervous System Infections.** CNS infection is rare. Bacterial meningitis, opportunistic bacterial infection, and fungal meningitis (aspergillosis, nocardiosis, and cryptococcosis) occur. Brain abscess may be difficult to differentiate from a multifocal vasculitis, but differentiation may be facilitated by serial neuroimaging.

**Lupus Aseptic Meningitis.** Lupus aseptic meningitis, accompanied by a sterile CSF lymphocytic pleocytosis, may be manifested by nuchal rigidity, fever, and headache and can occur in association with nonsteroidal antiinflammatory drugs and trimethoprim-sulfamethoxazole use. Manifestations and CSF abnormalities persist for several weeks before resolving spontaneously. Therapy with intravenous corticosteroids may improve this condition.

**Peripheral Nervous System Involvement.** Peripheral nervous system involvement occurs in 5% of children. Peripheral neuropathies are relatively mild. Severe forms of lumbosacral plexopathies have been reported as has mononeuritis multiplex. Polyradiculoneuropathy may mimic Guillain-Barré syndrome but is rare.

**Myopathy.** Myositis is rare, although myalgias and generalized weakness are common. Myasthenia gravis has been reported. Although children with myasthenia gravis may have circulating serum antinuclear antibodies, clinical SLE is unusual.

**Drug-Induced Lupus Syndrome.** Many drugs can induce a lupus-like syndrome. Arthritis, pneumonitis, and pericarditis are common, whereas rashes and alopecia are less frequent. Hepatosplenomegaly, lymphadenopathy, and acute pancreatitis occur in some patients; renal disease appears less often. Procainamide, hydralazine, and isoniazid most commonly induce this syndrome. Antiepileptic drugs (e.g., carbamazepine, ethosuximide, phenytoin, primidone, trimethadione, valproate, zonisamide, clobazam), clonidine, and phenothiazines all have been associated with this syndrome. Recurrent seizures in patients whose initial seizures were well controlled suggest a drug-induced, lupus-like syndrome. Although antinuclear antibodies are positive in systemic and drug-induced SLE, specific antihistone antibodies are associated with drug-induced disease, whereas antidouble-stranded DNA is elevated in SLE. Discontinuing the drug or substituting other antiepileptic drugs may reduce seizure activity. Only rarely will corticosteroids be necessary.

### Laboratory Findings

Laboratory features include a positive antinuclear antibody titer, low C3 and C4 levels, leukopenia, direct Coombs-positive hemolytic anemia, hematuria, and proteinuria. Abnormal autoantibodies include antibodies to double-stranded DNA, Sm (Smith), RNP (ribonucleoprotein), Ro (or SSA), La (or SSB), and anticardiolipin. Some correlation between disease and antiphospholipid antibodies has been demonstrated. Elevated lupus anticoagulant (LAC) confers an increased risk of arterial or venous thrombosis. The pathogenic mechanisms causing CNS lupus are reviewed in the online chapter.

### Neuroimaging Evaluation

Neuroimaging may show cortical or cerebellar atrophy (Fig. 121-1), infarction (Fig. 121-2), low-density lesions in the cerebral white matter (Fig. 121-3), or hemorrhage. Perfusion-weighted and diffusion-tensor imaging and MR spectroscopy are increasingly used to identify areas of hypoperfusion in NPSLE. MR angiography or venography may detect sinovenous thrombosis. Cerebral angiography may be helpful in further differentiating arterial thrombotic from embolic disease. Single-photon emission computed tomography (SPECT) is sensitive for demonstrating perfusion abnormalities (Fig. 121-4).

### Treatment of Neurologic Manifestations

Treatment requires controlling the underlying inflammatory disorder, correcting metabolic or systemic abnormalities, and administering symptom-directed medications such as antiepileptic drugs, analgesic medications, antidepressants, sedatives, antipsychotic agents, and dopamine-blocking agents for chorea. Although phenobarbital, phenytoin, diazepam, lorazepam, valproate, and carbamazepine have been used for the treatment of seizures, newer antiepileptic drugs may afford a more favorable risk profile. Discontinuation of antiepileptic drugs should be considered when the primary disease is well controlled. In moderate doses, corticosteroids have beneficial effects in adults with NPSLE. Treatment of CNS infection depends on the infectious agent and may necessitate reducing immunosuppressive therapy until the infection is controlled.

Anticoagulation may be considered in patients with cerebral ischemia; evaluation and treatment of arterial ischemic stroke and sinovenous thrombosis are discussed in selected chapters in Part XIII of this book.

Immunosuppressive therapy with corticosteroids is used for patients with NPSLE, vasculitis, coma, seizures, chorea,

and transverse myelitis. Cytotoxic agents such as mycophenolate or cyclophosphamide are used in patients with serious renal or neurologic disease. Candidates for such treatment include those with diffuse proliferative glomerulonephritis, CNS lupus, or myelopathy who are refractory to intravenous corticosteroids.

### Neuropathology

Neuropathologic studies of childhood and adult SLE are rare and discussed in the online chapter.

### Scleroderma

Scleroderma in children occurs in two distinct forms: localized and systemic. Localized scleroderma is further subdivided into morphea, generalized morphea, linear scleroderma, and coup-de-sabre lesions. Coup-de-sabre lesions present as linear sclerodermatous changes of the head or oral cavity. Although there may be CNS involvement, this form of scleroderma is an important finding. Systemic scleroderma is subdivided into progressive systemic sclerosis and a generally milder syndrome termed CREST (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia). Progressive systemic sclerosis manifests with progressive hardening of the skin and subcutaneous tissues, with involvement of the gastrointestinal tract, joints, heart, lungs, and kidneys. Raynaud's phenomenon, severe cardiac and pulmonary disease with congestive heart failure, pulmonary interstitial fibrosis, pulmonary vascular sclerosis, and renal sclerosis with acute renal failure contribute to mortality. Skin biopsy is diagnostic, demonstrating increased thickness of the dermal collagen, perivascular mononuclear cell infiltrates without immune complex deposition. Radiographic assessment demonstrates subcutaneous calcinosis, joint effusions, and diminished esophageal peristalsis. Decreased lung diffusion, pulmonary hypertension, and pericardial effusion also occur.

### Neurologic Manifestations

Children with the coup-de-sabre localized scleroderma develop intractable partial seizures, pseudopapilledema, strabismus, hemiparesis contralateral to the facial lesions, and developmental regression (Murray and Laxer, 2002). Periarticular muscle atrophy, common in children with systemic scleroderma, is due to disuse and subtle myopathic involvement. Creatine kinase activity is elevated and MRI may localize muscle disease. Children with progressive systemic sclerosis generally do not have primary CNS involvement.

### Laboratory Findings

Laboratory evaluation should include determination of antinuclear antibody titers, immunoglobulins, erythrocyte sedimentation rate, rheumatoid factor, and creatine kinase activity. Patients with progressive systemic sclerosis may have antibodies to DNA topoisomerase 1 (Scl-70) or RNA polymerase I, II, or III.

### Treatment

Treatment of progressive systemic scleroderma is supportive and is often unsuccessful. Initial management includes oral corticosteroids to improve myopathic weakness. There has been anecdotal support for steroids combined with methotrexate for linear scleroderma. Raynaud's phenomenon should be treated with calcium channel blockers. Occupational and physical therapy to maintain and improve joint mobility is important.

## Mixed Connective Tissue Disease

This disorder is characterized by signs and symptoms of SLE, scleroderma, and dermatomyositis or polymyositis. Antibodies reactive to the ribonuclease-sensitive component of extractable nuclear antigen (anti-RNP) are seen, with a speckled pattern antinuclear antibody.

Features include Raynaud's phenomenon, polyarthritis, fever, rash, thickening of subcutaneous tissues, hepatosplenomegaly, myositis, and cardiomyopathy. Secondary Sjögren syndrome may produce parotitis and keratoconjunctivitis sicca (dry eyes). Evaluation may demonstrate elevated erythrocyte sedimentation rate and rheumatoid factor, decreased esophageal motility, diminished tear production, keratoconjunctivitis, abnormal parotid sialography, pulmonary effusion, and abnormal pulmonary function tests.

### Neurologic Manifestations

Proximal muscle weakness, increased creatine kinase activity, myopathic electromyograms, and muscle biopsy are consistent with inflammatory myositis. Seizures, headache, increased CSF protein content, aseptic meningitis, stroke, and intracranial hemorrhage have been reported.

### Treatment

With mild organ involvement, hydroxychloroquine may be adequate. For more severe involvement or myositis, oral or intravenous corticosteroids may be necessary. Methotrexate, azathioprine, mycophenolate mofetil, rituximab, and cyclophosphamide have been used, similar to therapy for SLE.

## Sjögren Syndrome

Sjögren syndrome is a chronic autoimmune disorder in which lymphocytic infiltration of the salivary, lacrimal, and other exocrine glands leads to keratoconjunctivitis sicca, xerostomia, and recurrent salivary gland inflammation. Primary Sjögren syndrome is rare in children, but the secondary form—preceding, accompanying, or after SLE, JIA, mixed connective tissue disease, juvenile dermatomyositis, or scleroderma—is more frequent.

### Neurologic Manifestations

Children with primary Sjögren syndrome may develop optic neuritis, aseptic meningitis, cerebrovascular occlusive disease, and recurrent paresis associated with cerebral or spinal cord white matter involvement. Manifestations in adults include seizures, cognitive and behavioral disorders, acute encephalopathy, aseptic meningitis, progressive myelopathies, motor and sensory neuropathies, and carpal tunnel syndrome.

### Laboratory Findings

Findings include hypergammaglobulinemia, positive antinuclear antibody, anti-SSA, anti-SSB, and classic rheumatoid factor. Diagnostic confirmation is obtained by labial salivary gland biopsy, demonstrating periductal lymphocytic infiltration. The Schirmer test, sialogram, and salivary scintigraphy support the diagnosis. In adults, CSF abnormalities include increased protein content, pleocytosis, elevated IgG levels, elevated IgG index, increased oligoclonal bands, and abnormal CSF to serum glucose ratios.

### Treatment

Hydroxychloroquine and supportive care are used for non-neurologic manifestations. Corticosteroids are needed for

significant neurologic manifestations, and if progressive, cyclophosphamide is added.

## PRIMARY VASCULITIC DISEASES

Vasculitis may be primary or secondary to a multisystem disorder (Iannetti, et al., 2012). In Box 121-1, the vasculitides are organized by pathologic type. Size and location of affected vessels or, alternatively, distinct clinical patterns with specific laboratory tests may identify a specific disorder. The pathogenesis of vasculitides is discussed in the online chapter. The key neurologic findings are listed in Table 121-2(C).

### Necrotizing Vasculitis

These disorders include polyarteritis nodosa, microscopic polyangiitis, Kawasaki disease, and Cogan syndrome. They are characterized by fibrinoid necrosis of small-sized and medium-sized muscular arteries.

#### Polyarteritis Nodosa

Polyarteritis nodosa (PAN) occurs in older children and adolescents with unexplained fever, arthralgias, calf discomfort, abdominal pain, recurrent pulmonary infection, renal disease, hypertension, fatigability, weight loss, malar rash, and purpura. Severe renal impairment and marked hypertension occur. Renal biopsy shows diffuse glomerulonephritis or necrotizing arteritis. Mesenteric arteritis and bowel wall infarction may lead to gastrointestinal hemorrhage. Histopathology demonstrates necrotizing vasculitis, and angiography shows aneurysms, stenosis, or occlusion of medium or small arteries. Corticosteroid and cytotoxic agent use has dramatically reduced mortality and morbidity. Exacerbations occur despite aggressive immune suppression. Infliximab has been used in refractory disease.

**Neurologic Manifestations.** Approximately half the patients demonstrate neurologic manifestations including seizures, headache, disturbances of higher cortical function, and affective disorders. Less common symptoms include visual field defects, hemiparesis, increased intracranial pressure, nystagmus, ophthalmoplegia, ataxia, and aseptic meningitis. Neuropsychiatric symptoms (psychosis, encephalopathy) can occur in PAN. The sudden onset of stroke requires MRI and MR angiography, followed by cerebral angiography in selected patients. Evidence of segmental narrowing or microaneurysmal dilatation may be demonstrated (Fig. 121-5B).

Diffuse myalgias can occur. Myositis, although rare, may reveal necrotizing arteritis with fibrinoid necrosis and perivascular inflammation. Sensorimotor neuropathies and mononeuritis multiplex are treated with corticosteroids. Myelopathy occurs rarely and usually only in patients with chronic disease.

**Laboratory Findings.** Laboratory evaluation reveals leukocytosis, anemia, increased sedimentation rate, abnormal urinalysis, and evidence of nephrosis and nephritis, in the absence of complement consumption, antinuclear antibodies, and rheumatoid factor. Patients may have circulating antineutrophil cytoplasmic antibodies, elevated factor VIII-related antigen, positive serology for hepatitis B surface antigen, and evidence of a preceding streptococcal infection. CSF is usually normal; the presence of blood strongly suggests a ruptured microaneurysm. Angiography may demonstrate aneurysmal dilatation of the medium-sized mesenteric, celiac, or renal arteries (Fig. 121-5A).

**Neuropathology.** Postmortem studies of pediatric patients with arteritis demonstrate necrotizing angiitis accompanied

by polymorphonuclear infiltration of small-sized and medium-sized arteries.

**Treatment.** Corticosteroids are the mainstay of treatment. Aggressive treatment with high-dose intravenous corticosteroids and cyclophosphamide should be considered for patients with significant multisystem or CNS disease. Plasmapheresis is not beneficial. Overall, 5-year survival has improved substantially.

### Kawasaki Disease

Kawasaki disease is characterized by aneurysms that are limited primarily to the coronary arteries. It is diagnosed by the presence of fever of at least 5 days' duration with four of these five criteria:

1. Bilateral nonpurulent conjunctival injection
2. Mucosal involvement of the oropharynx (injected or dry, fissured lips, or strawberry tongue)
3. Changes in the peripheral extremities, including edema, erythema of hands or feet, and desquamation
4. Rash, which may be polymorphous but not vesicular
5. Unilateral cervical lymphadenopathy

Prognosis has been excellent since the use of intravenous immunoglobulin and acetylsalicylic acid. However, myocardial infarction, dysrhythmias, and sudden death may occur.

**Neurologic Manifestations.** Pronounced irritability, lethargy, and aseptic meningitis are common, but other neurologic manifestations are rare. Cerebral artery involvement including aneurysm development is rare in contrast to PAN.

**Neuropathology.** Little cerebrovascular involvement has been documented. Major findings have included leptomeningeal thickening, mild endarteritis, and periarteritis.

**Treatment.** Treatment consists of acetylsalicylic acid, 80 to 100 mg/kg per day in four divided doses, until the patient has been afebrile for 3 to 7 days, followed by 3 to 5 mg/kg per day in a single dose and continued until inflammatory markers return to normal, the thrombocytosis has resolved, and no coronary artery disease exists on follow-up echocardiogram at 4 to 6 weeks. Acutely, intravenous immunoglobulin, 2 g/kg as a single dose over 12 hours, is recommended preferably before the 10th day. In children who have failed this therapy, corticosteroids, other immunosuppressives, and biologic agents have been used.

### Cogan Syndrome

Cogan syndrome rarely occurs in children. Features include vertigo, deafness, photophobia, interstitial keratitis, aortitis, aortic valve insufficiency, arthralgia, myalgia, anorexia, episcleritis and/or uveitis, and fever.

### Leukocytoclastic Vasculitis

Leukocytoclastic vasculitis is a necrotizing vasculitis with polymorphonuclear leukocytic infiltration and necrosis in the walls of small arteries. These changes are seen most commonly in Henoch-Schönlein purpura, SLE, and hypersensitivity vasculitis.

### Henoch-Schönlein Purpura

This disorder is characterized by palpable purpura, petechiae, or ecchymotic rash, typically found over the buttocks and the lower extremities. It is often associated with large-joint arthritis, cramping abdominal pain, fever, peripheral edema, and renal involvement. The illness lasts about 1 to 3 months, and

recurrences occur. Microscopic hematuria, guaiac-positive stools, and elevated IgA levels are found. Skin, renal, and gastrointestinal biopsies demonstrate leukocytoclastic vasculitis with IgA, complement, and properdin deposition.

**Neurologic Characteristics.** CNS complications occur in 8% of children due to hypertension, renal failure, and vasculitis (Garzoni, et al., 2009). Headache, seizures, encephalopathy with or without hypertension, cerebral vasculitis, intracranial hemorrhage, spastic paralysis, and chorea may occur. Peripheral nervous system complications include lesions of the femoral, sciatic, and facial nerves, Guillain-Barré syndrome, and mononeuritis multiplex.

**Treatment.** Arthritis is managed with nonsteroidal anti-inflammatory drugs, and painful cutaneous edema is managed with steroids. Supportive care is required when massive gastrointestinal bleeding, dehydration, or hypertension occurs. High-dose steroids and plasmapheresis have been used for severe CNS disease.

### Hypersensitivity Angiitis

Hypersensitivity, or allergic, angiitis is an acute necrotizing inflammation of blood vessels similar to Henoch-Schönlein purpura. The disorder may be acute and rapidly fatal and may be caused by a hypersensitivity reaction to various drugs or infections. Decreased serum complement and cryoglobulinemia occur. Neurologic complications are rare as cerebral vessels tend to be spared.

### Granulomatous Angiitis

Granulomatous angiitis represents a category of systemic necrotizing arteritis manifested by extravascular granulomatous nodules, which consist of a central area of fibrinoid degeneration with surrounding eosinophils and epithelioid and giant cells.

### Churg-Strauss Syndrome

Churg-Strauss syndrome, also known as allergic granulomatosis, is associated with asthma, fever, eosinophilia, cardiac failure, renal damage, and peripheral neuropathy. The incidence in children is unknown. Established criteria require the presence of four of the following seven findings:

1. Asthma
2. Eosinophilia
3. History of allergy
4. Mononeuropathy or polyneuropathy
5. Pulmonary infiltrates that are migratory
6. Paranasal sinus abnormality
7. Extravascular eosinophils on biopsy

**Neurologic Manifestations.** Neurologic involvement is seen in more than half the children and includes mononeuritis multiplex, symmetric polyneuropathy, cranial neuropathies, optic neuritis, stroke, and chorea.

**Treatment.** Treatment is similar to that for PAN; most patients respond to corticosteroids. Azathioprine is also used. Cyclophosphamide, methotrexate, and omalizumab may be beneficial, whereas the therapeutic effects of etanercept, plasma exchange, and intravenous immunoglobulin therapy are controversial.

### Granulomatosis with Polyangiitis (formerly called Wegener's Granulomatosis)

Granulomatosis with polyangiitis is characterized by a necrotizing granulomatous vasculitis of the small vessels in the

upper and lower respiratory tract and the kidneys. Symptoms include fever, malaise, rhinorrhea, epistaxis, chronic sinusitis, nasal obstruction, pharyngeal ulcers, parenchymal pulmonary lesions, and chronic glomerulonephritis. The most common laboratory abnormality is a cytoplasmic staining antineutrophil cytoplasmic antibody due to anti-PR3 antibodies. Children are rarely affected.

**Neurologic Manifestations.** Fourteen to 25% of children have CNS symptoms including myalgias, cranial nerve palsies, seizures, cerebral vasculitis, keratitis, optic nerve granuloma, proptosis, orbital pseudotumor, laryngitis with accompanying aphonia, spasticity, and proximal muscle weakness.

**Treatment.** Prednisone and daily oral cyclophosphamide have improved the survival rate to greater than 90%. Pulse cyclophosphamide, intravenous immunoglobulin, trimethoprim-sulfamethoxazole, cyclosporine A, methotrexate, and the biologic agents also have variable success in inducing remission.

### Primary Angiitis of the Central Nervous System

Primary angiitis of the CNS, also called granulomatous angiitis, is characterized by granulomas in 80% of individuals. Clinical criteria require a history or finding of an acquired neurologic deficit associated with angiographic or histopathologic demonstration of vasculitic changes, exclusion of other etiologies, and no evidence of systemic disease (Calabrese, 1995). It may occur in young children and has an equal gender distribution. Clinical features include headache, confusion, nausea, altered mental status, focal neurologic deficits, and progressive intellectual deterioration.

**Neurologic Manifestations.** Clinical manifestations correlate with the size of the affected vessels. Patients with small-vessel disease present with headache, focal seizures, or progressive behavioral or multifocal neurologic impairment. Patients with medium-vessel or large-vessel disease present with acute ischemic stroke or transient ischemic attacks. In both groups, cranial nerve abnormalities, hemiparesis, language disorders, seizures, spinal cord abnormalities, cerebral hemorrhage, fever, and weight loss have been reported. Symptoms of this broad spectrum disorder fluctuate, and the prognosis is better for patients with small-vessel disease. A subgroup of patients has "benign angiopathy of the CNS." These patients tend to be young women with sudden onset of symptoms and near-normal CSF studies, and the disease often remits after a monophasic benign course. This condition has been described in children (Calabrese, 1995).

**Laboratory Findings.** Laboratory studies reveal elevated erythrocyte sedimentation rate, elevated CSF protein concentration, and moderate monocytosis with increased pressure. Cerebral angiography documents small-sized and medium-sized vessel occlusion or segmental narrowing with saccular aneurysms and areas of infarction. Patients with small-vessel disease demonstrate multifocal, hyperintense lesions on T2-weighted MRI with normal CSF, erythrocyte sedimentation rate, and cerebral angiograms. Those with medium-vessel or large-vessel disease demonstrate infarcts and are more likely to have abnormal CSF studies, erythrocyte sedimentation rates, and angiograms (Fig. 121-6).

**Treatment.** Therapeutic use of corticosteroids, with or without cyclophosphamide, is indicated.

### Necrotizing Sarcoid Granulomatosis

This condition is intermediate between sarcoidosis and granulomatosis with polyangiitis. It can cause multifocal neurologic disease and retinal angiitis, responds to corticosteroids, and does not require cytotoxic therapy.

### Sarcoidosis

Sarcoidosis is a chronic, multisystem granulomatous disease of unknown etiology that is rare in children. Younger children (younger than 4 years) tend to have different clinical manifestations than older children or adults, characterized by relatively painless, boggy polyarthritis with well-preserved range of motion. Uveitis and cutaneous sarcoid lesions are present; pulmonary involvement is rare. Older children present with pulmonary symptoms, fatigue, weight loss, anorexia, headache, fever, parotid enlargement, hypercalciuria, leukopenia, eosinophilia, hilar and paratracheal adenopathy with interstitial infiltrates, elevated erythrocyte sedimentation rate, and elevated serum immunoglobulins. Pulmonary function is abnormal, and mediastinal or peripheral lymph node biopsies show noncaseating granulomas. Musculoskeletal findings include joint pain, effusions, and noncaseating granulomatous palpable muscle masses.

**Neurologic Manifestations.** Neurologic findings include obstructive hydrocephalus with noncaseating granulomas, transient cranial nerve VII palsies, and myelopathy. There are reports of optic nerve and orbital involvement, pituitary and hypothalamic lesions, meningitis, and seizures.

About 5% of adult patients have neurologic involvement including meningeal, parameningeal, hypothalamic, pituitary, and intramedullary spinal cord sarcoid infiltration. Peripheral and cranial neuropathies occur. Neurologic symptoms in children include seizures, cranial nerve palsy, CNS mass lesions, hypothalamic dysfunction, and uveitis.

**Treatment.** Treatment of the early-onset form is with corticosteroids, azathioprine, methotrexate, or, occasionally, cyclophosphamide. Therapy of late-onset or adult-type sarcoidosis depends on whether the arthritis is acute, chronic, or relapsing. Nonsteroidal antiinflammatory drugs have been used. More painful episodes have been managed with colchicine. Attacks unresponsive to colchicine often respond to corticosteroids or methotrexate.

### Giant Cell Arteritis

#### Temporal Arteritis

Classic giant cell arteritis (temporal arteritis) most often affects men older than 50 years of age. A report of biopsy-proven temporal arteritis in a 9-year-old girl with sensorineural hearing loss, monocular blindness, a tortuous superficial temporal artery, and systemic illness with encephalopathy makes it clear that this disorder can occur in childhood. Headache, scalp tenderness, visual disturbances, and jaw claudication appearing in association with an elevated sedimentation rate suggest the diagnosis. Superficial temporal artery biopsy reveals giant cell perivascular inflammatory infiltrates. Optic neuritis, hemiparesis, vertigo, hearing loss, brainstem strokes, seizures, oculomotor disorders, and peripheral neuropathies have been reported. The superficial temporal, vertebral, ophthalmic, and posterior ciliary arteries are involved.

#### Takayasu Arteritis

Takayasu arteritis involves the aorta and its branches and has been reported in infants and children. In children, the abdominal aorta and its branches are more commonly affected than the aortic arch. In the prepulseless stage, nonspecific symptoms of fever, fatigue, dyspnea, anorexia, and arthralgia occur. The obstructive phase is characterized by aneurysmal dilation and stenosis of the aorta or pulmonary arteries. With abdominal aortic involvement, initial symptoms include abdominal pain or mass, congestive heart failure, and occlusive vascular disease of the abdominal organs or lower

extremities. Neurologic symptoms are quite rare and include headache, hypertensive encephalopathy, seizures, and hemiplegia. Treatment with corticosteroids improves the long-term prognosis; most immunosuppressive drugs provide little improvement over corticosteroids.

### Miscellaneous Vasculitic Disorders

About one third of vasculitic disorders are categorized as idiopathic or “polyangiitis overlap syndrome.” Other diseases, such as Behçet syndrome, do not fit any of these categories.

#### Behçet Disease

Behçet disease is rare in children, usually with onset in the second decade of life, suggesting that juvenile Behçet disease may differ from that in adults. Diagnosis is based on the presence of recurrent aphthous stomatitis and two of the following: recurrent genital ulcers, uveitis or retinal vasculitis, erythema nodosum, or pustules or pathergy (the appearance of a pustular skin lesion after skin puncture).

**Neurologic Manifestations.** Three forms of CNS involvement occur:

1. Diffuse involvement associated with an acute meningoencephalitis, psychosis, or dementia
2. Brainstem or spinal cord involvement, with cranial nerve palsies, hemiparesis, and ataxia
3. Intracranial sinovenous thrombosis with signs of intracranial hypertension

Lymphocytic meningitis, vasculitis with perivascular cuffing, and thrombosis of arterioles, venules, veins, and dural venous sinuses are found and associated with cerebral hypoperfusion detectable with neuroimaging.

**Treatment.** High dose corticosteroids appear beneficial. Thalidomide has been used in steroid resistant patients as has colchicine and various chemotherapeutic agents. Heparinization may be beneficial when sinovenous thrombosis is present. Disease-modifying therapies should be considered for CNS relapse or steroid-refractory disease and include azathioprine, mycophenolate mofetil, methotrexate, and cyclophosphamide. Infliximab, adalimumab, etanercept, or interferon alpha has been used for aggressive neurologic or systemic complications.

### Miscellaneous Disorders

#### Thrombotic Thrombocytopenic Purpura

Rapid onset of thrombocytopenia, severe microangiopathic hemolytic anemia, renal disease, widespread microvascular thrombosis, neurologic symptoms, and fever characterizes this disorder.

**Neurologic Manifestations.** Neurologic involvement includes headache, confusion, seizures, retinal hemorrhages, and occasionally focal deficits. Thrombotic occlusion may involve the CNS, peripheral nervous system, or skeletal muscles. CSF examination is usually normal and EEG changes are nonspecific. MRI and cerebral angiography may include evidence of arterial ischemic injury, sometimes with hemorrhagic transformation or involving the posterior cerebral artery territory, reversible posterior leukoencephalopathy, or edema.

**Laboratory Findings.** Decreased levels of protease activity with the presence of von Willebrand factor-cleaving protease inhibitors contribute to the bleeding diathesis. Affected individuals have a deficiency of ADAMTS13, a von Willebrand factor-cleaving metalloprotease. Although often resulting from

ADAMTS13 gene mutations, individuals may develop this syndrome as the result of autoimmune inhibitors against ADAMTS13. Pathologically, amorphous hyaline material occluding small cerebral arteries is seen, and cerebral gray matter contains vascular ischemic lesions.

**Treatment.** Previously, only 10% of children with this disorder survived for more than 1 year. Plasma exchange transfusion has been beneficial by removing pathogenic substances and supplying other factors that may be deficient. Rituximab has been used successfully.

#### Antiphospholipid Antibody Syndrome

Antiphospholipid (aPL) antibody syndrome is a multisystem, autoimmune disorder characterized by recurrent thrombosis, pregnancy loss, or thrombocytopenia. The aPL antibodies include lupus anticoagulants (LAC), anticardiolipin antibodies (aCL), antibodies to  $\beta_2$  glycoprotein-I ( $\beta_2$ GPI), and antibodies directed against prothrombin, annexin V, phosphatidylserine, and phosphatidylinositol. LAC is a group of antibodies directed against plasma proteins (e.g.,  $\beta_2$ GPI, prothrombin, and annexin V).

Diagnosis requires specific clinical manifestations in addition to antibody detection. Strict diagnostic criteria for “definite” aPL antibody syndrome have been developed. Individuals must meet at least one clinical and one laboratory criterion including either:

1. Evidence of arterial, venous, or small vessel thrombosis; or
2. Pregnancy morbidity, which can include either one or more unexplained deaths of a morphologically normal fetus; one or more premature births of a morphologically normal neonate before the 34th week of gestation from eclampsia or placental insufficiency; or three or more unexplained consecutive spontaneous abortions before the 10th week of gestation. One of the following three laboratory criteria must be met: (1) the presence of a LAC; (2) medium or high serum or plasma IgG or IgM aCL antibodies; or (3) high serum or plasma IgG or IgM aCL anti- $\beta_2$ GPI antibody. These antibodies must be detected on two or more occasions at least 12 weeks apart.

Patients with aPL antibody syndrome are usually classified as having “primary aPL antibody syndrome” if there is no evidence for another underlying autoimmune disorder or “secondary aPL antibody syndrome” if another autoimmune disorder is present.

Treatment focuses on preventing vascular occlusion and resulting ischemic injury. Low-dose aspirin therapy has been used for preventive treatment. Interventions aimed at inflammatory and immune mechanisms include hydroxychloroquine and avoidance of its fetal toxicity during pregnancy, rituximab and other anti-B cell agents, and eculizumab and other inhibitors of complement.

#### Erythromelalgia and Erythralgia

Erythromelalgia and erythralgia consist of episodes of intense, asymmetric burning sensations with associated erythema and elevated temperature in the extremities, must be distinguished from Raynaud’s phenomenon and reflex sympathetic dystrophy, and is discussed in the online chapter.

## INTRODUCTION

Primary central nervous system (CNS) tumors are the second most common form of childhood cancer, exceeded in incidence only by the leukemias, and constitute approximately one quarter of all childhood neoplasms (Louis et al., 2007). In the United States, between 3000 and 4000 children are diagnosed with a primary CNS tumor each year. Concepts and management of pediatric brain tumors are constantly evolving (Pomeroy et al., 2002). The classification of these neoplasms, on which treatment is increasingly based, is changing even more rapidly, primarily as a result of the incorporation of molecular diagnostics (Pomeroy et al., 2002).

For decades, childhood brain tumors were treated with surgery followed by radiotherapy for subtotally resected and/or malignant neoplasms. The need for aggressive surgery and “total” resections, although undeniable in some subtypes of neoplasms, is being increasingly scrutinized because of the risk for permanent surgery-related sequelae. Radiotherapy has been recognized as being crucial for the control of most forms of childhood malignant tumors but is also associated with devastating sequelae. Chemotherapy is now a standard form of adjuvant postsurgical treatment and in some situations is employed to delay, if not obviate, the need for radiotherapy. Molecularly targeted therapy is just beginning to be incorporated into management and holds the promise of radically altering approaches and improving outcome.

Advances and refinements in therapy, to date, have resulted in a modest improvement in overall survival rate (Smith et al., 2014). Given the relative infrequency of specific subtypes of childhood brain tumors, for progress to be made expeditiously, prospective, multicentered, cooperative, group-based trials are optimal. National and, in selected cases, international investigation protocols have become the standard of care of modern management of childhood brain tumors.

## INCIDENCE

The incidence rates of brain tumors for patients between 0 and 19 years of age ranges from 3.3 to 4.5 cases per 100,000 person years (see Fig. 122-1). Among the major histologic groupings, rates are highest for tumors of the neuroepithelial tissue, with pilocytic astrocytomas and medulloblastomas being the most common individual subtypes of tumors. Embryonal tumors, including medulloblastoma, comprise 15% to 20% of all tumors in children between 0 and 14 years of age, occurring in approximately 5% of those between the ages of 15 and 19 (see Fig. 122-2).

Primary CNS tumors are more common in the first decade of life. The reported incidence of brain tumors is higher in whites (4.7 per 100,000 person years) than in other racial

groups (3.0 per 100,000 person years). The overall incidence for all brain tumors is highest among those between 0 and 4 years of age (5.2 per 100,000 person years) and lowest among those between 10 and 14 years of age (4.1 per 100,000 person years). However, incidence varies depending on tumor type, with ependymomas and medulloblastomas decreasing with age, and pilocytic astrocytomas peaking at 5 to 9 years of age.

## ETIOLOGY

The cause of the majority of all childhood brain tumors is unknown. Despite this, there are genetic conditions and, to a lesser extent, environmental exposures that predispose to the development of tumors. Genetic syndromes related to increased development of specific tumor types have provided molecular genetic insights into childhood brain tumors that have been partially translatable to the study of tumors not apparently of genetic origin. The known syndromes that are associated with the development of childhood brain tumors usually have an autosomal-dominant pattern of inheritance (see Table 122-1).

Of the environmental exposures that predispose to the development of brain tumors, the best documented is ionizing radiation. Secondary brain tumors have been reported after cranial irradiation for leukemia, head and neck tumors, and primary brain tumors. The most common form of malignant brain tumor occurring after radiation is malignant gliomas, which tend to appear 5 to 15 years after radiation and are highly resistant to therapy. Meningiomas are the most common radiation-induced tumors, increase in frequency with time after radiotherapy, and do not begin to peak until 10 years after exposure.

The effects of a multitude of environmental exposures, including maternal diet, on the occurrence of childhood brain tumors have not been conclusively shown. Initial studies suggested an association between significant exposure to electromagnetic waves or the use of cell phones in the development of gliomas, but other studies have not been able to confirm this relationship. Immunosuppression, either because of an underlying disorder of the immune system or after treatment with chronic immunosuppressive agents in situations such as organ transplantation, has been associated with an increased incidence of CNS lymphoma.

## PATHOLOGY AND CLASSIFICATION

The World Health Organization (WHO) utilizes a grading scheme that is basically a malignancy scale. Although the WHO classification is applicable to pediatrics, the congenital nature of many tumors, often with elements that seem to show

mixed lineage, such as neuronal and glial elements, can make classification difficult. In addition, in the pediatric modifications, tumor location is also a component of classification. Molecular genetic findings, to date, have not been incorporated into the classification system.

Probably the most controversial aspect of the classification of pediatric brain tumors has been the nomenclature utilized for CNS embryonal tumors (Pomeroy et al., 2002). The introduction of immunohistochemical techniques demonstrated the variable cell types that occur in embryonal tumors, although the majority of cells are small, hyperchromatic

round or oval cells (small blue cells). Molecular genetic analysis has demonstrated that primitive embryonal tumors occurring in the cerebellum, pineal region, and cortex are molecularly distinct. Furthermore, it is now clear that even in the posterior fossa, medulloblastoma is comprised of at least four, and likely more, different biologic subtypes, with different propensities to disseminate throughout the nervous system, responsiveness to therapies, and prognosis (Kool et al., 2012). CNS primitive neuroectodermal tumors (PNETs) are similarly composed of different tumor subtypes.

By convention, childhood CNS gliomas are often grouped by location, and cerebellar astrocytomas, intrinsic brainstem gliomas, and visual pathway gliomas, especially optic nerve and/or chiasmatic tumors, are considered relatively distinct entities. Biologic information has given some credence to such separation (Jones et al., 2013). The majority, possibly all, pilocytic astrocytomas have aberrations in the RAS-MAPK signaling pathway, although the type of abnormality and prognosis may vary between site (Pfister et al., 2008). Over 90% of cerebellar tumors have an activating BRAF-fusion mutation, whereas 50% or less of chiasmatic gliomas have similar mutations. Abnormality in histone chromatin remodeling genes has been found to be the common molecular abnormality in some, but not all, pediatric higher-grade gliomas, although the incidence of the type of mutation varies, dependent on site of the tumor (Paugh et al., 2010). Midline (brainstem, thalamic tumors) high-grade gliomas harbor a different mutation than cortical tumors. Childhood high-grade gliomas also differ molecularly from those arising in adulthood (Paugh et al., 2010). Ependymomas arising in the posterior fossa and cortex are biologically different, and even within these two regions, molecularly distinct lesions exist.

**Figure 122-2. Distribution of childhood primary brain tumors by histology.** CBTRUS, Central Brain Tumor Registry of the United States; NOS, not otherwise specified; NPCR, National Program of Cancer Registries; SEER, National Cancer Institute’s Surveillance Epidemiology and End Results.

**STAGING AND STRATIFICATION**

Pre- and postoperative staging are the cornerstone of therapy for most embryonal childhood CNS tumors and, to a lesser extent, glial neoplasms. The utility of staging for both determination of prognosis and decisions concerning most appropriate therapy has been best shown for medulloblastoma; staging has been an accepted component of management since the mid-1980s. All schemas share the property of being based on degree of surgical resection or, more specifically, the amount of tumor left after surgery and the extent of tumor

**TABLE 122-1 Genetic Syndromes Associated with Pediatric Brain Tumors**

Syndrome	Inheritance	Molecular/Genetic Abnormality	Predominant Tumor Types
Neurofibromatosis type 1	Autosomal dominant	NF1 gene (Chr. 17); increased RAS/MAPK signaling	Pilocytic astrocytomas; visual pathway > brainstem > cortical
Tuberous sclerosis	Autosomal dominant	TSC1 (Chr. 9); TSC2 (Chr. 16); increased RAS/MAPK signaling	Giant cell astrocytomas
Cowden’s	Autosomal dominant	Germ line PTEN	Cerebellar gangliocytoma
Von Hippel-Landau	Autosomal dominant	VHL gene	Hemangioblastomas in cerebellum, spinal cord, and retina
Li-Fraumeni	Autosomal dominant	Germ line mutation TP 53	High- and low-grade gliomas; medulloblastoma, choroid plexus carcinomas
Gorlin’s	Autosomal dominant	Germ line mutation PATCHED 1 (Chr.9); increased SHH signaling	Medulloblastoma
Turcot’s (type 1)	Autosomal dominant	DNA mismatch repair	Gliomas
Turcot’s (type 2)	Autosomal dominant	APC gene; WNT signaling	Medulloblastoma
Atypical teratoid/Rhabdoid tumor predisposition syndrome	Autosomal dominant	Germ line mutation SMARCB1/h SNF5/INI1 (Chr. 22)	AT/RT tumors of brain; rhabdoid tumors of kidney

spread outside the primary tumor site. The latter is determined by a combination of results from magnetic resonance imaging (MRI) of the entire brain and spine and cerebrospinal fluid cytologic examination, preferably from the lumbar space, if deemed medically safe. Embryonal tumors and glial neoplasms rarely spread to nonneural sites; thus, evaluation for disease outside the CNS, at the time of diagnosis, is usually not indicated. The classical tumor, nodes, metastasis (TNM) staging system used for non-CNS tumors is replaced by a TM system for brain and spine tumors. Although the need for lumbar cerebrospinal fluid cytologic examination has been debated, studies have shown that it provides complementary information to imaging results.

Histology has been incorporated into risk stratification for many tumor types. For embryonal tumors, such as medulloblastoma, histologic features, including desmoplasia/nodularity in infants and anaplasia in infants and older children, are now increasingly accepted as important components of risk-stratification classifications. For glial tumors or ependymomas, histologic features that have been translated into grades are an accepted component of classification and are used for risk stratification.

## CLINICAL PRESENTATION

The clinical presentation of childhood CNS tumors is dependent not only on the location of the tumor in the nervous system, but also on the age of the patient and the rapidity and pattern of growth of the tumor (see [Tables 122-2](#) and [122-3](#)). With the wider availability of computed tomography (CT) and, more recently, MRI capabilities, especially in developed countries, the time between onset of symptoms and diagnosis, especially for malignant tumors, has decreased. Longer periods before diagnosis have not been associated with poorer outcomes. Although this may be somewhat counterintuitive, it suggests that more aggressive tumors may result in more severe neurologic symptoms and localizing signs

earlier in the course of illness, compared with slower-growing neoplasms that are more likely to have longer, less specific symptomatology.

The greatest delay in diagnosis usually occurs in infants and young children, for a variety of reasons, including the relative rarity of childhood brain tumors, the nonspecific nature of presentation, and the difficulty of evaluating such young patients. Because of age and the presence of open fontanels and sutures, head pain may not be apparent, despite the presence of a very large tumor. In those patients with hydrocephalus, detection of papilledema, which, once again, can be difficult to discern in a young child, is obviously helpful. However, in longstanding increased intracranial pressure, especially in those patients with a slow-growing tumor in the suprasellar region, optic pallor, rather than papilledema, is more likely to be present. Another symptom of increased intracranial pressure in infants is the “setting sun” sign, manifested by impaired upgaze and seemingly enforced downward deviation of the eyes. This is caused by dilation of the third ventricle with resultant tectal pressure as a result of obstructive hydrocephalus.

Large neoplasms in infants may present with developmental delay early in the course of illness, followed by regression of developmental milestones. Tumors of the hypothalamus are notoriously difficult to diagnose early in life, especially in infants. The diencephalic syndrome is a constellation of symptoms and signs, including failure to thrive and emaciation in an otherwise normal child who has seemingly adequate appetite and gastrointestinal function and no focal neurologic or ophthalmologic deficits. Although some children do present in this way, detailed neurologic and neuro-ophthalmologic examination often discloses abnormalities, including unilateral or bilateral nystagmus, optic pallor, some degree of loss of visual acuity or field, and subtle motor dysfunction. Although initial reports suggested that these children seemed happy or “euphoric,” children with this syndrome, who predominantly harbor infiltrative gliomas of the hypothalamus,

**TABLE 122-2** Differential Diagnosis: Supratentorial Tumors

Tumor Type	Incidence	Peak Age	Common Symptoms	Common Signs	Common Neuroimaging Features
Cortical low-grade glioma	50%	Infancy through childhood	Seizures Headaches Unilateral weakness	Seizures Hemiparesis Hemisensory loss Hemianopsia	Enhancing mass with cyst (juvenile pilocytic tumors) or nonenhancing mass, usually little edema (grade II)
Cortical high-grade glioma	20%	Later childhood through adolescence	Headaches Weakness Seizures	Focal neurologic deficits Hemiparesis Hemisensory loss Hemianopsia Aphasia Papilledema	Mass with edema Variable enhancement
Craniopharyngioma	10%	Throughout childhood, 5–15 years peak	Headaches Personality change Decreased vision Weight loss Slowing of growth School difficulties	Visual field loss Bitemporal hemianopsia ↓ Visual acuity Papilledema Optic atrophy	Cystic, calcified mass in the suprasellar region
Diencephalic low-grade glioma	10%	0–3 years of age	Visual difficulties Weight loss Anorexia	↓ Visual acuity Nystagmus, hemiparesis (if thalamic) Papilledema or optic atrophy Visual field loss Hemiparesis (if thalamic) Stigmata of neurofibromatosis type 1	Ill-defined, at times enhancing if juvenile pilocytic astrocytoma with/without optic nerve or pathway involvement; associated cyst

**TABLE 122-3** Differential Diagnosis: Infratentorial Tumors

Tumor Type	Incidence of all Posterior Fossa Tumors	Peak Age	Common Symptoms	Common Signs	Common Neuroimaging Features
Medulloblastoma	40%	1–4 years 7–10 years	Headache Vomiting Unsteadiness	Papilledema 6th-nerve palsy Truncal ataxia Dysmetria	Enhancing mass filling 4th ventricle Hydrocephalus
Cerebellar astrocytoma	40%	5–15 years	Headaches Unilateral dysmetria, early	Appendicular truncal unsteadiness Papilledema late	Cystic mass with enhancing smaller (mural) module
Ependymoma	10%–20%	1–4 years	Double vision Facial weakness Headaches	6th-, 7th-, and 8th-nerve paresis Unilateral and bilateral dysmetria	Solid, at times, laterally placed mass
Brainstem glioma	10%–20%	5–15 years	Double vision Facial weakness Unilateral weakness Unsteadiness Swallowing difficulties	Multiple cranial nerve palsies Ataxia Dysmetria Crossed hemiparesis	Diffusely enlarged, often nonenhancing mass
Atypical teratoid/rhabdoid tumor	10%–20% of infants	Infancy to 3 years	Vomiting Head pain Unsteadiness	6th- and 7th-nerve palsies Ataxia Dysmetria	Heterogeneously enhancing mass, often laterally placed

more commonly are quite irritable and have significant developmental delay.

## GENERAL ASPECTS OF TREATMENT

### Surgery

Surgery remains the initial step in the treatment for the overwhelming majority of childhood CNS tumors, and the degree of resection, even for malignant neoplasms that require other forms of adjuvant therapy, is often an important factor in determining outcome (Wisoff et al., 2011). Attainment of a representative portion of the neoplasm for histologic and, increasingly, biological analysis is crucial. Exceptions to the need for tissue for diagnosis include neuroradiographically characteristic diffuse intrinsic brainstem tumors; chiasmatic/hypothalamic infiltrating gliomas in children with neurofibromatosis type 1, and possibly for those without; and germ cell tumors, predominantly mixed germ cell tumors, which secrete diagnostic proteins into cerebrospinal fluid and blood.

Morbidity secondary to surgery in critical brain regions, especially those that subserve motor function, is at times essentially unavoidable, especially secondary to postoperative edema. Such postoperative impairment may be transient. Surgery in the suprasellar area is frequently associated with increased postoperative visual impairments, which may include decreases in visual acuity and increased deficits in visual fields. Hypothalamic abnormalities and significant hormonal deficits secondary to disruption of the hypothalamic-pituitary axis also frequently occur. In large tumors that extend to the subfrontal area, such as craniopharyngiomas, removal of the tumor may cause additional damage and both early and late emotional/personality changes. Such damage can exacerbate hypothalamic injury, which in itself causes abnormalities of satiety control and excessive weight gain.

Surgery for posterior fossa tumors may result in direct brainstem damage, with resultant cranial nerve deficits and damage to the cerebellum or cerebellar peduncles, with increased ataxia and dysmetria. Such direct brainstem damage

should be distinguishable from the increasingly recognized posterior fossa mutism syndrome, which is a constellation of the delayed onset of mutism (characteristically, a few hours to a day after surgery), hypotonia, cerebellar deficits, supra-nuclear palsies, emotional lability, and severe irritability. Seen primarily, but not exclusively, after medulloblastoma resection, it is thought to be secondary to unilateral or bilateral cerebellar dentate nuclei damage and/or disruption of critical pathways between the dentate nuclei and the cortex, especially the premotor and supplementary motor cortices. This syndrome results in permanent sequelae in approximately 50% of initially symptomatic patients, including persistent abnormalities in tone, coordination, speech, and cognitive abilities.

### Radiation Therapy

Radiation therapy is an integral component of treatment for many forms of childhood brain tumors. For children with benign tumors, its use is usually limited to those tumors that are not amenable to gross total resections. For children with more aggressive or malignant tumors, radiation therapy has been the backbone of most curative and palliative therapies, even in those patients whose tumors are totally resected (Packer et al., 2006). Craniospinal radiotherapy has been associated with improved survival, but also significant long-term endocrinologic growth, and cognitive sequelae. In very young children, especially infants, radiotherapy may result in even more severe sequelae, and attempts have been made to delay, if not obviate, the need for radiotherapy. Radiotherapy usually utilizes photon particles, delivered in different fractions and by different means (see Table 122-4). Recently proton particles (proton beam) have been increasingly used to decrease “scatter” radiation to nonaffected parts of brain and surrounding organs.

The determination of the optimal, often maximal, safe dose and volume of radiotherapy that can be used is dependent on the tumor type and the radiosensitivity of structures in the CNS, tempered by the age of the child. Younger children

are more sensitive to the detrimental effects of radiation on the brain. In general, larger daily-dose fractions cause more acute and possibly long-term neurologic toxicity; standard fractionation is 150 to 180 cGy daily. Preoperative conditions, such as hydrocephalus and preexisting brain injury, affect the tolerance of the developing brain to radiotherapy. Even in children of similar ages with similar diseases, there can be significant differences in how radiotherapy can be tolerated, suggesting that there are molecular genetic differences that affect host vulnerability (see Table 122-5).

Irradiation of the hypothalamic–pituitary axis often is unavoidable because of location of the tumor, and can result in permanent endocrinologic damage. Growth hormone secretion is usually the most sensitive to the effects of radiotherapy, followed, in order of degree of sensitivity, by thyroid-stimulating hormone, follicle-stimulating hormone–luteinizing hormone (FSH-LH), and adrenocorticotrophic hormone (ACTH). There is a dose relationship to such damage, with significant impairment of growth hormone secretion occurring more commonly after 2400 cGy, especially in doses greater than 2900 cGy, to the hypothalamus.

The severity of neurocognitive sequelae secondary to whole-brain radiotherapy is dependent on dose, age of the child, poorly understood host vulnerabilities, and probably preexisting brain injury. Craniospinal radiation therapy, especially in children less than 7 years of age, and particularly in those less than 5 years of age, results in a demonstrable drop in overall intelligence and a host of selective learning, attentional, and executive disabilities. In older children, depending on dose, decreases in overall intelligence may not occur, but selective learning disabilities and problems with executive function are common. Another long-term sequela of radiotherapy is development of secondary neoplasms.

## Chemotherapy

Within the last decade, chemotherapy has gained an expanded role in the treatment of childhood brain tumors. The most common chemotherapeutic agents utilized for pediatric CNS tumors are in the class of DNA alkylators, such as cisplatin, carboplatin, lomustine, cyclophosphamide, and ifosfamide, which typically serve as the backbone for treatment of medulloblastoma, low-grade glioma, ependymoma, and germ cell tumors (Rutkowski et al., 2005) (see Table 122-6). Plant alkaloids, such as the mitotic inhibitors vincristine and vinblastine or the topoisomerase inhibitor etoposide, are also commonly employed as part of combination regimens (Packer et al., 2006). The overall success of chemotherapy for pediatric CNS tumors has remained somewhat limited. Two major reasons for this limitation are impediments to drug delivery across the blood–brain barrier and resistance to chemotherapy. Means to improve the efficacy of chemotherapy include the use of high-dose systemic chemotherapy with stem cell rescue; regional delivery approaches, including intrathecal and intraventricular drug instillation; convection delivery; and the use of agents to overcome drug resistance.

## Biologic Therapy, Immunotherapy, Vaccines, and Gene Therapy

Therapy that specifically targets tumor biology has gained widespread attention due to its potential for greater antitumor efficacy while sparing normal cells from toxic side effects. In contrast to traditional chemotherapy, biologic therapy is more likely to be cytostatic rather than cytotoxic. Examples of this strategy include use of drugs that cause differentiation of tumor cells, receptor tyrosine kinase inhibitors, cellular pathway inhibitors, and antiangiogenesis agents.

## Immunotherapy

Immunotherapeutic approaches have great appeal and are increasingly being explored. The CNS is a relatively privileged site immunologically because of its lack of lymphatic drainage and its blood–brain barrier, but there is evidence that, to some degree, peripheral T-cell activity may be carried into the CNS. A variety of different approaches have been utilized in the immunotherapy of CNS tumors, primarily in adults but also, to some degree, in pediatrics. These include administration of cytokines such as interleukin and interferon, expansion of tumor-specific T cells, and the use of monoclonal antibodies, checkpoint inhibitors, and tumor vaccines.

## Gene Therapy

Introduced with great enthusiasm over 20 years ago, gene transfer therapy has yet to show efficacy in the majority of adults or children with CNS tumors. It is a process in which genetic material is transferred into cells and carries with it the information either to stop or to slow the ability of these cells to multiply. Gene therapy may also utilize genetic information that, after the tumor cells take up the gene material, makes them sensitive to other forms of treatment. Almost all of the gene transfer therapies have utilized a virus-mediated delivery system.

## PROGNOSIS

The specific prognosis of individual tumor types is discussed in subsequent chapters. In general, survival rates have slowly risen over the past twenty years, primarily in the most common embryonal tumor, medulloblastoma. There has been no appreciable improvement in survival for pediatric high-grade glial tumors. Quality of life for survivors remains a major concern, as intellectual, psychological, and neurologic sequelae, often progressive over time, remain common. Alterations in treatment, including more judicious use of surgery, reductions in the dose of craniospinal radiotherapy and volume of focal radiotherapy, and avoidance or at least delay of radiation therapy in infants, have seemed to decrease complications. However, the use of chemotherapy has resulted in other sequelae, such as cisplatin-induced hearing loss, vincristine-related neuropathy, and possibly alkylator-associated secondary tumors. Treatment remains a delicate balance between the need to control tumor growth and potential treatment-related sequelae. Molecularly targeted therapies and other approaches, such as immunotherapy, are being explored to try to improve outcomes with the hope of less neurologic compromise.

## INTRODUCTION

Medulloblastoma, which is defined by the World Health Organization (WHO) as an embryonal tumor of the cerebellum, is the single most common form of malignant brain tumor of childhood. Medulloblastomas are highly cellular tumors with deeply basophilic pleomorphic nuclei, little cytoplasm, and abundant mitoses. The WHO classification further subdivides medulloblastoma into histologic subtypes. Integrative molecular analysis has extended these distinctions, dramatically altering concepts of medulloblastoma classification and risk stratification, with at least four distinct molecular subtypes of medulloblastoma having been identified.

As a whole, medulloblastoma constitutes 20% of all primary central nervous system (CNS) tumors and has a bimodal incidence peak, arising most commonly in children between 3 and 4 years of age and then again in those between 7 and 10 years of age. Between 15% and 20% of all medulloblastomas are diagnosed in the first 2 years of life. There is also a male predominance in specific molecular subtypes of the tumor.

With current means of treatment, the majority of children with medulloblastoma can be expected to survive 5 years after diagnosis, and many of these children are cured. Increasing emphasis has been placed on the quality of life of survivors and on potential means to reduce treatment-related sequelae without decreasing the likelihood of survival.

## ETIOLOGY

Although the etiology of medulloblastoma is unknown for the majority of patients, several familial syndromes have been associated with increased risk of developing medulloblastoma, generating important insights into tumor pathogenesis. Gorlin's syndrome is present in less than 2% of patients with medulloblastoma, but its recognition led to the understanding that abnormalities of the sonic hedgehog (SHH) pathway may result in medulloblastoma. Also known as nevoid basal cell carcinoma syndrome, diagnosed by characteristic dermatologic and skeletal features, including multiple basal cell carcinomas, odontogenic keratocysts of the jaw, and rib abnormalities, it is caused by an inherited germ line mutation of the *PATCHED 1* gene on chromosome 9, a gene that encodes SHH receptor *PATCHED 1* and suppresses pathway signaling. Up to 25% of patients with medulloblastoma, especially infants and adults, will have SHH-pathway mutations. The diagnosis of Gorlin's syndrome early in life is difficult, but the presence of bifid or fused ribs, macrocephaly, or early calcification of the falx cerebri is helpful.

Turcot's syndrome (type 2) has also been associated with medulloblastoma. Caused by mutations of the adenomatous

polyposis gene, it is marked by colorectal adenomas and a variety of extracolonic manifestations. Patients with type 2 Turcot' disease are at increased risk of developing medulloblastoma as a result of aberrant WNT pathway signaling. WNT abnormalities, not related to Turcot's syndrome, have been noted in between 10% and 15% of children with medulloblastoma, primarily in those with tumors arising in late childhood and adolescence.

Li Fraumeni syndrome, caused by germ line mutations in the *TP53* gene, is also associated with medulloblastoma. Medulloblastoma has also been reported in rarer syndromes, including Rubenstein-Taybi and Fanconi's syndromes.

Other than radiation exposure, there are no clear-cut environmental factors that have been linked with medulloblastoma. Preliminary studies suggested a relationship with SV40 virus exposure, predominately as a contaminant of measles vaccination; however, subsequent studies have not confirmed this association.

## BIOLOGY

Medulloblastoma is believed to arise from stem cells and neuron progenitor cells in and around the cerebellum, including the ventricular zone (adjacent to the fourth ventricle), the external granular layer of the cerebellum, and the dorsal brainstem (Wang and Wechsler-Reya, 2014). SHH-associated medulloblastomas are believed to primarily arise from the granular neuron precursors present in the external granular layer of the cerebellum. There is increasing evidence that WNT-associated tumors arise from progenitor cells in the dorsal brainstem rather than the cerebellum. Other medulloblastoma tumors likely arise from stem cells, and in some cases, granular neuronal precursors arising from the ventricular zone. Giving even greater credence to the now well-accepted concept that medulloblastoma is biologically comprised of different tumor types is the multitude of recent molecular studies investigating medulloblastoma tumor samples (see Table 123-2). These subtypes have been classified as WNT, SHH, Group 3, and Group 4, with each group having relatively distinct demographics and associated clinical characteristics, including disease course (Taylor et al., 2012).

On the basis of molecular subgroups, it was possible for the first time to put frequently observed genetic changes into context. Examples for genetic lesions specifically enriched in WNT tumors include quasidefining *CTNNB1* mutations in exon 3, which are never observed in any other subgroup. For the SHH subgroup, in addition to the age-specific mutations in the tumor-driving SHH pathway, SHH signaling appears to cooperate with PI3K signaling, especially in adult SHH tumors, and with a plethora of different chromatin modifiers. For Group 3 tumors, it has long been established that *MYC* amplification is a hallmark genetic lesion (including *PVT1-MYC* fusion), but it is only present in about 30% of cases.

**TABLE 123-2** Molecular Subgrouping of Medulloblastoma

	<b>WNT</b>	<b>SHH</b>	<b>Group 3</b>	<b>Group 4</b>
Age	Late childhood; Adolescence	Infants, adults > childhood	Infant, childhood	All
Gender	F>M	F = M	M>F	M>F
Molecular findings	Intranuclear $\beta$ -catenin Staining; Monosomy 6; CTNNB1 mutation	SHH pathway mutations; PTCH1/SMO SUFU/GLI1; Occasional TP53 Mutation	MYC amplification; i179; GFI1; GFI1B	CDKG amplification SNCAIP
Genetic Expression	WNT signaling; MYC +	SHH signaling MYCN +	MYC +++	MYC↓
Histology	Classical, LCA	Desmoplastic; Desmoplastic/ nodular	Classical; LCA	Classical/LCA
Mets	Occasional	Occasional	Very frequent	Frequent
Prognosis	Excellent	Good in infants, Adults; poor if MYCN + or TP53 mutation (primarily childhood)	Poor if M + or MYC +; Average otherwise	Average

Recent integrative genomic and epigenomic analyses have identified GFI1 and GFI1B as additional highly recurrent driver genes for Group 3 medulloblastoma. For Group 4 medulloblastoma, in addition to known overrepresentation of CDK6 and MYCN amplifications, inactivating mutations in the histone3 lysine 27-specific histone demethylase KDM6A (located on the X chromosome) and ZMYM3 have been repeatedly identified. Duplication of a region on chromosome 5 around the SNCAIP gene represents another frequent genetic event.

## CLINICAL PRESENTATION AND DIAGNOSIS

### Clinical Features

Medulloblastoma most commonly presents with nonspecific findings of vomiting and headache, which occur in 80% of patients by the time of diagnosis. This is usually associated with obstruction of cerebrospinal fluid flow at either the third or fourth ventricular outlets, and hydrocephalus. Symptom duration is classically 1 to 3 months before diagnosis; patients with metastatic disease are more likely to be diagnosed earlier and have a poorer prognosis. Usually, by diagnosis, the headache has transformed into one more classically associated with increased intracranial pressure, occurring upon waking and accompanied by morning nausea and vomiting. Unsteadiness is noted in 50% to 80% of patients at diagnosis and is usually truncal, with significant gait abnormalities.

Medulloblastoma may present acutely with a severe alteration in consciousness and even coma. This is usually a result of macroscopic hemorrhage into the tumor and rapid tumor expansion with acute hydrocephalus and/or compression of the brainstem.

Although diagnosis can be difficult in infants, symptoms such as unexplained macrocephaly, intermittent lethargy, vomiting, and head tilt are noted in most infants by the time of diagnosis. The classical “setting sun” sign, with downward deviation of the eyes as a result of tectal pressure, is seen in only a minority of infants.

Medulloblastomas may be disseminated to other regions of the CNS at diagnosis. In the majority, there are no symptoms associated with dissemination.

### Radiographic Features

Medulloblastomas are usually radiographically distinguishable from other posterior fossa tumors because they tend to be relatively well-defined masses arising in the medullary

velum or roof of the fourth ventricle, often with some invasion of the middle cerebellar peduncle and compression or invasion of the brainstem. The tumor is hyperdense compared with normal cerebellum on computed tomography (CT), which distinguishes it from juvenile pilocytic astrocytoma. Calcifications may be present in up to 20% of cases, but are usually not conspicuous. On magnetic resonance imaging (MRI), medulloblastomas tend to be homogenous with iso- to hypointense signal on T1-weighted images and hypointense signal on T2-weighted images (Fig. 123-2). The majority of medulloblastomas enhance with contrast agent, although 5% to 10% do not enhance. In infancy, medulloblastoma with extensive nodularity may occur and display discrete contrasting-enhancing masses with an almost grapelike, clustered appearance.

Because between 15% and 30% of medulloblastomas are disseminated to other regions of the nervous system before diagnosis, neuroradiographic evaluation of the entire neuraxis is indicated, if possible, before surgery. Evaluation of dissemination can be difficult after surgery because of changes caused by postoperative blood. Pitfalls in the evaluation of extent of disease include nonenhancing dissemination, especially in patients with initially nonenhancing primary-site tumors, and spinal cord vascularity being interpreted as leptomeningeal disease.

## MANAGEMENT AND OUTCOME

The treatment of children with medulloblastoma is multidisciplinary and multimodality, requiring surgery, radiation, and chemotherapy. Treatment is also dependent on the age of the child, predominantly because of the potential neurotoxic effects of radiotherapy, and disease stratification.

### Surgery

Surgery is the initial step in management, to relieve hydrocephalus if present and to remove as much of the tumor as possible. Although temporary external ventricular drainage might be necessary, removal of the tumor results in avoidance of permanent ventricular-peritoneal shunting in 50% of cases. In some children with persistent hydrocephalus, third ventriculostomy is another option to avoid ventricular-peritoneal shunting. In nondisseminated patients, who comprise 70% to 80% of all patients with medulloblastoma, multiple studies have demonstrated that the extent of surgical resection is prognostic of outcome, with those patients undergoing more

**Figure 123-2.** Panel of MRIs of medulloblastoma. **A**, Axial FLAIR image demonstrating somewhat hyperintense mass filling the fourth ventricle. **B**, Sagittal T-weighted image, after gadolinium enhancement, demonstrating inhomogeneous enhancement. **C**, Axial ADC image demonstrating diffuse restriction (dark area) within tumor.

complete or near-total resections having better outcome than patients whose tumors were subtotally resected. Arbitrarily, patients with greater than 1.5 cm<sup>2</sup> of residual disease after surgery are considered to have subtotally resected tumors. In older series, children with nondisseminated disease and greater than 1.5 cm<sup>2</sup> of residual disease fared less well than those with less measurable disease. With current means of adjuvant therapy, there is no clear-cut statistical difference in outcome between patients who undergo a total resection and those undergoing a near-total resection. Patients who undergo a minimal resection or biopsy have an extremely poor prognosis. In those with disseminated disease, the degree of surgical resection has never been shown to have independent significance.

Although the goal of surgery is to remove all of the tumor, tumor resections (be they partial or complete) can be associated with significant immediate or delayed postoperative complications (Wells et al., 2010). Direct brainstem and cerebellar damage has been noted in 5% to 10% of patients. Increasingly, posterior fossa mutism syndrome has been recognized. This syndrome can be clinically difficult to separate from postoperative direct damage to the brainstem and is a delayed constellation of mutism, which characteristically is first recognized between 6 and 48 hours after surgery. Mutism is usually associated with hypotonia, cerebellar deficits, supranuclear palsies, emotional lability, and severe irritability. The irritability and personality change may be so predominant that they overshadow the other clinical findings. Likely a form of cerebellar affective disorder, posterior fossa mutism syndrome is believed to be secondary to unilateral (primarily right-sided) or bilateral cerebellar dentate nuclei damage and/or disruption of critical pathways between the cerebellum and cortex. Subsequent MRIs, especially those performed 1 year or later after diagnosis, will frequently disclose cerebellar atrophy. Nearly 25% of patients in one recent North American trial had the syndrome, initially thought to be a rare entity, and one half of all patients with this syndrome had sequelae 1 year later. Over 50% of patients with posterior fossa mutism have impaired neurocognitive outcomes.

### Staging and Stratification

Following surgery, patients with medulloblastoma have been traditionally staged by the amount of residual tumor after surgery, extent of dissemination assessed on both

neuroimaging evaluation of the entire neuraxis and cerebrospinal fluid cytologic examination, and, in some classification schemes, histology. Historically, children with medulloblastomas who are 3 years of age or older at diagnosis have been classified as having either average-risk or poor-risk disease (see Table 123-2). Patients with average-risk disease are those with nondisseminated, totally or near-totally resected tumors, with a nonanaplastic histology. All other patients are considered to have poor-risk disease. This stratification system has not incorporated biologic data.

In younger children, separation into major risk groups on the basis of similar criteria is also accepted. Young children, usually less than 3 years of age, with extensively nodular/desmoplastic medulloblastoma, presumably whose tumors are driven by signaling of the SHH pathway, have a better prognosis.

Molecular studies that have identified the four stable molecular subgroups are being incorporated into stratification schema. It is now feasible to perform molecular subgrouping from very small amounts of formalin-fixed and paraffin-embedded tissue. These subgroups have distinct demographics and associated clinical variables, including disease course, and demonstrate enrichment for histopathological subtypes (e.g., desmoplastic and extensive-nodular medulloblastomas almost exclusively fall in the SHH subgroup, and Group 3 is strongly enriched for large-cell and anaplastic histotypes).

As demonstrated in several independent studies, WNT-driven medulloblastoma (probably even when associated with microscopic metastases, i.e., M1) has a favorable clinical course. Recent evidence suggests that nuclear beta-catenin accumulation as assessed by immunohistochemistry alone is not specific enough to define this population. Thus the currently accepted recommendation is that any of two independent methods have to indicate the presence of a WNT-subgroup medulloblastoma to qualify for reduction of therapy intensity. These methods include CTNNB1 immunohistochemistry, sequencing of CTNNB1 exon 3, gene-expression profiling, and DNA methylation profiling.

SHH-driven medulloblastomas show a remarkable age distribution, with one peak in infants and a second peak in adults. Infant SHH disease is largely overlapping with infant desmoplastic or extensive nodular histology and associated with favorable prognosis. Most children with this subgroup can be cured by adjuvant chemotherapy alone. Because hereditary TP53 germline mutations (i.e., Li Fraumeni syndrome) are

almost entirely restricted to SHH medulloblastoma, mainly in older children, p53 immunohistochemistry is required in all SHH subgroup patients as a screening measure. In case of evidence for the presence of a TP53 mutation, TP53 should be sequenced in the tumor. SHH-driven medulloblastomas in adults (which in this age group comprise about two thirds of cases, with tumors often located in the cerebellar hemispheres rather than in the vermis) demonstrate good outcomes. In infants, downstream SUFU mutations are quite prevalent in addition to PATCHED 1, whereas in older children with TP53 mutations, downstream amplifications of MYCN and GLI2 are prototypic (Kool et al., 2014).

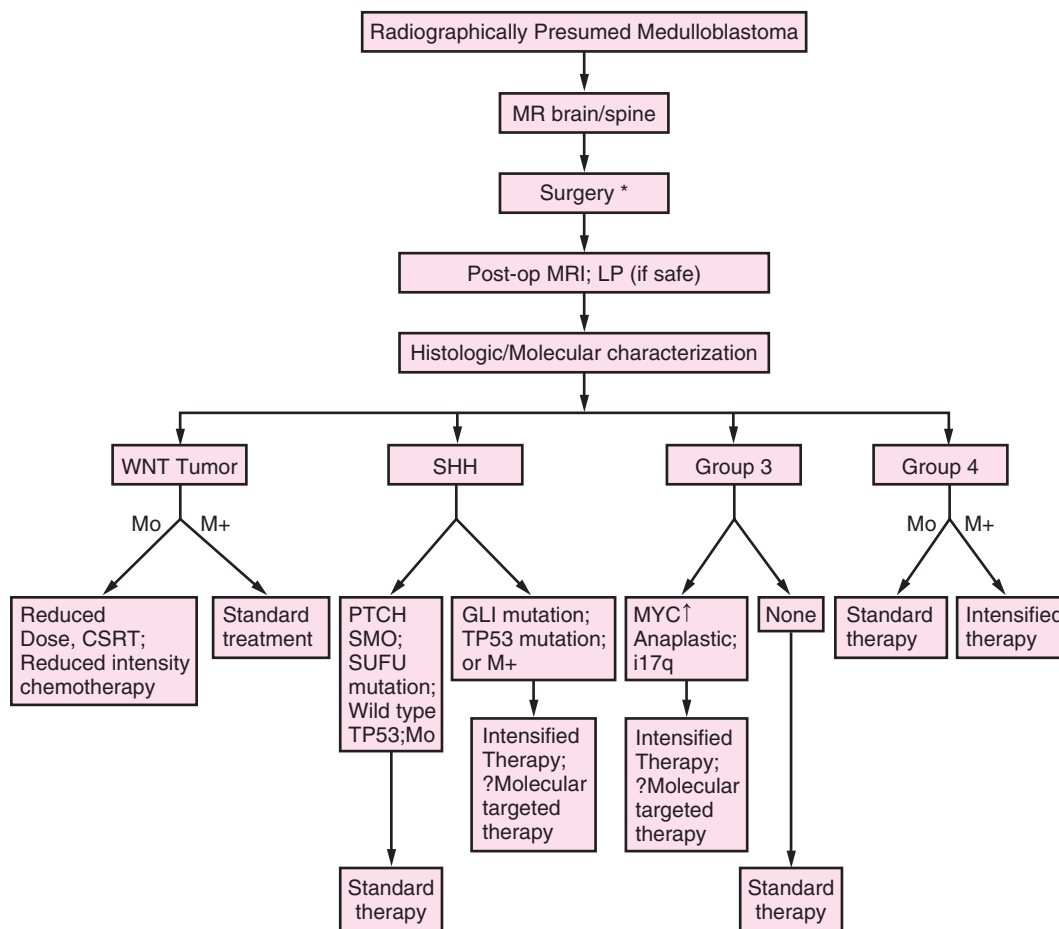

Within Group 3, an additional marker to identify very-high-risk patients is high-level focal MYC amplification. As for CTNNB1, the detection method and definition of MYC amplification is crucial to identify this very-high-risk population.

Medulloblastoma risk categorization (see Table 123-2 and Fig. 123-4) is still a work in progress and has not been uniformly incorporated into national/international multicenter studies. However, the combination of molecular and clinical parameters (age and extent of dissemination at diagnosis) results in the clearest separations and opens the best possibility for more personalized therapies. The significance of extent of resection is unclear within this framework, although patients undergoing biopsy alone or a minimal resection likely have a poorer prognosis.

## Postsurgical Management

Standard treatment for children with average-risk disease, over 3 years of age, includes radiation and chemotherapy. Survival rates improved dramatically when craniospinal irradiation therapy became a standard component of medulloblastoma treatment, independent of whether there was evidence on staging studies of dissemination. Initial doses of craniospinal radiation were chosen arbitrarily; conventionally, following surgery, average-risk patients were treated with 3600 cGy of craniospinal radiation and 1800 to 1960 cGy of boost radiotherapy to the primary tumor site, which, in most patients, included the entire posterior fossa (local tumor dose 5400-5580 cGy). With such treatment, 5-year progression-free survival rates were between 55% and 65%, with some, but not all, 5-year survivors being cured of their disease. Attempts to reduce the craniospinal dose of radiation therapy to 2340 cGy were considered unsuccessful because there was an increased early incidence of leptomeningeal disease failure; however, long-term follow up of the cohort of patients treated in a randomized study comparing 3600 cGy to 2340 cGy did not show a statistical difference in 8-year survival in patients treated with lower-dose radiotherapy compared with those who received higher-dose treatment.

Chemotherapy has improved survival for children with average-risk medulloblastomas (Packer et al., 2006; Gajjar

\* Patients who are biopsied alone or undergo subtotal resections likely should be considered high risk and are candidates for re-resections or more intensified therapies.

Figure 123-4. Algorithm for medulloblastoma, children 3 years of age or older.

et al., 2006). Treatment with craniospinal radiation therapy and chemotherapy, given during and after radiation therapy and utilizing various multiagent drug regimens, which included vincristine (given during radiation therapy) and CCNU, cisplatin, cyclophosphamide, and vincristine post radiotherapy, has demonstrated progression-free survival rates at 5 years in the 80% to 85% range in children greater than 3 years of age without disseminated disease, with few patients relapsing after 5 years. The sequencing of radiation and chemotherapy seems critical; studies that have delayed radiation by the use of preradiation chemotherapy have demonstrated poorer survival rates.

The addition of chemotherapy has allowed a reduction of the dose of craniospinal radiation therapy to 2340 cGy without any apparent deterioration in overall disease control in children with average-risk disease. This reduction was undertaken to reduce radiation-associated sequelae, and ongoing prospective randomized studies are reducing the dose of craniospinal radiation therapy even further, to 1800 cGy. An important caveat with these studies is that the staging of patients is of extreme importance. Upon central review in two international studies, approximately 20% of patients were judged to have been inappropriately entered into these studies as a result of either misinterpretation of tumor extent or inadequate imaging. Patients who were placed on these reduced-dose craniospinal radiation studies with inadequate imaging or errors in interpretation had a significantly poorer outcome.

It has become clear that the molecular subtype of the tumor dramatically affects the likelihood of successful therapy (Gajjar et al., 2014). WNT-driven tumors have nearly a 100% survival rate after treatment with radiotherapy and chemotherapy. In this subset of patients, studies are already under way to further reduce the amount of craniospinal radiotherapy and/or chemotherapy utilized. For SHH-driven tumors, although infants and adults tend to fare well, children often harbor tumors with TP53 abnormalities and/or downstream SHH pathway mutations; such patients carry a poorer prognosis, which is less than 30% surviving with current therapies, and should not be considered "average risk." Within the Group 3 tumors, a subgroup with MYC-amplified or possibly overexpressed tumors will do poorly, even if identified by other criteria as "average risk," and will require alternative approaches.

For children with poor-risk medulloblastoma, survival after craniospinal and local boost radiotherapy alone is only in the 30% to 40% range at 5 years. Within the poor-risk group, there are mis-stratified children who carry a favorable diagnosis, such as those with WNT-subclass tumors with metastatic disease. Studies that have added chemotherapy, once again primarily either during and/or after radiation therapy, have demonstrated survival rates ranging between 50% and 70%. A variety of different chemotherapeutic approaches have been utilized and are still being studied, including the use of radiosensitizing agents, such as carboplatin, during radiation therapy, and a variety of drugs after radiation therapy, in various combinations, including cisplatin, CCNU, cyclophosphamide, vincristine, and etoposide.

For infants and young children with medulloblastoma, treatment remains quite problematic. Because of concerns regarding the detrimental long-term effects of craniospinal radiation therapy, chemotherapeutic approaches have been used to delay, if not completely obviate, the need for radiotherapy. Approximately 20% of infants can be treated with chemotherapy alone, with a variety of different regimens. These approaches have now evolved into the use of postoperative chemotherapy and, for those patients who remain in remission or respond to the initial chemotherapy, consolidation with even higher doses of chemotherapy supported by autologous bone marrow transplantation or peripheral stem

cell rescue. Another approach to augment the efficacy of chemotherapy is to add methotrexate, in some studies intravenously at high dose and in other trials both intravenously and intrathecally/intraventricularly, to improve survival and avoid the need for radiation. It is likely the variable survival rates are a result of previously unappreciated differences in biologic subtypes. The infants most likely to survive are those with the nodular/desmoplastic form of the disease (Rutkowski et al., 2005). Survival for children with nonnodular/desmoplastic (SHH-driven) disease is not as favorable, but some (perhaps 30%) of these children do survive after treatment with chemotherapy alone. Treatment for infants and young children with disseminated disease remains suboptimal. Chemotherapeutic approaches alone have cured only a small group of these patients.

## Relapsed Medulloblastoma

Another extremely problematic group of patients to treat for medulloblastoma are those with relapsed disease. Although late relapses, 5 or more years after diagnosis, are reported, it is likely that many of such relapses are secondary, treatment-induced tumors. The majority are high-grade gliomas and resistant to therapy. Histologic confirmation of the type of tumor present at relapse is required in late relapse or in patients with unusual patterns of recurrence, such as intrinsic brainstem disease or cortical infiltrative disease. Because of the nearly universal use of chemotherapy as a part of initial treatment, extraneural relapse is rare.

Given that the majority of older patients are now treated with both radiation therapy and multiagent chemotherapy at time of initial diagnosis, most children over 3 years of age with relapsed disease are highly resistant to further therapy. Furthermore, approximately two thirds of patients with medulloblastoma, be they high-risk, low-risk, or falling in the infant and young child category, will relapse with at least some component of disease outside the primary tumor site. Patients with SHH-driven tumors are more likely to have only primary-site relapse and may respond better to retrieval therapies such as reirradiation at the primary tumor site.

For patients with disseminated disease at relapse, there are no proven effective retrieval regimens. For children who have relapsed only at the primary tumor site, possibly because they are biologically different, retrieval strategies have been somewhat more successful and have included attempts at resection followed by chemotherapy, followed by local radiotherapy. This approach has been most successful in young children who have not received prior radiation therapy.

## Future Therapy

Newer approaches are clearly needed for both older children and infants with disseminated tumors, and possibly, in the future, for those with unfavorable prognostic molecular indicators. Biologic agents are slowly being incorporated into therapeutic trials using drugs such as retinoic acid as maturation agents and specific inhibitors of aberrant cellular signaling pathways, such as SHH pathway inhibitors. Adult SHH patients probably comprise the best cohort for adjuvant or even neo-adjuvant administration of targeted Smoothed inhibitors, because in this age group, SHH mutations upstream of Smoothed (mainly in Patched or Smoothed itself) are most prevalent.

## Sequelae in Medulloblastoma Survivors

As more children survive medulloblastoma, it has become clearer that their quality of life is far from optimal. Although

the dose of craniospinal radiation therapy has been reduced by almost one-third for patients with nondisseminated disease, it is yet unclear how beneficial such reductions are. At the same time, although the radiotherapy dose has been decreased, there has been an increased use of chemotherapy, which carries its own inherent short- and long-term side effects. In addition, the presence of posterior fossa mutism syndrome negatively affects outcome.

Neurocognitive sequelae are frequently seen in children of all ages treated for medulloblastoma. It has been well documented that the majority of infant survivors are neurocognitively impaired at the time of diagnosis, probably as a result of multiple factors, including the tumor, associated hydrocephalus, and possibly the sequelae of surgery. Although radiation therapy has been avoided in some infants who survived medulloblastoma, follow-up testing demonstrates that the majority remain developmentally and, ultimately, neurocognitively impaired. The addition of potentially neurotoxic drugs, such as methotrexate, to the treatment of these children or the early use of focal radiotherapy may further cause neurocognitive issues.

In children with medulloblastoma who are between 3 and 7 years of age at the time of treatment, significant declines in overall intelligence have been demonstrated after 3600 cGy of craniospinal radiation (Ris et al., 2001). This drop in intelligence can be seen as early as 1 year posttreatment, is progressive, and may not plateau over time. Decline in intelligence in those children treated at full-dose radiation therapy (3600 cGy) has ranged between 20 and 30 IQ points within 3 years of treatment. Preliminary results suggest a lesser decrease in overall intelligence in younger children who are treated with reduced doses (2340 cGy) of craniospinal radiation, but still a 10- to 20-point overall drop in global intelligence is likely. Older children have not demonstrated as severe a drop in global intelligence; however, these patients often have selective learning and attentional difficulties. Global intelligence is a crude estimate of intellectual function, and patients of all ages have been noted, in follow up, to have selective sequelae, including memory difficulties, processing dysfunction, executive functioning abnormalities, visual-spatial difficulties, and attentional disorders. The attentional problems are often overlooked because of the lack of associated hyperactivity. Many of these children are hypoactive, and studies are under way to determine whether the use of stimulants or other agents will decrease fatigue and lethargy and improve attention.

Endocrinologic sequelae are the second most common long-term consequence of medulloblastoma treatment. Growth hormone production is most commonly affected, but over time there can also be deficits in thyroid function, follicle-stimulating hormone–luteinizing hormone (FSH-LH) production, and adrenocortical function. Although there is hesitancy to utilize growth hormone replacement in children with cancer, studies in children with medulloblastoma have not shown an increased incidence of tumor relapse associated with its use. Growth hormone insufficiency is exacerbated by the direct effects of radiation on vertebral growth, and many long-term survivors have disproportionate growth, with a decrease in truncal growth compared with extremity growth. The effects on growth are also exacerbated by associated obesity, which is more common in long-term survivors (Packer et al., 2003).

Increasingly, secondary tumors have been reported in children who have survived brain tumors, including medulloblas-

tomas. In a recent prospective Children's Oncology Group study of 379 children, 14 secondary malignancies occurred within 8 years of follow up, including multiple malignant gliomas. Because this patient population was less than 10 years from diagnosis at the time of the study, it is likely there will be an even greater rate of secondary tumor occurrence, especially the development of meningiomas, over time.

# 124 Other Embryonal and Pineal Malignancies of the Central Nervous System

Emily Gertsch, Yoon-Jae Cho, and Scott L. Pomeroy

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Embryonal tumors of the central nervous system (CNS) are recognized as the most common types of malignant pediatric brain tumors. As a group, they are poorly differentiated, highly cellular tumors with aggressive growth behaviors (Li et al., 2009). They include medulloblastomas and atypical teratoid rhabdoid tumors (ATRTs), which are discussed in detail in their own chapters, and an evolving group of tumors formerly classified as primitive neuroectodermal tumors (PNETs). The PNET classification is being phased out; more recently these tumors have been reclassified as CNS embryonal tumors. These other CNS embryonal tumors include embryonal tumors with multilayered rosettes (ETMRs), medulloepithelioma, CNS neuroblastoma, CNS ganglioneuroblastoma, and CNS embryonal tumor Not Otherwise Specified (NOS). These types of CNS embryonal tumors are rare, accounting for approximately 3% of childhood brain tumors. Their rarity combined with their substantial heterogeneity has resulted in a poor understanding of these tumors. However, classification of these tumors is rapidly evolving based on molecular profiling studies, and the mechanisms driving tumorigenesis of these CNS embryonal tumors are just beginning to be recognized.

Historically, CNS embryonal tumors have been treated with protocols used to treat medulloblastoma, perhaps a by-product of these tumors' similar histologic appearances. However, outcomes for patients with CNS embryonal tumors other than medulloblastomas have remained uniformly poor. This has led to the appreciation that these tumors respond poorly to medulloblastoma-based therapies and highlights the need for a better definition of the clinical, histologic, and genetic characteristics of these tumors to appropriately tailor effective therapies for patients.

## CLINICAL PRESENTATION

CNS embryonal tumors generally involve the frontal, temporal, and parietal lobes, more so than the deep or posterior fossa structures, and clinical manifestations are dependent on the site of tumor origin. Most children present with nonspecific complaints such as headache, nausea, vomiting, and problems with balance, all of which are manifestations of increased intracranial pressure (ICP). Complications of increased ICP include herniation, and care should be taken to approach lumbar puncture with extreme caution (or avoid completely) if an intracranial lesion is suspected. Other clinical manifestations of a supratentorial tumor might include motor deficits, alteration of consciousness, and seizures. Deeper-seated tumors such as those involving the pineal region may present with Parinaud's syndrome from compression of the pretectal region. Tumors in the suprasellar region may result in visual disturbances and/or endocrine abnormalities. Posterior fossa tumors may present with ataxia, cranial nerve deficits, and signs and symptoms of increased ICP.

## TYPES OF CNS EMBRYONAL TUMORS

### Embryonal Tumors with Multilayered Rosettes

Embryonal tumors with multilayered rosettes (ETMRs) were first identified in 2000 by Eberhart et al. as a distinct type of supratentorial embryonal tumor. Ependymoblastoma, formerly classified as a distinct entity, has been reclassified as being within the category of ETMR. These tumors, which also are known as embryonal tumors with abundant neuropil and true rosettes (ETANTRs), are rare CNS embryonal tumors that typically arise in the cerebrum but are occasionally seen in the cerebellum and brainstem. They occur in very young children (Ryzhova et al., 2011) and have a slightly higher predominance in girls than in boys (Gessi et al., 2009). Neuroimaging of an ETMR shows a large, well-delineated, solid mass with heterogeneous contrast enhancement (Gessi et al., 2009). Some tumors demonstrate a cystic component (Figure 124-1).

Their histologic characteristics are very distinctive and include focal high cellularity with abundant bands of neoplastic neuropil and the presence of both true rosettes and pseudorosettes (Louis et al., 2007) (Figure 124-2). These tumors are distinguished by high-frequency focal amplification at chromosome locus 19q13.42 of the *C19MC* oncogenic microRNA cluster, often associated with high levels of expression of LIN28 (Li et al., 2009; Ceccom et al., 2014). It has recently been shown that *C19MC* amplification occurs as a fusion of *C19MC* with the promoter of *TTYH1*, a brain-specific gene that encodes a chloride channel. The *TTYH1* promoter is highly active, driving high levels of *C19MC* expression, which in turn activates *DNMT3B*, a DNA methyl transferase that modulates the cells to induce a state of dedifferentiation and, ultimately, tumorigenesis (Kleinman et al., 2014). Thus the high-level amplicon activates a primitive developmental mechanism as part of the oncogenic mechanism (Archer and Pomeroy, 2014).

The prognosis of ETMR is exceptionally poor, with median survival of less than 1 year despite aggressive treatment.

### Medulloepithelioma

The most common site of origin for medulloepitheliomas is the periventricular region in the cerebrum. These tumors are typically quite large in size and may involve multiple lobes in one or both cerebral hemispheres. They sometimes occur intraventricularly and can be seen in sellar, infratentorial, and spinal regions, and in the optic nerve.

Their histologic features include neural tube formation, including papillary, tubular, or trabecular arrangements of neoplastic neuroepithelium. These rare malignant tumors are seen primarily in young children between the ages of 6 months and 5 years, and half occur in children less than 2 years old (Louis et al., 2007). There is an equal distribution between males and females.

Medulloepitheliomas have variable neuroimaging characteristics. They are generally well circumscribed and may be isodense or mildly hypodense on computed tomography (CT). Magnetic resonance imaging (MRI) shows hypointense or isointense lesions on T1-weighted sequences and hyperintense lesions on T2-weighted sequences. The tumors may not enhance with intravenous contrast on initial presentation but tend to enhance later as disease progresses (Figure 124-3). Calcifications and cysts are not typical features but have been reported. Medulloepitheliomas are often well circumscribed and have hemorrhagic and necrotic areas. They are frequently diffusely infiltrative in advanced disease.

These tumors have distinctive histopathologic features mimicking the embryonic neural tube, with pseudostratified epithelium arranged in papillary, tubular, or trabecular patterns. They may contain elements of glial, neural, and mesenchymal cell lines. The mitotic index is high, with a high rate of cellular proliferation, and both ependymoblastomatous and ependymal rosettes may be seen.

**Figure 124-1.** Axial T2-weighted MRI of ETANTR showing a large, well-circumscribed heterogeneous-appearing bifrontal mass. Note that the tumor extends into the frontal sinuses, an aggressive feature.

**Figure 124-2.** Histopathologic features of ETANTR showing abundant bands of neuropil with rosettes and pseudorosettes.

The prognosis of medulloepithelioma is very poor. Cerebrospinal dissemination is common at the time of death, which most often occurs within 1 year of diagnosis.

### CNS Embryonal Tumors Not Otherwise Specified

CNS embryonal tumors NOS are highly heterogeneous and may be difficult to distinguish from other high-grade tumors by histology alone (Picard et al., 2012). They may arise in the suprasellar region and deep structures, although they are most commonly found in the cerebrum. The mean age of patients with CNS embryonal tumor NOS is 5.5 years, with a range of 4 weeks to 20 years, and there is a slight male predominance (1.2:1) (Louis et al., 2007).

CNS embryonal tumors NOS appear isodense or hyperdense on CT. They may have cystic or necrotic areas, and many of these tumors have calcifications. On MRI, cystic and necrotic areas appear hyperintense on T2-weighted imaging, whereas solid portions of the tumor appear hypointense relative to gray matter on both T1- and T2-weighted imaging (Figure 124-4). The tumors typically enhance with gadolinium contrast. Cerebrospinal dissemination occurs in up to one-third of patients, and metastasis to extraneural sites, including bone, liver, and cervical lymph nodes, has been infrequently reported (Louis et al., 2007).

On histologic examination, these tumors are poorly differentiated, with Homer Wright rosettes often found in varying frequency, and with undifferentiated small anaplastic cells with minimal differentiation of the cell body. GFAP expression is occasionally detected by immunohistochemical techniques. Proliferation as measured by Ki-67 is typically high but may vary extensively. At times the tumors are difficult to distinguish histologically from other malignant supratentorial tumors, including CNS neuroblastomas, which have neuronal differentiation, or CNS ganglioneuroblastomas, which are poorly differentiated tumors that additionally contain differentiated neuronal cells.

The molecular features of CNS embryonal tumors NOS are poorly understood, and molecular profiling studies have revealed that many tumors initially diagnosed as CNS embryonal tumors NOS by histology are actually ETMRs/ETANTRs, glioblastomas, or ATRTs (Picard et al., 2012). Nevertheless, despite this molecular heterogeneity, all of these diagnoses share a poor clinical prognosis even with aggressive treatment, including neurosurgical resection, external beam radiation, and prolonged multidrug chemotherapy. Children less than 2

**Figure 124-3.** Sagittal T1-weighted postcontrast image of a pineal-region medulloepithelioma. Compression of the aqueduct causes the obstructive hydrocephalus.

**Figure 124-4.** Axial T1-weighted postcontrast MRI of a left parieto-occipital CNS embryonal tumor showing heterogeneous enhancement. Note that the tumor involves both cortex and white matter and extends through the skull into the subperiosteal space.

years of age at the time of diagnosis have worse clinical outcomes compared with older children.

## TREATMENT AND OUTCOMES

Treatment is typically multimodal and includes surgical resection, followed by irradiation appropriate for age and risk stratification, and chemotherapy (McGovern et al., 2014), although standard treatment regimens have not been established. Generally, gross total resection is a common feature of long-term survivors. One study showed good disease outcomes for a small cohort of young patients less than 5 years of age with CNS embryonal tumor NOS who received

**Figure 124-5.** Histopathologic features of pineocytoma showing small, well-differentiated cells with low mitotic index.

chemotherapy followed by proton radiation (Jimenez et al., 2013). Overall, however, patients with supratentorial embryonal tumors have very poor clinical outcomes and low survival rates.

## PINEAL TUMORS

Pineal tumors are tumors of pineal parenchymal origin that arise in the region of the pineal gland. They are relatively rare and heterogeneous. The two primary types of pineal tumors are pineocytomas and pineoblastomas.

### Pineocytomas

Pineocytomas are tumors of pineal parenchymal lineage histologically classified as World Health Organization (WHO) grade I tumors. They are primarily seen in adults and rarely occur in children. Pineocytomas typically arise in the pineal area. They may extend into the posterior third ventricle and compress adjacent structures.

Pineocytomas appear as hypodense, globular, well-defined masses, with occasional cystic components, peripheral calcifications, or hemorrhagic foci seen on CT. MRI shows a well-circumscribed mass that is isointense on T1-weighted sequences and hyperintense on T2-weighted sequences. Tumors demonstrate homogeneous contrast enhancement.

Histopathologic features of pineocytomas include small, well-differentiated cells reminiscent of pineocytes that grow in sheets or lobules (Figure 124-5). In addition, large pineocytomatous rosettes are often seen. Mitotic index is usually low, and microcalcifications are sometimes present.

### Pineoblastoma

Pineoblastomas are rare aggressive tumors of pineal parenchymal origin classified as WHO grade IV tumors based on histologic features. They more commonly occur in children, with the majority of pineoblastomas diagnosed in the first two decades of life (Louis et al., 2007). There is equal distribution between males and females.

Pineoblastomas appear as contrast-enhancing, large, ill-defined, lobulated masses on CT. Masses are hypointense or isointense on T1-weighted MRI. Cystic changes and calcifications are infrequently seen (Figure 124-6).

Cerebrospinal and leptomeningeal dissemination, and local infiltration, are common for these poorly delineated tumors. They are comprised of highly cellular small cells that

**Figure 124-6.** T2-weighted axial image of a pineoblastoma showing a hypointense lesion, indicating hypercellularity, with intralesional hemorrhage.

are compactly arranged. Pineocytomatous rosettes are absent, whereas Flexner-Wintersteiner rosettes and Homer Wright rosettes are more typically seen. Tumors tend to exhibit necrosis and high mitotic activity.

Trilateral retinoblastoma syndrome describes the occasional presence of pineoblastoma in patients with bilateral retinoblastoma. Prognosis in patients who have aberrations in the *RB1* gene is even less favorable than that for patients with sporadic occurrence. Pineoblastoma has also been reported to occur in patients with familial adenomatous polyposis (Louis et al., 2007).

## TREATMENT AND OUTCOMES

Treatment of pineal tumors typically includes a combination of surgical resection, irradiation, and chemotherapy. Given the location of these tumors, it is also important to manage the hydrocephalus commonly associated with pineal tumors.

The clinical prognosis of patients with pineocytoma is generally quite favorable. Pineocytomas are not known to metastasize. Five-year survival ranges from 86% to 100%, and there have been no relapses reported for patients who undergo a gross total resection (Louis et al., 2007).

In contrast, pineoblastomas are extremely aggressive tumors associated with poor clinical outcomes, particularly when seen in trilateral retinoblastoma syndrome. Craniospinal dissemination is common, as is leptomeningeal seeding, and metastasis to extracranial sites can occur. Survival largely depends on extent of disease at diagnosis and the extent of resection and radiation therapy. Patients with familial and sporadic trilateral retinoblastoma rarely survive beyond 1 year

after diagnosis, and patients who develop recurrent disease have an especially poor prognosis (Farnia et al., 2014).

## SUMMARY

In conclusion, embryonal tumors found in the supratentorial compartment represent, for the most part, histologically similar yet molecularly heterogeneous groups of tumors whose classification (and nomenclature) is rapidly evolving. Despite their molecular heterogeneity, they share in common an aggressive clinical course that is generally refractory to conventional chemotherapy and radiotherapy schedules. As our understanding of the genetic underpinnings of these diseases rapidly evolves, so too will our ability to more effectively treat them.

# 125 Ependymoma

Richard Grundy and Nicholas K. Foreman

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Ependymomas are enigmatic tumors, and despite advances in neurosurgery, neuroimaging, and postoperative adjuvant therapy, their clinical management remains one of the more difficult in pediatric neuro-oncology.

## INCIDENCE AND EPIDEMIOLOGY

Ependymomas are the second commonest malignant brain tumor occurring in children, accounting for approximately 10% of all such tumors. They have a predilection for young age at onset; indeed, over half of intracranial ependymomas arise in children under 5 years of age. There is slight male preponderance. Children with ependymoma have a worse outcome than adults.

Childhood ependymomas predominantly arise in the intracranial compartment, in contradistinction to the situation for adults, in whom spinal origin predominates. Approximately two-thirds of childhood intracranial tumors arise in the posterior fossa, where they are intimately associated with the fourth ventricle. Signs and symptoms at presentation are consequent on obstruction of cerebrospinal fluid (CSF) movement. The most common presentation is nonspecific with raised intracranial pressure, but patients may present with cerebellar or lower cranial nerve dysfunction. In very young children, irritability and lethargy may be the only presenting symptoms. The duration of these symptoms before presentation varies greatly depending on site and may be prolonged, particularly in spinal tumors (Box 125-1).

## LOCATION

Ependymomas probably arise from the ependymal lining of the ventricles and lining of the central canal. However, ependymomas may arise anywhere in the neuraxis, and supratentorial tumors are frequently not related to ventricular cavity. Dissemination via CSF is reported in 7% to 22% of cases. Spinal ependymomas may occur as intramedullary or as intradural extramedullary tumors. The latter arise predominantly of the caudal region (filum terminale) and are usually of the myxopapillary histologic subtype (Box 125-2).

## PATHOLOGY

The World Health Organization (WHO) 2016 (Ellison et al., 2016) classification defines grades I through III, with classic ependymoma (grade II) and anaplastic ependymoma (grade III) being prevalent (Box 125-2). A new entity of supratentorial ependymoma has been added defined by the presence of a *RELA*-fusion gene, comprising 80% of supratentorial ependymomas. Consistent histologic differentiation of ependymoma between Grade II and grade III has proven difficult because a spectrum of pathologic features exists (Wiestler et al., 2000). It is likely that grade will be determined by a combined morphologic and molecular profile in the near future.

## DIAGNOSTIC EVALUATION

### Imaging Studies

The imaging of intracranial ependymoma is challenging. On magnetic resonance imaging (MRI), ependymomas typically display iso- to hypointensity on T1-weighted images and hyperintensity on T2-weighted images. They usually enhance heterogeneously with gadolinium. Fourth-ventricle ependymomas can often be distinguished from medulloblastoma radiographically by their tendency to “squeeze” through the foramina of Luschka and Magendie. Complete neuraxis imaging is essential to exclude leptomeningeal disease, even in spinal tumors because these occasionally metastasize to the brain. An unresolved issue is exactly what surveillance protocol is optimal for children with ependymomas to maximize detection of recurrence without unduly wasting resources. The detection of asymptomatic recurrences through routine surveillance does appear to confer some benefit. A widely accepted strategy is acquiring an MRI every 3 to 4 months for up to 2 to 3 years and less frequently until age 6 to 7 years. MRI-visible spinal metastatic disease in the absence of intracranial metastases is uncommon.

## PROGNOSTIC FACTORS

Although a number of prognostic factors have been identified, these tend to be based on single-institution retrospective series involving limited numbers of patients accrued over a time span covering many different approaches to both the diagnosis and treatment of ependymoma.

However, the most widely accepted prognostic factor is the degree of surgical resection. Axiomatically, gross total resection is associated with a better prognosis.

Older children (above 3 years of age) appear to have a better prognosis, with a 5-year survival rate of 55% to 83% compared with 12% to 48% for children under 3 years of age. In this regard, factors likely to be important include surgical accessibility and a general reluctance to irradiate very young children. However, it is possible this difference is based on biology, with molecular stratification into two distinct subtypes of ependymoma, groups A and B, with a poorer outcome in group A, more commonly seen in the very young (Witt et al., 2011).

Supratentorial location is thought more favorable despite these tumors often being extensive at diagnosis. Based on small numbers, there is a possibility that completely resected grade II supratentorial ependymomas have a particularly favorable outlook. Recent work suggests that in supratentorial tumors, the presence or absence of *RELA* gene fusions may have prognostic significance (Parker et al., 2014).

## Tumor Grade

Despite a number of studies, the relationship between histologic grading and tumor outcome is unclear. Some studies have found that the presence of anaplasia carries a worse

prognosis, whereas others have found no difference. The lack of uniformity in the grading system used across series makes it difficult to conclude which histologic features are prognostic.

**GENETICS**

It has been postulated that embryonic neural stem cells (NSCs) arising from different parts of the central nervous system are transformed by different gene mutations, thereby giving rise to biologically distinct types of ependymoma. For example, *RELA* gene fusions are common in supratentorial ependymomas but virtually absent in fourth-ventricle tumors (Parker et al., 2014). Radial glia-like cancer stem cells have been proposed as the candidate cell of origin for supratentorial and spinal ependymoma.

**Cytogenetics**

Comparative genomic hybridization (CGH) studies have identified three broad groups of tumors. The first group of

structural tumors showed few, mainly partial, imbalances. A second numerical group showed 13 or more chromosome imbalances, with a nonrandom pattern of whole chromosome gains and losses that are also highly associated with adult ependymoma. The third group showed a balanced genetic profile that was significantly associated with a younger age at diagnosis, suggesting that ependymomas arising in infants are biologically distinct from those occurring in older children (Kilday et al., 2009). There is a correlation between the structural group and group A, as identified by array technology.

Overall, pediatric ependymomas most frequently demonstrate gain of chromosomes 1q, 7, and 9 and loss of chromosomes 22, 3, 9p, 13q, 6q, 1p, 17, and 6, whereas the commonest genomic aberrations in adult ependymomas are gain of chromosomes 7, 9, 12, 5, 18, X, and 2 and loss of 22/22q, 10, 13q, 6, and 14q (Table 125-1).

One of the most striking differences between the two age groups analyzed by CGH is the genomic gain of 1q seen in over 20% of pediatric ependymomas but in only 8% of adults. Importantly, the genomic imbalances found in adult and spinal ependymomas regularly involve whole chromosomal rearrangements; in contrast, partial and complex imbalances are frequently seen in pediatric cases. Indeed, a recent meta-analysis of pediatric and adult ependymoma revealed marked differences, underscoring the point that these should be considered separate conditions (Kilday et al., 2009).

Comparing childhood intracranial ependymomas from different locations has revealed significant genetic diversity. It has also been suggested that posterior fossa ependymomas can be subdivided based on their gene expression profiles (Witt et al., 2011) (Table 125-2).

Whole-genome sequencing of supratentorial and posterior fossa ependymomas, with the aim of identifying driver mutations of these tumors, has recently been performed (Parker et al., 2014; Mack et al., 2014). Both studies found very few single-nucleotide variations (SNVs), insertion/deletions, or focal (<5 genes) copy-number variations in ependymomas. The paucity of SNVs in ependymoma led to scrutiny of the epigenome in ependymoma.

## Epigenetic Phenomena

There is growing evidence that epigenetic deregulation is involved in pediatric cancers, and recent research has suggested this may be important in ependymoma. The DNA methylation profile can be used to segregate ependymomas according to anatomic location, and supratentorial and spinal tumors display a more hypermethylated phenotype. A more recent study using higher-resolution DNA methylation analysis has identified two distinct groups of posterior ependymomas: group A, which have a much greater extent of CpG island methylation and Group B. Group A tumours predominantly have stable genomes and present predominantly in very young children and have a poor outcome. The methylated genes in PFA-CIMP converge on genes that are silenced in embryonic stem cells by the Polycomb repressive complex 2 (PRC2) (Mack et al., 2014).

These data suggest that drugs that target DNA CpG methylation, PRC2/EZH2, and/or histone deacetylase inhibitors could represent a rational strategy for treatment of PFA-CIMP ependymoma.

In summary, there is a pressing need to identify robust biomarkers in ependymomas to define biologically relevant subclasses that will, in turn, help to stratify patient management.

## Biomarkers

Difficulty in predicting tumor behavior from clinical and histologic factors has shifted the focus to the molecular and cellular biology of ependymoma to identify new correlates of disease outcome and potentially novel therapeutic targets. Several candidate biomarkers have been proposed. However, markers showing reproducible results in prospective and sizeable groups of young ependymoma patients treated in a consistent way within clinical trials are still required (Kilday et al., 2012). Indeed, several purported biologic prognostic markers have lost significance when assessed across clinical trial cohorts, highlighting the importance of analyzing any prospective marker in standardized therapeutic groups (Kilday et al., 2012). To date, only two biomarkers (1q gain [Kilday et al., 2012] and Tenascin C [TNC]) have been evaluated in retrospective national clinical trial cohorts of childhood ependymoma.

It is clearly unlikely that a single biomarker will represent the complex biology and varied clinical presentation of ependymoma, and defining the molecular determinants of the clinical biology of this intriguing disease is the next major task.

## TREATMENT OF EPENDYMOMA

Once the acute presentation has been stabilized, it is widely accepted that surgical resection should be the initial treatment, with the aim of gross total resection; a second surgical procedure may be warranted to achieve a gross total resection, albeit mindful of surgical morbidity. However, ependymomas arising in the fourth ventricle have the propensity to adhere to and invade the brainstem and to extend through the

foramen of Luschka, enveloping the lower cranial nerves and making complete surgical resection without morbidity difficult. The extent of surgery must be assessed postoperatively by MRI; if there is still residual tumor, referral to a major center to evaluate the need for further surgery should be undertaken—such is the importance of complete resection.

It is now widely accepted that adjuvant therapy is required in most patients with ependymoma and probably all patients with fourth-ventricle tumors. Research is ongoing to define which patients may be spared further treatment. The closed large trial (ACNS 0121) from the Children's Oncology Group will soon answer important questions related to the role of observation after gross total resection for grade II supratentorial ependymoma.

Concerns over the late effects of cranial irradiation in very young children have led a number of national groups to use adjuvant chemotherapy to avoid or delay radiation. There has been divergence between Europe and North America in the age at which focal radiation is considered acceptable, being as young as 1 year of age in North America but generally being over the age 3 in Europe. The large but unreported Children's Oncology Group trial ACNS 0121 radiated focally down to 1 year of age, but long-term toxicity data are not available for this trial.

ACNS 0121 accrued more than 350 patients between August 2003 and September 2007. It explored the role of chemotherapy to achieve complete resection at second surgery after initial subtotal resection. However, for initially completely resected, nonmetastatic ependymomas, this study used radiation without chemotherapy.

## Chemotherapy

Chemotherapy has a role in the management of ependymoma, although this remains a controversial area. There is increasing evidence that a proportion of ependymomas are chemoresponsive, but debate exists over the degree of response, and a convincing role for chemotherapy has still to be demonstrated. This in part reflects the difficulties in interpretation of postchemotherapy imaging, and more sophisticated imaging studies are now needed. Early studies from the Pediatric Oncology Group (POG) reported a response rate of 48% in infants using a combination of vincristine and cyclophosphamide. However, this finding was based on computed tomography (CT) imaging. More recently, the Children's Cancer Group (CCG) study 9942 was reported, which used chemotherapy in children with initial incomplete resections before radiation and showed a 57% complete or partial response to this therapy. The outcomes for those treated with chemotherapy for incompletely resected tumor were equivalent to outcomes for those with completely resected tumors who did not receive adjuvant chemotherapy. This benefit was restricted to those who had at least 90% of the tumor resected.

The question of whether chemotherapy is of benefit to children with completely resected tumors postradiation has not been answered, but this is being explored in the Children's Oncology Group (COG) study ACNS 0831 and the international SIOP Ependymoma II study.

Furthermore, it is now clear that a proportion of infants can be cured following adjuvant chemotherapy without the use of radiotherapy (Geyer et al., 2005; Grundy et al., 2007; Strother et al., 2014). Similar results were reported from the U.S. children's CCG (CCG-9921) and the POG, with both reporting "radiotherapy" event-free survival of over 40% (Geyer et al., 2005). although, at least in the CCG data, the extent of resection was a very significant contributor to overall cure and survival for nonmetastatic patients. An important

observation was the beneficial effect of dose intensity on event-free survival.

A recent study by the Head Start group, which used myeloablative therapy in newly diagnosed ependymoma to avoid radiotherapy, did not demonstrate outcomes superior to reported chemotherapeutic strategies.

Chemotherapy may improve outcome by enabling second-look surgery. Prospective studies to confirm or refute this are awaited.

In summary, there is increasing evidence that in a proportion of cases, ependymomas are chemo-responsive and chemo-curable. The systematic analysis of tumor specimens may provide useful information as to which tumors would benefit from chemotherapy, which from radiotherapy alone, and perhaps even which can be observed.

Current recommendations for chemotherapy in ependymoma include the following: (i) infants when the aim is to delay or avoid radiotherapy because of concerns about neurocognitive outcomes, particularly those under 12 to 18 months of age, and (ii) patients with residual tumor after initial surgery. Importantly, it remains necessary to define which drugs are active in ependymoma; this might be best achieved through phase II window studies in patients with residual disease postsurgery, as proposed in the new European study (SIOP Ependymoma). Another important question to be addressed is whether the addition of chemotherapy to radiotherapy improves the cure rate, as has been demonstrated in medulloblastoma. Defining which patients are likely to benefit from chemotherapy, which from radiation therapy, and which from both is clearly an important goal, albeit a significant challenge as well.

## Radiation Therapy

Postoperative radiation therapy to the tumor bed is an important component in the treatment of localized ependymoma, and its role in the treatment of very young children is changing. Newer radiotherapy methods that incorporate three-dimensional imaging have improved treatment. Only two decades ago, ependymoma was treated with surgery and postoperative craniospinal irradiation with or without chemotherapy. The long-term event-free survival was less than 40%, and most patients experienced primary site progression because a high proportion had a residual tumor at the time of irradiation. Because of concerns about neuraxis dissemination, especially in patients with high-grade tumors, 36Gy craniospinal irradiation was administered to many patients, and 54Gy was prescribed to the primary tumor site using conventional techniques that irradiated large volumes of normal tissue. Survivors treated with craniospinal irradiation experienced debilitating side effects. Craniospinal irradiation was abandoned when investigators learned that neuraxis dissemination at the time of diagnosis was uncommon, and tumor grade was no longer used to determine the treatment volume.

The ability of newer treatment methods to limit the highest dose to the tumor bed and spare normal tissues has been objectively demonstrated in a recent prospective trial (Merchant et al., 2009). Eighty-eight children with ependymoma, including 48 children under the age of 3 years at the time of irradiation, were treated at St. Jude Children's Research Hospital with conformal radiation therapy to 54 to 59.4 Gy using a 1-cm clinical target volume margin surrounding the postoperatively defined tumor bed. Preliminary results reveal a 3-year progression-free survival of 75%  $\pm$  6% (Merchant et al., 2009). Patients were serially evaluated using objective measures of cognitive function that included testing of IQ, memory, academic achievement, and adaptive behavior. No

decline in cognitive function was observed among these patients. However, a subsequent study by the same group suggested attention and school problems in these children postradiation and that these were associated with age at diagnosis and at administration of conformal radiation (Willard et al., 2014). It is essential to obtain long-term data about the effects of radiation on academic and behavioral function and cognition into early adulthood.

A spectrum of complications with various levels of severity has been observed for patients treated with radiation therapy, including cognitive decline, hearing loss, endocrine deficits, and abnormalities in growth and development. Rare but devastating complications such as symptomatic vasculopathy, brain and spinal cord necrosis, and secondary malignancies have been reported. Although functional outcomes after radiation therapy are directly related to the age of the patient at the time of irradiation and morbidity associated with the tumor and surgical intervention, there is a statistically significant relationship between cognitive function after radiation therapy and dosimetry to the supratentorial brain.

Cranio-spinal irradiation is reserved for the treatment of patients with obvious neuraxis dissemination from intracranial or spinal primary tumors. Although the curability of patients with metastatic ependymoma has never been convincingly demonstrated, long-term survivors have been reported. The effectiveness of craniospinal irradiation is likely to be related to the extent and bulk of neuraxis dissemination, ranging from cytologic involvement of CSF to isolated ventricular or spinal metastases to bulky tumor filling the subarachnoid spaces.

Spinal cord ependymomas in children are rare; when completely resected, they do not require radiation therapy. In the setting of incomplete or piecemeal resection, radiation therapy is most often indicated. Treatment of spinal cord ependymoma is challenging and requires detailed neuraxis staging and delineation of the extent of disease. The known association of NF2 and ependymoma should prompt evaluation for suspected metastatic or multifocal disease.

## Experimental Therapy

It is possible that the success of targeted therapeutic agents has been limited, in part, as a result of the focus of early-phase clinical trials on molecular aberrations in primary ependymoma, with little understanding of the biology of relapsed disease. A better understanding of the biology at relapse is needed to improve therapy at this critical event.

The use of immunotherapy is being studied in ependymoma. This has some rationale given the potential influence of the difference in the immune microenvironment on prognosis. There is currently a study using vaccination with tumor antigen peptides for ependymoma ongoing in Pittsburgh, but it is too early to know its results.

## Recurrence and Patterns of Failure

The majority of recurrences occur as a result of the failure of local tumor control and are identified between 9 and 24 months after therapy. However, an increasing number of distant failures are being recorded in patients treated with conformal radiotherapy to the primary site. The prognosis for relapse is relatively poor; overall, only 25% of children survive first or subsequent relapses (Messahel et al., 2009). Survival at first relapse may be better if it is local only with complete excision of the recurrence and reirradiation, but this needs longer follow-up to be certain.

Relapsed ependymoma presents distinct challenges. Increasingly, children are experiencing multiple relapses and

treatments before finally succumbing to the disease. Although children may be salvaged a number of times, the law of diminishing returns applies, and there are few long-term survivors of multiple relapses. Importantly, ependymomas may recur several years after seemingly successful therapy, and long follow-up of 10 to 15 years is essential.

Treatment options following relapse depend on initial treatment. Surgery should always be considered in patients with local recurrence, as should irradiation for infants in whom radiotherapy was not given as part of the primary treatment. The role of chemotherapy in relapse remains uncertain, and international studies are now required.

In the absence of effective salvage therapy, reirradiation in various forms has been considered for patients who relapse after their initial course of radiation therapy. Single-dose radiosurgery and fractionated external-beam reirradiation have both been employed successfully in patients with local recurrence after radiation therapy. The indications for reirradiation and the selection of the best modality are generally based on the feasibility of performing additional surgery at the time of relapse, the presence or absence of residual disease, and the perceived tolerance of the tissues to be encompassed within the reirradiated volume. There have been studies showing prolonged remissions, and potentially cures, after complete surgery and reirradiation for locally recurrent tumor. For unexplained reasons, time to second remission after reirradiation was longer than time to first progression. The benefit of reirradiation may, however, be dependent partly on the biology of tumor, with much better outcomes for children with group B tumors than younger ones with group A disease. Unpublished experience (NKF) would suggest that reirradiation is of very limited benefit when there is substantial residual mass; when it is done within 1 year from prior radiation, it may have unacceptable morbidity.

More challenging is the use of reirradiation in patients who fail with disseminated disease after prior focal irradiation. The options for these patients range from single or multifocal radiosurgery to craniospinal irradiation. In patients with limited metastatic burden and for whom metastasectomy can be performed, craniospinal irradiation with overlap of the primary site is preferred. Shielding of the previously irradiated spinal cord may be indicated.

## SUMMARY

Important issues remain to be addressed in childhood ependymoma. Importantly, we need to reach an international consensus on whether, and which, biological characteristics of this tumor determine outcomes and whether there are distinct biological subgroups, as was previously done for medulloblastoma. This has been rendered difficult by very the different median age of patients in large studies. The relationship of biology to traditionally important prognostic factors such as extent of surgery and tumor grade needs more definition. We need to investigate novel imaging methods for assessing chemosensitivity, investigate active chemotherapy or biological agents, and assess the long-term outcomes and side effects of conformal radiotherapy through multicenter studies (Box 125-4).

Significant challenges for the years ahead include defining the place for chemotherapy in completely resected ependymoma and in the very young. New agents need to be developed, using the insights obtained from biological discovery, and then rapidly tested in relapsed cohorts of patients.

There is a clear need to better understand the underlying biology of this disease to improve the therapeutic options and outcomes.

# 126 Pediatric Brain Tumors – High-Grade Glioma

Sabine Mueller and Matthias A. Karajannis

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Gliomas are tumors of the central nervous system (CNS) that arise from glial precursors and most commonly are differentiated along the astrocytic or oligodendroglial lineages. Gliomas may occur at all ages and throughout the entire neuraxis. Traditionally, gliomas have been grouped into two main categories according to histologic features: low-grade gliomas (LGGs) and high-grade gliomas (HGGs). This is also reflected in the current World Health Organization (WHO) classification, which distinguishes low-grade (WHO grade I/II) and high-grade (WHO grade III and IV) gliomas. The current WHO classification of HGGs is summarized in [Table 126-1](#).

HGGs are relatively rare in children and comprise approximately 4% of all brain tumors diagnosed in children aged 0 to 14 years and up to 14% in children aged 10 to 19 years. Histologically, the vast majority of pediatric HGGs are either anaplastic astrocytomas (WHO grade III) or glioblastomas (WHO grade IV).

A unifying feature of HGGs is the diffusely infiltrative nature of the disease, representing a major therapeutic challenge. Diffuse intrinsic gliomas (DIPGs) are HGGs arising in the brainstem, and they are discussed in detail in [Chapter 129](#). The molecular features and dismal clinical outcome of DIPGs are highly similar to those of other pediatric HGGs arising in other anatomic midline structures of the CNS, such as thalamic or spinal cord HGGs. As a result, these “midline pediatric HGGs” can be viewed as comprising a spectrum within a single clinico-pathologic entity.

A number of inheritable tumor predisposition syndromes have been found to be associated with HGGs. Patients with Li-Fraumeni syndrome (LFS), an autosomal-dominant condition caused by mutations in the tumor suppressor p53, have an increased risk of developing HGGs ([Schwartzentruber et al., 2012](#)). Patients with the autosomal-recessive constitutional mismatch repair deficiency syndrome (CMMR-D) frequently have café-au-lait macules similar to neurofibromatosis type 1 (NF1), resulting in occasional misdiagnosis. CMMR-D is caused by germline biallelic (homozygous or compound heterozygous) mutations in one of the DNA mismatch repair (MMR) genes MLH1, MSH2, MSH6, and PMS2. Germline monoallelic mutations in MMR genes are also found in hereditary nonpolyposis colon cancer, Lynch syndrome, and brain tumor polyposis syndrome type 1 (BTSP1 or Turcot type 1). Patients with CMMR-D are at increased risk for development of HGGs and other brain tumors, typically within the first 2 decades of life.

## CLINICAL PRESENTATION

The initial clinical presentation of children with HGGs greatly depends on the anatomic location of the tumor and the age of the patient. The clinical history is typically short, with signs or symptoms of focal neurologic dysfunction, such as weakness or seizures.

## DIAGNOSIS AND INITIAL MANAGEMENT

In patients with imaging features consistent with an HGG, maximum safe surgical resection most often is the initial therapeutic step. Depending on location, resection might not be feasible, and a biopsy is performed to establish the diagnosis. It is important to recognize that small biopsy samples may not be fully representative of the entire tumor. Postoperative imaging should be performed within 24 hours after surgery. Leptomeningeal dissemination in pediatric HGGs is rare (approximately 3%) at presentation, but later on occurs in over 20% of patients. Therefore, imaging of the entire neuraxis should be performed either routinely or at least in patients with a clinical suspicion of spinal involvement.

## Histopathology and Molecular Pathology

Neuropathology of pediatric brain tumors has changed significantly as a result of deeper understanding of molecular biology. Although the most recent 2007 WHO classification is still based predominantly on histopathology alone and pediatric HGGs are embedded within the adult HGGs, the molecular data indicate that adult and pediatric HGGs are biologically distinct.

In children, two main histopathological and clinical variants of HGGs are recognized. Whereas supratentorial glioblastoma multiforme (GBM) is histologically, albeit not molecularly, similar to its adult counterpart, DIPGs can range in histologic features from diffuse astrocytoma, WHO grade II, to GBM, WHO grade IV, despite aggressive behavior across all grades. Histologic criteria show little, if any, correlation with clinical outcome.

Most pediatric HGGs develop as a result of somatic mutations. The number of somatic mutations in children is relatively low compared with adult GBM (61 mutations per sample); however, it is higher than in many other pediatric cancers, with a median of 15 nonsynonymous coding mutations per sample in both DIPGs and noninfant HGGs. The genomic complexity of pediatric HGGs spans a wide range, with infant HGGs showing extremely low numbers of mutations, with a median of 2. On the opposite side of the spectrum are HGGs from patients with mismatch repair abnormalities, which show the highest mutational burden of all tumors, with a median of 6810 nonsynonymous coding mutations per sample ([Jones and Baker, 2014](#)).

Pediatric HGGs show genetic alterations in the same canonical cancer pathways that are affected in adult GBM, including the PI3K pathway, the TP53 pathway, and the RB pathway; however, there are specific differences in what part of the pathway may be affected. For example, PI3K mutations are found in both pediatric and adult tumors. Loss of PTEN function via deletion and/or mutation is rare in pediatric HGGs. The BRAF-V600E mutation is found in approximately 10% of pediatric supratentorial HGGs but is rare in adult gliomas.

**TABLE 126-1** World Health Organization Classification of High-Grade Glial Tumors

Astrocytic Tumors	Oligodendroglial and Oligoastrocytic Tumors
Anaplastic Astrocytoma (III)	Anaplastic oligodendroglioma (III) Anaplastic oligoastrocytoma (III) Pleomorphic xanthoastrocytoma with anaplastic features (III)
Glioblastoma (IV), including giant-cell glioblastoma and gliosarcoma	

(Adapted from Luis, D.N. Ohgaki, H. Wiestler, O.D., et al. [Eds.], 2007. WHO Classification of Tumors of the Central Nervous System, 4th ed. Lyon, France: International Agency for Research on Cancer.)

Up to 50% of HGGs in children show some DNA structural abnormalities. The copy-number-variation landscape in pediatric HGGs is highly variable and can range from stable genomes to simple rearrangements and complicated multifocal abnormalities caused by chromothripsis. In addition to the previously mentioned BRAF tandem duplication, NTRK1, 2, and 3 fusions are typically involved and can be the sole molecular aberration, particularly in infant HGGs.

Receptor tyrosine kinases (RTKs) are the most commonly amplified genes both in pediatric and adult HGGs. Whereas EGFR is the most common RTK amplified in adult primary GBM (up to 40% of cases), it is rare in pediatric gliomas. Only 10% to 15% of cases of adult GBM show amplifications and/or mutations of PDGFRA, whereas it is the most commonly mutated RTK in pediatric HGGs, with approximately 30% of pediatric diffuse gliomas showing amplification and/or mutation (Paugh et al., 2013). Amplification of MET and IGF1R and mutations in FGFR1 were also found in pediatric HGGs (Wu et al., 2014). Mosaic heterogeneity described in adult GBM (Snuderl et al., 2011), in which different RTK genes are amplified in a mutually exclusive fashion, has also been described in pediatric gliomas, with coexisting glioma subclones harboring either PDGFRA or MET amplification.

Approximately 55% of pediatric HGGs harbor mutations of the TP53 gene. Up to 20% of DIPGs and midline HGGs carry mutations in PPM1D, which functions downstream of p53 (Taylor et al., 2014). Mutations of TP53 and PPM1D are mutually exclusive in HGGs.

The RB pathway is less commonly affected in pediatric HGGs compared with adult HGGs. Homozygous deletions of CDKN2A are found in approximately 25% of supratentorial HGGs, although they are rare in DIPGs. Amplification of the components of the cyclin-CDK complex were identified across all the subgroups of HGGs from all brain regions. Homozygous loss of function in RB is extremely rare in pediatric HGGs; however, loss of chromosome 13q is found in approximately one third of pediatric HGGs, regardless of location.

In striking contrast to adult gliomas, the most prevalent molecular alterations of pediatric HGGs involve recurrent alterations of genes regulating epigenetic modifications of the genome (Schwartzentruber et al., 2012). Genome-wide studies identified recurrent hotspot mutations in H3 histone, family 3A (H3F3A) and histone cluster 1, H3b (HIST1H3B), which encode the histone H3 variants H3.3 and H3.1, respectively. This was the first example of a human tumor or other disease driven by direct mutation of histones. Point mutations of H3F3A and HIST1H3B genes occur at hotspots, either at amino acid residue 27, resulting in a lysine-to-methionine (K27M) amino acid change, or 34, resulting in either a

glycine-to-arginine (G34R) or glycine-to-valine (G34V) amino acid change. Mutations lead to marked changes of the epigenome, resulting in distinct methylation signatures. The H3.3 mutations are mutually exclusive with IDH1/2 mutations, which are most commonly observed in diffuse gliomas of young adults. Interestingly, both IDH1/2 and H3.3 mutations seem to drive oncogenesis via genome-wide epigenomic changes. The different H3 histone mutations present at different ages, with a median of 6 to 7 years for K27M mutants and a median of 13 to 14 years for G34R/V mutants. Furthermore, survival seems to be different as well. The median survival of patients with the G34R/V mutation is 24 months, whereas K27M-mutated tumors are associated with worse survival, with a median of 12 months. Although these mutations are characteristic of pediatric HGGs, H3 variant mutations can be present in young adult gliomas as well.

In addition to the mutations in the genes encoding the histone variants, other chromatin regulators can also be mutated in pediatric HGGs. Although more prevalent in adult low-grade diffuse gliomas and secondary GBM, the ATRX or DAXX genes are mutated in approximately 20% of pediatric HGGs, often with concurrent G34 mutations (Schwartzentruber et al., 2012; Wu et al., 2014). ATRX and DAXX mutant tumors are strongly associated with a telomerase-independent alternative lengthening of telomeres in pediatric HGGs (Schwartzentruber et al., 2012). Mutations of the telomerase reverse transcriptase TERT promoter, which represent different mechanisms to lengthen telomeres and are typically found in primary adult GBM, are rare in pediatric HGGs. Additional mechanisms to alter the epigenome found in pediatric HGGs include mutations in variety of genes, such as SETD2, MLL, and CHD, further stressing the complexity of epigenetic interactions in these tumors (Wu et al., 2014).

The association between certain molecular aberrations and tumor site has long been appreciated, and points to developmental rather than carcinogenic origins of pediatric HGGs. Whereas histone H3.3 G34R or G34V mutations and BRAF-V600E mutations are predominantly found in supratentorial hemispheric tumors, histone H3 K27M mutations are found in midline tumors, including tumors of the thalamus and brainstem, with the highest frequency in DIPGs. In midline tumors, FGFR1 mutations are found in thalamic HGGs, whereas ACVR1 mutations are restricted to DIPGs. Furthermore, PIK3CA and PIK3R1 mutations, as well as FGF1R and MET amplifications, are prevalent in DIPGs, whereas loss of CDKN2A and NF1 aberrations are more prevalent in supratentorial GBM. In contrast to adult GBM, loss of PTEN is not common in pediatric HGGs, and IDH1/2 mutations are most common in the frontal lobes, whereas H3.3 G34R or G34V are most common in other lobes (Jones and Baker, 2014).

The previously mentioned molecular findings present challenges both for diagnosis and clinical management. Given the molecular heterogeneity of pediatric HGGs, genome-wide and in situ methods are necessary to assess the molecular profile for prognostic and predictive markers. Technically, this stratification can be best achieved by a combination of genome-wide DNA methylation profiling and targeted methods such as sequencing or immunohistochemistry for verification. In situ hybridization methods should also be used for assessment of focal gene amplifications and tumor heterogeneity.

## Imaging

Magnetic resonance imaging (MRI) is an essential tool in the diagnosis and treatment of brain tumors, and is considered the current imaging standard for any child with a brain tumor. A complete series should include the following

sequences: T1-weighted axial and coronal (both before and after gadolinium), T2-weighted axial and coronal, and fluid-attenuated inversion recovery (FLAIR). In addition, sagittal plane sequences are helpful in defining the anatomy of suprasellar and midline tumors. Other sequences, such as fat suppression and magnetic resonance (MR) angiography, may also be required in specific situations. Contrast-enhanced neuroimaging of the entire neuraxis should be considered as baseline evaluation for any child with a brain tumor. On T1-weighted images, HGGs often demonstrate central areas of low density corresponding to necrosis and are typically poorly circumscribed. The peritumoral edema surrounding most HGGs appears as a hyperintense region of signal abnormality on T2-weighted images. Most centers also include diffusion-weighted images in their standard imaging protocol, and evidence exists that in addition to enhancement and presence

of necrosis, a low apparent diffusion coefficient is a predictor for HGG.

### Metabolic Imaging

Proton MR spectroscopy (MRS) is a powerful and sensitive technique that can be added to any standard MR study and allows the measurement of the relative composition of different metabolites, including N-acetyl-aspartate (NAA), choline, creatine, lipid, and lactate. MRS can be useful to differentiate tumor from normal tissue, to help stratify neoplasms as high- or low-grade tumors, and to distinguish between treatment injury and recurrent neoplasm. An HGG is often associated with lower levels of NAA and creatine and higher levels of choline and lactate (see Fig. 126-1). Further, MRS spectra of childhood brain tumors at first relapse do not differ

**Figure 126-1.** Axial fluid-attenuated inversion recovery (FLAIR) image and magnetic resonance spectroscopy (MRS) from an 18-year-old child with infiltrative glioma. The locations for which spectra are reconstructed are shown by the grid. (A) shows a typical MRS pattern of tumor with high choline (Cho) and creatine (CR) and low N-acetyl-aspartate (NAA), in contrast to (B), which depicts a typical MRS pattern from a normal brain with low Cho/CR and high NAA peak.

significantly from those at initial diagnosis, making MRS effective in helping to distinguish between tumor recurrence versus treatment-related changes. In most centers MRS is now a standard part of the initial evaluation of a lesion concerning for a primary brain tumor and often is added if there is ambiguity of tumor recurrence versus treatment-related changes.

Future directions include novel metabolic imaging using hyperpolarized  $^{13}\text{C}$  MR metabolic imaging. Hyperpolarized  $^{13}\text{C}$  MR metabolic imaging is a promising new technology that offers an exciting method of assessing *in vivo* metabolism, with a greater than 10,000-fold signal enhancement over conventional  $^{13}\text{C}$  MR methods. Preclinical studies of GBM xenograft tumors demonstrated that pyruvate can be used to monitor the rate and magnitude of conversion to lactate, which is elevated in tumors as a result of increased activity of the enzyme lactate dehydrogenase (LDH). Of particular interest is that reductions in the ratio of lactate/pyruvate can be observed in as little as 1 to 2 days after treatment with temozolomide (Park et al., 2014). This novel technology has been successfully applied to adult patients with prostate cancer, and is currently being evaluated in adult patients with glioblastoma.

### Perfusion Magnetic Resonance Imaging

Perfusion MRI is a relatively new technology that provides information on cerebral hemodynamic parameters such as relative cerebral blood volume (rCBV) and cerebral blood flow (CBF). Perfusion MR studies can be obtained using either endogenous (arterial water) or exogenous (gadolinium) contrast agents (Cha et al., 2002). Imaging with dynamic susceptibility contrast (DSC) perfusion MRI is based on the principles of tracer kinetic modeling to determine the cerebral microvasculature and is one of the most commonly used techniques for perfusion quantification. The basic principle of perfusion MRI exploits the signal changes during bolus passage of a contrast agent through the cerebral vessels, and these values are then used to generate perfusion maps of various hemodynamic parameters.

Clinical applications for DSC perfusion MRI include grading of brain tumors, guiding biopsies, distinguishing therapy-related brain injury from residual or recurrent tumor, and predicting clinical outcome. Recently, perfusion MRI technology has also been assessed to predict survival in response to antiangiogenic therapy. Dedicated pediatric studies have shown that this technique can be successfully applied to children with high-grade tumors. However, DSC perfusion MRI results should be interpreted with caution in heterogeneous tumors because cCBV can vary depending on the location. A region of interest placed in an area of necrosis or more benign portion of the brain tumor could erroneously underestimate rCBV and result in undergrading of tumor. Alternatively, cortically based neoplasms that are contiguous with the brain surface vessels may be falsely given a higher grade as a result of a high rCBV from a region of interest placed over vessels.

## THERAPY

### Current Therapy

Despite many efforts, the outcome for children with HGGs is dismal and has remained virtually unchanged over recent decades. Age younger than 3 years, radical resection, WHO grade III histology, and presence of IDH1 mutations are factors associated with longer survival. External beam radiation therapy (RT) remains the mainstay of adjuvant therapy for HGGs. Currently, three-dimensional conformal radiotherapy (3D-CRT) or intensity-modulated radiation therapy (IMRT) is used at most centers, with 5400 to 594 cGy administered in approximately 30 fractions.

Single-agent temozolomide, considered the standard of care (SOC) for adult GBM, did not improve outcome for children with HGGs compared with historical controls (study ACNS0126). The most recent Children's Oncology Group HGG study, ACNS0822, compared two combined-modality experimental arms that included either vorinostat or bevacizumab with "standard" therapy (i.e., combined modality that included temozolomide). This study was recently closed after interim analysis showed that the predefined endpoint (i.e., improved 1-year event-free survival compared with standard therapy) could not be met (M. Fouladi, personal communication). In the setting of the recent disappointing results of upfront therapy with bevacizumab in adults and the lack of efficacy of bevacizumab-containing regimens in children with recurrent HGGs, bevacizumab is unlikely to play a substantial role in future pediatric HGG trials.

Because no studies have compared RT alone versus RT and chemotherapy in a randomized fashion in pediatric HGGs, it remains unproven whether adding adjuvant chemotherapy of any type is superior to RT alone in this population. Nevertheless, given the lack of proven superiority of any one chemotherapy regimen, most practitioners currently treat pediatric patients with newly diagnosed nonbrainstem HGGs with adjuvant temozolomide.

Given the histologic and biologic heterogeneity of pediatric HGGs, and in some cases the difficulty in differentiating HGGs from other entities on a histologic basis alone, the lack of molecular profiling data in all of the published prospective pediatric HGG studies to date leaves significant uncertainty surrounding the "long-term survivors" and the biology of their disease.

A recently published, and clinically well-annotated, study of a uniformly treated retrospective cohort of pediatric patients with tumors that met histologic criteria of GBM has provided key insights into the molecular heterogeneity of pediatric GBM and striking differences in outcome among them. Patients younger than 3 years of age were treated according to the "Baby-POG" chemotherapy protocol, whereas older patients received chemotherapy and RT, including temozolomide. Based on genome-wide methylation profiling signatures, major subgroups with highly divergent outcome emerged: (1) "LGG-like" tumors and "IDH" mutant tumors with favorable outcome (3-year overall survival [OS] of 91% and 90%, respectively), "PXA-like" tumors with intermediate outcome (3-year OS of 70%), and "GBM" with poor outcome (3-year OS < 20%). Among the GBM subgroup, a high-risk population was identified that included patients whose tumors harbored either K27M mutations or any amplifications of known oncogenes, such as *EGFR*, *PDGFRA*, and *MYCN*. Interestingly, patients in the subset of "long-term survivors" (OS > 36 months) were highly enriched in IDH mutant tumors and G34 mutant tumors without oncogene amplification. K27M mutant GBM had a dismal outcome nearly identical to that of DIPGs, and the fact that nearly all tumors were MGMT promoter nonmethylated provides a biologic explanation for the failure of temozolomide and other alkylator-based chemotherapy in prior DIPG trials. The G34 mutant subset had frequent MGMT promoter methylation, which may explain the more favorable outcome with alkylator-based therapy.

## FUTURE DIRECTIONS

### Targeted Therapies for Children With High-Grade Gliomas

As outlined previously, current treatment strategies do not lead to acceptable clinical outcomes for children with HGGs, and with the exceptions of surgical resection and focal

radiation therapy, there is currently no established SOC. Children with HGGs are usually enrolled in an investigational trial as first-line therapy. Many of the agents being evaluated in clinical trials are chosen empirically, and, not surprisingly, there has been little progress in improving outcomes over the last decades. Presently, there is no validated mechanism to prioritize treatment recommendations for an individual patient with pediatric HGG. We now understand that there are significant biologic differences between adult and pediatric malignant gliomas and differences based on tumor location (Wu et al., 2014). These findings highlight that treatment needs to be tailored to each individual child's tumor.

Individualized treatment based on single-gene expression or mutation has proven to be an effective strategy in multiple cancer types. For children with HGGs, recent studies have shown that approximately 10% to 15% carry the BRAF-V600E mutation, a genetic alteration that is also shared with other tumor types, such as melanoma, thyroid cancer, and colon cancer. There are now several specific BRAF-V600E inhibitors in clinical use, and individual case reports are encouraging regarding the clinical response of pediatric BRAF-V600E-mutated tumors to such targeted therapy. The Pacific Pediatric Neuro-Oncology Consortium (PNOC) is currently conducting a phase I clinical trial of the specific BRAF-V600E inhibitor vemurafenib in children with BRAF-V600E-mutated gliomas.

With advances in bioinformatics and molecular technologies, such as shortened turnaround times for whole-genome sequencing (WGS), combined with our expanding knowledge of molecular networks and mechanisms of action of the existing pharmacopeia (drugs approved by the U.S. Food and Drug Administration [FDA]), strategies using more in-depth profiling of the tumor to guide therapy are slowly entering the clinic, including for children with HGGs (clinical trials NCT02274987, NCT02060890, and NCT02162732). Molecular profiling has provided clinical benefit for patients with various advanced adult cancers, but the clinical benefit derived from such analyses remains unknown in the pediatric population. One of the major challenges in the application of precision medicine remains the classification and prioritization of identified variants by genomic analyses and possible association with drug response. But despite the ongoing challenges, this strategy opens an exciting new area for the treating neurooncologist when therapy is informed by the individual characteristics of the child's tumor. Results of these ongoing precision medicine trials will be critical to inform how this approach can be integrated in the care of children with HGGs.

## CNS-Directed Delivery Strategies

A fundamental limitation in the treatment of children with HGGs is that most therapeutic agents do not cross the blood-brain barrier (BBB) and blood-tumor barrier (BTB), and therefore never reach the tumor target. Several delivery strategies have been explored to overcome the BBB and BTB, of which convection-enhanced delivery (CED) and intranasal delivery show promise and have already entered the clinic.

### Convection-Enhanced Delivery

CED improves chemotherapeutic delivery to brain tumors intraparenchymally by utilizing bulk flow, or fluid convection, established as a result of a pressure gradient, rather than a concentration gradient. The advantages of CED over diffusion based delivery include (1) an expanded volume of distribution (Vd), (2) a uniform concentration of the infused therapeutic within the target Vd, and (3) the delivery of the vast majority of the infused therapeutic within the target volume. Additionally, CED obviates the challenges of systemic agents

crossing the BBB and BTB while minimizing systemic exposure and toxicity. A major advance in the safe and potentially efficacious use of CED in neurosurgery has been the development of real-time convective delivery (RCD), which utilizes MRI to visualize the CED process with the aid of coconvected contrast agents (Krauze et al., 2008). The use of RCD allows physicians to directly monitor the distribution of therapeutics within the brain. Thus, reflux along the CED catheter or leakage outside the target area, especially at higher flow rates, can be monitored and corrective steps taken, such as retargeting the catheter or altering the rate of infusion.

CED of carmustine has shown to prolong survival in mice with brainstem tumors, and other studies have shown that CED of nanoliposomal irinotecan is superior compared with intravenous administration in an orthotopic model of HGG. A feasibility study using coinjected imaging tracers with interleukin-13-*Pseudomonas* exotoxin in children with DIPGs has shown that with use of CED, clinically relevant distributions of agents can be achieved in humans. An ongoing clinical trial is currently investigating the feasibility of CED of <sup>125</sup>I-8H9, a radiolabeled antibody, in children with DIPGs (NCT01502917).

### Intranasal Delivery

Intranasal delivery is a noninvasive method of bypassing the BBB and BTB, and studies have shown that intranasal delivery of an antisense oligonucleotide-targeting telomerase (GRN163) inhibits orthotopic brain tumor growth and significantly prolongs survival in vivo (Hashizume et al., 2008). Other studies have supported intranasal delivery strategies in animal studies using different agents, such as insulin-like growth factor 1, interferon beta, and methotrexate. Intranasal delivery strategies have already entered the clinic for patients with neurodegenerative diseases and have been tested in adult patients with recurrent GBM. For example, intranasal administration of perillyl alcohol in adult patients with recurrent GBM showed good tolerability and regression of tumor size in some patients. Intranasal delivery is an attractive delivery strategy for long-term administration of therapeutics and is especially well suited for children because of the noninvasive nature of the procedure.

## INTRODUCTION

Pediatric low-grade glioma (PLGG) represents the most common brain tumor in childhood and constitutes more than 20% of primary brain tumors in children. Most PLGGs occur in the cerebellum, visual pathways, and diencephalon and comprise a histologically diverse and biologically heterogeneous group of neoplasms. Many low-grade gliomas (LGGs) have defined borders and are amenable to complete surgical resection, with excellent overall survival when treated with surgery alone. However, some LGGs are either invasive to critical structures or located in inaccessible regions, and are thus not amenable to surgical resection. Historically, these tumors were treated with radiotherapy, but in the last three decades, chemotherapy has become increasingly common as the initial postsurgical intervention. The goal of chemotherapy is to both to overcome residual or recurrent disease, and to minimize the toxicity associated with radiation therapy. Although radiation therapy may ultimately be necessary, the current practice among physicians who treat children with brain tumors generally aims to delay cranial irradiation until multiple attempts at other therapies have failed. There have been significant advances in our understanding of the molecular underpinnings of LGGs, which provide compelling preclinical evidence that targeted treatments directed at critical points along the molecular signaling pathways may be a successful approach to management. This chapter reviews the classification, clinical and pathologic features, molecular biology, and current standard and experimental therapeutic strategies for these tumors.

The incidence of LGGs in the United States approximates 2 per 100,000 persons aged 0 to 19 years of age (SEER Program, 2012; Ostrom et al., 2014). The majority of PLGGs arise sporadically; however, they can be associated with an underlying familial cancer predisposition syndrome or neurocutaneous syndromes. For example, children with a diagnosis of neurofibromatosis type 1 (NF1) are at increased risk to develop an LGG involving the visual pathway, which is found in 15% to 20% of children with NF1 and children with tuberous sclerosis complex (TSC) have a higher incidence of subependymal giant cell astrocytoma (SEGA), a subtype of LGG (Listernick et al., 1997; Gutmann, 2014).

## CLINICAL PRESENTATION

PLGGs typically are slow-growing tumors, and the clinical presentation depends largely on the tumor location and age of the patient. Symptoms result because of either invasion into the surrounding brain parenchyma, local compression of brain tissue, or generalized increased intracranial pressure (ICP). Children can present with focal or diffuse signs and/or symptoms, or a combination of both (Table 127-1). Generalized increased ICP can result in headaches, vomiting, irritability, and behavioral symptoms that are very different from a child's usual demeanor. Tumors in eloquent regions of the brain often produce focal neurologic signs and symptoms reflecting the anatomic function of the involvement. Older

children aware of their visual and motor function are more likely to communicate these symptoms. For example, cerebellar tumors will present with progressive gait changes, ataxia, and/or nystagmus. Tumors within the optic pathway often present with loss of visual acuity, changes in visual fields, hormonal abnormalities, and/or behavioral changes. Lesions within the brainstem typically cause the combination of progressive cranial nerve palsies such as bulbar dysfunction, upper motor neuron signs such as contralateral hyperreflexia or weakness, and ipsilateral ataxia. Supratentorial hemispheric lesions often present with localizing signs that include hemiparesis or seizures. Seizures are more common with tumors involving the temporal lobe, especially mesial structures and the frontal lobe. Seizures with LGG typically have a focal onset but may quickly generalize and thus appear as a generalized seizure from onset. Last, tumors in the region of the pineal gland, including the posterior third ventricle, or with mass effect compressing the nearby tectal plate, may lead to Parinaud syndrome, which is the triad of upgaze paresis, pupillary dilation with poor or absent response to light, and retraction convergence nystagmus.

Slow-growing, space-occupying lesions often result in poorly localizable symptoms. In general, these symptoms are a result of increased ICP caused by disruption of CSF pathways and resulting hydrocephalus, and lead to a combination of headaches, lethargy, and vomiting. Nausea resulting from increased ICP is often position sensitive and is accompanied by other neurologic symptoms. At times, persistent increased ICP can produce irritability, uncharacteristic behavioral changes, and progressive cognitive dysfunction. In young infants with an open fontanelle, increased head circumference may be the first manifestation of hydrocephalus. Infants may also demonstrate stagnation of development, irritability, failure to thrive, and the "sun-setting sign," where the gaze is in a near-fixed downward position, and so the sclera above the iris is visible.

## CLASSIFICATION AND HISTOLOGIC FEATURES

Gliomas are among the most diverse histologic group of brain tumors affecting children and the term LGGs refer to those tumors classified by the World Health Organization (WHO) system as grade I or II gliomas, and can be divided into several distinct entities based on both the dominant cell type observed histologically and by location (Table 127-2). Approximately 15% to 25% of all pediatric brain tumors are grade I juvenile pilocytic astrocytomas of the cerebellum, followed by grade II LGG of the cerebellum (10% to 15%), deep midline structures (10% to 15%), and grade I and II LGGs of the optic nerves and visual pathways (5%) (Bandopadhyay et al., 2014).

### Pilocytic Astrocytoma (WHO Grade I)

Pilocytic astrocytomas are the second most common brain tumors, with the embryonal neoplasms (primarily medulloblastomas) the most common brain tumor in children. These tumors are considered histologically benign. Histologic

**TABLE 127-1** Clinical Presentation of Primary Brain Tumors in Children

Focal Symptoms	Diffuse Symptoms
Seizures	Headache
Ataxia	Neck stiffness
Hemiparesis or weakness	
Nystagmus	Vomiting
Cranial nerve palsies	Lethargy
Focal sensory changes	Cognitive deterioration
Decreased visual acuity/visual fields	Behavior change
Parinaud syndrome	
Diabetes insipidus	Seizure
Growth retardation	Irritability
Aphasia	Infants: increased head circumference, split sutures, Bulging fontanelle, "setting-sun" sign

**TABLE 127-2** Classification of Pediatric Low-Grade Glioma (Based on World Health Organization 2007 Central Nervous System Classification)

Tumor Subtype	Tumor Grade
Astrocytic tumors	
Subependymal giant cell astrocytoma	I
Pilocytic astrocytoma	I
Pilomyxoid astrocytoma	II
Diffuse astrocytoma	II
Pleomorphic xanthroastrocytoma	II
Protoplasmic astrocytoma	II
Oligodendroglial and oligoastrocytic tumors	
Oligodendroglioma	II
Oligoastrocytoma	II
Neuronal and mixed neuronal-gliial	
Ganglioglioma	I
Desmoplastic infantile ganglioglioma	I
Dysembryoplastic neuroepithelial tumor	I
Central neurocytoma	II

characteristics include well-differentiated astrocytes, with Rosenthal fibers and eosinophilic granular bodies as the characteristic findings in these tumors, but usually without any cellular atypia. Cystic formations are common, and in some cases, the majority of the tumor volume is a cyst. The goal of surgery is complete resection, typically with minimal or no sequelae. Survival with this histology is excellent overall, with 1-year and 10-year survival of 98.6% and 95.8%, respectively.

### Pilomyxoid Astrocytoma (WHO Grade II)

Pilomyxoid astrocytomas are grade II neoplasms most often located in the hypothalamic and nearby midline regions, and occur in younger children (typically less than 1 year old). Pathologically, these tumors are closely related to pilocytic astrocytoma with bipolar cells within a myxoid matrix, but

lack the Rosenthal fibers and eosinophilic granular bodies. A less favorable subset is represented by young children who present with *hypothalamic syndrome*, also known as *diencephalic syndrome*, a distinct clinical phenotype that includes normal or excessive food consumption with failure to gain weight. There is a worse overall prognosis in this tumor subtype, and in one report, the 1-year progression-free survival was only 37.8%; of the total cohort, 6/18 patients had died.

### Dysembryoplastic Neuroepithelial Tumor (WHO Grade I)

Dysembryoplastic neuroepithelial tumors are usually cortical tumors that usually present with refractory seizures, often without other neurologic signs. Pathologically, this neoplasm is composed of glial nodules, with associated cortical dysplasia and glioneuronal elements. In many cases these tumors are small and are amenable to complete surgical resection, which often effectively treats the epilepsy. Because of the cortical location, however, gross total resection (GTR) may be challenging. In general, these tumors have a low recurrence rate after surgery and despite incomplete resection, sometimes the remaining tumor does not grow.

### Ganglioglioma (WHO Grade I)

The ganglioglioma is a grade II neoplasm consisting of mixed neuronal and glial elements with mature ganglion cells and abnormal glial cells. These are most frequently located in the temporal lobes, present around 10 years of age, and typically present with seizures. As with DNETs, these tumors are most often completely resectable with a favorable prognosis.

### Pleomorphic Xanthroastrocytoma (WHO Grade II)

Pleomorphic xanthroastrocytomas occur most commonly in teenagers and young adults, and usually involves the cortex, especially the temporal lobes. These tumors were once classified as a giant cell glioblastoma. They are cellular tumors with more nuclear atypia than other LGGs, and can be misdiagnosed as high-grade gliomas. Many of these tumors have clear borders and are amenable to gross-total resection, with a favorable prognosis.

### Diffuse Fibrillary Astrocytoma

Diffuse fibrillary astrocytomas are a WHO grade II neoplasm and can be morphologically similar to their adult counterparts. They occur most commonly in the supratentorial space, deep midline structures, and lower brainstem. Microscopically, they are characterized by modest cellularity, lack of significant mitoses, and presence of both fine and coarse neuroglial fibrils that form a matrix between the cells. These tumors, because of their infiltrating nature, are more difficult to resect completely and have a less favorable outcome than pilocytic astrocytoma. Over time, these tumors can transform into malignant gliomas. Recent data suggest that these tumors are similar to their adult counterparts in terms of pathologic appearance, but have distinct genetic molecular alterations.

### Pediatric Low-Grade Glioma; Not Otherwise Specified

As many as one quarter of PLGGs may not fit into a particular WHO LGG subtype classification and are designated as pediatric LGG; not otherwise specified (PLGG, NOS). This category

includes tumors that have not been biopsied and then are designated also by the site of origin, such as the optic glioma, which accounts for 3% to 5% of all childhood brain tumors. These tumors can be located anywhere along the visual pathway, including the optic nerve, optic chiasm, optic tract, and optic radiations and often involve the hypothalamus, and the terms *visual pathway glioma*, *optic pathway glioma*, or *hypothalamic-chiasmatic glioma* may be more fitting. Approximately 15% to 20% of children with NF1 have an optic glioma as seen on imaging, although only one fifth of these children require treatment; this treatment is typically initiated when a change in visual acuity or change in visual function occurs, and not because of incremental growth of the mass. Because of the distinct clinical phenotype and tumor location, a surgical biopsy is typically not required to make the diagnosis. In general, in the absence of any signs of progressive neurologic dysfunction or vision loss (e.g., absence of optic nerve pallor, loss of visual acuity, or visual fields), clinical observation with serial ophthalmologic assessments and neuroimaging studies is generally recommended.

## EVALUATION, DIAGNOSIS, AND MANAGEMENT

The diagnosis of an LGG is likely when characteristic neuroimaging findings are seen during the evaluation of a neurologic disturbance such as a seizure or motor dysfunction. PLGGs tend to be isodense or hyperdense on CT, with varying degrees of cystic changes and contrast enhancement. The solid portion of pilocytic astrocytoma enhances vividly with contrast, which should not be mistaken as a sign of a malignant or high-grade nature. Less malignant tumors tend to have a more focal appearance with variable enhancement, with the lowest grade neoplasms demonstrating more confluent enhancement patterns or no enhancement at all. In contrast to higher grade tumors, PLGGs are not typically accompanied by mass effect, edema, or restricted diffusivity. Pilocytic astrocytomas may demonstrate a classical cyst with a mural nodule. The mural nodule may be quite small, and in some instances only the wall of the cyst demonstrates enhancement. Postoperative MRI is suggested, preferably within a day or so from the time of initial surgical resection, to adequately assess extent of surgical resection. After a GTR, these tumors seldom recur, with a survival approaching 100% at 5 years in many series. If the tumor does recur, subsequent attempts at GTR are usually attempted. Some of these tumors may extend into the brainstem and are therefore less amenable to surgical resection. Although these are typically considered "benign" tumors, they may be accompanied by metastatic foci of tumor; this is particularly true for suprasellar tumors in infants and young children.

Depending on the tumor location, other assessments may be needed. An ophthalmologic evaluation and testing of endocrine function are needed for tumors located along the visual pathway and hypothalamic region. Children should be examined for neurocutaneous stigmata of NF1 and TSC. Electroencephalogram may be helpful at diagnosis or any time if there is a question of seizures. Because many of these tumors will affect higher cortical function, including those located in the posterior fossa, all children should have a neuropsychological assessment near the beginning of their illness, at the conclusion of primary therapy and at points post-therapy if educational, social, or employment issues arise.

## DIFFERENTIAL DIAGNOSIS

LGGs must be distinguished from other lesions, such as (1) "high-grade" gliomas, including anaplastic astrocytoma, glioblastoma multiforme, and anaplastic oligodendroglioma; (2)

other brain neoplasms; (3) nonneoplastic lesions, including infarction; (4) inflammation; and (5) cerebritis/encephalitis, acute demyelinating encephalitis, and antibody-mediated encephalitis (such as NMDA-receptor encephalitis). Occasionally, a large area of focal demyelination can demonstrate mass effect and resemble a glioma. Tumorifactive multiple sclerosis is an aggressive form of multiple sclerosis in which the lesion mimics a brain neoplasm, often accompanied by mass effect and contrast enhancement. None of these entities has a pathognomonic clinical or radiographic presentation, and so histologic, antibody, or other biomarker diagnosis is required.

## PATHOGENESIS

Intensive efforts to elucidate the genetic underpinnings of PLGGs are in progress. The gene *BRAF*, which is an oncogene linked to melanoma and some carcinomas, functions to upregulate the RAS/RAR/MEK pathway. Genetic rearrangements, typically duplications and rearrangements, are the most common genetic finding in sporadic PLGGs, and are found in 50% to 100% of pediatric pilocytic astrocytoma. These duplications, however, are not typically identified in NF1-associated LGGs or other PLGGs, which, by contrast, often demonstrate an abnormal gain of function or duplication in the MAP-kinase signaling pathway, with the implication that targeted therapies could be developed along this pathway. Investigation as to environmental impact on LGG occurrence has not been informative.

## TREATMENT

Because of the excellent overall prognosis of PLGGs, the goals of therapy must take into account the dual aims of tumor control and reduction of treatment/tumor-associated morbidity. In some children, especially in NF1, PLGGs are found incidentally and may not be causing any acute symptoms, and do not require tumor-directed therapy. In general, treatment approaches include observation, surgery, chemotherapy, and cranial irradiation.

## Surgery

Surgery is the mainstay of treatment for many PLGGs. Surgery provides tissue for histopathologic interpretation and molecular characterization. When possible, a gross total or complete resection should be considered, as this is often curative. When a GTR is not safe to perform, removal of some or most of the tumor often provides a therapeutic benefit. The tumor location typically determines the extent of surgical resection; tumors in surgically accessible areas such as the cerebellum or noneloquent cortex can often be excised without sequela. A report from a large cooperative group supported the postulate that the extent of tumor resection is the most significant factor associated with favorable outcome. In children with LGGs who had undergone GTR, the 5-year progression-free survival is about 90%, whereas more than half of children with subtotal resection had disease recurrence during that interval (Wisoff et al., 2011). However, progressive disease or relapse is not indicative of an overall poor prognosis. An analysis of over 4000 children with PLGG showed no overall survival advantage in those children with an initial GTR compared with children not having a complete resection. The 20-year overall survival in this subset of patients was  $87\% \pm 0.8\%$ , with deaths attributable to the glioma at  $12\% \pm 0.8\%$ . The risks of permanent surgical morbidity need to be considered when approaching the goal of complete resection, and if the risk is above minimal, the prognostic data for overall survival favor a less aggressive surgical approach.

## Chemotherapy

Many LGGs, especially those located in the optic pathway, brainstem, and other cerebral midline structures may not be amenable to surgery or GTR, and adjuvant therapy is used to achieve tumor control and prolong survival. The successful use of chemotherapy before radiotherapy, both at initial diagnosis and recurrence, demonstrated the efficacy of chemotherapy, which can delay or completely avoid the need for subsequent cranial irradiation. Studies conducted since the 1980s have demonstrated that chemotherapy is an effective mode of treatment to achieve disease stability, either when GTR is not possible or cannot be safely achieved, or when these tumors become symptomatic with regrowth (Ater et al., 2012). Standard chemotherapy is administered for approximately 1 year;

however, chemotherapy can be halted a cycle or two after maximum therapeutic effect is confirmed by imaging or when dose-limiting toxicity occurs. Some patients may progress during or after completion of chemotherapy, and require one or more additional treatment regimens at time of tumor recurrence (Figs. 127-1 and 127-2). Although there is no standard of care, most pediatric neuro-oncologists advise using several chemotherapy regimens before proceeding with radiotherapy. Progression-free survival for most chemotherapeutic regimens tested is typically in the range of 30% to 40% at 5 years.

There are several chemotherapy regimens used to treat PLGG. The combination of vincristine and carboplatin (CV), administered weekly, has been used since the late 1980s, as well as the combination of thioguanine, procarbazine, dibromodulcitol, lomustine, and vincristine (referred to as TPDCV),

**Figure 127-1.** a, b, FLAIR (left) and T1 gadolinium-enhanced (right) images from a 19-year-old male who was diagnosed initially at 11 months of life after a single seizure with a low-grade astrocytoma. After a gross-total resection he was stable for 4 years and experienced subsequent tumor progression. Follow-up treatments included resection and three different chemotherapeutic regimens. After cystic progression, his imaging has remained stable at 5 years. FLAIR imaging demonstrates multiple cysts (curved red arc shows one hyperintense cyst). After administration of gadolinium, multiple solid enhancing nodules are visible (one is marked by an arrow on both images). He is currently a college student with a normal neurologic exam.

**Figure 127-2.** A 20-year-old man diagnosed at age 6 years with a left temporal lobe astrocytoma. He has experienced nine recurrences, and treated with two additional surgeries, cranial irradiation, and five different chemotherapy regimens at time of relapse or progression. He developed severe myelodysplastic syndrome preventing further treatment with cytotoxic agents. FLAIR image demonstrates increased signal surrounding tumor resection bed (shown only in left image with arrows). The corresponding gadolinium-enhanced images demonstrate several small enhancing nodules (not shown). His examination demonstrates mild cognitive impairment with speech difficulties and a mild right hemiparesis.

and when dibromodulcitol became unavailable, TPCV. A randomized study comparing these two regimens was conducted through the Children's Oncology Group in 274 children with newly diagnosed grade 1 or grade 2 LGG having less than a 95% resection, residual tumor measuring more than 1.5 cm<sup>2</sup>, or radiographically progressing tumors after surgery. There were 137 children in each treatment arm and overall results in the combined groups showed a 45% ± 3.2% 5-year event-free survival and a 86% ± 2.2% 5-year overall survival. The difference in the two treatment arms was not significant (stratified log-rank  $p = 0.1$ ). The 5-year event-free survival in those treated with TPCV was 52% ± 5% and in those treated with carboplatin–vincristine, 39% ± 4%. The 5-year overall survival was essentially identical showing 86% ± 3% for those treated with CV and 87% ± 7% for those treated with TPCV (log-rank  $p = 0.52$ ). This report added several details that add clarity to the understanding of how location, pathology, and extent of resection affect outcome. The 5-year event-free survival (and overall survival) for pilocytic astrocytoma was 49% ± 6% (88% ± 4%), for hypothalamic/optic chiasmal tumors was 44% ± 5% (87% ± 3%), and for fibrillary astrocytoma was 34% ± 10% (79% ± 8%). The relative risk for progression or relapse was 0.65 times lower (95% CI, 0.44–0.97) in children with tumor volume (after surgery is performed) of less than 3.0 cm<sup>2</sup> than in patients with a residual tumor of greater than or equal to 3.0 cm<sup>2</sup>. Independent factors associated with overall survival included age at diagnosis, tumor site, and amount of residual tumor. The risk of secondary neoplasm caused by the use of the alkylating agents in the TPCV treatment arm has been a source of ongoing concern, but in this trial only one patient developed leukemia. The issue of secondary neoplasms caused by alkylating therapy remains a concern, especially in children with NF1, who have an underlying tumor suppressor inactivating syndrome and a higher risk for development of leukemia and who therefore should avoid the use of alkylating agents.

A number of other chemotherapy-based treatments have been explored, including vinblastine; tamoxifen and carboplatin; cisplatin and etoposide; temozolomide; bevacizumab and irinotecan; carboplatin, vincristine, and temozolomide; and procarbazine, carboplatin, vincristine, etoposide, cisplatin, and cyclophosphamide. Some of these regimens have been studied primarily in the immediate postoperative period, but have not demonstrated added therapeutic advantages over the more conventional initial therapies such as CV or TPCV. These treatment regimens, however, are an important part of the armamentarium, as they are useful in the setting of the multiply relapsed patient (see Figs. 127-1 and 127-2).

Progression or relapse after any initial treatment is common, and additional therapy is required. This treatment may include surgery aimed at further debulking of the recurrent tumor or to drain tumor-associated cysts. In most circumstances, when a child has been treated with chemotherapy, s/he will be treated with a subsequent, typically different, chemotherapy regimen. This approach to treatment with several different chemotherapy regimens will be repeated until the child is free of progressive disease or until such a decision is made to proceed with radiation.

## Radiation Therapy

Although radiotherapy was the earliest treatment approach used after incomplete resection or at the time of tumor recurrence, the data supporting its use as an immediate postsurgical treatment for residual disease are not clear, with conflicting data regarding any benefit for progression-free survival. Radiotherapy has not been shown to improve overall survival. Currently irradiation is typically reserved for those children who

have no remaining surgical or chemotherapeutic options. Irradiation is generally avoided in young children because of concern for the long-term risks of cognitive effects, secondary radiation-related tumors, vasculopathy, and endocrine dysfunction (Ullrich, 2009; Armstrong et al., 2011).

The duration of disease control after radiation therapy is similar to that of chemotherapy. Because controlled trials randomizing children to receive radiotherapy versus chemotherapy (or observation) after maximal surgery have not been performed, and initial treatment paradigms have not stratified randomized treatments to GTR versus subtotal surgical resections, it is not possible to draw any definitive conclusions about the comparative efficacy of radiotherapy or chemotherapy.

The use of newer radiotherapy techniques permits delivery of the ionizing radiation to a smaller brain volume, which can often avoid or lessen the injury to eloquent brain regions. These techniques include three-dimensional conformal techniques, the use of nonparallel rotating photon arcs, intensity-modulated radiotherapy, and proton beam irradiation.

## SUPPORTIVE CARE

### Seizures

Seizures follow headache as the most common presenting symptom in supratentorial tumors in childhood and the prevalence may be as high as 75% in children with LGG. The wide variation is in part that some centers have concentrated efforts in the surgical management of epilepsy, and therefore there is a referral bias in the evaluation of patients with both seizure and brain tumor.

## GENETIC FEATURES OF PEDIATRIC LOW-GRADE GLIOMA

Years before there was any clear understanding of the molecular genetics of brain tumors, the observation was made that visual pathway gliomas occurred in NF1 at a rate of about 4000-fold greater than in the general population. The most common findings are a gain of chromosome 7 (most true for pilocytic astrocytomas), followed by gains of chromosomes 4, 5, 6, 8, and 11, and deletion of 17p or 1.q. This is quite different from adult LGGs such as oligodendroglioma, where the loss of 19q and 1p is most common. Mutations in *IDH1* and *IDH2*, common in adult gliomas, are rare in childhood gliomas. The mitogen-activated protein kinases (MAPK) and mTOR pathways were found to be activated in NF1, and known to be the major contributory pathway to the formation of LGG in NF1. Similarly, the mTOR pathway is dysregulated in tuberous sclerosis (Berghold et al., 2015).

## CURRENT CLINICAL TRIALS

### Targeting the RAS/MAP-Kinase Pathway

The majority of PLGGs have alterations of the RAS/MAP-kinase pathway. In NF1-associated LGG, this pathway is constitutively activated because of loss or altered function of neurofibromin. In non-NF1-associated PLGG, the most common alteration is a fusion and tandem duplication of BRAF with KIAA1659. This fusion results in a constitutively active BRAF. A group of diffuse astrocytomas has activating mutations of the *MYB* or *MYBL1* transcription factors and resulting MAP-kinase activation that is equivalent to that observed in BRAF-driven tumors. This suggests that MAP-kinase may also be a driver pathway in PLGG. The presence of common mutations provides a rational treatment target.

The BRAF inhibitor dabrafenib has been used in melanoma and is currently being investigated in a national pediatric phase I/II trial in patients with known BRAF tumors (NCT01677741). Development of more defined MAP-kinase pathway inhibitors has led to successful preclinical testing and currently a clinical trial of one such inhibitor, selumetinib, which appears to inhibit ERK phosphorylation, in patients with LGG (NCT01089101).

### mTOR Pathway Inhibition

Increased activation of the mTOR pathway has been well-defined in PLGGs as demonstrated by the success of rapamycin trials in treating subependymal giant cell astrocytomas. These results suggested that mTOR inhibitors might have activity in other PLGGs. A trial of everolimus in refractory/recurrent PLGG has recently completed enrollment (NCT00782626) as has a second phase II trial with larger numbers of patients (NCT01734512). Last, a separate study using everolimus in children with NF1-associated LGG has recently completed enrollment (NCT01158651).

### Antiangiogenic Therapy

There is increased expression of vascular growth factors in PLGG, suggesting that neovascularization may be a crucial step for continued growth stimulation in these tumors. The use of the VEGF inhibitor bevacizumab along with irinotecan resulted in radiologic and clinical responses in small numbers of children. Monotherapy with bevacizumab has also led to tumor regression and disease stability in some patients.

### Immunomodulatory Therapy

PLGGs contain characteristic mutations that are not found in nontumor cells, which raises the possibility of using these abnormal peptides as a target for therapy. Lenalidomide alters the immune environment and antiangiogenesis, with direct antitumor effects. Results from a phase I trial using lenalidomide demonstrated decreased tumor progression in PLGG. A phase II study is currently underway comparing two dose levels of lenalidomide (NCT01553149).

### OUTCOME

PLGGs are clinically and genetically different from LGGs in adulthood. One of the biggest distinctions is the response to chemotherapy and overall excellent overall survival. Results from the Surveillance, Epidemiology and End Results (SEER) database have provided important prognostic information about PLGGs.

Prognosis for children is excellent, with an overall survival at 30 years of 87%. This favorable survival is not intuitively expected because of the high rate of progressive disease, 5-year progression-free survival of 45%. Although the pilocytic astrocytoma is truly a benign neoplasm that can often be surgically cured with minimal surgical morbidity, this is not universally the case. Because of their location, tumors along the midline diencephalon with a similar histologic appearance often are not amenable to surgical resection. Patients with tumors in these locations often require multiple surgical interventions, repeated courses of chemotherapy, and, occasionally, irradiation. Children with tumors in these locations can experience significant tumor morbidity from the tumor and its treatments; therefore, although they are histologically consistent with LGG, they do not necessarily behave in a *benign* manner and patients can experience severe morbidity and/or mortality.

Ultimately, the genetic features of the tumor itself may direct therapy and correlate with outcome, but this hypothesis will be tested in future trials.

### CONCLUSIONS

PLGGs encompass several histologic subgroups of tumors. Most children with an LGG present with specific neurologic signs and symptoms, such as seizure or headaches. Optimal management is often guided by tumor location, size, and clinical presentation. Current management for most PLGGs includes consideration and attempt of a GTR. Survival in PLGG is generally very good, though this is influenced by degree of resection, age, and histologic classification. Current management of PLGGs continues to evolve, with advances in neurosurgical techniques, targeted chemotherapy, tailored radiation, and molecular biology discoveries, which will hopefully improve the overall quality of life and survival.

# 128 Diffuse Intrinsic Pontine Glioma

Nicholas A. Vitanza, Paul G. Fisher, and Michelle Monje Deisseroth

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## BACKGROUND

Since the initial report by Wilfred Harris and W.D. Newcomb nearly a century ago, the clinical outcome for children with diffuse intrinsic pontine gliomas (DIPG) has changed very little, and the 2-year overall survival remains less than 10%. As a biopsy was previously suspected to carry a significant morbidity, diagnosis over the past 2 decades has been made by magnetic resonance imaging (MRI), such that laboratory investigation has been hampered by a lack of surgical specimens. Although radiation therapy and oral steroids provide symptomatic relief and modestly prolong survival, the majority of patients survive less than a year from their onset of symptoms. However, armed with new molecular findings, made possible now through an increasing trend toward biopsy, autopsy tissue collection, and international collaboration to share these precious tissue resources, advances finally are being made against the most fatal childhood brain tumor.

## EPIDEMIOLOGY

DIPG affect 200 to 400 children in the United States each year, comprising approximately 10% to 15% of all pediatric central nervous system (CNS) tumors and 80% of brainstem gliomas. Peak incidence of DIPG occurs in middle childhood, with median age of diagnosis around age 7 years. Occasional cases have been reported in patients as young as 1 year or as old as 26 years, with an equal distribution between males and females.

## PRESENTATION AND DIAGNOSIS

The median duration of symptoms before diagnosis of a DIPG is 1 month and, although these can last for greater than a year in atypical cases, prodromes almost universally last for less than 6 months. On presentation, patients often display a classic triad of symptoms comprised of ataxia, cranial nerve palsies, and pyramidal tract signs. An abducens palsy, reflected in dysconjugate gaze and diplopia, is typically the first symptom, the most common symptom, and associated with a worse outcome. Facial nerve palsies, characterized by facial muscle weakness and asymmetry, are not uncommon. Patients with DIPG experience pyramidal tract dysfunction, resulting in weakness and hyperreflexia and can also experience dysuria, consistent with the location of the pontine micturition center. Pathologic laughter (pseudobulbar affect) can also be a symptom of patients with DIPG, including laughter as the presenting symptom, even during sleep. As these tumors frequently extend into the cerebellum at time of progression, patients often experience ataxia, dysarthria, or dysmetria. Less than 10% of patients also present with obstructive hydrocephalus due to dorsal extension of disease.

Until recently, DIPG were not routinely biopsied, and diagnosis relied upon neuroimaging. Zimmerman provided the initial radiologic description of brainstem gliomas and, although this has been built upon, there remains no formal

radiologic classification. However, DIPG share some typical characteristics on magnetic resonance imaging (MRI), including infiltration of the majority of the pons, hypointense to isointense signal on T1-weighted imaging, and hyperintensity on T2-weighted imaging and fluid-attenuated inversion recovery (FLAIR) (Fig. 128-1). Unlike pilocytic astrocytomas, DIPG are generally tumors that do not enhance with gadolinium contrast, except for areas of necrosis, and frequently engulf the basilar artery, which is a poor prognostic finding.

A history of symptoms greater than 6 months or atypical radiographic features should prompt evaluation of a broader differential, which would include pilocytic astrocytomas, primitive neuroectodermal tumors (PNET), or much less commonly demyelinating or vascular diseases of the brainstem. On MRI, the exophytic appearance, definitive borders, frequent mural nodule and cyst formation, and contrast enhancement can distinguish a pilocytic astrocytoma from a DIPG. The location is most frequently pontomidbrain, pontomedullary, or, less commonly, at the cervicomedullary junction and often present more indolently and have a higher association with neurofibromatosis type 1 (NF1). Histologically, pilocytic astrocytomas (WHO grade I) may display vascular proliferation and even several mitotic figures but will lack necrosis and invasion. PNET (WHO grade IV) on MRI is frequently heterogeneously enhancing with significant peritumoral edema. In up to 22% of cases, the postmortem diagnosis of PNET is made in tumors previously thought to be DIPG, though this percentage is certainly dropping with greater diagnostic techniques and better understanding of the distinct malignancies of the brainstem. Diffuse tensor imaging (DTI) fiber tracking can be used to differentiate between brainstem malignancies and demyelinating processes.

## PROGNOSIS

The natural course of a DIPG is swift and devastating, with a median survival of 4 months if radiation therapy is not delivered. With the advent of focal irradiation the progression free survival (PFS) has improved to 5 to 9 months with a median overall survival (OS) of only 8 to 11 months. A small subset of patients, constituting only 2% to 3%, are reported to achieve long-term survival and, though difficult to predict, may share atypical radiologic features. Otherwise, only approximately 30% of children survive beyond 1 year and less than 10% survive beyond 2 years.

## HISTOPATHOLOGY

The WHO grading system of diffuse, or fibrillary, astrocytomas fails to distinguish clinically significant subgroups in DIPG, which can be diffuse astrocytomas (WHO grade II), anaplastic astrocytomas (WHO grade III), or glioblastomas (WHO grade IV). In fact, WHO grading is not consistent between primary lesions and metastases, and it remains unknown if the grade II or III lesions for which later histology suggests grade IV underwent evolution or if there is simply an unreconciled

**Figure 128-1.** Diffuse Intrinsic Pontine Glioma (DIPG). Axial fluid-attenuated inversion recovery (FLAIR) MRI.

degree of tumor heterogeneity that breeds sampling error. There does, however, seem to be a correlation between increasing histologic grade and increasing age, although this has not been confirmed to be a truly developmental phenomenon. Regardless of grade II, III or IV histology, DIPG portends incredibly high mortality.

### EXTENT OF SPREAD

DIPGs can infiltrate beyond the pons, commonly extending into the middle cerebellar peduncles, thalami, basal ganglia, or directly into the supratentorium. Metastatic disease is also common; one recent series identified neuraxis dissemination detected by neuroimaging in 17.3% of patients, with a median time of 15 months to the development of metastases. Metastatic disease is likely to be even more common, as a recent autopsy series of patients with DIPG revealed 63% had developed extension into their midbrain and medulla, 63% in the subventricular zone of the lateral ventricles, 56% in the thalamus and/or cerebellum, and 25% in the frontal cortex (Caretta, et al., 2014). As chemotherapy is not curative for DIPG, assessing the tumor size and its change on serial MRI scans is highly important in clinical trials with any therapeutic agents. Although their poorly defined borders often lead to interobserver variability, both FLAIR sequences and volumetric methods based on region of interest (ROI) currently provide the greatest agreement between observers. Specific MRI sequences may also be useful in disease stratification, as both increased enhancement and decreased apparent diffusion coefficient (ADC) values, derived from diffusion-weighted imaging, may coincide with more aggressive disease. Although currently not routine, fluorodeoxyglucose positron emission (FDG-PET) uptake of greater than 50% at the primary site correlated with a decreased PFS and OS, and the majority of DIPG metastases are also FDG-PET positive.

Surgery had been generally deferred due to the impossibility of a gross total or meaningful subtotal resection of a lesion diffusely affecting the pons, potential morbidity associated with a biopsy, and the lack of clinical benefit to the patient in the majority of cases. Coinciding with the molecular revolution in childhood CNS tumors, there is a renewed interest in

obtaining tissue for laboratory investigation and for clinical testing of novel therapeutic agents. Advances in neurosurgery have allowed for relatively safe biopsy of DIPGs, even in typical-appearing cases, and in skilled hands the morbidities are most often transient though reported in 3.9% to 20% of patients. Biopsies are increasingly performed in the setting of clinical trials at specialized medical centers and should be performed to confirm diagnosis if features are nonclassical, such as a prodrome lasting greater than 6 months and/or atypical radiologic features. The greatest immediate clinical influence of doing a biopsy to the patient would be revealing a pilocytic astrocytoma (WHO grade I) or a nonastrocytic lesion, such as PNET, which alters both the treatment and the prognosis.

### DEVELOPMENTAL CONTEXT OF DIPG

The region-specific and age-specific nature of brainstem gliomas suggests that the underlying pathophysiology involves dysregulation of a postnatal neurodevelopmental process. Examination of normal human brainstem samples from all three brainstem regions—midbrain, pons, and medulla—in subjects aged 1 day to 19 years revealed a population of neural precursor cells, expressing the oligodendroglial lineage marker Olig2, restricted to the ventral brainstem. This precursor cell type, characterized by immunostaining for the primitive neural cell markers nestin, vimentin, and Olig2 and by a distinct morphology with long thin processes in a bipolar arrangement, is present in the ventral brainstem during infancy and then wanes by 2 years of age. In the human pons, this cell type again increases in density in middle childhood, peaking around age 6 (Monje, et al., 2011). This second peak in the ventral pontine precursor cell population corresponds strikingly with the incidence of DIPG, suggesting a candidate Olig2 + cell of origin for DIPG in the oligodendroglial lineage. In contrast, this cell type is conspicuously absent from the childhood midbrain, a region in which high-grade gliomas essentially never occur (Monje, et al., 2011). In a recent study incorporating MRI-based morphometric and histologic analyses, robust proliferation of Olig2 + progenitors and increased myelination of white matter tracts were found to accompany a striking postnatal volume expansion of the ventral pons observed from birth to middle childhood. A putative oligodendroglial lineage precursor cell of origin for DIPG fits well with observations of PDGFRA expression and signaling in DIPG cells (Monje, et al., 2011). Also consistent with the idea that DIPG originate from an Olig2 + neural precursor cell, analysis of postmortem DIPG specimens reveal that most express the markers Olig2 and/or Sox2 (Monje, et al., 2011; Ballester, et al., 2013).

### MOLECULAR CHARACTERISTICS OF DIPG

The molecular investigation of DIPG has been limited historically by the paucity of tissues samples; however, as more specimens have become available for molecular analyses, it has become clear that DIPGs and other pediatric high-grade glioma (HGG) are genomically distinct from adult HGG. The most revolutionary insight gleaned from whole exome and whole genome sequencing studies has been the recognition of specific mutations affecting genes encoding for histone H3 in pediatric HGG, with midline HGG (i.e., DIPG and thalamic HGG) exhibiting H3K27M mutations affecting the genes encoding either H3.3 or H3.1, and cortical HGG exhibiting H3K34R/V mutations (Khuong-Quang, et al., 2012; Wu, et al., 2012). In DIPG, about 80% of tumors exhibit this K27M mutation. H3.3K27M mutations tend to occur in conjunction with p53 aberrations, whereas H3.1K27M tends to coincide

with *ACVR1* activating mutations and occurs in patients who tend to be younger females (Taylor, et al., 2014). The substitution of methionine for lysine at position 27 of the histone 3 N-terminal tail results in pan-hypomethylation of K27 in all histone H3 variants, despite the fact that heterozygous mutation in one copy of a histone H3 gene (*H3F3A* for H3.3 or *Hist1H3B* for H3.1) accounts for only approximately 10% of total cellular histone H3 (Lewis, et al., 2013). This dominant effect of the mutant histone is due to “poisoning” of the *EZH2* methyltransferase by the methionine residue, which binds to *EZH2* and sequesters it at the mutant histone and suppresses the polycomb repressive complex 2 (*PRC2*), an epigenetic gene silencer. As a result of pan-cellular histone H3 hypomethylation, broad epigenetic dysregulation of gene expression occurs, resulting in a “K27M” gene expression signature exhibiting dysregulation of numerous oncogenic pathways (Chan, et al., 2013).

In terms of other genomic aberrations, DIPGs frequently display chromosomal aberrations with the most common gain being of 1q in 13% to 43% of cases and the most common loss being of 16q in about 25% of cases. Other common chromosomal gains include 2p, 2q, 8q, and 9q, while other common losses include 14q, 17p, and 20p. DIPG also exhibits inactivating mutations of *p53* (40% to 77%) and *PTEN* (10% to 54%), which are associated with a worse prognosis in pediatric HGG (Khuong-Quang, et al., 2012). Unlike adult HGG, DIPG does not harbor deletions of *CDKN2A/B*, but 30% will have gains in other cell-cycle regulatory components, such as *CDK4*, *CDK6*, of D-type cyclins. As noted previously, 24% of patients with DIPG harbor mutations in *ACVR1*, the gene encoding the receptor serine/threonine kinase *ALK2*, which occurs twice as commonly in female patients, is associated with a better overall survival, and occurs in the setting of histone H3.1 mutations (Fontebasso, et al., 2014; Taylor, et al., 2014; Wu, et al., 2014). Although *EGFR* amplifications appear infrequent, several series have shown a majority of pediatric DIPG exhibit immunopositivity for *EGFR*, though this may be tempered by the fact that *EGFR* expression can be induced by irradiation, which many of these patients received. Radiation treatment has been shown to correlate with *PDGFRA* expression, possibly explaining the variable frequency of *PDGFRA* expression, ranging from 15% to the majority of patients in varying studies (Khuong-Quang, et al., 2012). Interestingly, amplifications of *PDGFRA* and loss of *PTEN* appear mutually exclusive from *PI3KCA* mutations, although *PDGFRA* amplifications occur entirely in the setting of histone H3.3 mutations (Khuong-Quang, et al., 2012).

Aurora B, a cell-cycle regulatory kinase, has been shown to be overexpressed in two-thirds of DIPG. Aurora kinase B acts both by recruitment of checkpoint protein complexes and by phosphorylation of mitotic centromere-associated kinesin (*MCAK*), a controller of spindle microtubule-kinetochore attachments during mitosis. Furthermore, aurora kinases also phosphorylate histone H3, offering a layer of epigenetic control. Therefore as a high percentage of DIPG have cell-cycle dysregulation, either through deletion of *p53* or aberrant expression of other cell-cycle kinases or cyclins; the overexpression of aurora kinase B may contribute to either DIPG tumorigenesis or tumor maintenance. Several proteins have also been associated with DIPG, most interestingly clusterin, encoded by *CLU*, and talin 1, encoded by *TLN1*. Clusterin is a secreted chaperone protein associated with apoptosis and malignant transformation. Talin 1 is an actin binding protein, already suspected to promote cell migration and adhesion in gliomas, which is a proposed biomarker for colon cancer and whose loss of function increases chemotherapy sensitivity in resistant breast cancer.

Ultimately, DIPG likely are comprised of distinct molecular subgroups, differentiated by predominant molecular pathways, though current subgrouping proposals have limited power due to small numbers of samples (Buczkwicz, et al., 2014). There may be separate *MYCN* oncogene and hedgehog pathway groups, which form distinct clusters through mRNA expression profiling and can be regularly separated by immunohistochemistry as hedgehog pathway lesions demonstrate *PTCH1* positivity and *GLI1* nuclear expression. DIPG may also be divided into groups characterized by two smaller subgroups of *MYCN* overexpression and genetically stable lesions, as well as a third larger group with histone H3K27 mutations (Buczkwicz, et al., 2014). Interestingly, other midline gliomas, especially thalamic gliomas and WHO grade III and IV spinal cord gliomas, also display mutations in histone H3, suggesting potential benefit to classifying together as “diffuse midline gliomas, H3-K27M mutants” (Shankar, et al., 2016).

## CURRENT TREATMENT

The only treatment modality that has consistently prolonged survival in DIPG is radiation therapy (RT), most frequently delivered conformally to the tumor at 54 Gy divided in 1.8 Gy daily fractions over 6 weeks. Hyperfractionated RT at doses as high as 7800 cGy has been attempted with no improvement in survival and likely prolongation of steroid requirement. Hypofractionated RT of 39 Gy delivered over 13 fractions, however, appears to have comparable results to standard dosing and significantly decreased burden on patients and families, especially in the patient’s requiring sedation for their treatments. However, a further hypofractionated approach with an elevated daily dose of 5 Gy for 5 days increased necrosis and possibly shortened overall survival. Although many studies have examined the benefit of cytotoxic and myeloablative chemotherapy for patients with DIPG, no standard regimen extends overall survival. Chemotherapy during radiation therapy has not provided a clear benefit, as Pediatric Oncology Group’s POG 9239 trial of cisplatin during RT showed an unexpected worsening of outcome and radiosensitizing agents failed to prolong survival. The Istituto Nazionale dei Tumori in Milan, Italy, attempted multiple, ambitious treatment plans including: etoposide, cytarabine, ifosfamide, cisplatin, and dactinomycin given with RT in study 1; cisplatin, etoposide, vincristine, cyclophosphamide, high-dose methotrexate, and then autologous stem cell transplant after thiotepa, followed by RT and maintenance with vincristine and lomustine in study 2; cisplatin and vincristine along with isotretinoin and RT in study 3; and vinorelbine during RT in study 4. The 1- and 2-year OS were 43% and 21%, respectively, with no differences amongst studies and with the two long-term survivors never having biopsy confirmation. German trials using oral trofosfamide and etoposide (HIT-GBM-A), intravenous (IV) carboplatin, etoposide, and ifosfamide (HIT-GBM-B), and IV carboplatin, etoposide, ifosfamide, and vincristine (HIT-GBM-C) resulted in a 1- and 2-year OS of 39.9% and 9.2%, respectively. Intensive chemotherapy with tamoxifen, carmustine, cisplatin, and high-dose methotrexate with radiation given at time of progression had the greatest 1-year OS of 70% but showed no difference in long-term OS, and the average length of stay for chemotherapy and/or complications was 43 days. Temozolomide also has not improved outcomes in either conventional or metronomic dosing. Several phase I studies utilizing more targeted agents, including imatinib, erlotinib, tipifarnib, and vandetanib, have been completed and patients enrolled in a phase II study of gefitinib, an *EGFR*-inhibitor, by the Pediatric Brain Tumor Consortium (PBTC) had 1- and 2-year OS of 56.4% and 19.6% OS, respectively.

## EMERGING THERAPEUTIC STRATEGIES

Although the aberrant genetic signature produced by histone H3 mutations—also found in other pediatric HGG and a subgroup of posterior fossa ependymomas (PFA-CIMP +)—may share some of the responsibility for radiation resistance and poor prognosis, it may also provide actionable targets with epigenetic agents. JMJD3 and UTX, two histone H3K27 demethylases, may also be targeted in order to restore methylation to H3K27 to the nonmutant histones in the cell. GSKJ4, a selective histone demethylase inhibitor, has already been shown to inhibit JMJD3, increase H3K27me3 levels, and subsequently extend survival in H3K27M-mutant orthotopic xenograft brainstem tumor models. Therapies targeted at molecular anomalies specific to the development of this tumor afford hope for some improvement in the course or survival of this challenging cancer.

# 129 Atypical Teratoid/Rhabdoid Tumors

Alyssa T. Reddy, Susan N. Chi, and Jaclyn A. Biegel

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Atypical teratoid/rhabdoid tumor (AT/RT) is a highly malignant central nervous system tumor that occurs predominantly in very young children. The tumor was first described in 1987 by Lucy Rorke and colleagues and officially recognized by the World Health Organization as a WHO grade IV neoplasm in 1993 (Rorke, et al., 1995). Before this distinct recognition, the tumor was often misdiagnosed as medulloblastoma or another embryonal tumor. AT/RT is the first pediatric brain tumor with a consistent known genetic alteration. In recent years, identification of AT/RT has been dramatically simplified with an immunohistochemical assay for the SMARCB1 (also referred to as INI1, hSNF5, BAF47) gene product, the aberrant tumor suppressor gene found in the majority of AT/RTs (Judkins, et al., 2004). Early accounts of the disease reported it to be rapidly fatal in all but a very small minority of patients. Recent prospective studies that incorporated intensified multimodal therapy have reported improved long-term survival rates approaching 50% (Chi, et al., 2009). Although these results are encouraging, much work remains to be done to understand why durable disease control is not obtained for roughly half of the patients with current therapies and to also identify therapies with less toxicity. A better understanding of the function of the SMARCB1 gene will hopefully improve our understanding of the disease and lead to specific targeted treatment.

## HISTORICAL BACKGROUND AND INCIDENCE

In the late 1980s, a distinctive brain neoplasm characterized by diverse histologic components was identified and termed atypical teratoid tumor of infancy. The tumor contained mixed elements and had a rapidly fatal course. It took careful inspection of multiple fields to separate this tumor from other embryonal tumors. As more cases were recognized, it was noted that the tumors contained areas of rhabdoid cells in addition to areas of primitive neuroectodermal, mesenchymal, or epithelial cells. The tumor was subsequently renamed atypical teratoid/rhabdoid tumor (AT/RT) in the mid-1990s (Rorke, et al., 1995) and given its own distinction by the World Health Organization as a Grade IV embryonal neoplasm in 1993. Before being recognized as a distinct tumor, AT/RT was often misdiagnosed as medulloblastoma, primitive neuroectodermal tumor, or choroid plexus carcinoma. A heightened awareness of AT/RT led neuropathologists to more extensively examine embryonal tumors in young patients to look for mixed cellular histology and common immunophenotypic patterns, even in the absence of a clear rhabdoid component. The first patients reported with AT/RT all died from their disease within a year of diagnosis despite surgery and chemotherapy. Most patients were initially treated either on or according to protocols that treated a variety of malignant brain tumors. It was not until the 2000s that prospective clinical trials specific to AT/RT were initiated.

AT/RT was initially thought to be extraordinarily rare. With the increased clinical awareness of this tumor and the utility

of the immunohistochemistry assay for SMARCB1, it is now estimated that AT/RT accounts for at least 3% of brain tumors in children. All published series report a peak incidence in very young children, less than 3 years of age. Based on prior Pediatric Oncology Group and Pediatric Brain Tumor Consortium studies, approximately 15% of children less than 36 months with malignant brain tumors have AT/RT. In one series the ratio of AT/RT to primitive neuroectodermal tumors was found to be 1 to 3.8 (26%) among patients younger than 3 years of age. A recent Austrian study of 311 newly diagnosed patients demonstrated that AT/RT was the sixth most common entity (6.1%). The number of reported patients with AT/RT has increased 5.5-fold in an analysis of the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) data from 1992 to 2008, likely reflecting greater awareness and improved diagnostic techniques (Buscariollo, et al., 2012). Although it is much less common in older children and adults, AT/RT has been reported with increasing frequency in these populations as well.

There are several names given to the mutated gene in AT/RT. It is referred to throughout this chapter as SMARCB1 as that is its official Human Genome Organization (HUGO) name (Kim and Roberts, 2014). Other names that have been used for the gene are SPF5, INI1, and BAF47.

## CLINICAL PRESENTATION AND RADIOGRAPHIC FINDINGS

Due to the aggressive nature of AT/RT, the vast majority of patients present with very short histories of progressive symptoms that can be measured in days to weeks. Because AT/RT can arise anywhere in the nervous system, neurologic signs and symptoms are nonspecific and referable to the tumor location. About half the patients have tumors that arise in the posterior fossa, and they often present with symptoms related to hydrocephalus, particularly early morning headaches, vomiting, and lethargy. Ambulatory children may have ataxia and other cerebellar dysfunction. Nonspecific symptoms such as lethargy, regression of milestones, and seizures are often seen in very young children with cortical tumors. Focal weakness may also be seen especially in a child who is old enough to cooperate with the examination. Because infants have open sutures and fairly pliable skulls, a rapidly enlarging head size should alert the clinician to evaluate the patient for a brain tumor as this may be the only sign at presentation. Rarely, AT/RT can arise primarily in the spinal cord, and those patients can present with back pain, diplegia, or bowel and bladder dysfunction.

Imaging characteristics are helpful but also nonspecific for AT/RT. All patients with suspected AT/RT should undergo MRI imaging of brain and spine before surgery unless emergent resection is medically necessary. On T1-weighted MRI, the tumor mass is typically isointense with frequent hyperintense foci secondary to intratumoral hemorrhage. On postgadolinium images, AT/RT does vividly take up contrast but in a heterogeneous pattern (Fig. 129-1). On T2-weighted and flair MRI, the tumor appears heterogeneous as a result of the

**Figure 129-1.** Axial gadolinium enhanced T1 brain MRI of a 12-year-old patient with bifrontal AT/RT. The mass has a heterogeneous pattern with more enhancement around the margins and central hypovascularity suggesting necrosis. The patient presented with 1-month history of progressive headaches, morning vomiting, and personality changes.

**Figure 129-4.** Axial diffusion-weighted image (DWI) of an 18-month-old patient with posterior fossa AT/RT. The image demonstrates increased signal intensity (restricted diffusion) within the tumor, related to increased cell density of the AT/RT.

- ⊙ mixture of tumor cellularity, hemorrhage, necrosis, and cysts (Fig. 129-2). There is often significant peritumoral edema due to rapid growth and high cellular turnover. The tumors often invade into brain parenchyma. The CT appearance is typically that of a large hyperdense mass that enhances intensely with contrast. Dissemination throughout the neuraxis at diagnosis is not uncommon and occurs in approximately 25% of cases (Fig. 129-3) (Packer, et al., 2002). MR spectroscopy is similar to primitive neuroectodermal tumors with marked elevation of choline and low or absent N-acetyl-aspartate and creatine. Other MR sequences such as diffusion weighted imaging (DWI) may augment the suspicion that a tumor is highly cellular. Densely cellular neoplasms have a greater restriction of water diffusion than less dense tissues and therefore give rise to increased signal on DWI (Fig. 129-4).

## HISTOPATHOLOGY

As previously mentioned, the pathologic diagnosis of AT/RT requires careful histologic examination of multiple fields of tumor and application of a panel of immunohistochemical markers. Whereas some tumors are composed almost entirely of rhabdoid cells, the more typical finding is that of sheets of rhabdoid cells adjacent to areas of primitive neuroectodermal cells, mesenchymal cells, and/or epithelial cells, as shown in the hematoxylin and eosin (H and E) stained section in Figure 129-5. Immunohistochemical features can help to identify the disease but vary depending on the cellular composition of the tumor. Rhabdoid cells express vimentin, epithelial membrane antigen (EMA), and smooth muscle actin (SMA). The primitive neuroectodermal cells variably express neurofilament protein (NFP), glial fibrillary acidic protein (GFAP), keratin, or desmin. MIB-1 is a marker of cellular proliferation. Not surprisingly, MIB-1 is extremely high in AT/RT with labeling

**Figure 129-5.** Hematoxylin and eosin (H and E) stain of AT/RT demonstrates densely packed rhabdoid cells intermixed with areas of primitive neuroectodermal cells. There is a clump of primitive neuroectodermal cells, so called “small blue cells” in the middle of the picture (arrow).

indices of 50% to 100% (Fig. 129-6). Development of an immunohistochemical stain with a SMARCB1 (BAF47) antibody has greatly assisted the identification of AT/RT (Judkins, et al., 2004). There should be no staining with the antibody in the nuclei of tumor cells due to homozygous inactivation of the gene product (Fig. 129-7).

## GENETICS OF AT/RT

Cytogenetic studies of AT/RT demonstrate simple karyotypes, with loss of all or part of chromosome 22 as the primary and often solitary finding. The deletions target the SMARCB1 gene

**Figure 129-7.** Immunohistochemical staining for the SMARCB1 protein is absent in AT/RT tumor nuclei. Nonneoplastic tissue including blood vessels and inflammatory cells serve as positive internal control (dark brown) with retained nuclear reactivity. (Photo courtesy of Rong Li, MD.)

in chromosome band 22q11.2, which demonstrates biallelic mutations, deletions, or intragenic duplications in up to 98% of AT/RTs (Biegel, et al., 1999). The homozygous inactivation of the gene leads to loss of expression of the protein, which is the basis for the diagnostic immunohistochemistry assay noted previously, showing loss of nuclear expression of SMARCB1 in the tumor cells. Loss of SMARCB1 expression has now been reported in a variety of CNS malignancies, such as cribriform neuroepithelial tumor; therefore the assay must be performed in the setting of careful histologic evaluation and assessment of other clinical presenting features.

The most common alterations of SMARCB1 are homozygous losses, due to monosomy 22 and/or partial 22q deletions; loss of one copy of SMARCB1 and a mutation in the remaining allele; and deletion or mutation followed by a copy number loss of heterozygosity event such as loss of the normal chromosome 22 and duplication of the remaining homologue. Biallelic mutations, however, are very uncommon. Whole exome sequencing studies of primary rhabdoid tumors have shown that this group of tumors has the lowest total number of mutations among all tumors examined to date. Based on the genomic analyses, loss of SMARCB1 alone appears to be sufficient for tumorigenesis.

SMARCB1 functions as a classic tumor suppressor gene in AT/RT. A germline mutation or copy number alteration is present in up to 35% of patients, which predisposes individuals to rhabdoid tumors of the kidney or soft tissues, as well as AT/RT. Loss of the remaining SMARCB1 allele is a somatic, or acquired, event. Patients may present with multiple primary tumors at diagnosis, strongly implicating the presence of a germline alteration. Careful staging workups for all patients with newly diagnosed AT/RT must therefore include abdominal ultrasound or whole body imaging. Germline mutations, as well as intragenic gains or losses of one or more exons of the gene, may be inherited, often from an unaffected carrier, whereas whole gene deletions are typically *de novo*, thus reducing the risk to other family members. Germline mutations may be mosaic, affecting only certain cells in the body, and gonadal mosaicism may lead to the development of rhabdoid tumors in siblings even when neither parent appears to be a carrier. Genetic counseling for all families in which a child has presented with a rhabdoid tumor is therefore highly recommended. Germline mutations in SMARCB1, as well as

other members of the SWI/SNF complex, may also predispose carriers to schwannomatosis, and in fact two-thirds of patients with familial schwannomatosis have germline mutations in SMARCB1. Of note, whole gene deletions of SMARCB1, or 22q11.2 deletions that include SMARCB1, appear to be restricted to patients with rhabdoid tumors. There are families in which a carrier parent had one or more schwannomas, but the offspring had AT/RT, suggesting that there is a window in development in which the risk of rhabdoid tumor is high, which diminishes with age. Long-term survivors of AT/RT may therefore be at risk for additional primary rhabdoid tumors, as well as schwannomas and other malignant tumors. The latency for second tumors may be as long as 15 or more years. SMARCB1 is a member of the SWI/SNF chromatin-remodeling complex, which acts in an ATP-dependent manner to remodel nucleosomes, thus allowing or restricting transcription factor and other protein complexes to bind to the regulatory regions of target genes. The specific function of SMARCB1 as it relates to malignant transformation, however, is still unknown. Numerous cell-signaling pathways are altered in primary rhabdoid tumors, thus providing a variety of potential biologic targets for therapy (Kim and Roberts, 2014).

## STAGING AND THERAPEUTIC INTERVENTIONS

The initial staging evaluation for all patients should include an MRI of the brain unless emergent surgery is necessary. Preoperative MRI with and without contrast is important to assess the extent of disease both at primary and distant sites. A postoperative MRI should be done within 48 hours of surgery to confirm extent of resection. MRI of the whole spine should also be done preoperatively or within 48 hours of surgical resection. These scans will help the neurooncologist and radiation oncologist formulate treatment plans and are critically important to the care of the patient. A lumbar puncture to obtain cerebrospinal fluid should be obtained 7 to 10 days after surgery to look for disease dissemination, unless medically contraindicated. Molecular genetic analysis of the primary tumor and blood to look for a germline SMARCB1 alteration and abdominal ultrasound or full body imaging are recommended at diagnosis given the risk of concurrent rhabdoid tumors in patients with germline mutations.

There is general consensus that aggressive multimodal therapy is necessary to treat AT/RT, but standard-of-care guidelines have not been established. Published series and case-reports include a variety of multifaceted approaches that include combinations of surgery, conventional and high-dose chemotherapy, and radiation. Neurosurgical tumor resection is usually the first intervention for patients and is necessary to establish the diagnosis. In some cases, the tumor may be so vascular or located in a very eloquent area of brain that only a biopsy is feasible. A prospective clinical trial and retrospective data available from the AT/RT registry demonstrate that patients who have had a gross total resection (GTR) have a longer disease-free and overall survival (Chi, et al., 2009; Hilden, et al., 2004). The Canadian Pediatric Brain Tumor Consortium reported in their population-based registry that patients who achieved a GTR had a better survival with a 2-year overall survival of 60% compared with 21.7% for patients who underwent less than GTR ( $p = 0.03$ ) (Lafay-Cousins, et al., 2012). However, only a third of these patients had a GTR. Due to the invasive nature of AT/RT, complete resection may not be possible, as it may present unacceptable risk to the patient. It has been estimated that less than one-third of patients have tumors that are amenable to complete resection. A less invasive tumor may be biologically different and influence outcome. The goal of surgery should be to

remove as much tumor as is deemed safely possible by the surgeon. In the case of a highly vascular tumor that cannot be safely resected at diagnosis, treatment with chemotherapy may decrease vascularity and improve the surgeon's ability to safely resect the tumor. Consideration of "second look surgery" should be given in cases in which complete resection is not possible at the time of diagnosis. Surgery also provides tumor tissue for diagnostic and research purposes. It is highly recommended that fresh frozen tissue be obtained as evolving sequencing of tumors is likely to yield both prognostic and therapeutic information in the future.

## CHEMOTHERAPY

Given the very young age of most patients with AT/RT, chemotherapy has been a mainstay of postsurgical therapy. Because of the historical misdiagnosis of AT/RT, in the earliest reports, treatment regimens designed for other CNS neoplasms were utilized in patients with AT/RT. Most commonly, these were regimens designed for embryonal tumors (e.g., medulloblastoma, supratentorial primitive neuroectodermal tumor). Even once AT/RT was more readily recognized, the regimens employed were designed with chemotherapy to delay or exclude radiotherapy altogether (i.e., "baby brain" protocols) because of the young age at which most children with AT/RT were diagnosed. The overall results of many "baby brain" chemotherapy protocols, however, were generally disappointing, although the ability to defer radiation therapy in subsets of patients was an important advance. Consequently, the generally accepted outcome for patients with AT/RT treated with standard chemotherapy regimens is dismal with median survival time reported between 6 to 11 months.

Information presented at a National Cancer Institute Workshop in 2002 incorporating data from a national rhabdoid tumor registry demonstrated a median survival of approximately 8.5 months (Packer, et al., 2002). In a review of 32 infants and children treated for CNS AT/RT, treatment was highly variable but typically included multimodality treatment, including surgery, radiation, and chemotherapy (Hilden, et al., 2004). Median survival in this analysis was 6.5 months. A similar retrospective study of 31 children treated at St. Jude Children's Research Hospital reported equally dismal outcomes for children under the age of 3 years, with 2-year event-free (EFS) and overall survival (OS) of 11% and 17%, respectively (Tekautz, et al., 2005). For children older than 3 years, survival outcomes were much more encouraging, likely due to the inclusion of radiation therapy and high-dose alkylator chemotherapy agents.

In two case series, several patients with newly diagnosed AT/RT achieved prolonged remission after surgery, radiation therapy, and chemotherapy based upon a protocol for children with rhabdomyosarcoma with parameningeal extension (Intergroup Rhabdomyosarcoma Study-III or IRS-III, Regimen 36). Since these initial reports, several investigators have shown that multiagent chemotherapy containing the anthracycline doxorubicin, the backbone chemotherapeutic agent for IRS-III, can be efficacious. Because AT/RT often shows leptomeningeal dissemination, intrathecal chemotherapy has been employed as a method of delivering local treatment to these areas. The first prospective clinical trial for children with newly diagnosed AT/RT using an intensive multimodality approach, systemic and intrathecal chemotherapy, and age-adapted radiation therapy, based on the IRS-III regimen, demonstrated the highest event-free and overall survivals to date, with 2-year progression-free survival (PFS) and overall survival (OS) at 53% and 70%, respectively (Chi, et al., 2009). Long-term survival outcomes have remained encouraging.

High-dose chemotherapy (HDC) with stem cell rescue is a strategy that allows higher doses of cytotoxic agents to be given, and this approach has also shown efficacy in treating AT/RT. The "head start" chemotherapy protocols used high-dose methotrexate as a key component to its chemotherapy backbone before its consolidative stem-cell rescue. Several investigators have shown that long-term survival is achievable using this approach. The Canadian Pediatric Brain Tumor Consortium reported that 9 of the 18 patients who received various HDC regimens were alive at a median follow up time of 40.8 months (10 to 90) from diagnosis (Lafay-Cousin, et al., 2012). HDC was associated with a significant survival benefit with a 2-year overall survival of 47.9% (plus or minus 12.1) versus 27.3% (plus or minus 9.5) for the conventional chemotherapy group ( $p = 0.036$ ). The Children's Oncology Group (COG) conducted a pilot study, 99703, to treat a variety of malignant brain tumors, including AT/RT, which incorporated three cycles of conventional chemotherapy with cyclophosphamide, etoposide, vincristine, and cisplatin, followed by three high dose cycles of carboplatin and dose escalation of thiotepa with stem cell transplants (Cohen et al., 2015). This study demonstrated feasibility of this approach and improved survival. The current national Children's Oncology Group phase III study (ACNS0333) utilizes the chemotherapeutic backbone of 99703 with the additional of high-dose methotrexate during induction and conformal field radiation therapy. The study accrued 70 patients and is currently in analysis. For 55 patients treated on the study who were younger than 36 months at diagnosis, the 2 year event free and overall survival are 39% and 48% respectively. For 11 patients greater than 3 years of age, the 2 year event free and overall survival are 60% and 80% (Reddy et al., 2016). Given the very young age of these patients, these results are also very encouraging.

## RADIATION

The vast majority of AT/RT survivors in the literature have received some form of radiation therapy as a component of their treatment and its positive effect on long-term survival has been reported in several series (Hilden, et al., 2004; Tekautz, et al., 2005; Chi, et al., 2009). The most recent compelling evidence comes from analysis of the National Cancer Institute's SEER database, which identified 144 patients with AT/RT from 1973 to 2008 (Buscariollo, et al., 2012). As expected, the majority of patients (82%) were less than age 3 years and approximately one-third of patients received radiation. The median overall survival (OS) of patients who did not receive radiation therapy was 6 months. For those who had received some form of radiation as part of their primary therapy, the mean overall survival had not been reached at the time patients were reported. There was an increased use of radiation in young children after 2005. Both the IRSIII and COG trials, ACNS0333, mentioned in the previous section, both included conformal radiation for all patients. There are some long-term survivors of AT/RT reported in the literature who were treated with HDC but did not receive radiation. Until we are better able to risk-stratify patients, there is good evidence that focal radiation coupled with intensive chemotherapy provides the best chance at durable control of AT/RT.

## TOXICITY OF THERAPY

The intensive therapeutic regimens carry potential morbidity, and a few deaths due to treatment toxicity have been reported. It is very well established that craniospinal radiation has significant deleterious effects on the developing nervous system,

and its use in young children gives many clinicians great angst. Advanced radiation techniques, specifically 3D conformal therapy and the wider availability of proton beam radiation, are showing decreased long-term neurologic sequelae and less effect on cognitive function. Chemotherapy, surgery, and the tumor itself also contribute to the long-term neurologic sequelae. Intensive chemotherapy also has significant long-term systemic sequelae and the risk of major organ dysfunction. As more patients are long-term survivors of AT/RT, their long-term cognitive, neurologic, endocrine, and systemic function will need to be monitored. Early and ongoing intervention from psychologists, teachers, and therapists is highly important to help patients maximize their potential. Although treatment will likely continue to be refined, the importance of these posttreatment interventions cannot be overemphasized.

## FUTURE DIRECTIONS

As current treatment regimens are highly intensive and consequently highly toxic, further improvements in outcome will require improved understanding of the biology of this tumor and targeting of therapy to the tumor. Extensive laboratory investigations have been carried out to better understand the tumorigenesis of AT/RT as well as to identify potential therapeutic targets. Preclinical testing of rhabdoid cell lines and xenografts has shown data that are provocative with regard to the chemo-responsiveness of AT/RT. These have given biologic rationale to early experimental clinical trials with small molecule inhibitors, for example, targeting HDAC, Aurora a kinase, CDK, and EZH2. What remains a limitation, however, is the lack of genetically engineered or orthotopic CNS AT/RT animal models that reflect the human condition. Current modern technologies, including whole exome and genome sequencing and epigenetic assays, have propelled our understanding of AT/RT but will require validation. Undoubtedly, future clinical studies will incorporate targeted approaches based on an improved biological understanding of these tumors.

## CONCLUSIONS

Since first being recognized as a distinct tumor in the late 1980s, significant strides have been made in understanding the biology and treatment of AT/RT. It is the first pediatric brain tumor for which a common genetic abnormality has been identified. Immunohistochemical antibody staining for the SMARCB1 gene product has simplified identification of the tumor. Although the function of SMARCB1 is not yet known, modern and evolving technologies will likely help identify targeted therapies. Once a disease that was considered to be universally fatal, recent intensive multimodal regimens have improved long-term overall survival for patients with AT/RT to approximately 50%. Genetic sequencing of tumors in recent trials may also help identify prognostic factors. There is optimism that targeted therapy can be combined with more traditional modalities to improve survival rates. Ideally, targeted therapies will also allow for reduction of more conventional therapies for at least some patients. Although much work remains to be done, continued multidisciplinary collaboration of preclinical and clinical researchers will likely continue to unravel this high aggressive tumor.

## INTRODUCTION

Germ cell tumors (GCTs) of the central nervous system (CNS) are a heterogeneous group of benign and malignant tumors currently classified as germinoma, teratoma (mature, immature, and teratoma with malignant transformation), and nongerminomatous germ cell tumors (NGGCTs). NGGCTs can include either a single tumor type or combinations of embryonal carcinoma, yolk sac tumors (or endodermal sinus tumors), choriocarcinoma, teratoma, and Germinoma. The term NGGCT is considered inaccurate, and efforts are ongoing to seek consensus for a new terminology (Finlay et al., 2008).

The management of this group of rare CNS tumors has been the recent focus of prospective clinical trials throughout Asia, the Americas, and Europe, and the clinical approach to these tumors is undergoing continuous modification. Because of their rarity, most of the research is conducted in large cooperative groups. Most encouraging is the recent exploration of the biologic basis of CNS GCTs, an effort that will likely lead to more targeted, safer therapies. Insight into the biology and management of CNS GCTs has been obtained from experience with these tumors outside the CNS, where they are of highest incidence in the gonads, mediastinum, and retroperitoneum.

From a biologic perspective, unusual features of CNS GCTs include their demographics (males > females, especially in the pineal region; higher incidence in people from Asia); onset primarily during adolescence and early adulthood; midline, extraaxial location in the CNS (pineal region, suprasellar region/neurohypophyseal); unique patterns of presentation in particular locations (bifocal pineal/suprasellar, basal ganglia); histologic distinctions by age and location (germinoma in pineal and bifocal locations; NGGCTs more common in females in suprasellar location; immature teratoma more common in infants); the ability to use tumor markers (alpha fetoprotein and human chorionic gonadotropin) in serum and cerebrospinal fluid (CSF) to diagnose and monitor response to treatment; and association with various genetic syndromes such as trisomy 21, Klinefelter syndrome, and Noonan syndrome. Pure germinomas may produce very low levels of human chorionic gonadotropin (hCG), but never alpha fetoprotein (AFP), in either CSF or serum, whereas NGGCT can produce any combination of both tumor markers.

In general, CNS GCTs often require multimodality therapy for optimum care. With the exception of low-grade variants such as mature or immature teratoma, where a gross total resection may be curative, combinations of chemotherapy and radiation therapy are necessary for most patients. Germinomas are very responsive to chemotherapy, and radiation and current clinical research is aimed at minimizing treatment and its consequences while preserving a high cure rate (5-year overall survival [OS] > 85%). For NGGCTs, more intensive preradiation chemotherapy combined with maximum surgical debulking of the tumor followed by radiation

therapy appears to have dramatically improved survival (5-year OS > 70%).

## EPIDEMIOLOGY

In a population-based study in Canada using data from a tumor registry, the mean annual incidence of CNS GCT was reported to be 1.06 per million children (0–18 years of age). In this study, the annual incidence of germinoma was approximately twice that of NGGCT. Whereas other Western countries estimate similar incidence rates, with CNS GCTs accounting for up to 3.6% of all pediatric intracranial CNS tumors, the rates appear higher in Japan and the Far East, accounting for up to 15.3% of all pediatric intracranial CNS tumors (Report of Brain Tumor Registry of Japan, 2003). The reasons for these variations in incidence remain elusive, but genetic predisposition and geographic or environmental factors may contribute.

The peak incidence of CNS GCT is in the second decade of life, and male gender increases the likelihood of this diagnosis. The male predominance is striking in GCTs arising in the pineal area, with a male:female ratio as high as 15:1. In contrast, girls are slightly more affected by GCTs arising in the suprasellar region.

## PATHOLOGY AND ETIOLOGY OF GERM CELL TUMORS

CNS GCTs are immunophenotypic and morphologic homologues of GCTs arising in extracranial locations, but the distribution of histologic subtypes appears to differ by site of origin. Mature and immature teratomas mimic elements of all three embryonic germ layers: endoderm, mesoderm, and ectoderm. Uncertainty remains regarding the cells of origin of other subtypes, such as choriocarcinoma, germinoma, yolk sac tumors, and embryonal carcinoma. The primordial stem cells that give rise to normal and abnormal germ cell components are totipotent and capable of differentiation along several pathways. As such, the primary occurrence of GCTs in gonadal tissue is not surprising, but they also arise in several unique “midline” locations in the body and CNS, related to either aberrant migratory behavior and eventual neoplastic transformation or the failure of migratory stem cells in the embryo to undergo spontaneous apoptosis. That this aberrant ontogeny is under genetic control is suggested by the occurrence of multiple first-degree relatives affected by primary GCTs, both in the body and CNS, and the occurrence of GCTs in certain genetic syndromes such as Noonan syndrome and trisomy 21. Gonadotropins may also have a role in the etiology of GCTs, as suggested by their midline location, the “neighborhood” of diencephalic centers that regulate gonadotropins, and the increased prevalence in children of peripubertal age and in boys affected by Klinefelter syndrome (47 XXY).

## GERMINOMA

The predominant type of CNS GCT is a germinoma, accounting for approximately 60% to 70% of intracranial GCTs (Report of Brain Tumor Registry of Japan, 2003; Calaminus et al., 2013). This section focuses primarily on its clinical management. Most germinomas develop in the suprasellar/neurohypophyseal and pineal regions. Occurrences outside the midline and in the basal ganglia are rare. Progression-free survival (PFS) in germinomas is excellent, with 5-year OS exceeding 90% in retrospective and prospective series.

### Clinical Presentation

The clinical presentation is determined by the location of the germinoma. Protracted courses, up to years, of symptoms before diagnosis are not uncommon. Diabetes insipidus, a symptom of the vast majority of patients with suprasellar and bifocal germinoma, can remain clinically compensated for a prolonged time period. Hence diligent history taking and review for polyuria and polydipsia are important. Symptoms of increased fluid intake, nocturia, weight loss, and personality changes are common. New onset of diabetes insipidus should prompt a diagnostic workup, including a referral to a pediatric endocrinologist and brain magnetic resonance imaging (MRI) without and with contrast and with attention to the suprasellar region. Sometimes the initial MRI is nondiagnostic or may show slight infundibular thickening. In the case of documented pituitary stalk thickening, a careful clinical and imaging follow up is recommended because about 15% to 25% of affected individuals may eventually develop germinoma. Other symptoms associated with suprasellar germinoma location are visual disturbances, as a result of the close proximity to the optic chiasm and optic nerves, and endocrinopathies.

The most common symptoms of a pineal germinoma are those related to increased intracranial pressure resulting from obstruction of the aqueduct and, if the mass is large enough, Parinaud syndrome. This syndrome consists of vertical gaze impairment, convergence nystagmus, and pupils that respond to accommodation but not to light. It is a classical sign of tectal compression.

Rare off-midline germinomas, arising in the basal ganglia, thalamus, or internal capsule, are often characterized by insidious (i.e., over 1–4.5 years) onset of cognitive or motor symptoms. They can occur in isolation or synchronously in multiple locations. Affected patients may present with symptoms related to corticospinal tract or extrapyramidal dysfunction, such as hemiparesis and/or choreoathetotic movements, personality changes, and speech disturbances.

### Radiology

Classical imaging characteristics of suprasellar and pineal (or bifocal) germinoma are homogenous isointense or hypointense lesions on T1-weighted MRI and isointense or hyperintense lesions on T2-weighted MRI (isodense or hyperdense on computed tomography [CT]), with avid enhancement after contrast administration. However, the tumor may also heterogeneously enhance and include cystic components and intratumoral calcifications. Subependymal ventricular dissemination is common and usually characterized by linear or nodular enhancement along the ependymal ventricular lining of the lateral or third ventricles, especially in the frontal horns. Large tumors may be surrounded by a 2- to 3-cm penumbra of FLAIR signal abnormality suggestive of either edema or infiltration. Basal ganglia germinomas may lack this avid enhancement and sometimes

show little or no mass effect, especially in the early stages of the disease. Ipsilateral cerebral and/or brainstem atrophy (Wallerian degeneration) is present in one third of patients with basal ganglia germinoma. Infiltrative disease appears to exert an anatomic and, most likely, physiologic “toxic” effect on brain parenchyma. After treatment, the tumor bed and surrounding tissue usually become atrophic, with calcium deposition.

### Tumor Markers

Intracranial GCTs can secrete tumor markers into the bloodstream and/or CSF. For some tumor markers, such as hCG, there appears to be a CNS/systemic gradient, and lumbar assay values are usually higher. For others, such as AFP, the serum and CSF values are often similar. Germinomas do not secrete AFP but may secrete low levels of hCG and hCG $\beta$  either into serum and/or into CSF, possibly as a result of the presence of a small component of syncytiotrophoblastic giant cells (STGCs). Retrospective and prospective analyses found elevated hCG levels in serum and/or CSF in up to 42% of germinoma patients (Allen et al., 2012). The majority of cases have mild elevations of hCG levels solely in CSF; however, the presence of both or an elevated concentration in serum with a normal concentration in CSF have been described. Different timing of the sampling of hCG in serum and CSF (because of the short half-life of hCG [1.5 days]) and different units and kits may contribute to some of the variability in these findings.

Some authors have suggested a different prognosis for germinoma with elevated levels of hCG, but many studies do not specify the site of hCG measurement, and a recent publication suggests that serum hCG is an insensitive screening tool and that lumbar, but not ventricular, CSF is much more sensitive. Nonetheless, tumor marker analysis is currently being used in lieu of biopsy to diagnose germinoma and to distinguish germinoma from NGGCT. Patients with typical midline tumors and modest elevations of hCG are treated as cases of germinoma, and patients with any elevation of AFP are treated as cases of NGGCT in the Children’s Oncology Group (COG) Germ Cell Tumor study (ACNS1123) protocol. For patients with normal tumor markers, biopsy is required.

### S-Kit in Germinoma

Immunohistochemical studies have shown that c-kit, a proto-oncogene and transmembrane tyrosine receptor, is highly expressed in germinoma cells. S-kit is its soluble equivalent and can be measured in CSF. S-kit values in CSF are usually higher in germinoma compared with NGGCT patients, and levels correlate with treatment response and relapse (Miyano-hara et al., 2002). These data suggest that CSF s-kit may represent a valuable tumor marker of germinomatous components, but currently the assay is used mostly for research purposes in Japan.

### Staging

As with malignant childhood brain tumors in general, MRI of the entire CNS at the time of initial diagnosis is essential for staging. Should surgery be required as a result of obstructive hydrocephalus, MRI of the brain and spine should be obtained within a 48- to 72-hour window after the surgical intervention. This minimizes misinterpretation of the contrast enhancement that occurs between 72 hours and 6 weeks after surgery as a result of disruption of the blood–brain barrier. Tumor marker determinations in serum and CSF should be

included in the staging. In the case of uncontrolled raised intracranial pressure or a lesion with mass effect, performance of a lumbar puncture is contraindicated. In most cases, however, lumbar CSF for cytology and marker analysis can safely be obtained following either an endoscopic third ventriculostomy (ETV) or placement of a ventriculoperitoneal (VP) shunt. To date, there are insufficient data on the significance and reliability of ventricular CSF tumor or cytology assays. The International Society of Pediatric Oncology (SIOP-CNS-GCT) trial allowed enrollment of patients if CSF cytology was undertaken via either the ventricular route or lumbar puncture. Interestingly, the Japanese working group dismisses CSF cytology because it is not taken into consideration for treatment decisions. Data from prospective studies suggest that 15% to 20% of germinoma patients have disseminated disease at diagnosis either on imaging (M+) or on CSF investigation (M1). Although bifocal involvement is considered metachronous but not metastatic disease, there is some controversy about whether observed studding on endoscopic inspection, which is invisible on MRI, or diffuse basal ganglia involvement should be classified as M0 or M+.

## Treatment

### Role of Radiation and Chemotherapy

Historically, craniospinal irradiation has been the gold standard of treatment for CNS germinoma. Because of concerns about the long-term sequelae of both large-volume and high-dose radiation, there has been a concerted effort to either completely substitute intensive chemotherapy for radiation therapy or reduce both volume and dose in select cohorts of patients based on response to preradiotherapy chemotherapy. The outcome measures by which success will be gauged include maintenance of high survival rates with decreased long-term negative effects on cognitive and endocrine function and quality of life. Given the rarity of this disease and paucity of cooperative group phase III clinical trials, documentation of the achievement of these goals may be difficult. The current state-of-the-art treatment therapies are reviewed here, with the expectation that changes may emerge as clinical trials progress.

**Radiation Therapy.** Although reduction of craniospinal irradiation to whole-ventricular (WV) or whole-brain (WB) irradiation in completely staged, M0, primary germinoma appears relatively safe from the standpoint of tumor eradication and has evolved as an accepted practice throughout the world, the safety of elimination of WV irradiation and substitution with involved field (IF) irradiation has been questioned since the observation of increased numbers of ventricular relapses. Currently WV radiation is utilized by the Japanese, French, SIOP, and COG working groups in combination with chemotherapy as the standard of care for nonmetastatic suprasellar and pineal-region germinoma. The relative contributions of chemotherapy and irradiation remain a topic of debate.

Rogers, Mosleh-Shirazi, and Saran (2005) conducted a meta-analysis of radiation therapy for germinoma patients and found a recurrence rate of 7.6% after WB or WV radiation and a rate of 3.8% after craniospinal irradiation (CSI). No predilection for isolated spinal metastasis was found when CSI was omitted (2.9% versus 1.2%). The authors concluded that reduced-volume irradiation should replace craniospinal irradiation (Rogers et al., 2005). Ogawa et al.'s (2004) retrospective review of the Japanese experience concurs with a low risk of spinal relapse, reporting an incidence of 4% (2/56) for patients treated with CSI and 3% (2/70) for patients treated without spinal radiation. Excellent PFS rates for localized

germinomas with the use of either WB or WV irradiation have been reported by several institutions. Nevertheless, the volume of radiation should cover all areas of measurable disease identified at the initial MRI staging.

In addition to the controversies surrounding the optimum volume of radiation therapy, there has also been controversy about the optimum dose to both the primary tumor and any prophylactic field. Small retrospective experiences suggest that radiation doses can be reduced to 36 and 30 Gy WV irradiation, respectively, without preirradiation chemotherapy. However, the use of radiation therapy alone has been associated with the risk of extra-CNS relapses. Several clinical trials have proposed that preradiation chemotherapy may be used to triage patients who can more safely be treated with both volume and dose reductions of radiation, thereby reducing radiation-related long-term sequelae.

**Chemotherapy.** Germinomas are highly sensitive to radiation therapy and chemotherapy. Platinum compounds and cyclophosphamide are particularly efficacious chemotherapeutic agents in treating germinomas. The largest "chemotherapy-only" experience in newly diagnosed patients is reported in the First, Second, and Third International CNS Germ Cell Tumor Studies. In the first study, chemotherapy consisted of four cycles of carboplatin (500 mg/m<sup>2</sup>/day, days 1 and 2), etoposide (150 mg/m<sup>2</sup>/day, day 3), and bleomycin (15 mg/m<sup>2</sup>/day, day 3). Patients with complete radiologic and tumor marker response proceeded to two more identical cycles, whereas cyclophosphamide (65 mg/kg) was added to the three-drug regimen for those with incomplete response. Of the CNS germinoma patients, 22 of 45 eventually relapsed. Although most relapsed patients were salvageable with high doses and volumes of radiation therapy, the 2-year OS in this study was only 84%. Nineteen germinoma patients were enrolled in the second study using an intensified cisplatin- and cyclophosphamide-based chemotherapy induction. Despite proof of effectiveness with a high rate of complete remission, the 5-year event-free survival (EFS) and OS rates were unsatisfactory at 47% ± 2.3% and 68% ± 2.2%, respectively. Moreover, chemotherapy was associated with unacceptable morbidity and mortality (4 deaths), predominantly in patients with diabetes insipidus. The third study included 25 patients and confirmed the inferior outcome of this strategy, with a 6-year EFS of 45.6% when avoiding radiation. In conclusion, "chemotherapy-only" strategies have not matched the long-term survival rates obtained with either radiation therapy alone or combined chemotherapy and radiation therapy. Chemotherapy should therefore not be used in isolation in patients with germinoma unless new targeted agents or new molecular markers for tumor responsiveness afford the hope of better outcomes.

**Combined Chemotherapy and Radiation Therapy.** One of the first trials of single-agent, neoadjuvant chemotherapy with carboplatin followed by response-dependent reductions in radiation volume and fields in biopsy-proven CNS germinoma observed a high complete response rate (7/11) and favorable outcome, with 10 of 11 patients experiencing long-term survival (Allen, Kim, and Packer, 1987). Preirradiation chemotherapy with carboplatin, etoposide, and ifosfamide followed by focal irradiation (40 Gy) has been studied in the SIOP-CNS-GCT-96 protocol for patients with nonmetastatic germinomas. Physicians had the option to use this approach or craniospinal irradiation without chemotherapy. This prospective multinational study included 190 patients with localized germinoma. The 5-year EFS and OS rates for patients treated with preirradiation chemotherapy ( $n = 65$ ) were 88% ± 0.4% and 96% ± 0.3%, respectively, whereas the 5-year EFS and OS rates of patients treated with craniospinal radiation

( $n = 125$ ) were  $94\% \pm 0.2\%$  and  $95\% \pm 0.2\%$ . Whereas relapses (4/125) only occurred locally in the CSI group, six of seven relapses occurred in the ventricular area in the chemotherapy/focal radiation treatment group. As a consequence, the current open SIOP trial combines preirradiation chemotherapy with ventricular irradiation (24 Gy) with an additional boost of 16 Gy to the primary tumor bed in patients with localized disease. Metastatic germinoma patients will continue to be treated with CSI only at the doses outlined previously without chemotherapy, as the 45 metastatic patients included in the aforementioned study showed an excellent 5-year EFS and OS of  $98\% \pm 0.2\%$ .

The risk of ventricular recurrence in patients treated with chemotherapy and focal radiation has also been well documented by the French and Japanese working groups. [Alapetite et al. \(2010\)](#) reported the SFOP (Société Française d'Oncologie Pédiatrique) experience, which included 60 patients treated for CNS germinoma with a combination of carboplatin, etoposide, and ifosfamide followed by focal radiation (40 Gy). The 5-year EFS and OS rates were 84.2% and 98.2%, respectively. Ten of 60 patients relapsed at a median time of 32 months (range: 10–121 months), with the majority ( $n = 8$ ) of relapses occurring within the ventricular system ([Alapetite et al., 2010](#)). The second trial of the Japanese GCT study group consisted of three cycles of carboplatin (450 mg/m<sup>2</sup>/day, day 1) and etoposide (150 mg/m<sup>2</sup>/day, days 1–3) chemotherapy followed by local irradiation (24 Gy). The 5-year OS rate was 98%. However, 13% of the patients (16/123) developed recurrence. In an interim analysis, a high incidence of ventricular/locoregional relapses was reported. As a consequence, current treatment in Japan, Europe, and North America combines chemotherapy with WV irradiation. Although the dose of WV irradiation is 24 Gy in Europe and Japan, the current Children's Oncology Group GCT trial evaluates the efficacy of a reduced dose of 18-Gy WV irradiation (plus boost to tumor bed to a total of 30 Gy) in chemotherapy-responsive germinoma patients with localized disease.

The vast majority of patients with suprasellar germinoma suffer from diabetes insipidus. Cisplatin- or ifosfamide-based chemotherapy requires hyperhydration, which significantly increases the risk for electrolyte imbalances and subsequent complications such as seizures ([Afzal et al., 2008](#)). A combination of carboplatin and etoposide chemotherapy is currently employed by the Japanese and North American working groups. This offers the advantage of easier outpatient administration and reduced risk of hyperhydration associated metabolic complications. Interestingly, whereas carboplatin alone has been proven effective ([Allen, DaRoso, Donahue, and Nirenberg, 1994](#)), etoposide has never been evaluated as an active single agent in the treatment of germinoma.

## Role of Surgery

### The Need for Biopsy and Second-Look Surgery

Currently, it is not sufficient to treat patients with isolated pineal or suprasellar tumors as cases of germinoma without biopsy confirmation or demonstration of hCG elevation. There are several types of tumors that arise in these locations, including those with low-grade and malignant histologies. In the era when the risks of operating on a patient with a pineal-region tumor were high, the practice was to use a radiographic response to 2 weeks of radiation therapy to confirm the assumption that a germinoma was involved. However, this practice is no longer viable because tumor types such as pineoblastomas or ependymomas may also briefly respond but would require very different doses and volumes of radiation for potential cure. Second, low-grade tumors such as

pineocytomas or teratomas would be irradiated needlessly when surgery could be curative. Currently, the risks of surgery in this area of the CNS are greatly reduced with the use of modern operating techniques and equipment and steroids. In addition, endoscopic procedures often provide very useful diagnostic information and serve to relieve intracranial hypertension via third ventriculostomy (ETV).

Thus it is the gold standard to establish the histologic presence of a GCT by either open or endoscopic biopsy if the tumor markers are normal. The choice of technique (stereotactic, endoscopic, open craniotomy) and the goal of surgery (tissue diagnosis versus tumor resection) are complex and largely determined by the anatomy of the lesion (size, accessibility through the ventricle, etc.) and the presence and extent of ventriculomegaly. If the tumor is confirmed to be a germinoma, the general goal of surgical intervention (apart from hydrocephalus management) is tissue diagnosis rather than tumor resection, because germinoma is so responsive to medical therapy. Symptomatic obstructive hydrocephalus may necessitate an emergent intervention such as placement of an external ventricular drain (EVD) and/or an ETV. At the time of ETV, many groups favor attempted tumor biopsy to confirm the histology.

The need for tissue biopsy in patients with a bifocal lesion, considered metachronous and not metastatic, is debatable. In accordance with the current SFOP, SIOP, and North American approach, a biopsy is not required if the clinical presentation, imaging characteristics, and tumor marker profile (AFP negative, no or mild elevation of hCG) are consistent with a bifocal germinoma. With very rare exceptions, bifocal lesions associated with negative serum and CSF tumor markers are almost always pure germinoma. However, some very rare cases of different pathologies have been reported.

The current North American GCT trial does not mandate a biopsy for suprasellar, pineal, or unifocal ventricular lesions (radiologically consistent with germinoma) if AFP is negative and if serum and/or CSF hCG is elevated but is less than or equal to 50 IU/L. However, in this protocol, a biopsy is required for patients with hCG values above 50 IU/L to a maximum of 100 IU/L. The Japanese approach has been surgical removal of lesions whenever feasible, and subsequent treatment is based on the final pathology result.

Germinomas are highly chemosensitive, and response to treatment is often obvious within days after the first cycle. At the Hospital for Sick Children in Toronto, a transient EVD is favored over a permanent shunt in patients with obstructive hydrocephalus likely caused by a germinoma in whom an ETV is not possible. After the diagnosis of a germinoma is confirmed, one cycle of chemotherapy is administered, and if the patient tolerates clamping of the drain, it is removed before the child becomes neutropenic.

The presence of residual disease at the end of treatment is not predictive of worse outcome, and patients with residual MRI abnormality following chemotherapy and radiation therapy fare as well as those without, as long as the tumor markers remain normal in serum and CSF ([Calaminus et al., 2013](#)). Lack of responsiveness to chemotherapy in either an hCG-positive or a biopsy-proven germinoma raises concerns of a potential mixed GCT, especially if there is persistence of or increase in the tumor markers; hence the current Children's Oncology Group GCT trial mandates second surgery at the end of chemotherapy in case of incomplete response if the residual suprasellar or pineal lesion is larger than 1 cm<sup>2</sup> and 1.5 cm<sup>2</sup>, respectively, or the tumor markers do not normalize. The "growing teratoma" syndrome has been described primarily in patients with NGGCTs undergoing resection of a residual or enlarging primary tumor whose tumor markers are normal. The histology reflects a mature or immature teratoma.

## Prognosis and Summary

The overall survival in germinoma exceeds 90%, with either radiation alone or with combinations of chemotherapy and radiation. Current treatment strategies include preradiation chemotherapy to reduce radiation doses and minimize long-term sequelae. Current evidence suggests that extent of resection does not contribute to superior outcome but may add morbidity. Hence, surgery should be limited to a biopsy or avoided where possible. There are many advances to be made, such as in the search for more specific and sensitive tumor markers, studies of whether responses to neoadjuvant chemotherapy justify radiation dose reductions, determination of the optimum dose and volume of radiation therapy, and determination of whether current efforts to further reduce radiation dose and volume justify the potential avoidance of late effects. Only through cooperative group trials and international collaboration around this rare disease can we make clinical progress. The exploration of the molecular basis of the origin and treatment sensitivity of GCTs deserves further effort, but currently the rate-limiting step is the paucity of tumor tissue given the small size of a biopsy specimen. With improvements in technology, more research will be possible and smaller amounts of tissue and CSF may be required, allowing some of these critical questions to be addressed.

Craniopharyngiomas, meningiomas, and schwannomas are less common than other childhood brain tumors, frequently present insidiously over months to years, and often are amenable to successful surgical and medical intervention. The advent of improved neuroimaging has allowed earlier diagnosis, targeted treatment, and the ability to noninvasively and serially monitor patients. This chapter reviews the epidemiology, clinical presentation, neuroimaging findings, histology, genetics, surgical and medical management, and outcomes of these three tumors as they occur in the pediatric population.

## CRANIOPHARYNGIOMAS

Few topics in neurosurgery inspire more controversy than the optimal treatment of craniopharyngiomas. The benign histology of these tumors often belies their malignant clinical course, particularly in children. The location of craniopharyngiomas, and specifically their intimate association with the visual pathways, pituitary, hypothalamus, and limbic system, predisposes patients to severe visual, endocrine, and cognitive deficits, both at presentation and as a result of treatment. Although most children can compensate for neurologic deficits and endocrinologic deficiencies, the cognitive and psychosocial sequelae can be functionally devastating, interfering with education, limiting independence, and adversely affecting the quality of life as these children approach adulthood.

### Epidemiology

The Central Brain Tumor Registry found craniopharyngiomas to comprise 4.2% of all tumors in children aged 0 to 14 years (Ostrom et al., 2015). Craniopharyngiomas have a bimodal age distribution with a peak in the pediatric population between age 5 and 14 years and another peak in the adult population between age 50 and 74 years (McCrea et al., 2015). Thirty-three percent to 54% of all craniopharyngiomas occur in children, accounting for 6% to 9% of all pediatric brain tumors. These tumors are the most common nonglial tumors of childhood.

Although there does not appear to be any racial or ethnic predilection for craniopharyngiomas, the influence of gender is not as clear. Considering the available data, craniopharyngiomas may occur slightly more often in males than in females.

### Clinical Presentation

The slow growth of craniopharyngiomas often results in a delay between onset of symptoms and diagnosis, with a typical prodrome of 1 to 2 years. The main presenting signs and symptoms of craniopharyngiomas are secondary to pressure upon adjacent neural structures. Headaches from raised intracranial pressure are the most common complaint, occurring in 60% to 75% of patients.

Visual impairment, caused by compression of optic pathway structures, is the presenting complaint in approximately 50% of children. On preoperative neuroophthalmo-

logic testing, 70% to 80% of children have abnormal visual acuity or visual fields. The specific deficits are a reflection of the direction of tumor growth and its compression of various portions of the visual apparatus. Prechiasmatic extension will compress optic nerves with loss of visual acuity, whereas posterior tumors cause chiasmatic compression with complex visual field defects. Papilledema is present in approximately 20% of children (Fig. 131-1).

Hypothalamic and endocrine dysfunction, including growth failure (short stature), delayed sexual maturation, excessive weight gain, and diabetes insipidus, is present in 20% to 50% of children at the time of diagnosis, but is less commonly the symptom that brings the child to medical attention. At the time of presentation, less than one third of children are endocrinologically normal, making preoperative endocrine assessment mandatory.

### Neuroimaging

The role of neuroimaging is to establish a preoperative diagnosis and then define the location and extent of the cystic, solid, and calcified portions of the tumor and its relation to the distorted normal anatomy. Radiographic evaluation includes computed tomography (CT), magnetic resonance imaging (MRI), magnetic resonance angiography (MRA), and, where available, magnetic resonance spectroscopy (MRS). Vascular anatomy can be well demonstrated by MRI and MRA obviating the need for invasive cerebral angiography.

The noncontrast CT usually demonstrates a suprasellar and often intrasellar mass with calcifications as well as hypodense solid and cystic components (Fig. 131-2). The low-density component usually has an attenuation greater than that of CSF. A small percentage of craniopharyngiomas may be of high density. CT shows secondary changes in the skull base such as enlargement of the sella turcica and/or erosion of the dorsum sellae.

MRI provides invaluable information regarding the relation of the tumor to the surrounding critical structures, including the visual pathway, hypothalamus, blood vessels of the circle of Willis, and ventricles (Fig. 131-3). The appearance of a normal pituitary gland helps to make the correct diagnosis. Administration of gadolinium demonstrates the avidly enhancing cystic capsule and solid tumor. The appearance of the cyst fluid is uniformly hyperintense on T2-weighted sequences, but can vary in intensity on T1-weighted sequences based on its biochemical composition (Fig. 131-4).

Solid craniopharyngiomas without calcifications can be difficult to differentiate from other pediatric suprasellar tumors. In these instances, MR spectroscopy can provide additional findings that may help to establish a specific diagnosis. Craniopharyngiomas exhibit an elevated lactate peak and only trace amounts of other spectral metabolites. This is in contrast to gliomas that demonstrate an increased choline-to-N-acetylaspartate ratio compared with normal brain. Pituitary adenomas will exhibit either a choline peak or no abnormal metabolite peaks.

**Figure 131-3. Craniopharyngioma.** Magnetic resonance imaging (MRI)—Note the heterogeneous nature (solid > cystic) of this craniopharyngioma on MRI with significant suprasellar extension. Despite its location, potentially obstructing the foramen of Monro(s), there was no hydrocephalus.

## Histopathology

Craniopharyngiomas develop from epithelial nests that are embryonic remnants of Rathke's pouch located along an axis extending from the sella turcica along the pituitary stalk to the hypothalamus and the floor of the third ventricle. The tumors gradually enlarge as partially calcified, heterogeneous solid, and cystic masses predominantly in the suprasellar region. They extend along the path of least resistance into the basal cisterns or invaginate into the third ventricle. Hydrocephalus can result from continued growth superiorly into the third ventricle.

Craniopharyngiomas have two basic patterns of cellular growth—adamantinomatous and papillary. Mixed tumors with both adamantinomatous and squamous papillary components or combinations of craniopharyngioma and Rathke's cleft cysts can occur.

Adamantinomatous tumors are the more common variant. They resemble the epithelium of tooth-forming tumors containing three distinct components: a basal layer of small cells; an intermediate layer of variable thickness with loose, stellate cells; and a top layer facing the cystic lumen where the cells are abruptly enlarged, flattened, and keratinized. At the cyst surface, desquamated epithelial cells are present either singly or in characteristic stacked clusters (keratin nodules). These nodules may undergo mineralization with accumulation of calcium salts, which, in rare instances, progress to metaplastic bone formation. The cysts in these tumors usually contain an oily liquid composed of this desquamated epithelium, rich in cholesterol, keratin, and occasionally calcium (Fig. 131-5).

Squamous papillary tumors occur nearly exclusively in adults and often involve the third ventricle. They consist of solid epithelium, without loose stellate zones, in a papillary architecture that resembles metaplastic respiratory epithelium. They are predominantly solid and rarely undergo mineralization. When cysts occur, the fluid is less oily and dark than in adamantinomatous tumors. As a result of the absence of calcification and minimal cyst formation, complete curative

surgical resection may be obtained more often in these tumors than in adamantinomatous or mixed craniopharyngiomas (Fig. 131-6).

Microscopic islets or "fingers" of adamantinomatous tumor embedded in densely gliotic parenchyma are frequently seen when this tumor arises in the region of the tuber cinereum, hypothalamus, and floor of the third ventricle. The gliotic reaction of Rosenthal fibers and fibrillary astrocytes, varying between several hundred micrometers to millimeters in thickness, effectively separates the tumor from the brain, thus providing a safe plane for surgical dissection. The presence of this gliotic tissue on surgical pathology is associated with a decreased risk of recurrence after gross total tumor resection.

## Treatment

The treatment goal for craniopharyngiomas in the pediatric population is permanent tumor control or cure. However, the optimal treatment strategy remains controversial, with the debate centered on the extent of tumor resection, the role of radiation therapy, and the utilization of intracystic therapies, including radionuclides, baclofen, and interferon. The philosophy of curative treatment of craniopharyngiomas is predicated on children and their families having unimpeded access to long-term medical care and the personal or societal financial resources for the costs of lifetime hormone replacement therapy.

A multidisciplinary team including pediatric endocrinology, neuropsychology, pediatric neurosurgery, pediatric oncology, radiation oncology, and pediatric neurology is essential. Primary irradiation without resection, intracystic therapies, and palliative strategies may be more appropriate in those settings in which resources are limited or multidisciplinary expertise is lacking. Although partial resection without adjuvant radiation or cyst aspiration alone may provide temporary relief from symptoms, progressive solid and cystic tumor growth is inevitable. The management of craniopharyngiomas that have failed primary therapy is associated with significantly increased morbidity and mortality.

## Radical Surgical Resection

Many pediatric neurosurgeons in North America and Europe favor complete microsurgical resection as the treatment of choice for newly diagnosed craniopharyngiomas (Fig. 131-7). The feasibility and success of such radical resection is dependent on the size and extent of the tumor, whether the tumor is primary or recurrent, the availability of surgical expertise and postoperative endocrinologic support, as well as the presence of societal resources to cope with potential postoperative deficits. If the socioeconomic conditions applicable to an individual patient do not provide appropriate long-term neurologic care and endocrinologic support, functional morbidity may overshadow the merits of curative resection. Proponents of radical surgical resection argue that the advances of microsurgical techniques have facilitated treatment of these tumors and substitutive therapy can ameliorate endocrinologic sequelae secondary to hypothalamic injury. The greater immediate morbidity of this approach may be mitigated by the fact that radiation therapy carries the risk of unpredictable late neurologic, vascular, and oncogenic side effects as well as long-term development of neuropsychologic deficits in children.

Radiographically confirmed total resection can be accomplished in 60% to 100% of primary tumors in children with mortality rates of 0% to 4%. Recurrence rates after total resection range from 0% to 20%, and most recurrences occur within 2 to 3 years after surgery.

The philosophy and experience of the surgeon significantly affect the likelihood of achieving a curative total resection with a low mortality and without disabling morbidity. Centers performing fewer than 2 radical resections per year had a good outcome in only 52% of patients, whereas institutions that performed radical resections more often had a good outcome in 87% of patients. Factors such as tumor size, severity of preoperative deficits, and the presence of hydrocephalus all play a role in postoperative morbidity but not in disease control.

### Subtotal Resection With Irradiation

Craniopharyngiomas are radiosensitive tumors. To reduce the morbidity associated with radical surgery, particularly when there is significant involvement of the hypothalamus, subtotal resection with adjuvant irradiation may provide similar disease control and less endocrinologic morbidity compared with radical resection alone. The addition of postoperative radiotherapy in the setting of gross residual disease can decrease the recurrence rate to 15% to 20%, whereas subtotal resection alone results in progression rates of 55% to 85%. Although radiation therapy has significantly improved progression-free outcomes, it does carry its own set of risks. The adjacent critical structures surrounding the tumor bed can be injured as a result of radiation treatment, with risks of visual problems, endocrine derangements, or cognitive changes.

Several radiation modalities have been used in treatment of craniopharyngiomas, including conventional external beam radiation, intensity-modulated radiation, single-fraction stereotactic radiosurgery, fractionated stereotactic radiotherapy, and proton beam radiotherapy. With improvements in neuroimaging and radiation modalities, radiation treatment has become more accurate, resulting in decreased complication rates and improved survival (Lee et al., 2014; Kim et al., 2015). At this time, there is no standard of care regarding radiation for craniopharyngiomas although fractionated external beam radiation with a dose of 54 to 55.8 Gy in 1.8 Gy fractions is commonly used.

Recently a large case series of patients treated for residual tumor or tumor regrowth with single-dose gamma knife radiosurgery was published. In this series, progression-free survival was 70% at 5 years and 43.8% at 10 years, with an overall survival rate of 83.9% at 10-year follow-up. Most of the patients who developed new neurologic or endocrine disturbances demonstrated tumor regrowth; however, a total 10.9% of patients were thought to develop complications as a result of radiosurgery (Kim et al., 2015).

### Aspiration

Simple stereotactic aspiration of tumor cysts or placement of an Ommaya reservoir into the cyst for serial aspirations is never indicated as primary therapy in children and should be reserved for palliation when all other treatment modalities have failed. Frequent aspirations tend to stimulate cyst fluid production, leading to progressively shorter symptom-free intervals. Solid tumor growth is unimpeded and may extend into areas of the decompressed cysts. Aspiration may be required to control cyst volume while waiting for the therapeutic effects of intracavitary irradiation (Fig. 131-8).

### Intracystic Therapy

Intracystic therapy with bleomycin, interferon, or radionuclide can also be delivered through an Ommaya catheter.

**Intracavitary Irradiation.** Local treatment of cystic craniopharyngiomas with intracavitary beta irradiation was first

described by Leksell and Liden in the 1950s. The procedure is performed by using a fine needle to puncture the cyst or cysts under stereotactic guidance. The amount of radionuclide to be delivered is calculated using a standard formula based on the cyst's volume. This calculation can be difficult in very small cysts. An equivalent volume of cyst fluid is first aspirated before the radionuclide is injected into the cysts. It is important not to alter the size and shape of the cysts, as this ensures even distribution of the radioisotope over the entire internal cyst wall without wall collapse or "wrinkling."

Cyst regression after intracavitary irradiation occurs gradually over several months. It does not control solid tumor growth, nor does it prevent the development of new cysts. Intracystic irradiation is generally well tolerated. Cyst leakage can occur in up to 10% of patients, with no subsequent sequelae. It can often be used in combination with stereotactic radiosurgery in patients with tumors that have a larger cystic component and a smaller residual solid component (Kim et al., 2015).

**Intracystic Bleomycin.** Bleomycin inhibits DNA production and has shown clinical efficacy in the treatment of analogous epithelial tumors. The cell cycle kinetics and spatial distribution of S-phase proliferative cells in the squamous epithelium of craniopharyngioma cysts provide a rationale for the use of antineoplastic agents.

An Ommaya catheter is placed into the cyst either stereotactically or at the time of craniotomy. Several days after placement, a contrast injection and CT are performed to verify no leakage of cyst contents. Between 1.5 and 10 mg of bleomycin is injected at 1- to 2-day intervals depending on the cyst volume. Repeat injections are performed over a 10- to 21-day period for average total dose of 60 to 80 mg. Similar to intracystic irradiation, involution of cysts occurs slowly over several months. Although the total number of patients treated remains small, the reported series demonstrate reduction in cyst volume in almost all patients, with up to 50% of patients showing complete disappearance of the cyst and indefinite remission.

Despite proper positing of the catheter, bleomycin has been reported to leak into normal surrounding brain with significant complications of hypothalamic injury, seizures, hemiparesis, panhypopituitarism, blindness, and, rarely, death.

**Intracystic Interferon.** Interferon-alpha has been advocated as a safer alternative to bleomycin. Interferon-alpha is a cytokine with established antitumoral activity with the advantage of not having any neurotoxicity. Interferon-alpha has been used as both systemic and intracavitary therapy for primary craniopharyngiomas. In one of the initial studies, all 19 patients receiving intracystic interferon-alpha showed reduction in tumor size with a mean initial volume 33.50 cm<sup>3</sup> and mean final tumor volume of 3.10 cm<sup>3</sup>. Cavalheiro et al. reported an international multiinstitutional open-label trial of intracavitary interferon-alpha in 60 children. This study demonstrated a greater than 50% reduction in cyst size in 78% of children; however, with relatively short follow-up, 22% showed disease progression requiring repeat surgery. Three of the responders had previously experienced tumor progression after bleomycin but were salvaged with interferon. There was no information on long-term outcome or durability of disease control. Side effects in both studies included fatigue and headache with no development of new hormonal deficits or need to stop treatment because of side effects.

### Outcomes and Quality of Life

Hypothalamic dysfunction is a unique complication of craniopharyngiomas and can be life-threatening. Symptoms can

include obesity, hyperphagia, memory deficits, thermoregulatory abnormalities, labile behavior, and sleep-wake cycle abnormalities. Severe obesity with a body mass index defined as greater than three standard deviations above average has been reported in up to 44% of children after surgical resection (Müller, 2015).

## Overview

Craniopharyngiomas are histologically benign epithelial neoplasms that arise in the sellar and suprasellar region. Their intimate relationship with the optic chiasm, pituitary, hypothalamus, and cerebral vasculature leads a unique set of challenges in both treatment and management. There is no current consensus on optimal management strategies with outcomes supporting similar survival rates between gross total resection and subtotal resection followed by radiation. After treatment, patients must be followed with frequent imaging studies for early detection of recurrent tumors.

## MENINGIOMAS

Meningiomas are benign tumors that arise from the arachnoid cap cells of the meninges. Although meningiomas are the most common primary brain tumor diagnosed in adults, they are rare in the pediatric population, comprising only 2.6% of pediatric brain tumors. Because of their relatively low frequency, there are little data published regarding pediatric meningiomas. Much of the treatment strategies and management options are based on extrapolations from the adult literature despite significant differences being found between the two groups. In general, pediatric meningiomas are most often related to a pre-existing genetic condition (e.g., neurofibromatosis-2, NF-2), a history of radiation, or arise *de novo*.

## Epidemiology

The central brain tumor registry of the United States reported that meningiomas comprise 2.6% of all pediatric brain tumors with a similar rate of 2.4% reported in a recent meta-analysis of all published cases of pediatric meningiomas. A previous diagnosis of NF-2 was found in 10.2% of patients. In contrast to the female predilection seen in adult meningiomas, differing series in children have reported equal gender distributions or a slight male predominance (Stanuszek et al., 2014).

Being derived from arachnoid cells, meningiomas can develop in any location where meninges are present. In approximately 90% of patients, meningiomas are supratentorial and are usually found at the convexity. However, atypical lesions such as intraventricular or locations without obvious dural attachments can be seen in children at higher rates than seen in adults (Stanuszek et al., 2014). For example, intraventricular meningiomas comprise only 0.5% to 2% of tumors in adults, in contrast to 11% in children (Stanuszek et al., 2014). Additionally, tumors that lack dural attachment have been reported to be as high as 30% in children (Stanuszek et al., 2014).

## Clinical Presentation

As with any intracranial lesion, the presenting signs and symptoms depend on the size and location of the lesion. Compared with adults, pediatric meningiomas tend to be larger at the time of presentation and thus children often present with signs of increased intracranial pressure such as headache, nausea, vomiting, increased head circumference, or frontal bossing. Seizures have been the presenting symptom in up to 30% of pediatric patients with meningiomas. Based

**TABLE 131-1** Presenting Symptoms and Signs of Pediatric Meningiomas

Seizures	33%
Headache	13%
Ataxia	10%
Hemiparesis	10%
Scalp mass	3%
Surveillance	3%
Incidental	1%

(Data from Rushing et al. Central nervous system meningiomas in the first two decades of life: a clinicopathological analysis of 87 patients. *J Neurosurg* 2005;103:489–95.)

on published series, children present most commonly with headaches, followed by seizures, and least commonly with neurologic deficits (Table 131-1).

## Molecular Genetics

Much of the knowledge regarding molecular genetics of meningiomas is due to studies in the adult meningioma population but which has not been further extended to assessment of children. The precipitating cytogenetic event resulting in meningioma development is thought to be caused by a deletion on chromosome 22, close to the NF-2 gene. Deletions in both 1p and 14q have also been found in pediatric meningiomas and are associated with higher rates of tumor recurrence.

## Meningiomas and Genetic Conditions

In the pediatric population, meningiomas are commonly associated with several disorders, including NF-2, Gorlin syndrome, Rubenstein-Taybi syndrome, and Castleman disease.

Pediatric meningiomas are most frequently seen in patients with NF-2. It is estimated that 20% to 40% of all pediatric meningiomas are in patients with NF-2 and 53% of patients with NF-2 will develop meningiomas (Stanuszek et al., 2014). The Wishart variant of NF-2 has meningioma rates as high as 83% (Stanuszek et al., 2014). Patients with NF-2 have a much higher risk of being diagnosed with multifocal meningiomas. Children presenting with an isolated meningioma have a 20% risk of developing NF-2 and evaluation for the disease should be undertaken at diagnosis (Stanuszek et al., 2014).

The disease course of NF-2 meningiomas can vary greatly from that of sporadic meningiomas. The location of NF-2-associated meningiomas are different from that in the general population, with higher rates in the spinal canal and optic nerve sheath. Although sporadic meningiomas tend to invade brain tissue causing a poorer short-term prognosis, NF-2 meningiomas have less of a tendency for brain invasion, offering a more favorable short-term prognosis. However, because of multiple tumors that tend to develop in NF-2, the overall long-term prognosis is less favorable than that seen for the general population (Stanuszek et al., 2014). NF-2-associated meningiomas also have been calculated to grow at faster rates than sporadic meningiomas with growth rates of 0.01 to 6.7 cm<sup>3</sup>/year and 0.2 to 2.5 cm<sup>3</sup>/year, respectively.

Treatment of patients with NF-2 meningiomas differs compared with the regular pediatric population. Because of the frequency of meningiomas and other associated tumors, management of NF-2 focuses on quality of life and conservation of neurologic function (Stanuszek et al., 2014). For

these reasons, it is recommended to operate only on lesions that are causing progressive symptoms and not necessarily for radiographic progression alone (Stanuszek et al., 2014). NF-2 meningiomas have been reported to be less sensitive to stereotactic radiosurgery compared with sporadic tumors (Stanuszek et al., 2014).

### Radiation-Induced Meningiomas

Radiation therapy for treatment of other malignancies is a well-documented cause for meningioma development. The interval between initial radiation exposure and development of meningiomas is dependent on the intensity of radiation received, with the earliest reports of meningioma occurrence at 2 years after treatment to as late as 63 years after radiation therapy. Meningiomas caused by radiation damage often will show complex structural chromosomal abnormalities as a result of DNA damage. Because of the increased risk of meningioma development, all children who received prior cranial radiation should be followed with serial surveillance MRI screenings into adulthood.

### Neuroimaging

Imaging characteristics of meningiomas are similar in both pediatric and adult tumors. Typical findings on CT are isodense or hypodense lesions with surrounding edema. Additionally, hyperostosis of the surrounding bone is a common finding. On MRI, meningiomas appear as hypointense on T1-weighted imaging and hyperintense on T2-weighted imaging (Fig. 131-9). With contrast administration, meningiomas show avid and homogenous enhancement. A dural tail is characteristic of meningiomas but not pathognomonic. Calcifications and cystic transformation can be seen more commonly in children.

As opposed to adults, any patient with a newly diagnosed meningioma should undergo imaging of the complete neuroaxis to evaluate for either multiple lesions or metastatic lesions.

### Histopathology

The revised WHO classification divides meningiomas into grade I (benign), grade II (atypical), and, grade III (anaplastic). Based on histopathologic characteristics, meningiomas can be further subdivided into 13 variants. Although this classification scheme is based on adult meningiomas, all variants have been described in pediatric meningiomas as well (Fig. 131-10).

As with adults, WHO grade I meningiomas are most common, with transitional, meningiothelial, and fibrous histopathologic types occurring most frequently (Stanuszek et al., 2014) (Table 131-2). However, in contrast to adults, there are higher rates of atypical histopathology in children,

especially with the clear cell and papillary variants. In the adult population, the incidence of WHO grade II and III meningiomas is 1 to 2.8% whereas in children the incidence reaches 4.7% to 7.2% (Stanuszek et al., 2014). Although histologic grade usually does influence treatment, 15-year survival was not influenced in children and adolescents (Stanuszek et al., 2014). Unlike adults, the behavior of childhood meningiomas can be very difficult to predict based on the WHO grade. There is, however, a tendency for WHO grade III meningiomas to behave in a more aggressive manner, as seen in smaller case series.

The risk of developing recurrent disease in pediatric patients has been shown to be linked to the WHO grade. WHO grade I tumors have a 92% 10-year event-free survival, whereas 10-year event-free survival for WHO grade II and III tumors is 70% and 33%, respectively.

### Treatment

Because of the largely benign nature of the disease, treatment options for meningiomas can be either conservative (observation) or via surgical intervention. Because of the rare nature of the disease and often atypical imaging findings, the need for a tissue diagnosis may necessitate operative intervention. Radiation therapy has been shown to be an effective adjuvant treatment, although the risks of radiation in the pediatric brain must be considered, especially with the possibility of malignant transformation. To date, chemotherapy has not been found to be efficacious in the management of meningiomas and is not a reasonable treatment option.

### Observation

Conservative management via observation is a potential option in the pediatric population; however, the potential for long-term complications must be taken into account. Characteristics of the lesion, such as size, location, and symptomatology, should be evaluated before deciding on conservative management. Observation is a common strategy in incidentally found meningiomas in adults. Studies of the adult population have shown that over 90% of meningiomas managed with observation grew over time with tumors larger than 2.5 cm tending to grow at more significant rates. With the long life expectancy of children, patients and parents should appropriately be counseled on the likely need for future surgical intervention. If conservative management is chosen, patients should be closely monitored with serial MRI every 6 to 12 months. If at any point there is radiographic evidence of tumor growth or if tumor-related symptoms develop, surgical intervention is strongly recommended.

### Surgery

The definitive treatment for meningiomas is complete surgical resection, and the extent of surgical resection has been shown to be the most important prognostic factor for survival across all WHO tumor grades. Subtotal resection is associated with disease progression and the potential for malignant transformation. Surgical planning, including patient positioning, approach, and technique, is specifically dependent on tumor location, vascular supply, and patient-related factors. In the pediatric population, where blood loss is a major concern, staged procedures may also be an option in order to achieve gross total resection. Because of the large size of tumors at presentation and small blood volumes in pediatric patients, surgical mortality is estimated to be as high as 3% with a postoperative morbidity of as high as 40%.

As meningiomas tend to be vascular tumors, preoperative angiograms for tumor embolization are commonly employed

**TABLE 131-2** Pathologic Classification of Pediatric Meningiomas

Grade I	Typical (<4 mit/10hpf)	Meningiothelial fibrous, transitional, psammomatous, angiomatous
Grade II	Atypical (4–20 mit/10hpf)	Chordoid, clear cell
Grade III	Anaplastic (>20 mit/10hpf)	Papillary, rhabdoid

(Adapted from Louis et al. World Health Organization classification of tumors. Pathology and genetics of tumors. Lyon: IARC Press; 2000. p. 176–84.)

in adults (Stanuszek et al., 2014). Evidence has shown that selective embolization of feeding vessels has reduced operative blood loss and the length of surgery. However, because of the small-caliber vessels in children, there may be a significant risk of procedural complications, and treatment decisions must be made on an individual basis (Stanuszek et al., 2014). If preoperative embolization is not undertaken, attempts should be made to access and disrupt the major vascular supply (usually extradural) of the tumor early during surgery. This technique reduces intraoperative blood loss and also may make the tumor softer and more amenable to resection (Fig. 131-11).

For the most part, low-grade meningiomas maintain an arachnoid plane between the tumor and surrounding brain. In cases of atypical or malignant meningiomas, tumors are more likely to violate the arachnoid barrier and invade brain tissue, dura, and vessels. For these reasons, complete resection becomes considerably more difficult. If dura or bone appears to be invaded by tumor, it should be resected as much as possible. Small tumors may be able to be removed *en bloc*; however, larger tumors may require piecemeal resection.

The greatest difficulties arise when a patient's venous sinus is invaded by the tumor. In such cases, it may be prudent to leave a small portion of the tumor behind, rather than sacrificing an open dural sinus. Even in the anterior third of the sagittal sinus, sacrifice of this portion of the vessel cannot always be done with impunity. Close observation, even allowing the affected dural sinus to occlude slowly over time, will often permit an additional attempt at total tumor extirpation. Stereotactic radiosurgery may also be considered a therapeutic option, although the risk of malignant transformation cannot be discounted.

Recurrence rates of meningiomas are largely based on data obtained from the adult literature. With complete resection, recurrence rates of up to 20% within 25 years have been reported. In patients with subtotal resections, recurrence rates may be as high as 80% to 90%. These data necessitate long-term follow-up of children with meningiomas into adulthood.

## Radiation

Data regarding adjuvant radiation to childhood meningiomas are limited; however, radiation therapy has been proven to be effective as an adjuvant to surgery in adults. The National Institute for Health and Clinical Excellence recommends radiation treatment for adult patients with WHO grade 2/3 tumors, presence of adjacent brain or local invasion, tumor relapse, or if there is a contraindication to initial surgical resection. With conventional fractionated radiotherapy, doses of 50 to 55 Gy with dose increases to 60 Gy only considered in exceptional circumstances. Progression-free survival was shown to improve from 50% to 80% in adults with subtotal resection after radiation. In the pediatric population, the long-term neurocognitive sequelae must also be taken into account before delivering radiation.

## Overview

Meningiomas in the pediatric population manifest significant differences from their adult counterparts with a much lower incidence. Tumors in children are highly associated with genetic syndromes, especially NF-2, and evaluation for such conditions should be done at the time of diagnosis. Although conservative management with close observation is an option, complete surgical resection portends the best long-term outcome of patients.

## SCHWANNOMAS

Although intracranial schwannomas are the most common tumor of the cerebellopontine angle in adults, they are exceedingly rare in children. Only 0.7% of all schwannomas develop in the pediatric population and account for 2% of posterior fossa tumors in children. Schwannomas can arise from any cranial nerve and have been reported to grown from nerves III, V, VII, VIII, IX, X, XI, and XII. As in adults, vestibular schwannomas are the most common form and are typically associated with NF-2. Although these are benign lesions, their size and location can make these tumors particularly challenging to treat (Fig. 131-12).

## Clinical Presentation

The clinical presentation of intracranial schwannomas is quite varied. As with all mass lesions, common presentation includes signs of increased intracranial pressure with accelerations in head growth, developmental delay, papilledema, headaches, or vomiting. Tumors arising in the cerebellopontine angle can result in obstructive hydrocephalus from mass effect on the fourth ventricle, cerebral aqueduct, or fourth ventricular outflow pathways. As the tumors enlarge, cerebellar symptoms may also develop.

Schwannomas are tumors of the nerve sheath rather than the nerves themselves. For this reason, tumors will grow centripetally outward from the nerve. Cranial nerve palsies will occur only if tumor growth is restricted, usually by local bony anatomy.

## Schwannomas and Genetic Conditions

The development of intracranial schwannomas is associated with both NF2 and schwannomatosis. These conditions are a result of genetic mutations in the merlin gene on chromosome 22q12 (Hilton and Hanemann, 2014). In cases of sporadic schwannomas, the majority have also shown loss of the chromosome 22q as well.

Bilateral vestibular schwannomas are pathognomonic for the diagnosis of NF-2, and the presence of a unilateral vestibular schwannoma in patients aged under 30 years should prompt an evaluation for NF-2.

*Schwannomatosis* is a relatively newly reported clinically distinct form of neurofibromatosis. It is characterized by the development of multiple spinal peripheral, and cranial nerve schwannomas as well as rhabdoid tumors. However, these patients lack vestibular schwannomas and the other diagnostic criteria of NF-2 (Hilton and Hanemann, 2014). In 2007, it was first identified that a mutation in the SMARCB1 tumor suppressor gene is responsible for this condition.

## Neuroimaging

Intracranial schwannomas are typically found in the cerebellopontine angle. Noncontrast CT imaging shows isodense lesions to normal brain. On cranial bone imaging, tumors may have expansion of the porus acusticus, jugular foramen, or any other bony foramina. MRI generally shows a T1-weighted isointense lesion to gray matter and homogenous enhancement with contrast delivery.

## Histopathology

Schwannomas are benign tumors of Schwann cell origin and are classified by the World Health Organization as a grade I benign nerve sheath tumor. They can originate from any peripheral, cranial, or autonomic nerve (Agarwal, 2015).

Classically, schwannomas are composed of two distinct cellular patterns. *Antoni A* fibers are compact cellular structures with spindle-shaped cells. These cells can palisade to form Verocay bodies. Contrarily, *Antoni B* fibers are less compact with a loose microcystic matrix. They are relatively hypocellular but rich in collagen fibers and macrophages.

Often pediatric schwannomas lack the biphasic histology of adult schwannomas. Rather, they are more uniformly hypercellular with the presence of Verocay bodies. Other features unique to pediatric schwannomas include hemosiderin deposits and reactive vascular changes. Although mitotic figures are not seen in adult schwannomas, they may be present in their pediatric counterparts.

## Treatment

Because of the rare nature of pediatric schwannomas, treatment options are extrapolated from the adult literature. Management includes three strategies: observation, radiosurgery, or microsurgery (Zygorakis et al., 2014). Tumor size and symptomatology as well as patient and family preferences dictate the best course of treatment. Complete surgical resection is curative for schwannomas, and symptomatic lesions should be surgically resected when possible. Surgical approaches vary based on tumor location, with the retrosigmoid approach being commonly used. If tumors appear to be highly vascular, preoperative embolization is an option to reduce blood loss.

## Overview

Schwannomas are rare in childhood. They occur more frequently in patients with NF-2 but, even then, are seen more commonly in adults than in children. When possible, complete surgical resection is indicated and curative.

## INTRODUCTION

Intradural spinal cord tumors (SCTs) are composed of a heterogeneous group of neoplasms, accounting for approximately 10% of pediatric central nervous system tumors (Russell & Rubinstein 1989). Over the past five decades, the overall mortality and morbidity caused by these tumors has been reduced dramatically. The advantages of early diagnosis via modern imaging and modern neurosurgical tools such as intraoperative electrophysiological monitoring, the surgical microscope, and the ultrasonic aspirator have led to improvements in surgical morbidity and in general prognosis. Today, the standard of care of SCTs is complete surgical resection when possible, although adjuvant therapy provides benefit in selected cases.

This chapter focuses on the diagnosis and management of common intradural (extramedullary and intramedullary) primary pediatric SCTs.

## EPIDEMIOLOGY

There is little population-based data available on pediatric primary SCTs. Many of the existing statistics are not current, having often been obtained from outdated surgical series. Intradural spinal tumors as a whole are believed to occur with an incidence that ranges from 0.7 to 1.1 cases per 100,000 persons. Intramedullary spinal cord tumors (IMSCTs) account for approximately 2% to 4% of all CNS tumors in the general population.

It has been estimated that approximately 30% of SCTs in the pediatric population are intramedullary, 24% are extramedullary, 35% are extradural (and not included in this chapter), and 10% are of other types. Astroglial tumors are the most common type of intramedullary tumors, accounting for around 90% of all pediatric IMSCTs, with a mean presentation age of 5 to 10 years and 60% in adolescence. Neurofibromatosis (NF) 1 and 2 are associated with IMSCTs, with as many as 19% of patients suffering from such tumors. Among NF1 patients, astrocytomas are more common. In NF2, ependymomas are more frequent. NF1 and NF2 are also known for their hallmark extramedullary nerve-sheath tumors (NSTs): neurofibromas and schwannomas, respectively.

## PRESENTATION

Reported clinical manifestations of SCTs have changed since the beginning of the magnetic resonance imaging (MRI) era, potentially due to earlier diagnosis. Yet even today the primary physician, neurologist, and orthopedist must have a high index of suspicion of primary sensory complaints such as dysesthesia and localized back pain to make an early diagnosis before permanent damage occurs.

In the pediatric age group, it is common for parents to become aware of a problem before any objective signs are apparent on the neurologic examination. In many of these patients the onset of symptoms is attributed to an apparently trivial injury. Occasionally, parents describe symptomatic exacerbations and remissions. For both children and adults,

the most common early symptom is local pain along the spinal axis that is usually most acute in the bony segment directly over the tumor. Typically pain is worse in the recumbent position because venous congestion further distends the dural tube, resulting in characteristic night pain.

Other symptoms include motor disturbances, radicular pain (occurring in about 10% of patients, usually limited to one or two dermatomes), paresthesias, painful dysesthesia (hot or cold painful sensations), and rarely, sphincter dysfunction. Weakness of the lower limbs is usually first manifested as an alteration in normal gait. This is often very subtle and may only be evident initially to a watchful parent who notes more frequent falling and/or walking on heels or toes. In young children there is often a history of being a "late walker," and in very young children (under 3 years) there is often a history of motor regression.

IMSCTs usually present with myelopathic symptoms of insidious onset. Localized pain and upper extremity paresthesias are the initial symptoms in 50% to 90% of patients with cervical lesions. Thoracic lesions may present with lower limb sensory losses and with upper motor neuron signs. Sphincter dysfunction is present in up to 40% of patients. In the pediatric population, pain is less often a presenting symptom, but is present in approximately 50% of patients. Symptoms usually last for months or even years before diagnosis.

Different SCT subtypes may present with slightly different clinical pictures. For rare malignant astrocytomas, the clinical presentation will include a more rapid decline in gait and pain of increasing intensity. Cervical ependymomas characteristically present with bilateral, symmetric dysesthesias.

The anatomic location of the tumor usually correlates with the clinical presentation. Cervical tumors may present with torticollis. Scoliosis is the most common early sign of an intramedullary thoracic cord tumor. Sphincter laxity is considered a late sign except in tumors that originate in the conus/cauda equina area. Higher tumors present less commonly with sphincter abnormalities, even with cystic components extending into the conus. Spinal cord compression is more common at presentation of EMSCTs than IMSCTs.

Hydrocephalus due to protein secretion into the cerebrospinal fluid is a common presentation of IMSCTs in infants. Torticollis and progressive kyphoscoliosis are also common (Box 132-1).

## DIAGNOSIS

Once an SCT is suspected, spinal MRI (preferably of the entire neuroaxis) is the imaging method of choice. The MRI protocol should always be carefully planned according to the clinical symptoms and neurologic signs in conjunction with a neuroradiologist. It should consist of unenhanced T1- and T2-weighted images and contrast-enhanced T1-weighted images. Gadolinium may enhance the solid component of the tumor and help delineate it from surrounding edema. Ependymomas, meningiomas, and NSTs typically contrast-enhance brightly after gadolinium injection. Astrocytomas have a

**TABLE 132-1** Tumor Characteristics, Treatment Recommendations, and Average Prognosis

Tumor	MR Appearance	Typical Location	Treatment	Prognosis
<b>EXTRAMEDULLARY</b>				
Meningioma	T1-hypo T2-hyper Contrast enhancing	Thoracic region Dural based	CR	Generally good Beware of anteriorly located tumors
Schwannoma and Neurofibroma	Solid T1-iso T2-hyper Contrast enhancing	Sometimes dumbbell shaped Extending toward the foramen	Resection	Generally good
Ependymoma of cauda equina (Myxopapillary)	Expansile T2-hyper Contrast enhancing	Filum/Conus/Cauda	Resection RT	Good Beware of infiltration into the conus
<b>INTRAMEDULLARY</b>				
Astrocytoma	Expansile T2-hyper Heterogeneous enhancement Cyst and/or syrinx	Cervical/thoracic	Aggressive resection RT/CT	Good
Malignant Glioma	T2-hyper Contrast enhancing	Cervical/thoracic	Resection RT/CT	Poor
Hemangioblastoma	Syringobulbia Syringomyelia Highly vascular Cord edema	Cervical/thoracic	Resection	Good
Ependymoma	Expansile T2-hyper Contrast enhancing Cyst and/or syrinx	Cervical	Resection RT reserved for special cases	Very good

CR, Complete resection; CT, chemotherapy; MR, magnetic resonance; RT, radiotherapy T1-hypo, T1 hypointense; T2-hyper, T2 hyperintense.

**BOX 132-1** When to Obtain an MRI on a Patient With Scoliosis

1. Documented rapid progression
2. Atypical curve
3. Age: early onset (<8 years)
4. Any neurologic/urologic sign
5. Vertebral and midline anomalies
6. Persistent pain (especially at night)
7. Screening in all dysraphic children

variable enhancement pattern and may give the cord a lumpy appearance. These images should be acquired in both sagittal and axial planes. Anesthesia is sometimes needed in pediatric patients. Table 132-1 describes the radiologic characteristics, recommended treatment method, and overall prognosis of the different SCTs.

Plain films and computed tomography (CT) are not sensitive enough to effectively evaluate patients with suspected intradural—and especially intramedullary—lesions. Secondary bony changes, such as pedicle erosion, scalloping, or foraminal widening, are better demonstrated with CT. Plain films are better for diagnosis of instability and quantification of scoliotic and kyphotic deformities, however. Bladder ultrasound with an examination after emptying is an important baseline study to be done before surgery.

**TUMOR SUBTYPES**  
**Extramedullary Spinal Cord Tumors**

The most common primary extramedullary spinal cord tumors (EMSCTs) are derived from sheath cells covering the spinal nerve roots (neurofibromas and schwannomas) or the endothelial lining of the meninges (meningiomas). Myxopapillary

ependymomas are glial EMSCTs arising from the conus medullaris or the filum terminale. Other lesion types, such as lipomas and epidermoid/dermoid cysts, are less common but should be considered in the differential diagnosis.

EMSCTs generally cause chronic, slowly progressive compression of the cord. Symptomatology is due to the displacement and compression of the cord and adjacent nerve roots and secondary venous engorgement. Most patients will be symptomatic at the time of diagnosis; symptom onset can precede diagnosis by months to years. Due to the chronic, slow course of these tumors, the cord often looks atrophic, yet neurologic function may be preserved. The most common clinical presentation of EMSCTs is with back pain that may be indistinguishable from that seen with non-neoplastic causes. This pain is often described as aching, pressing, and dull, and is usually more severe at night. Radicular pain is uncommon with meningiomas but is common with NSTs. Paresthesias and numbness are common symptoms, and hypoesthesia or anesthesia at and below the level of the tumor is often evident on clinical examination. Patterns of sensory deficit such as posterior cord syndrome can suggest tumor localization. Upper motor neuron injury manifested as spastic paraparesis is common, too, and is usually first evident when the patient climbs stairs and tries to use proximal muscle groups. High cervical tumors may cause quadriplegia. When the tumor or the associated cyst extends rostrally into the brainstem, low cranial nerve involvement, dysphagia, and respiratory disturbances can occur.

**Spinal Meningiomas**

Spinal meningiomas are extremely rare in the pediatric population and are almost always associated with NF2. More than 90% of meningiomas are intradural, and more than 95% are benign tumors arising from the endothelium that lines the leptomeningeal spaces (arachnoid cap cells). Most

meningiomas arise in the thoracic region (80%). Less common is involvement of the cervical (15%) or lumbar (5%) regions. Intradural meningiomas are usually located laterally or posteriorly to the spinal cord; anterior location is less common.

On MRI, spinal meningiomas appear hypointense to isointense on T1 and hyperintense on T2. They often display homogenous enhancement with gadolinium contrast, but calcifications are common and may preclude gadolinium enhancement.

Spinal meningiomas are managed by surgery. Even with the technical challenges of anteriorly located tumors, gross total removal (GTR; defined as over 99%) of meningiomas is attainable in more than 90% of patients. Tumor recurrence rate is between 3% and 7%. Radiotherapy could be considered after subtotal removal (STR) or recurrence, but is seldom needed and may not add significant therapeutic efficacy. Neurologic morbidity of the surgical procedure is directly related to preoperative neurologic status. Patients with little or no disability are at little risk of sustaining an injury, whereas patients with more advanced neurologic dysfunction have a greater risk of impairment. With modern use of electrophysiological monitoring, perioperative complications are usually limited to wound healing and cerebrospinal fluid fistulas. Long-term recovery is usually excellent. Anteriorly located spinal meningiomas require a very lateral approach, with special care to avoid injury to the pyramidal tracts and to the anterior spinal artery. These cases may be more challenging, carrying a potential risk of spinal cord damage. The use of the ultrasonic aspirator to internally debulk the tumor allows better manipulation of the capsule and careful microsurgical separation from the spinal cord without the need for cord retraction.

### Peripheral Nerve Tumors (Neurofibromas, Schwannomas)

NSTs are World Health Organization (WHO) grade I tumors. They usually present as solitary lesions, typically in the fourth or fifth decade of life. Earlier presentation or multiple lesions are usually associated with genetic syndromes such as neurofibromatosis I, II, and schwannomatosis. These syndromes are respectively associated with multiple neurofibromas, spinal meningiomas, and schwannomas. Schwannomas are more common than neurofibromas. Approximately 60% to 80% of NSTs arise from nerve roots before leaving the dural sac, usually affecting the lumbosacral region. Anatomically, schwannomas tend to arise from the dorsal nerve root, whereas neurofibromas are more common on the ventral root. Other than this difference, schwannomas and neurofibromas are indistinguishable on MRI. NSTs have an isointense signal on T1 and a hyperintense signal on T2. Their characteristic pattern on fluid-sensitive sequences has been described as "target lesion." Tumor enhancement varies, ranging from homogenous to a peripheral ring-like enhancement. Schwannoma pathology usually contains neoplastic Schwann cells, whereas neurofibromas more frequently invade the nerve root and contain Schwann cells, nerve fibers, and fibroblasts.

NST management depends on the patient's clinical presentation and radiologic follow up. A clinically and radiologically stable tumor needs only close follow up with MRI and physical examination. Surgical intervention is warranted if the tumor causes additional symptoms or displays imaging progression at presentation or during follow up. In NF, when many such tumors are present and the clinical presentation is often vague and complicated, the threshold for surgery is higher. GTR is the definitive treatment of such lesions, resulting in only a 5% recurrence rate.

To achieve total resection, the ventral or dorsal roots are commonly sacrificed. This, however, is usually not associated with pronounced postoperative motor or sensory deficit. Resection of schwannomas is usually safer because of their typical location on the dorsal root and the fact that they are less invasive than neurofibromas. Subtotal resection may be preferable if the tumor is attached to the spinal cord, if the origin of the tumor is an important ventral rootlet, or if the tumor exhibits extradural components closely associated with vital structures.

### EPENDYMOMAS OF THE CONUS-CAUDA REGION

These tumors are usually extradural myxopapillary ependymomas, which account for approximately 40% to 50% of spinal ependymomas. They are more common in young adults. Patients usually present with a long history of back pain, lower sensorimotor deficit, and sphincter dysfunction.

On MRI they are often seen as well-circumscribed masses with hypointense signal on T1 and hyperintense signal on T2. Gadolinium enhancement is usually homogenous.

Complete resection is the treatment of choice and is generally feasible if nerve roots are not entrapped by the tumor. STR is reserved for cases with severe encasement of cauda equina nerve roots, especially low sacral S2–S4 innervation. Radiotherapy after complete or subtotal resection is still controversial. Recurrence after complete resection is less rare than previously thought and may be associated with poor outcome.

### INTRAMEDULLARY SPINAL CORD TUMORS (IMSCTS)

A comprehensive discussion of these tumors can be found in Sloof (1964) (Figure 132-1).

#### Glial Tumors

Although IMSCTs make up only about 20% of all adult SCTs, at least 35% of pediatric SCTs are intramedullary. The vast majority of IMSCTs are members of the glioma family. Among 164 pediatric patients with IMSCTs operated on by Dr. Fred Epstein between 1980 and 1994 (Constantini et al. 2000):

- 48% presented with astrocytomas
  - 76% low-grade
  - 24% high-grade
- 26% presented with gangliogliomas
- 11% presented with ependymomas
- 6% presented with mixed gliomas
- 9% presented with other lesions, such as hemangioblastomas, primitive neuroectodermal tumors (PNETs), lipomas, and ganglioneurocytomas

Intramedullary ependymomas almost never appear in the first decade. Note that within the spectrum of low-grade glial tumors, significant differences are found in reported series in the rates of different tumor subtypes such as low-grade astrocytomas, juvenile pilocytic astrocytomas, gangliogliomas, oligodendrogliomas, and others. Maximal surgical resection is considered the optimal treatment for nonastrocytic neuroglial tumors, and adjuvant radiotherapy is usually not indicated.

#### Intramedullary Ependymomas

Ependymomas are very rare in children, constituting only 11% to 35% of IMSCTs in the pediatric population. Categorization of ependymomas, both spinal and cranial, is based on histologic properties. Classical (WHO grade II and III) cellular ependymomas arise from the spinal canal and usually occupy

**Figure 132-1.** An 11-year-old basketball player, presenting with 2 weeks of focal back pain and bilateral hand pain, especially at night. Physical examination was normal beside alert, brisk reflexes, and mild weakness of left hand. MRI revealed intramedullary space-occupying lesion, spanning from C5 to T1 with a large cystic component, receiving inhomogeneous enhancement on T1 with gadolinium (A), and a large cystic component and T2 changes (B). Resection under electrophysiological monitoring was decided upon. Intraoperatively, following C5-T1 laminotomy, a bulky cord rotated to the left was evident (C). A gross total resection was achieved via a left DREZ approach (D), and the child was discharged a few days later with no neurologic deficit.

the cervical and thoracic regions. Myxopapillary (WHO grade I) ependymomas arise from the filum terminale, occupy the conus medullaris almost exclusively, and are usually extradural. Most ependymomas are WHO low-grade tumors (class I and II) (Hsu et al. 2009). Malignant subtype anaplastic ependymomas are rarely encountered in the spine.

On MRI, these tumors appear hypointense on T1 and hyperintense in T2. Ependymomas display homogenous enhancement. Although usually not encapsulated, there is often a clear plane evident between the tumor and the cord. Cysts, syrinx, and hemorrhage may also be evident.

Management of ependymomas is aggressive resection in most cases. Complete resection with the aid of intraoperative electrophysiological monitoring yields local control in 90% to 100% of patients. In partial resections of grade II and III tumors, the addition of adjuvant radiotherapy may be warranted but is still debatable. It is important to remember that adjuvant radiotherapy may make future surgical intervention more difficult and increases postoperative neurologic morbidity. The role of adjuvant chemotherapy is unclear at this time. Spinal intramedullary ependymomas generally have a good prognosis, with an average progression-free survival (PFS) of 82 months and an average overall survival of 180 months.

### Low-Grade Astrocytomas

(Figure 132-2)

On MRI, these lesions appear as a fusiform expansion of the cord, sometimes including a cystic component. Syrinx is seen in approximately 40% of patients, and edema is often present. This tumor is hypointense or isointense on T1 image, and hyperintense on T2 and FLAIR, displaying partial enhancement. It is very difficult to differentiate astrocytomas from ependymomas based on MRI alone.

Management of intramedullary astrocytomas is based on maximal safe resection followed by observation. Because of the infiltrative nature of these tumors, complete resection is highly dependent on the surgeon's experience, mostly to identify a change in color (interphase) between the tumor and the normal white matter around it.

**Figure 132-2.** An MRI of a 10-year-old boy who presented with drooling and neck pain. The intramedullary low-grade astrocytoma spans from C3–C6.

In the pediatric population, adjuvant oncological treatment is usually reserved for those with multifocal disease, patients who have progressive disease without an adequate surgical option, or children who are at a high risk of developing plegia after a second, or even third, operation. The

standard gentle chemotherapy used for low-grade astrocytomas in the brain has been shown to be effective in selected cases of intramedullary astrocytomas, especially in infants (Constantini et al. 1996). Radiation should be avoided in children younger than 5 years because of the detrimental effects on the immature central nervous system (Duffner et al. 1993). Susceptibility to the destructive effects of radiation on the spinal cord increases with the extent of cord irradiation and with the total dose. Therapeutic irradiation in substantial doses over extensive segments of spinal cord may result in myelitis. In addition, irradiation subsequent to spinal surgery predisposes to kyphosis and subluxation. Finally, irradiation may trigger development of a second malignant tumor.

Because there is no clear evidence that radiation or chemotherapy has a significant impact on the outcome for patients presenting with IMSCs, especially astrocytomas, the role of surgery upon presentation remains substantial. If a pediatric patient with a low-grade IMSC astrocytoma is treated with radical excision, long-term progression-free survival generally ensues without the need for adjuvant treatment. In many cases, pediatric intramedullary tumors are a “surgical disease.”

### Malignant Spinal Gliomas

High-grade gliomas of the spinal cord represent approximately 25% of intramedullary gliomas in adults and less than 10% in the pediatric population. These tumors are associated with poor prognosis and almost 100% recurrence. On MRI they display malignant characteristics such as heterogeneous enhancement caused by the presence of intramural cysts, necrosis, and surrounding edema. High-grade astroglial IMSCs, especially glioblastomas, invariably progress. The optimal treatment for this entity has yet to be determined. Despite aggressive adjuvant therapy, patients with malignant IMSCs have a postoperative median survival of up to 12 months. This is usually because of progressive infiltration of the tumor within the cord and through its pial banks, resulting in paraplegia, quadriplegia, and eventually death. A patient

with a high-grade spinal astrocytoma has an average life expectancy of 15 months.

# 133 System Cancer and the Central Nervous System Involvement

Sharyu Hanmantgad and Yasmin Khakoo

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Children with systemic cancer may develop neurologic symptoms/complications from either metastatic disease or the side effects of treatment. Although primary central nervous system (CNS) tumors are the most common solid tumors of childhood, metastasis of systemic tumors to the CNS is rare. Adults with systemic malignancies develop CNS metastases 20% to 40% of the time, whereas less than 10% of children with systemic malignancies are so affected. In one series of almost 4000 children diagnosed with systemic solid tumors between 1990 and 2012, only 1.4% had brain metastases. In contrast, 3% to 5% of all children with acute lymphoblastic leukemia develop a CNS relapse, and 20% to 40% of children in relapse have CNS disease. Additionally, treatment of systemic malignancy, including surgery, radiation, and chemotherapy, may cause neurologic symptoms. This chapter discusses CNS involvement in systemic childhood cancer (Suki et al., 2014).

## Central Nervous System Leukemia

CNS leukemia occurs in approximately 4% of children with leukemia. All children with acute lymphocytic leukemia (ALL) receive routine lumbar punctures at the time of diagnosis and, for the majority, such involvement, if present, is asymptomatic. The leukemic cells found in the cerebrospinal fluid (CSF) are cytogenetically identical to those found in the bone marrow. Protein expression profiles may define subsets of leukemic B cells that are more likely to metastasize to the CNS, and signaling of the cytokine CCL19 through its receptor, CCR7, is required for CNS infiltration by leukemic T cells (Jin et al., 2016).

Leukemic lymphocytes appear to metastasize to the CNS by hematogenous spread with extravasation that depends in animal models on myosin-IIA, or through the CNS lymphatics near the dural sinuses.

Although rare, neurologic symptoms associated with CNS leukemia include headaches (17%), nausea and vomiting (14%), lethargy, and irritability. Symptoms were present in half of patients with greater than or equal to 5 leukocytes/ $\mu$ L with blasts in the CSF or signs of CNS involvement on neurologic examination, and only 20% of patients with less than 5 leukocytes/ $\mu$ L CSF had signs or symptoms whether or not the CSF contained blasts. On examination, there may be nuchal rigidity and papilledema. Cranial nerve involvement is less common but may include seventh, third, fourth, and sixth nerve impairment. Infiltration of the optic nerve can also be seen. Hypothalamic obesity caused by direct infiltration of the hypothalamus is a rare syndrome. Spinal cord involvement has been reported but is quite uncommon. Rarely, patients develop choroidomas, distinct masses of leukemic cells, in the CNS.

The presence of CNS leukemia has important implications for treatment and prognosis. Before the common understanding of the likelihood of the CNS acting as a sanctuary for leukemic cells, relapse in the CNS was seen frequently. Leukemic relapse

was difficult to eradicate and required aggressive, neurotoxic treatment. To prevent CNS relapse, upfront cranial irradiation was widely employed. Patients experienced neurotoxicities, including cognitive decline, intractable seizures, strokes, and secondary CNS malignancies (e.g., meningiomas). Neurologic sequelae of cranial irradiation, including impaired working memory capacity, inhibition, cognitive flexibility, executive visuomotor control, and attentional fluctuations, may persist into adulthood. Over time, in an effort to reduce the use of prophylactic radiation therapy, intrathecal chemotherapies, such as methotrexate and Ara-C, replaced prophylactic radiation affording similar survival curves but less neurotoxicity. Recent studies of stem cell therapy for childhood ALL suggest that neither additional prophylactic craniospinal irradiation nor intrathecal chemotherapy enhances prognosis beyond that seen in patients treated with a pretransplantation ablative regimen alone.

With the use of methotrexate, intravenously at high doses, orally at lower doses, and intrathecally at any dose, 23% of patients developed leukoencephalopathy. Patients with symptomatic leukoencephalopathy may have generalized or partial seizures, stroke-like episodes, and ataxia. Twenty percent of children receiving methotrexate demonstrate MRI changes consistent with leukoencephalopathy regardless of symptoms. A genome-wide association study revealed enrichment in polymorphisms in genes known to play a role in neurodevelopmental pathways, raising the possibility that the products of these genes contribute to propensity of a given patient to develop methotrexate neurotoxicity. Those patients with high-risk leukemia with CNS involvement may require radiation plus chemotherapy. Neurocognitive outcomes, including measures of intelligence and executive function, were negatively correlated with the cumulative dose of craniospinal irradiation and intrathecally administered methotrexate.

Another neurologic complication observed in children undergoing treatment for leukemia has been the development of arterial and venous strokes, including dural sinus thrombosis. Dural sinus thrombosis may develop secondary to leukemic infiltration of the dural sinus (Fig. 133-1). Both arterial and venous strokes have been more often related to the use of L-asparaginase, which causes deficiencies of antithrombin, plasminogen, fibrinogen, and factors IX and XI. L-Asparaginase is utilized in the induction therapy of children with leukemia, and is associated with an initial hypocoagulable state, followed by a presumed rebound hypercoagulable state, which may result in thrombosis. L-Asparaginase-associated thrombotic strokes tend to occur at the end of induction, characteristically 7 to 10 days after completion of induction, and may result in seizures, focal neurologic deficit, or, less frequently, coma. Arterial strokes have also been reported with intrathecal administration of cytosine arabinoside. Other factors that can cause strokes in children with leukemia include dehydration with secondary venous thrombosis, CNS infection, and later radiation vasculopathy (Levensen et al., 2014).

**Figure 133-1.** Postcontrast magnetic resonance venography (MRV) demonstrating right transverse sinus filling defect secondary to clot formation from L-asparaginase.

CNS involvement is less frequent in children with acute myelogenous leukemia, but still has been reported to be as high as 20%, and some form of CNS prophylaxis is employed in all patients. Chloromas may occur and may result in focal neurologic deficits, including cranial nerve or spinal cord compression.

A rarer form of leukemia—acute promyelocytic leukemia—can be associated with neurologic complications, especially intracranial hemorrhage and stroke, at presentation or early during treatment in children and adults. This is thought to result from acute tumor lysis and release of procoagulants from the large leukemic granular cells. An intracranial disseminated intravenous coagulation picture can be seen.

CNS infection, especially with fungal organisms, may complicate the course of leukemia, particularly in patients who are immunosuppressed for long periods and in patients from low- and middle-income countries. Similarly, in patients with prolonged immunosuppression, brain abscesses occur because of a variety of organisms. Abscesses are usually associated with pulmonary lesions and may be caused by bacterial involvement with either aerobic or anaerobic bacteria, or by fungal infections, including *Aspergillus*, *Mucor*, and *Candida*. Encephalitis may also occur, especially after hematopoietic stem cell transplantation, and is caused by viruses, including herpes simplex, varicella zoster, and human herpes virus 6. Progressive multifocal leukoencephalopathy is a rare complication of prolonged immunosuppression, especially with agents such as rituximab.

Recently, chimeric antigen receptor T cells (CAR T cells) have been used with moderate success in treatment of refractory hematologic malignancies in children and adults. Unfortunately, the toxicities associated with this treatment can be life-threatening, affecting many organ systems. Although the cells target tumor-associated antigens, they may also cross react with normal tissue. The mechanism of action is thought to be a cytokine release syndrome that causes a massive inflammatory response leading to potentially irreversible end-organ damage. Neurologic toxicity includes encephalopathy and intractable seizures. There appears to be no correlation with CNS leukemia. The mainstay of therapy is supportive care with anticonvulsants and correction of metabolic abnormalities as

**Figure 133-2.** Sagittal T2 spine magnetic resonance imaging demonstrating radiation myelitis.

well as interleukin-6 receptor blockade using tocilizumab. Steroid administration is considered a last resort in some instances because of concern of diminishing efficacy of the CAR T cells. As CAR T-cell therapy gains acceptance for treatment of other malignancies as well as nononcologic disorders, neurologic adverse events may increase in prevalence, requiring the practitioner to become familiar with the treatment of these secondary effects (Brudno and Kochenderfer, 2016).

## Lymphoma

Primary CNS lymphoma, a subtype of non-Hodgkin lymphoma, is rare in children and is seen primarily in severely immunosuppressed patients, such as those with HIV infection, those who have undergone transplant and require chronic immunosuppression, and those with hemophagocytic disorders. Patients who have undergone bone marrow transplant for other disorders may also develop Epstein-Barr virus (EBV)-associated CNS lymphoma. Cytotoxic T-cell therapy has successfully treated many such patients.

Treatment is challenging; because of the rarity of the illness and the immunosuppressed nature of the patients, patients are often treated with B-cell lymphoma protocols with or without the use of focal, more extensive radiation therapy.

Systemic lymphoma can metastasize directly to the CNS, to the vertebral bodies with secondary spinal cord compression (Hauser et al., 2005), and to the leptomeninges. Non-Hodgkin lymphoma affects the CNS of children and adolescents in approximately 10% of cases.

Mantle radiation therapy, a mainstay of treatment for Hodgkin lymphoma, may cause radiation myelitis in a small subset of patients (Fig. 133-2). Neurologic manifestations include Lhermitte's sign with upper extremity weakness and sensory changes. Treatments have included steroids and hyperbaric oxygen.

## Histiocytosis

Langerhans cell histiocytosis (LCH) may involve the CNS in as many as 20% of patients. Diabetes insipidus secondary to posterior pituitary infiltration is the most common presenting symptom. Less commonly, granulomas may develop within the neuroaxis. LCH may be difficult to distinguish clinically from primary CNS tumors (Imashuku and Arcenci, 2015).

Years after initial, apparently successful treatment of LCH, subtle neurologic deficits, which may be progressive, can occur. Depending on the area of involvement of the CNS, symptoms include ataxia, vertigo, dysarthria, nystagmus, tremor, and

focal motor impairments. Lesions may arise anywhere within the CNS, but they tend to predominate in the hypothalamic-pituitary axis, pineal gland, gray matter of the dentate nucleus and basal ganglia, and in the deep white matter of the pons and hippocampus. There may or may not be associated infiltration by histiocytes. Such lesions may be progressive or static over time. It is unclear whether they represent a paraneoplastic syndrome or direct infiltration of histiocytosis into the brain. Treatments have included 2-chlorodeoxyadenosine, retinoic acid, and intravenous immunoglobulins (with or without antineoplastic chemotherapy), and have had variable success.

## Neuroblastoma

Neuroblastoma is a tumor that originates from the sympathetic ganglia and typically occurs in younger children. Neuroblastoma may invade through neural foramina into the spinal canal (classically with a dumbbell shape) and cause cord compression. In addition, neuroblastoma can spread to other extra- and intracranial sites—most notoriously, to the torcula with resultant dural venous thrombosis that can precipitate severe neurologic compromise, including seizures and coma. Recent advances in therapies include the use of radio-labeled anti-GD2 antibodies that target gangliosides specifically expressed on tumors of neural crest origin. With the widespread use of antibody therapy, the long-term survival rate for patients with stage 4 neuroblastoma has risen significantly. However, these intravenously administered antibodies do not cross the blood-brain barrier, and result in a relative increase in the number of patients with CNS neuroblastoma. Treatment of these patients with CNS metastasis includes surgery followed by low-dose external beam craniospinal radiation with a boost to the primary site followed by administration of intrathecal radiolabeled anti-GD2 antibodies ( $^{131}\text{I}$  3F8 or 8H9). A recent report has shown that 17/21 patients were alive at a median of 33 months from diagnosis of CNS neuroblastoma. Future research will involve attempts to identify which patients are at risk for seeding the CNS, followed by targeted attempts to prophylactically treat these individuals. A recent report suggested that traumatic lumbar puncture in patients with active stage 4 neuroblastoma may increase the risk of CNS seeding, but this observation requires further investigation. Neurologic sequelae of intravenous anti-GD2 antibodies include Horner syndrome, neuropathic pain, and posterior reversible leukoencephalopathy syndrome (PRES).

Spinal cord compression may be acute and cause the rapid onset of motor deficits, including quadriplegia or paraplegia. Conus or cauda equina involvement may result in early bowel and bladder dysfunction. Management of such compression requires immediate commencement of chemotherapy, with surgical decompression generally reserved for benign variants (e.g., ganglioneuroma) (Fawzy et al., 2015).

Neuroblastoma also has been associated with a unique paraneoplastic syndrome, opsoclonus-myoclonus. (See Chapter 118 for a discussion of this syndrome.)

An unusual form of neuroblastoma is esthesioneuroblastoma—neuroblastoma that occurs in the nasopharynx or paranasal sinuses. It accounts for less than 3% of tumors of childhood and adolescence. Radiotherapy is effective in adults with esthesioneuroblastoma, but the scarcity of data in children with this tumor and the significant morbidity of radiation therapy to the head and neck of children have fueled attempts to treat with newer, perhaps safer modalities. One study employing proton beam radiotherapy appeared to demonstrate locoregional control of intracranial and leptomeningeal metastases and tolerable toxicity, but ultimate survival was limited by disease in these sites (Lucas et al., 2015).

## Sarcoma

In a study reviewing 12 years of data on pediatric cancer patients, 3950 patients had a solid non-CNS primary cancer. Of those patients, 1.4% had metastases to the brain. Of the primary solid pediatric cancers associated with metastases, sarcomas constituted 54%, whereas melanomas, the next most common tumor, accounted for only 15%. Children between the age of 10 and 15 years are at highest risk. In a postmortem report of 139 pediatric patients with primary solid tumors, 18 patients were found to have CNS metastases. Osteogenic sarcoma and rhabdomyosarcoma were the most frequently reported primary cancers to cause CNS metastases in patients under the age of 15 years.

Pulmonary metastases were found in over 90% of patients with CNS involvement, suggesting that the metastases arise hematogenously from the lungs. In general, primary solid tumors with associated CNS metastases are associated with rapid clinical deterioration (Porto et al., 2010). Patients with brain metastases presented with headache, nausea/vomiting, and seizures as the most common chief complaints. The primary tumor and brain metastasis present synchronously in 15% of patients, and in these patients, other extracranial metastases are also present. The remaining 85% of patients are diagnosed with brain metastasis after treatment of the primary disease has been initiated, with a median presentation interval of 17 months after primary cancer diagnosis.

Treatment of pediatric sarcoma may also result in neurologic compromise. Intravenous ifosfamide, a commonly used alkylating chemotherapeutic agent, causes encephalopathy, asterixis, and seizures during infusion in 2% to 5% of children without CNS tumors. Symptoms may begin during drug infusion or hours to days later. The encephalopathy results from breakdown of ifosfamide to chloroacetaldehyde and subsequent inhibition of the mitochondrial respiratory chain. Treatment includes longer infusion time of ifosfamide; administration of methylene blue and/or thiamine; or switching from ifosfamide to cyclophosphamide. The neurologic outcome is generally good. Other toxicities include vincristine neuropathy.

## OSTEOSARCOMA

Osteosarcoma is the most frequently occurring malignant primary bone tumor and most common bone cancer in children. Spread of osteosarcoma is typically hematogenous, primarily reaching the lungs and other bones. Although rare, brain metastases are hypothesized to develop when lung tumor emboli invade the brain; however, there are occasional reports of patients with metastases who have no detectable lung involvement. Dissemination to the brain typically targets the dura and skull and spares the parenchyma (Fig. 133-3). Brain involvement is associated with metastatic disease at diagnosis or with relapse within 12 months of diagnosis.

## EWING'S SARCOMA

Ewing's sarcoma comprises about 10% of primary malignant bone tumors and is commonly seen in young adults with a male predominance. Metastases to the lung and other skeletal tissues are common and up to 80% of patients have metastases at the time of diagnosis. In contrast to osteosarcoma, Ewing's sarcoma is frequently associated with CNS involvement because of direct bony extension, rather than by hematogenous spread. Brain metastases usually occur with lung involvement in over 85% of individuals and as a part of systemic disease involvement. Overall, the presence of brain involvement suggests a poor prognosis in patients with Ewing's sarcoma;

**Figure 133-3.** Sagittal postcontrast magnetic resonance imaging of brain demonstrating dural-based osteosarcoma metastasis.

however, it is difficult to determine whether this is a function of the systemic disease or the brain involvement.

## RHABDOMYOSARCOMA

Rhabdomyosarcoma is the most common soft tissue sarcoma in childhood. Twenty percent of cases arise in the parameningeal area, including the middle ear, nasal cavity and paranasal sinuses, nasopharynx, infratemporal fossa/pterygopalatine, and parapharyngeal area, whereas the remaining cases typically occur in the genitourinary system and the extremities. Parameningeal rhabdomyosarcoma requires more aggressive treatment as its proximity to critical anatomic structures allows for more frequent invasion into the CNS. Systemic dissemination of rhabdomyosarcoma occurs hematogenously or through lymphatics with common metastatic sites in the lungs, pancreas, and bone. Although brain metastases are uncommon, there has been an association with pulmonary metastases and history of recurrent metastasis.

## Conclusions

Both systemic cancer and its therapy contribute to the neurologic morbidity in pediatric cancer patients (Khan et al., 2014). Prevention depends on pretreatment identification of children at risk, and treatment of neurologic sequelae requires development of agents that will not compromise anticancer treatment efficacy. There is no standard therapy for CNS metastases of systemic solid tumors in children and

adolescents. The relative rarity of CNS metastases of systemic cancer in children has meant that, despite the difference in the primary tumors from which these metastases come, their treatment has been guided by standard clinical practice in adults. Proton beam radiotherapy holds the promise of less toxic radiotherapy for intracranial metastases. In addition, prophylactic cognitive interventions may allow conventional craniospinal radiotherapy to be used without significant deterioration in IQ, memory, or executive function.

# 134 Posttreatment Neurologic Sequelae of Pediatric Central Nervous System Tumors

Elizabeth M. Wells and Colin R. Kennedy

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

As more children and adolescents with cancer are becoming long-term survivors as a result of improved multimodal and risk-based therapy, there is increased recognition of long-term consequences. Childhood cancer and its treatment predispose survivors to a variety of chronic conditions that may impair function, limit participatory activity, and reduce quality of life. Central nervous system (CNS) tumors and their treatment may cause acute and chronic adverse effects, including neurologic and neurosensory deficits, seizures, headaches, cognitive impairment, neuroendocrine dysfunction, neurovascular abnormalities, and secondary malignancies. Variation in the incidence of presenting neurologic features by tumor region within the brain is summarized in [Figure 134-1](#). Increased recognition of late effects has prompted organized attempts to prevent and mitigate neurologic sequelae from CNS tumor treatment through risk-stratified treatment and increased surveillance of survivors.

Treatment-related injury may appear early or late and may be transient or permanent. Distinguishing direct tumor effects from treatment effects requires assessment of the timing of symptoms in relation to tumor diagnosis and treatment, whether there is radiographic growth or stability, evidence of posttreatment magnetic resonance imaging (MRI) change, and the location of the tumor and radiation portal if applicable. Sequelae that develop or persist long after tumor diagnosis are referred to as *late effects*. The milestone of 5 years from diagnosis is often used in epidemiologic studies and for survivorship screening guidelines. However, with more children receiving sequential therapies for progressive or recurrent disease and more children remaining on biologic therapies for extended periods of time, the term *posttreatment sequelae* has a broader definition. This chapter takes a symptom-based approach to discussing early and late neurologic sequelae, including epidemiology, risk factors, and management.

## MORTALITY IN LONG-TERM TUMOR SURVIVORS

Childhood CNS tumor survivors experience high rates of mortality, subsequent cancers, and other chronic medical conditions. Despite reaching the 5-year survivorship milestone, 25% percent of Childhood Cancer Survivor Study (CCSS) participants treated between 1970 and 1986 died within 30 years of their diagnosis. The cohort experienced a nearly 13-fold increased risk of death compared with their peers as a result of recurrent disease, secondary malignant neoplasms, and cerebrovascular and cardiovascular events ([Box 134-1](#)) ([Armstrong et al., 2014](#)).

## CENTRAL NERVOUS SYSTEM POSTTREATMENT SEQUELAE

### Weakness

Patients with CNS tumors may experience weakness in various anatomic distributions depending on the tumor location and type of treatment. The incidence of motor or coordination problems is highest at presentation and during initial treatment. In the acute posttreatment period, upper motor neuron weakness may result from intraoperative injury or swelling, radiation injury, or cerebrovascular infarct. Recovery from these insults depends on patient age and mechanism of injury (e.g., immediate postsurgical weakness often improves) ([Escalas et al., 2015](#)). Some patients experience new focal weakness years after therapy as a result of new intracranial events, such as strokes, seizures, or hemorrhage. Weakness that localizes to the spinal cord may result from myelopathy from spinal radiation therapy or chemotherapy, particularly if intrathecal, and may be accompanied by bowel or bladder dysfunction and sensory deficits.

### Seizures

Seizures are a common complication of pediatric brain tumors and their treatment, appearing at presentation in 24% of patients and ongoing in about 15% ([Ullrich et al., 2015](#)). Although the subject is still debated, a 2000 American Academy of Neurology (AAN) practice parameter advised against prophylactic antiepileptic medications in patients of all ages. New onset or worsening of seizures posttreatment may signify tumor progression or recurrence, treatment-related neurotoxicity, and other causes, including metabolic disturbances.

Careful selection of antiepileptic medication is needed for patients with a CNS tumor. Nonenzyme-inducing antiepileptic drugs are preferred to avoid interactions with chemotherapy ([Ruggiero et al., 2010](#)), and monitoring for leukopenia or thrombocytopenia is needed. The antitumoral properties of valproic acid as a histone deacetylase inhibitor have been explored but are unproven and therefore not a reason to start valproic acid over other antiepileptic medications. Patients with CNS tumors may be more sensitive to sedating effects.

Initial tumor surgery, termed lesionectomy, cures more than 75% to 80% of cases of pediatric tumor-associated seizures, and there have been no controlled studies assessing the role of electrocorticography (ECog) during initial surgery. Factors predicting epilepsy cure after brain tumor resection include gross-total resection, preoperative seizure control, duration of seizures of 1 year or less, and semiology, with simple partial seizures having the worst prognosis. Medications may be

### BOX 134-1 Causes of Acute-Onset Neurologic Impairment in Tumor Survivors

Cerebrovascular event  
 Metabolic abnormality  
 Posterior reversible encephalopathy syndrome (PRES)  
 Radiation injury or necrosis  
 Shunt failure/increased intracranial pressure  
 Secondary malignancy  
 Seizure  
 Sinus venous thrombosis  
 Stroke-like migraine after radiation therapy (SMART) syndrome  
 Tumor recurrence

discontinued soon after surgery for children who present with epilepsy and have no seizures following surgical resection. Twenty percent of patients with epilepsy associated with brain tumors have refractory seizures, and additional surgery may be needed to resect epileptogenic tissue surrounding the original lesion. When epilepsy follows treatment of a brain tumor, a trial off medication may be attempted after a patient has been seizure-free for 2 to 3 years. Research is limited, but one study found a recurrence rate of 27% in patients who were weaned off antiepileptic medication. Higher risk was associated with

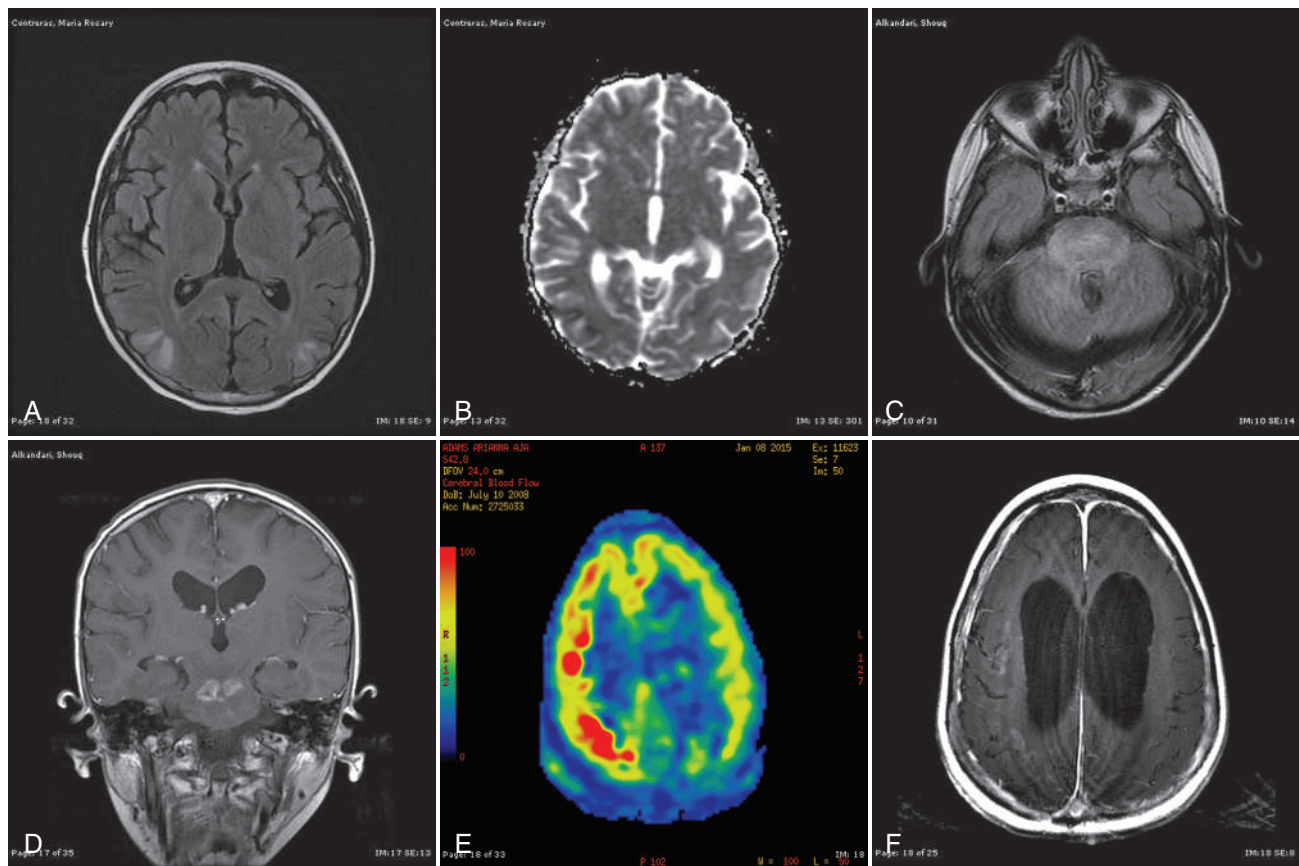

having more than one tumor resection or whole-brain radiation; spikes or slow waves on electroencephalogram (EEG) before withdrawal did not correlate with recurrence.

## Posttreatment Encephalopathy With Neurologic Impairment

### Posterior Reversible Encephalopathy

Posterior reversible encephalopathy syndrome (PRES) has been reported in association with cisplatin, cytarabine, cyclosporins, cyclophosphamide, methotrexate, rituximab, paclitaxel, and other chemotherapies. (Fig. 134-2A and B) Presenting symptoms consist of headache, visual disturbances, seizures that may be intractable and require aggressive acute therapy, nausea and vomiting, altered mental status, and possibly focal deficits (McCoy et al., 2010). PRES is usually associated with hypertension or hypotension, sometimes in association with metabolic abnormalities; symptoms and neurologic deficit are usually reversible upon regulation of blood pressure and withdrawal of chemotherapy. Chemotherapy is often resumed after blood pressure control is attained, although this has not been studied, and therefore the risk is unknown. Chemotherapeutic agents such as high-dose arabinosylcytosine (Ara-C), ifosfamide, and methotrexate are also known to cause subacute neurotoxicity, with headaches, seizures, auditory and visual hallucinations, visual disturbances, pseudobulbar palsy, extrapyramidal signs, and paresis.

**Figure 134-2.** Cases of posttreatment syndromes with encephalopathy. **A**, Magnetic resonance imaging (MRI) of stroke-like migraine after radiation therapy (SMART) syndrome with T2 multifocal patchy enhancement of the cortex involving the right frontal, parietal, and temporal lobes. **B**, Corresponding hyperperfusion. **C**, MRI of posterior reversible encephalopathy syndrome (PRES) with numerous cortical/subcortical white-matter areas of increased T2 signal. **D**, Diffusion restriction raised concern for irreversible methotrexate toxicity, although this ultimately resolved. **E**, MRI of acute postradiation injury with abnormal T2 prolongation involving the pons and cerebral peduncles, medulla, right cerebellar peduncle, and anteromedial right cerebellar hemisphere. **F**, Patchy heterogeneous enhancement, predominantly in the pons.

### Pseudoprogression

Another cause of encephalopathy with multifocal neurologic deficits is tumor pseudoprogression from cerebral necrosis, which may present as progressive neurologic deterioration with cerebral edema on imaging, typically 6 weeks to 3 months after radiation therapy (Fig. 134-2C and D). Concurrent treatment with chemotherapy may be a risk factor. When symptomatic, the condition is treated with high-dose corticosteroids, and bevacizumab is increasingly employed for patients who experience rapid deterioration despite corticoid therapy and/or intolerable steroid side effects.

### Cerebrovascular Events

Cerebrovascular complications in childhood CNS tumor survivors include stroke, moyamoya, mineralizing microangiopathy, cavernomas and other vascular malformations, and stroke-like migraines. The incidence of neurovascular events in childhood brain tumor survivors has been found to be 100-fold higher than that in the general pediatric population (Campen et al., 2012). Cranial irradiation, particularly to the circle of Willis, is an important dose-dependent risk factor for stroke and cerebrovascular abnormalities (Mueller et al., 2013). Chemotherapy, including methotrexate, anthracyclines, mitomycins, asparaginase (especially venous sinus thrombosis), or antivascular endothelial growth factor (VEGF) may also increase risk (Di Giannatale et al., 2014).

Asymptomatic radiographic findings include microbleeds and superficial siderosis. Radiation-induced cavernous malformations (RICMs) may occur within the radiation field on average 12 years after radiation treatment and may cause symptomatic hemorrhage.

There are no standardized guidelines for posttreatment imaging surveillance for cerebrovascular disease. Magnetic resonance (MR) angiography may not necessarily identify stroke risk because many CNS tumor survivors have small vessel disease. An annual neurologic evaluation is recommended by the Children’s Oncology Group (COG). The pathophysiology of vascular damage from radiation is complex and dependent on the targeted blood vessels, and possibly upregulation of proinflammatory and hypoxia-related genes. Moyamoya may occur, and patients with neurofibromatosis type I should not receive radiation therapy because of their very high risk of stroke and high risk of secondary malignancies. The use of antiplatelet agents in asymptomatic individuals has not been systematically studied (Murphy et al., 2015).

Stroke-like migraine after radiation therapy (SMART) syndrome causes acute or subacute focal impairment, often accompanied by encephalopathy and headache. It may be associated with hypointensities on susceptibility-weighted imaging (SWI) and gyriform enhancement on T1-weighted MRI (Fig. 134-2E and F). SWI may help distinguish SMART from other conditions that may have a similar postcontrast MRI appearance. Treatment includes the use of hydration and

neuroprotective measures, including avoidance of hypotension, and prophylactic complex migraine treatment for recurrent or prolonged episodes.

### Postoperative Cerebellar Mutism Syndrome

Postoperative cerebellar mutism syndrome, also called *posterior fossa syndrome*, was originally described in 1984 and was reported with increased frequency in the late 1990s and early 2000s in association with more aggressive surgery to resect posterior fossa tumors, particularly, but not exclusively, medulloblastoma (Robertson et al., 2006). A multicenter study by the COG found that 107/450 patients with medulloblastoma (24%) manifested the syndrome. It is characterized by development of mutism in the perioperative period, often associated with neurobehavioral abnormalities that may include personality change, emotional lability, decreased initiation of voluntary movements, swallowing dysfunction, ataxia, axial hypotonia, and weakness. Although the mutism is transient, patients have more significant neurologic and cognitive deficits at 1 year and more cerebellar atrophy than those without cerebellar mutism syndrome. Brainstem invasiveness of the tumor appears to be a risk factor, and recent studies have identified postoperative abnormalities in efferent cerebellar pathways, including the dentate-thalamo-cortical outflow tracts, on diffusion-tensor MRI.

### Chronic Leukoencephalopathy

Leukoencephalopathy in childhood cancer survivors is a demyelinating process commonly seen after radiotherapy and some chemotherapy, including intravenous or intrathecal methotrexate. A grading system proposed by Zimmerman et al. (1986) is still in use. MR spectroscopic evidence of neuro-axonal damage in normal-appearing white and gray matter associated with radiation and chemotherapy have also been described, and white-matter tract volume and anisotropy have been linked to cognitive and motor function in pediatric posterior fossa tumor survivors (Mabbott et al., 2008; Rueckriegel et al., 2015).

### Cognitive Impairment

#### Definition and Measurement of Neurocognitive Effects

A neurocognitive deficit is a reduction or impairment of cognitive function, particularly when a definable physical change has occurred in the brain, as is the case after a brain tumor. Assessment tools validated in the fields of oncology, neurology, and cognition are used with increasing standardization across studies. A degree of consensus has been achieved in both Europe (Limond et al., 2015) and North America that assessing quality of survival, including health-related quality of life, should involve administration of not only questionnaires for parents and patients (Packer et al., 2003) (e.g., NIH toolbox and Patient Reported Outcome Measurement Information System—PROMIS) but also short batteries of direct psychometric assessments (e.g., IQ, CANTAB and CogState). Intelligence quotient (IQ) testing using the Wechsler Intelligence Scales (WISC) has been the most common means to measure neurocognitive deficits in children treated for brain tumors. Limitations of studies using IQ alone include missing subtle but important deficits in selective attention and executive function, failing to capture important aspects of quality of survival, such as ability to live independently, and questionable generalizability as a result of sample bias from centers where direct assessment is available.

### Risk Factors for Neurocognitive Deficits

Risks of neurocognitive impairment in children treated for brain tumors are substantial, and there is a progressive decline in IQ over time, particularly associated with, but not entirely attributable to, craniospinal irradiation (CSI). Three main conclusions can be drawn from a growing body of research in this field. First, longitudinal studies of children treated with CSI for medulloblastoma have consistently found a decline in IQ over time. Second, cross-sectional comparative studies have found that children treated either for ependymoma with postoperative radiation to the posterior fossa alone or treated for low-grade astrocytoma with surgery alone demonstrate less severe deficits in IQ than those treated for medulloblastoma with CSI. Third, younger age at time of treatment increases the risk of decline in IQ. The three cardinal risk factors for neurocognitive deficits are age at diagnosis, neuroanatomical tumor- or surgery-related damage, and adjuvant treatment with radiotherapy and chemotherapy.

**1. Age:** Infants diagnosed in the first year are at high risk of neurologic and cognitive deficits sufficient to interfere with school function, social functioning, choice of occupation, and ability to live independently. Younger children are more vulnerable to surgical insult to the brain than older children even in the absence of additional treatments. In one study, over 70% of young children treated with CSI evaluated at least 5 years postdiagnosis had IQs of less than 70, which represents learning disability. For medulloblastoma, the most common malignant tumor of the posterior fossa, children treated with CSI had lower verbal, nonverbal, and overall IQ scores and lower scores for spelling, reading, and mathematics than those expected for age. The greatest rates of decline have been observed in children younger than 7 years old and appear to be a result of failure to acquire new skills at the expected rate rather than loss of existing skills. Some studies have shown preservation of cognition in children less than 3 years of age at diagnosis treated with systemic chemotherapy without radiation, although young children who receive intraventricular methotrexate may have lower IQ scores.

**2. Radiotherapy and chemotherapy:** Dose, fractionation, volume, and location of radiotherapy (RT) and the combination of RT with chemotherapy are significant risk factors in the neurocognitive effects of treatment. Compared with those receiving CSI, children who have received radiation to the posterior fossa alone may have fewer deficits and may avoid the decline over time. Information about the potentiating effect on the long-term toxicity of adding chemotherapy to cranial or craniospinal irradiation is very limited. Because risk-based strategies are implemented according to the new molecular stratification of medulloblastoma, more information may be gleaned about relative treatment effects.

The neuroanatomical substrate of IQ decline following RT is not clearly understood and may be attributed to volume loss in the cerebral cortex or hippocampus or a reduction in white matter. Newer imaging methods have uncovered associations between structural and functional white-matter connectivity and cognitive outcomes. Specific areas of the brain receiving the same dose of RT are affected differently, with frontal lobes showing a greater deterioration in white matter than parietal lobes. Patients with hemispheric tumors have a significantly greater decline in IQ than those with midline tumors. There is a strong correlation between overall white-matter loss and IQ and between volume of white-matter loss in specific areas (cingulate gyrus, frontal and prefrontal lobes) and attention. Large areas of the supratentorial hemispheres and white matter are spared with local posterior fossa RT, which may partially explain why a moderate reduction in IQ is seen but,

in contrast to those treated with CSI, no decline in IQ over time.

**3. Neuroanatomical damage—tumor location and surgery:** Many tumors always occur in one intracranial location (e.g., craniopharyngioma in the suprasellar region, medulloblastoma in the posterior fossa), but others occur in several locations, enabling examination of the effect of site. Survivors of pilocytic astrocytomas, assessed at least 3 years after diagnosis, were compared with respect to cognitive deficits by tumor location. Those with supratentorial midline tumors did not have tumor- or surgery-ascribable deficits, excepting some language and verbal memory problems in the subgroup with dorsally placed (thalamic) tumors; those with supratentorial hemispheric tumors had problems with selective attention and executive function; and those with infratentorial tumors had deficits in verbal intelligence, visual-spatial memory, executive function, and naming. All groups had problems with sustained attention and processing speed.

Patients with cerebellar tumors typically exhibit neurocognitive deficits, including impaired executive functioning. These deficits have also been observed in the absence of RT and chemotherapy in children treated with surgery alone for benign low grade astrocytoma in the cerebellum (Bull et al., 2014). The combination of these deficits with behavioral and emotional regulation was first described as the cognitive affective syndrome. It is thought that the severing of cerebral-cerebellar connections during surgery leads to a disruption of access to the cognitive control systems in the frontal lobes. In particular, cerebellar mutism syndrome (described earlier in the chapter) is strongly associated with decreased IQ scores. Damage to the dentate nuclei and inferior vermis has also been related to poor neurologic and cognitive outcomes in children treated for posterior fossa tumors, irrespective of RT schedule, age of patient, and pre- and postoperative complications (Puget et al., 2009).

Greater perioperative and short-term medical complications contribute to lower IQ scores. A study showed that the diminished postoperative IQ scores of children with cerebellar astrocytomas typically recover and normalize, in contrast to the IQ scores of children treated for medulloblastomas, indicating additive effects from RT and chemotherapy (Bull et al., 2014).

**4. Other factors:** Shunted hydrocephalus has been implicated as a possible additional contributor to poorer cognitive functioning, including lower overall IQ, performance IQ, perceptual organization, and visual-motor functioning. Shunt infections and meningitis have been associated with a reduction of overall IQ and verbal IQ and with neurologic deficits such as compromised dexterity, oculomotor deficits, and cerebellar mutism. Gender, attributional style, maternal depression, income, and intensity of targeted rehabilitation, including pharmacotherapy, have been shown to influence neurocognitive outcome. Some of the variability in outcome is likely genetic as a result of allelic variation in recovery following acquired brain injury, either through effects on brain repair mechanisms or through genetic variation in pharmacologic handling of tumoricidal or rehabilitative treatments.

The effect of intellectual decline on academic functioning is evident, and underlies, for example, poor reading, writing, and mathematical skills. Neurocognitive deficits are important to the child's academic, social, and psychological well-being because the effect of poor academic skills on the quality of life of the child is most apparent in school, the main setting in which children socialize with their peers. These deficits have far-reaching consequences not only for a child's academic achievements but also for the child's psychological and social development and ability to be self-sufficient. The effects of early brain damage on development become evident as

progressively more functions are expected to mature. Thus many survivors of CNS tumors can be expected to "grow into deficits." Surveillance for detection of deficits is required because the deficits may only become apparent over time, and learning support is an essential prerequisite for successful transition to independent adult life.

## NEUROSENSORY DEFICITS

### Visual Impairment

More than half of all children with brain tumors develop visual difficulties in the symptom interval between onset of the first symptom and diagnosis, and as a group, children presenting with visual difficulties have a longer-than-average symptom interval. Among children with a brain tumor and a diagnosis of neurofibromatosis (NF1), 41% have impaired visual acuity at diagnosis, 15% have optic atrophy, and 16% have exophthalmos. Hydrocephalus can be chronic or acute and present with lethargy or with asymptomatic papilledema, which may lead to with progressive visual impairment of which the child does not complain. Monocular visual loss is rarely noticed by the patient. Regular assessment of visual function and eye movements is key both to early diagnosis of brain tumors and to early detection of late-onset hydrocephalus, shunt malfunction, or tumor progression. A low threshold for requesting formal visual field testing is prudent because bedside testing may be unreliable.

Visual impairment is often a dramatic part of PRES but fortunately is often largely reversible in that context. It may also feature in SMART and as symptomatic small strokes arising from postradiation cavernous hemangiomas. The management of visual deficits seen in association with centrally placed tumors, especially germinomas, craniopharyngiomas, hypothalamic tumors, and optic pathway gliomas, is beyond the scope of this chapter.

### Hearing Loss

A degree of hearing loss after treatment for a brain tumor in childhood is common. The causes may be multifactorial but include tumor location, surgery, RT, and chemotherapy. Ototoxic chemotherapy drugs include the platinum compounds (cisplatin is much more ototoxic than carboplatin) and ifosfamide. Cisplatin causes sensorineural high-frequency hearing loss (with or without tinnitus) by direct injury to the outer hair cells in the organ of Corti or indirectly through biochemical factors affecting the cochlea. Hypomagnesemia during cisplatin treatment may contribute because magnesium is important for maintaining blood flow to the cochlea, hair cell permeability, and the ionic concentration of the endolymph and perilymph in the stria vascularis. Carboplatin affects the ear in a similar way but is less ototoxic than cisplatin. Ototoxicity is dose dependent, occurring with higher doses, and worsened with high cumulative exposure. The high-frequency hearing loss induced by the platinum agents is permanent, although in young children apparent improvement may occur as a result of an increasing ability to cooperate with hearing tests.

High-frequency hearing loss results in difficulty understanding speech and discriminating between words because high-frequency consonants are lost. This may cause educational, social, and educational adaptation difficulties; an increased sense of isolation; and an overall decrease in quality of life. High-frequency hearing loss may become apparent years after the last dose of cisplatin, and it is important to monitor hearing for some time after completion of treatment.

## PERIPHERAL NERVOUS SYSTEM IMPAIRMENT

Lower motor neuron weakness may result from toxicity from chemotherapy, in particular, vinca alkaloids (vincristine), platinum drugs (cisplatin, oxaliplatin, carboplatin), methotrexate, and some biologic agents, including those with antiangiogenic properties. Chemotherapy-induced peripheral neuropathy may be purely sensory (e.g., diminished temperature and vibratory sensation, burning paresthesias, jaw pain), predominantly motor (e.g., foot drop), and/or have an autonomic component, including constipation and orthostatic hypotension. Symptoms are nerve-length dependent and drug-dose dependent, and severity varies, with manifestations ranging from subclinical findings to mild discomfort to severely debilitating symptoms. Neuropathy is often worse in individuals of older age. Attempts to prevent or treat chemotherapy-associated neuropathies have failed, with the exception of medications for hyperesthesia and pain control. The dose for chemotherapy may be reduced when neuropathy is severe. Recent research has focused on molecular genetic predictors such as alterations in CYP5a enzymes, with goals of facilitating risk-adjusted dosing and better prevention of hearing loss.

## GROWTH AND OTHER SEQUELAE WITH A NEUROENDOCRINE COMPONENT

Posttreatment neuroendocrine effects are common. In the Childhood Cancer Survivor study, 43% of survivors reported one or more endocrine conditions, and compared with siblings, survivors had a significantly increased risk of late-onset hypothyroidism, growth hormone deficiency, the need for medications to induce puberty, and osteoporosis (Armstrong et al., 2009). Radiation dosimetry, tumor location, and tumor type are predictors of neuroendocrinopathies. COG guidelines recommend annual evaluation for endocrinopathies in survivors who have received cranial radiation. Children with craniopharyngioma show a high rate of endocrine deterioration (e.g., persistent diabetes insipidus and panhypopituitarism). Long-term management of neuroendocrinopathies includes regular monitoring and replacement of hormones as needed, including temporary increase in cortisol dose during intercurrent infection or other physiologic stress of cortisol. Concerns about secondary malignancies from growth hormone have not been supported by research studies.

Fertility in childhood cancer survivors is a major concern. A survey of 1110 childhood cancer survivors found that female survivors receiving 30 Gy or more to the pituitary gland reported fewer pregnancies and higher frequency of permanent amenorrhea compared with patients receiving lower doses of radiation. Chemotherapeutic agents, in particular, high-dose alkylating agents, have been associated with decreased fertility. Recovery from fertility impairment is possible in some patients. Research in this field is increasing, risk counseling is becoming standard, and fertility preservation methods may be offered to eligible patients before treatment (Vargo et al., 2011).

## CONCLUSIONS

Survivors of childhood CNS tumors experience posttreatment sequelae, including high rates of neurologic and neurocognitive impairment and other medical conditions that affect quality of life and put them at risk for early mortality. Little is known about the exact mechanisms of injury from brain tumor treatment. It is understood that in addition to killing target tissues, surgery, cranial irradiation, and chemotherapy may induce damage to adjacent healthy tissues, leading to

neurologic damage for which there are few treatments of any efficacy; endogenous healing within the CNS is supported by generic neurorehabilitation to promote the processes whereby healing or undamaged areas recover the ability to perform impaired functions.

Increased recognition of treatment effects has affected tumor treatment and led to efforts to prevent neurologic and neurocognitive impairment. Multicenter cooperative clinical trials involve risk stratification, such that more aggressive therapy is given to patients with higher-risk disease and less aggressive treatment to patients with lower-risk disease. Reductions in radiation have been incremental because risks of adverse sequelae must be balanced against the need for cure. Patients require continued follow-up to monitor disease status and late effects. The high incidence of posttreatment sequelae, often with an insidious and delayed onset, necessitates ongoing monitoring for years and probably throughout the survivor's lifespan. Future research will address whether epidemiology has changed with modern therapies. Increased awareness of risk factors in patients and providers, promotion of healthy lifestyles, and prompt response to new symptoms may reduce and prevent morbidity and mortality from late effects.

# 135 Muscle and Nerve Development in Health and Disease

Jeremy K. Deisch

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

One of the most important functions of the central nervous system and the primary outwardly visible manifestation of brain function is movement. Despite the apparent simplicity of achieving purposeful movement, a dizzyingly complex series of electrochemical signals and biochemical transitions is required for completion of even the simplest of motions. The appropriate neural pathways leading from neurons in the brain and terminating on the often remote target skeletal muscle fibers must be intact, the junctions between the nervous system and the muscle fibers (neuromuscular junctions) properly formed and maintained, and the target muscle fibers functional and supplied with metabolic substrates. Defects in any of these components result in weakness. This chapter reviews the embryology, anatomy, and function of the peripheral nervous and skeletal muscle systems. (Also see recent texts by [Dubowitz et al., 2013](#); [Goebel et al., 2013](#); [Carpenter and Karpati, 2001](#).) Subsequent chapters address clinical and laboratory investigations into diseases of skeletal muscle, as well as the diverse array of diseases resulting from both intrinsic and acquired defects.

## EMBRYOLOGY AND DEVELOPMENT

### Skeletal Muscle

Premyoblasts, the primitive cells that form skeletal muscle, arise from condensations of paraxial mesoderm called somites, structures that lie adjacent to the neural tube and notochord. As these structures mature, dermomyotomes and myotomes are formed, eventually forming the musculature of the body walls and extremities. Craniofacial muscles derive from mesoderm rostral to the first somite, and axial muscles arise from more rostral somites; the limb muscles derive from condensations in the region of the limb buds. The migration of myocytes is not haphazard but rather is guided by preformed mesodermal structures. In the developing limb buds, the proximal tendon primordium is a mesodermal condensation that guides migration of myogenic precursors and serves as an early scaffold for muscle formation. During the process of myogenesis, groups of cells split and recombine, resulting in contributions from several adjacent myotomes in an individual muscle. In the limb bud, the cells coalesce into dorsal and ventral masses (the epimere and hypomeres, respectively).

Orchestration of muscle development is under the guidance of a complex array of genetically determined growth and transcription factors. Premyoblasts express the paired box transcription factors, Pax-3 and Pax-7. Bone morphogenetic protein 4 (BMP4), released from adjacent neural tube and lateral plate mesoderm, inhibits gene expression of myogenic transcription factors, MyoD and Myf-5. Wnt and sonic hedgehog (SHH) signals from adjacent notochord, neural tube, and

surface ectoderm activate muscle specific genes Myf-5 and MyoD in premyoblasts. Scatter factor, a growth factor secreted by the lateral plate mesoderm, acts as a chemoattractant by promoting myocyte migration. The transition from the premyoblast to myoblast stage of muscle maturation is marked by the cessation of DNA synthesis. Postmitotic myoblasts elongate and begin attachment and fusion with other myoblasts, end to end, to form a long and slender primary myotube. Secondary and tertiary myotubes are formed from side-to-side fusion of myoblasts to existing myotubes. In the absence of innervation, maturation beyond primary myotubes does not occur, and the muscle develops abnormally. Myofilaments begin to polymerize at 4 weeks gestation, forming recognizable myofibrils with characteristic striations at around 5 weeks gestation. At this stage, the nuclei are located with the center of the muscle fiber. Muscle contraction and fetal movements commences with the onset of muscle innervation at around 8 weeks gestation. At around 16 weeks, the nuclei migrate superficially to adult-type subsarcolemmal position, although a few fibers with centrally located nuclei may persist into adulthood.

Distinctive fiber types do not appear until muscle innervation. Undifferentiated primitive fibers (type IIc) are the precursors of mature fibers. Type I fibers appear at about 18 weeks gestation. Type IIa and IIb fibers appear during the last month of gestation. Only a small percentage of type IIc fibers persist after birth. Differentiation into distinct fiber types depends on neural influences, resulting into the biochemical and physiologic diversity of mature muscle fibers. The neural determination of fiber subtype is modulated by calcineurin, a  $Ca^{2+}$ -calmodulin-regulated phosphatase. Firing of motor neurons and the resultant sarcolemmal depolarization results in an increase in sarcoplasmic  $Ca^{2+}$ , which in turn activates calcineurin, an indirect activation of the slow myosin heavy chain 2 gene (slow MyHC2) promoter. Fast fibers result from motor neurons with infrequent firing, resulting in sarcoplasmic calcium concentrations that are insufficient to maintain calcineurin activation.

Satellite cells, abundant in fetal muscle, are mononuclear muscle cells that lie beneath the basement membrane of mature muscle fibers. During embryogenesis, satellite cells migrate from the dorsal somites to dermatomyotomes. Transcription factor Pax-7 is a key protein involved in myogenic determination of satellite cells. Transcription factor Pax-3 is required for the migration of these cells from the dorsal somite; Pax-7 is required for the transition to mature muscle cells. Satellite cells are the primary stem cell and are capable of forming individual muscle fibers as well as complete muscle fascicles.

The growth and strength of muscle postnatally is dependent on functional demands, gender, age, training, and other

factors. Physiologic enlargement of a muscle body results from hypertrophy of muscle fibers rather than from growth of new fibers. Training and disuse can increase and decrease the cross-sectional diameter of muscle fibers. Muscle atrophy associated with aging is caused by loss of muscle fibers, rather than by fiber atrophy, and a decrease in satellite cells.

## Peripheral Nerve

The peripheral nervous system arises from the neural plate, a dorsal thickening of the embryonic ectoderm. Progressive maturation of the neural plate is influenced by a complex milieu of transcription factors, including members of the PAX, MSX, bone morphogenic protein (BMP), and sonic hedgehog (SHH) families. The neural plate invaginates, with eventual fusion of the edges forming an open neural tube. Primitive cells from the apices of the folds form the primitive neural crest, from which cells destined for various sites throughout the body arise, including constituents of the peripheral nervous system such as neurons within the dorsal root ganglia. The neural tube, in addition to forming the brain and spinal cord, is also the origin of the majority of the peripheral nervous system. The motoneuronal system arises from the basal plates, ventral thickenings in the neuroblastic layer of the neural tube. Thickenings on the dorsal surface, the alar plates, form the sensorineural system. Outgrowths of motoneurons from the basal plate penetrate the developing ventral cord, in which they form in the fourth week of development, after the preceding migrating muscle precursors. SHH, expressed early during spinal cord development, specifies motor neurons in the developing neural tube. The developing axons are guided to their appropriate motor compartments by differential expression of a variety of transcription factors, including Hb9, Mnx1, Lhx3/4 (Sharma and Izpisua Belmonte, 2001). Myelination proceeds after formation of the peripheral nerve, beginning in the fourth month of development. In the central nervous system, multiple axons are myelinated by oligodendroglia, cells of glioblastic origin. In the peripheral nervous system, Schwann cells arise from the neural crest, migrate to the developing peripheral nerves, and associate with axons of varying caliber. The numeric relationship between Schwann cells varies based upon myelination status of the axons; larger caliber, myelinated axons are ensheathed by a single Schwann cell in a given segment, whereas groups of several smaller unmyelinated axons lie within the processes of a single Schwann cell, resulting in a structure called a Remak bundle.

Attainment of proper myelinated axonal structure is under the control of several factors. Mutations in the genes encoding these factors result in abnormal structure of myelinated axons and in delayed nerve conduction velocity and resultant clinical manifestations. Neuregulin 1 (Nrg1), secreted by axons, regulates myelin thickness. The protein Periaxin regulates myelin internode length. Periaxin mutations result in decreased nerve conduction velocity and, in humans, recessive periaxin gene mutations result in a subtype of Charcot-Marie-Tooth disease (CMT4F). Axonal diameter is regulated by neurofilament light chain expression; mutations in the neurofilament light subunit (NEFL) gene result in early onset CMT disease. Proper myelin compaction and maintenance is regulated by peripheral myelin protein-22 (PMP22); mutations in the PMP22 gene result in the autosomal dominant inherited disorder hereditary neuropathy with liability to pressure palsies (HNPP).

## Neuromuscular Junction

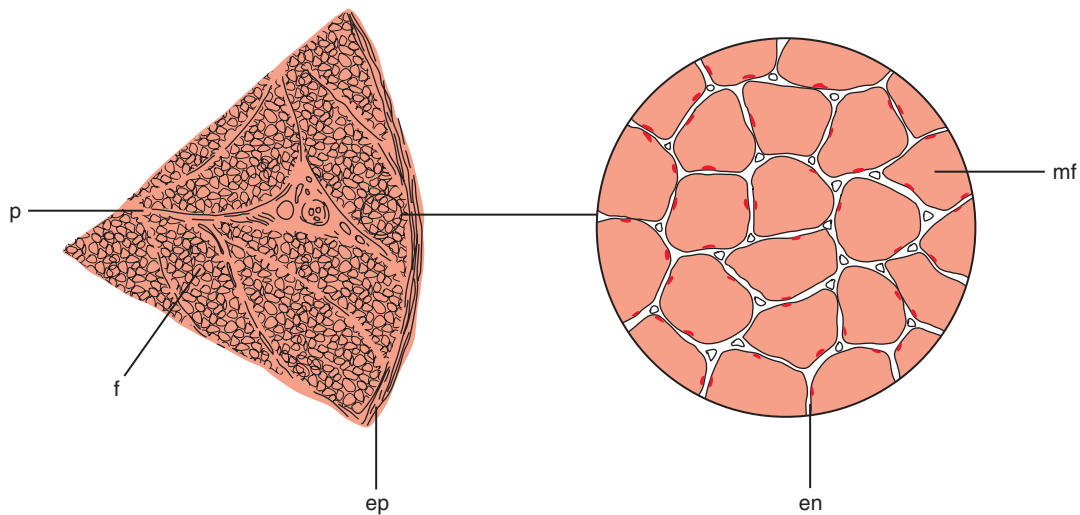

During the transition from embryonic to fetal myogenesis, developing peripheral nerve bundles contact the developing

musculature, resulting in formation of specialized neuromuscular junctions. Before innervation, acetylcholine receptors are present diffusely throughout the membrane in relatively low numbers. In a process known as pre patterning, clusters of acetylcholine receptors begin to form in the central region of the aneural muscle fiber. Shortly thereafter, motor nerve axons reach the muscle fiber and overlap the pre patterned areas, beginning the process of neuromuscular junction formation. In the areas of overlap, the innervated clusters progressively enlarge while the nonoverlapped clusters disappear (Yang et al., 2001). It is through this process that neuromuscular junction formation progresses in an organized fashion, resulting in rows of neuromuscular junctions innervating the central region of a myofiber and forming a linear end plate. The molecular signaling pathway resulting in acetylcholine receptor accumulation in the neuromuscular junction is regulated by the agrin/lipoprotein receptor-related protein 4 (Lrp4)/muscle-specific tyrosine kinase (MuSK) pathway. The synthesis of agrin by motor neurons, subsequent axonal transport, and influence of neuromuscular junction formation is a prime example of how the nervous system profoundly influences the muscle development (Lin et al., 2001). Agrin serves to activate the postsynaptic membrane tyrosine kinase receptor MuSK through the coreceptor Lrp4. Both Lrp4 and MuSK are necessary for pre patterning and for proper neuromuscular junction formation. Once activated, MuSK activates docking protein-7 (DOK-7), a downstream regulator of neuromuscular junction assembly. Acetylcholine receptors are restricted to the postsynaptic membrane via the interaction with rapsyn, a membrane-bound protein that interacts with cytoskeletal proteins and anchors acetylcholine receptors; proper rapsyn functioning is necessary for pre patterning. These pathways are factors that promote acetylcholine receptor formation and neuromuscular junction formation. Inhibition of acetylcholine receptor formation away from the neuromuscular junction results from acetylcholine-induced sarcolemmal depolarization, resulting in dispersion and decreased stability of acetylcholine receptors through activation of regulatory factors and suppression of AChR gene transcription via inactivation of the myogenin gene (Sanes and Lichtman, 2001). Initially, individual mammalian muscle fibers are multiply innervated. Between 16 and 25 weeks gestation and in association with secondary myotubular formation, all but one synapse is eliminated. Other mammalian species differ in the timing of this process. For example, polyneuronal innervation persists postnatally in the mouse and is an important concept to remember when comparing animal models to human neuromuscular disorders. There is constant denervation and reinnervation as neuromuscular interactions forms physiologic innervations of the motor units. Multiple motor neurons compete for innervation. Competition weakens some synapses and strengthens others so that, ultimately, a single input prevails.

## GENERAL ANATOMY AND STRUCTURE OF SKELETAL MUSCLE

### Morphology

Muscle as an organ comprises all the individual muscles in the body. Each muscle has an origin and an insertion site on the skeleton and bridges one or more bony articulations; contraction across the articulation results in movement of the joint. The muscle is enclosed within the epimysium, a thick sheath of fibrous connective tissue that is contiguous with the muscle tendon. The muscle is subdivided into individual fascicles by the perimysium, fibrous septae that are contiguous with the epimysium. Within the perimysium are the blood vessels, intramuscular nerves, and muscle spindles (Fig. 135-3). The

**Figure 135-3. Cross-sectional anatomy of skeletal muscle.** en, endomysium; ep, epimysium; f, fascicle; mf, muscle fiber; p, perimysium.

**Figure 135-4. Sarcomeric structure.** Schematic showing the structure of the sarcomere, which occupies the space between two adjacent Z lines. The M line occupies the midportion of the A band, and is the point of crosslinking of the myosin filaments. The A (anisotropic) band is the portion of the sarcomere occupied by myosin filaments, partially overlapped by actin. The H band is the region of thick filaments not overlapped by actin filaments. The I (isotropic) band comprises thin filaments without superimposed myosin filaments.

muscle fascicle, which is bounded by perimysial connective tissue, is a wedge-shaped structure comprising numerous individual muscle fibers. Surrounding each muscle fiber is a network of fine connective tissue, called the endomysium. The terminal axons and a rich capillary network reside within the endomysium. Individual muscle cells, myofibers, are multinucleated, elongated tubular structures that vary in diameter from 10 to 20  $\mu\text{m}$  in the infant to about 50 to 70  $\mu\text{m}$  in the adult.

### Sarcomere

The most striking feature of skeletal muscle seen on microscopic examination is the characteristic striations ("striated" muscle) seen under polarized light. Striations are linear bands resulting from the differences in the refractive index of the contractile proteins that are in phase with each other. A repeating unit is called a sarcomere, comprising interdigitating myofilaments and bound on either end by the Z line (Fig. 135-4). The Z disk anchors the thin filaments of actin that extend into each adjacent sarcomere and are located in the I band. The M line bisects the sarcomere and divides the A band, which is formed by an array of thick filaments composed

of myosin. The area within the A band in which the thin and thick filaments do not overlap is called the H band.

### Contractile and Sarcomeric Proteins

The two major proteins involved in muscle contraction are actin and myosin, which form the thin and thick filaments and jointly interact to convert chemical energy to mechanical work. Thin filaments are composed of two chains of actin molecules arranged in a double helix. Alpha-actinin is a major component of the Z disk and plays a role in the binding of actin to other cytoskeletal structures. Mutation in the  $\alpha$ -actinin gene, ACTA1, has been associated with congenital myopathy with actin filament aggregate myopathies, nemaline myopathy, cap myopathy, congenital fiber type disproportion myopathy, intranuclear rod myopathy, and hypertrophic and dilated cardiomyopathies.

Myosin molecules form the thick filaments. The contractile properties of a muscle fiber are due to the mechanochemical properties of myosin. Myosin heavy chain isoforms vary in different fiber types; the different myosin isoforms are determined by neural influences (see previous mention); variation in the myosin isoforms influences the physiologic properties

of the muscle fibers. Mutations in myosin gene MYH7 cause hyaline body myopathy with or without cardiomyopathy or familial cardiomyoneuromyopathy. Respiratory failure occurs with mutations in exons 37 and 38 of the MYH7 gene.

Actin and myosin have an inherent affinity for each other; this affinity is influenced by sarcoplasmic calcium ion concentrations and regulated by troponin and tropomyosin. Tropomyosin exists as a helical structure, comprising two long filaments that reside within the groove of the actin chains. One tropomyosin molecule binds one troponin complex, positioning the troponin molecules regularly along the actin filament. The troponin complex holds tropomyosin in an "off" or "on" position on the actin helix, depending on the level of calcium. There are at least two isoforms of tropomyosin. Fast-twitch skeletal muscle contains both  $\alpha$ - and  $\beta$ -isoforms; slow-twitch muscle contains only  $\beta$ -tropomyosin. The troponin molecules are located periodically along tropomyosin and comprise three subunits. Troponin T anchors troponin to tropomyosin. Troponin C binds calcium, which induces a conformational change of the protein and results in activation of actomyosin adenosine triphosphatase and muscle contraction. Troponin I inhibits actomyosin adenosine triphosphatase. Thus the contraction of striated muscle is regulated by the troponin complex, which acts as a  $\text{Ca}^{2+}$  sensor.  $\text{Ca}^{2+}$  binding to the regulatory sites of troponin C strengthens the interaction with troponin I, weakening the inhibitory activity of troponin I for actin and the affinity of troponin T for tropomyosin (Tm). Tropomyosin then moves toward the groove of the helical actin filament, switching on the myosin active site and resulting in muscle contraction. Troponin binds to actin-tropomyosin in the absence of  $\text{Ca}^{2+}$ , and the changes in interactions among these thin filament components in the presence of  $\text{Ca}^{2+}$  promote strong binding of myosin to actin. Mutations of the troponin T1 and tropomyosin genes may cause nemaline myopathy and/or cardiomyopathies.

Titin, the largest known protein of about 3 to 3.7 megadaltons, constitutes about 10% of myofibrillary proteins and is important for maintaining tension during stretch and recentering the sarcomere after relaxation. Titin spans the sarcomere, binding to the Z-disc and anchoring myosin, interconnecting actin and myosin, and providing elasticity to the sarcomere. Titin plays a major role in myofibrillogenesis, and abnormal expression of titin leads to disruption of assembly of the Z disk and sarcomere. Mutations in the titin gene cause familial dilated cardiomyopathy.

Nebulin, another large sarcomeric protein, closely associates with actin and binds to titin, myopalladin, and the actin-capping protein. Nebulin regulates the length of thin filaments in sarcomeres. Nebulin functions to stabilize the thin filaments at a determined length and is critical for generation of optimal force. Nebulin mutations cause nemaline and distal myopathy.

Obscurin is the most recently discovered member of a family of giant proteins involved in maintaining the structure of the sarcomere. Obscurin is localized at the M line and Z disk in skeletal and cardiac muscle. Obscurin binds and interacts with numerous muscle proteins, including titin, ankyrin, calmodulin, and myomesin. Obscurin functions in promoting lateral alignment and fusion of myofibrils into larger bundles. It also has an important part in assembly and stabilization of A bands and M bands in the sarcomere. Mutations of the obscurin gene produce hypertrophic cardiomyopathy by causing loss of binding with titin.

### Sarcotubular System

The sarcolemma is the plasma membrane of the muscle cell and is surrounded by basement membrane and endomysial

connective tissue. The sarcolemma is an excitable membrane and shares many properties with the neuronal cell membrane. T-tubules are invaginations of the sarcolemma, extending into the interior of the muscle fiber as the sarcotubular system. Depolarization of the sarcolemma is propagated throughout the interior of the muscle fiber through this system. The T tubules project into the interior of the muscle fibers in the area of the junction of the A and I bands, where they come into immediate contact with a second tubular system within the sarcoplasm, the sarcoplasmic reticulum. The close apposition of one T-tubule, bound on either side by the sarcoplasmic reticulum, is referred to as a "triad." The sarcoplasmic reticulum forms a fine plexus around the myofibrils. Excitation of the sarcolemma and T tubules causes  $\text{Ca}^{2+}$  release from the sarcoplasmic reticulum and initiation of contraction by the myofilaments.

Several important proteins are localized to the triads. The voltage sensors of the T-tubule calcium channels are regulated by dihydropyridine receptors. Ryanodine receptors mediate the calcium release of the sarcoplasmic reticulum during muscle activation. Calcium adenosine triphosphatase pumps calcium back into the sarcoplasmic reticulum during relaxation. Calsequestrin is a calcium-binding protein that increases the storage capacity of calcium in the sarcoplasmic reticulum. Some patients with myasthenia gravis, especially associated with thymoma, have autoantibodies directed against the ryanodine receptor antigens, as well as to titin. Autosomal-dominant and autosomal-recessive mutations of the ryanodine receptor gene (RYR) cause central core disease, myopathy with type 1 fiber dominance, and malignant hyperthermia.

Other features seen on ultrastructural examination of muscle fibers are nuclei and the sarcoplasm and its organelles. A typical muscle fiber has thousands of nuclei located beneath the sarcolemma throughout the length of the fiber. The sarcoplasm contains many of the elements found in the cytoplasm of other tissues. Most important are the mitochondria, which are located primarily in the intermyofibrillary space near the Z line and adjacent to the A bands. Numerous unbound glycogen granules and small fat droplets are present within the sarcoplasm.

### Cytoskeletal Proteins

The structural integrity of the muscle is maintained against the physical forces of contraction exerted on the sarcolemma by an intricate system of cytoskeletal and sarcolemmal proteins. These proteins, through a complex pattern of arrangement, anchor the internal structure of the muscle to the basement membrane and extracellular matrix. Abnormalities in many of these proteins have been identified as causing a number of different types of myopathies (Table 135-1).

### Dystrophin

Dystrophin is a 427 kilodalton protein that constitutes 0.01% of total muscle protein and 5% of the sarcolemmal cytoskeletal proteins. Dystrophin is localized in the inner aspect of the sarcolemma, and is abundant at the myotendinous junction and at the postsynaptic membrane of the neuromuscular junction. Dystrophin forms an integral part of a muscle's cytoskeleton and links the contractile apparatus to the sarcolemma. The N-terminus is the actin-binding domain, and the carboxy-terminal domain interacts with  $\beta$ -dystroglycan as well as dystrobrevin and the syntrophin. The central rod domain comprises the majority of the mass of the dystrophin molecule, forming a flexible, rod-shaped structure. The fourth cysteine rich domain also binds to  $\beta$ -dystroglycan.

(Adapted from Vainzof, M., Zatz, M., 2003.. *Protein defects in neuromuscular diseases. Braz J Med Biol Res* 36, 543-555. Updates from Online Mendelian Inheritance in Man—[www.omim.org](http://www.omim.org).)

The dystrophin-glycoprotein complex consists of numerous proteins, including dystroglycans ( $\alpha$  and  $\beta$ ), sarcoglycans ( $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ ,  $\epsilon$ ), sarcospan, syntrophin, and dystrobrevin. The peripheral members of the complex include neuronal nitric oxide synthase, caveolin, laminin, and merosin.

The DMD gene coding for the protein dystrophin is located on the short arm of the X chromosome near the region Xp21. The dystrophin gene is the largest gene identified so far, covering more than 2.5 megabases (Mb), and contains at least 79 exons; the high spontaneous mutation rate is a reflection of the large gene size. Dystrophin is primarily expressed in skeletal, cardiac, and smooth muscle cells, with smaller amounts expressed in the brain and retina. Isoforms of dystrophin, which are smaller in size, are expressed in nearly all tissues examined. Dystrophin in the brain is important in synapse maintenance; deficiency of the brain isoform of dystrophin is associated with cognitive deficits seen in patients with dystrophin mutations. Deletions or abnormalities of the dystrophin gene cause an absence or deficiency of dystrophin, resulting in the X-linked Duchenne and Becker muscular dystrophies (Chapter 146).

### Dystrophin-Glycoprotein Complex

The dystrophin-glycoprotein complex is a sophisticated linkage that spans the sarcolemma and links the sarcoplasmic

contractile apparatus to laminins in the extracellular matrix, serving to transfer the force of muscle contraction between the myofibrils and surrounding connective tissues. This dystrophin-glycoprotein complex consists of cytoskeletal, transmembrane, and extracellular components and is composed of two subgroups of protein complexes: the dystroglycans and sarcoglycans.

Dystroglycan consists of a transmembrane and an extracellular component encoded by a single messenger RNA and subsequently processed to  $\alpha$ - and  $\beta$ -dystroglycan molecules. The  $\alpha$ -dystroglycan protein undergoes extensive posttranslational glycosylation and is located on the extracellular side of the sarcolemmal membrane. The size and molecular weight of the dystroglycan molecule expressed in various tissues varies based upon differential glycosylation patterns in those tissues. The glycosylation is mediated by several glycosyl transferases; mutations in these enzymes cause myopathies and brain and eye malformations, as the dystroglycan complex also plays an important role in normal migration of neurons in the cerebral neocortex (Chapter 147).

Primary mutations in the dystroglycans have not yet been identified in human disease. Defective glycosylation, however, results in a spectrum of disorders, in which a limb-girdle muscle dystrophy (type 2-I, due to FKRP mutation) is the mildest manifestation, and structural brain and ocular abnormalities comprise the most severe end of the spectrum

in the congenital muscular dystrophies. In the past, these conditions were referred to as Walker-Warburg syndrome, muscle-eye-brain disease, and a subtype of limb-girdle muscular dystrophy. Currently, given the improved understanding of the shared underlying pathogenesis of defective glycosylation of dystroglycan, the conditions are now referred to as muscular dystrophy-dystroglycanopathies (MDDG) (Chapter 147). [Table 135-1](#) lists the genes involved with isolated muscular dystrophy resulting from abnormal glycosylation of dystroglycan.

### Sarcoglycans

The sarcoglycan complex consists of  $\alpha$ -,  $\beta$ -,  $\gamma$ -, and  $\delta$ -sarcoglycan, and is integral to the dystrophin-associated glycoprotein complex, conferring structural stability to the sarcolemma and protecting muscle fibers from mechanical stress during muscle contraction. Alpha-sarcoglycan is present only in cardiac and skeletal muscles; the other sarcoglycans are also found in smooth muscle. Gamma-sarcoglycan binds to dystrophin, and  $\delta$ -sarcoglycan binds to  $\beta$ -dystroglycan. Mutations in any of the sarcoglycan genes cause destabilization of the complex, resulting in different forms of limb-girdle muscular dystrophy (Chapter 147). In muscle biopsies from sarcoglycanopathy patients, this primary loss or reduction of expression of one sarcoglycan, due to a mutation in that gene, is frequently associated with secondary loss of other sarcoglycans. Mutations in the sarcoglycan genes result in limb-girdle muscular dystrophies types LGMD-2C through LGMD2F ([Table 135-1](#)).

### Utrophin

Utrophin is an autosomally encoded protein that is smaller in size than dystrophin and is localized to the sarcolemmal postsynaptic membrane at the neuromuscular junction and myotendinous junction in the mature muscle fiber. At the neuromuscular junction, it is preferentially concentrated at the acetylcholine receptor-rich crests. Utrophin production is regulated by growth factors released from the neurite such as heregulin, resulting in gene transcription occurring preferentially in the nuclei close to the neuromuscular junction. In animal models, induced utrophin expression has been shown to partially compensate for dystrophin deficiency and attenuate the resultant myopathy. Muscle biopsies from humans with Duchenne muscular dystrophy characteristically demonstrate upregulation of utrophin, with diffuse distribution of this protein along muscle fibers. This feature helps distinguish a primary dystrophinopathy from those with secondary dystrophin reduction. This alternative pathway provides a possible therapeutic target for patients with dystrophinopathies.

### Dysferlin

Dysferlin is a sarcolemmal protein expressed in skeletal muscle, cardiac muscle, placenta, and brain tissue. Dysferlin does not directly associate with the dystrophin-glycoprotein complex but rather is peripheral, interacting with multiple proteins including caveolin-3. Dysferlin functions in membrane trafficking and repair of sarcolemmal defects. Defects in dysferlin result in limb-girdle muscular dystrophy type 2B and Miyoshi myopathy.

### Caveolin

Caveolin, a family of membrane associated proteins expressed in fibroblasts, adipocytes, endothelium, and muscle cells, regulates caveolae formation. Caveolae are flask-shaped membrane invaginations that function in membrane trafficking, transport, and signal transduction. Mutations in the muscle

isoform, caveolin-3, result in limb-girdle muscular dystrophy type 1C, rippling muscle disease, familial hypertrophic cardiomyopathy, and long QT syndrome and have been associated with sudden infant death syndrome.

### Merosin (Laminin- $\alpha_2$ )

Laminin- $\alpha_2$  is a major component of laminin in the basal lamina of postnatal muscle and cardiac muscle and is also expressed in mesenchymal tissue in other organs. Laminin interacts with the sarcolemma through the dystrophin-glycoprotein and vinculin-integrin complexes. Mutations of laminin- $\alpha_2$  manifest as congenital muscular dystrophy, complete absence of muscle merosin, and abnormalities of cerebral deep white matter. Prenatal diagnosis can be made by merosin immunostaining of chorionic villus biopsy samples.

### Intermediate Filaments

Intermediate filaments are cytoskeletal proteins with a diameter intermediate between the thin and thick myofibrils, measuring between 10 and 12 nm in diameter. Intermediate filaments are seen in cells of ectodermal, mesodermal, and endodermal derivation. Desmin, vimentin, nestin, lamin, and plectin are intermediate filaments expressed in muscle.

Desmin is the major intermediate filament in skeletal muscle, cardiac, and smooth muscle. Desmin is located at the Z band beneath the sarcolemma and is denser at the myotendinous junction. Desmin is involved with the alignment of sarcomeres with one another and the plasma membrane by forming a three-dimensional scaffold around the Z disks. Mutations of the desmin gene result in the desmin-related myopathies, also known as myofibrillar myopathies, and cardiomyopathies.

Vimentin is an additional intermediate filament that is expressed in immature muscle cells during myogenesis. After the postnatal period, its expression in muscle is primarily in regenerating and immature cells.

Nestin is a protein that is coexpressed with desmin in developing muscle cells. Postnatally, nestin is found with desmin in regenerating muscle fibers in patients with dystrophic and inflammatory myopathies.

Plectin is a large protein of more than 500 kilodaltons that serves as a cytoskeletal linking protein for desmin and keratin organization. The carboxy-terminus binds intermediate filaments, and the amino terminus binds actin. Plectin provides mechanical strength to tolerate the forces of physical stress. Deficiency of plectin has been identified as the cause of recessive epidermolysis bullosa with congenital muscular dystrophy.

### Nuclear Membrane Proteins

Emerin, a 254 amino acid protein encoded by a gene on the X chromosome, is a protein associated with the inner nuclear membrane. Emerin is important in the organization of nuclear membrane during cell division. Mutation of the emerin gene causes X-linked Emery-Dreifuss muscular dystrophy.

Lamins are major components of the nuclear lamina, which is the major structural framework of nuclei in eukaryotic cells. In humans, two forms of type A (A and C) and B (B1 and B2) are present. Lamins interact with themselves, lamin-associated proteins, and chromatin and play a role in DNA replication, chromatin organization, spatial arrangement of nuclear pores, nuclear growth, and mechanical stability of the nucleus. Mutations in the lamin A gene result in increased susceptibility to nuclear injury in response to mechanical stress. Mutations in the lamin A/C gene cause autosomal-dominant Emery-Dreifuss muscular dystrophy, Charcot-Marie-Tooth

disease type 2, dilated cardiomyopathy with conduction defects, Dunnigan-type familial partial lipodystrophy, mandibuloacral dysplasia type B, Hutchinson-Gilford progeria syndrome, and restrictive dermopathy.

## Muscle Fiber Types

Clinical use commonly divides human muscle fibers into types I and II. Type I fibers have slow-twitch characteristics, are resistant to fatigue, and are rich in mitochondria and substrates for aerobic (oxidative) metabolism, imparting a red appearance ("red muscle"). They are slightly smaller than type II fibers and have a less well-developed sarcoplasmic reticulum and T-tubule systems. Type II fibers, grossly pale in appearance, have fast-twitch characteristics, are susceptible to fatigue, and are rich in glycogen and other substrates and enzymes needed for anaerobic (glycolytic) metabolism. Type II fibers can be subdivided into type IIa and IIb fibers. Type IIb fibers are the prototype for the type II fibers, whereas type IIa fibers are intermediate, with both oxidative and glycolytic properties. Type I fibers are generally found in muscles needed for sustained tonic contraction such as the antigravity muscles of the limbs and trunk. Type II fibers are usually found in muscles concerned with rapid, forceful movement such as those found in the extraocular muscles. The division of muscle fibers into three basic types is an oversimplification, as in reality there is a continuum of physiologic properties of skeletal muscle fibers.

All muscle fibers of a motor unit are of a single type. The physiologic, metabolic, and morphologic properties of the muscle fiber depend on innervation from the anterior horn cell. Small  $\alpha$  motor neurons innervate type I fibers, and large  $\alpha$  motor neurons innervate type II fibers. Given this determination of fiber type by the type of innervating motor neuron, sprouting and reinnervation from adjacent unaffected motor axons after muscle fiber denervation often results in fiber-type switching. The clinical significance of this phenomenon is fiber-type grouping, in which the normal random "mosaic pattern" distribution of muscle fiber types is lost, and abnormal grouping of myofibers is apparent by electromyography and enzyme histochemistry.

## GENERAL ANATOMY AND STRUCTURE OF PERIPHERAL NERVES

Although the functional components of peripheral nerves vary greatly (i.e., compound versus pure sensory, motor, autonomic, etc.), the cellular structure of nerves is quite homogeneous. In the motor nervous system, the motor neuron soma lies within the anterior horn of the spinal cord or from motor brainstem nuclei. In sensory nerves, the neuronal cell bodies lie within the dorsal root ganglia. Axons then exit via the cranial nerves or nerve roots and travel along peripheral nerves. The juncture between the central and peripheral nervous system is delineated by the Redlich-Obersteiner zone, the point at which peripheral nerves join with the spinal cord or brainstem. In this zone, differences in myelin staining mark where oligodendrial myelination transitions to the myelin of Schwann cell origin in the peripheral nervous system. Pulsatile vascular compression in this region may be responsible for the clinical manifestations of trigeminal neuralgia and other localized cranial neuralgias.

To the naked eye, peripheral nerves are smooth, firm white plump structures. In the atrophic state, nerves are smaller in diameter and take on a dull gray color. When viewed by routine light microscopy, the cross-sectional organization of peripheral nerve bundles mirrors that seen in skeletal muscle. In the nerve, individual axons lie within the endoneurium, along with endoneurial capillaries, collagen, fibroblasts, and

Schwann cells. The endoneurial compartment is ensheathed by a layer of specialized perineurial cells and their associated basement membranes into rounded nerve bundles. In this region, tight junctions and adherens junctions between adjacent perineurial cells result in a protective microenvironment, the "blood-nerve barrier" (Peltonen et al., 2013). Finally, the entire peripheral nerve is surrounded by a fibroblast and collagen-rich layer, the epineurium. The longitudinal anatomy of peripheral nerves varies by axonal myelination status. The large myelinated axons demonstrate a one-to-one relationship with Schwann cells, so that a single Schwann cell wraps around a segment of the axon, with multiple layers of Schwann cell cytoplasmic membrane forming the myelin sheath. Between each myelinated segment, gaps of unmyelinated axon are present, the nodes of Ranvier. The segment of axon myelinated by a single Schwann cell is termed the myelin internode. Figure 135-9 demonstrates the longitudinal anatomy of a typical myelinated axon. Unmyelinated small caliber axons lie in groups within the processes of Schwann cells, albeit without the previously-described one-to-one relationship and surrounding myelin sheath. The properties of myelinated axons with periodic unmyelinated nodes of Ranvier allow for saltatory nerve conduction, resulting in a dramatic increase in nerve conduction velocity and minimizing the energy required for nodal repolarization. Factors that result in faster conduction velocity include thicker diameter of the myelin sheath, larger axon caliber, and longer internodal length such that the axons with fastest nerve conduction have larger axon caliber, thicker myelin sheaths, and longer myelin internodes. Pathologic processes that diminish any of these characteristics will result in slowed nerve conduction velocity, detectable on clinical nerve conduction velocity studies.

## NEURAL CONTROL OF MOVEMENT

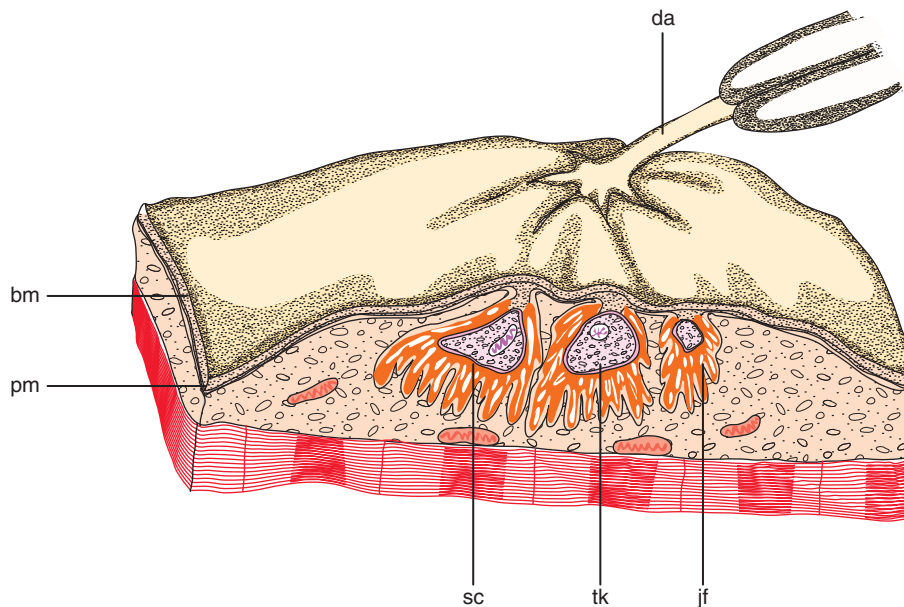

Contraction of a muscle fiber is initiated by depolarization of its anterior horn cell, which is the final common pathway for all cortical and spinal influences that affect movement. The axonal processes of these cells innervate varying numbers of muscle fibers (the "motor unit") via a specialized neuromuscular junction. In the normal state, the muscle fibers within the motor unit are scattered randomly within a segment of muscle. When the anterior horn cell discharges, all the muscle fibers innervated by that anterior horn cell contract nearly simultaneously, the variability ("jitter") due to factors of transmission at the neuromuscular junction. The finer and more coordinated the movement of a muscle, the fewer the fibers in the motor unit such that extraocular muscles and some hand muscles may have 30 to 50 fibers per motor unit, whereas larger muscles such as paraspinal muscles may have hundreds of fiber per unit. The nervous system regulates the force of muscle contraction by recruiting motor units in an orderly fashion; increasingly larger motor units are recruited for larger amounts of generated force. During the process of recruitment, slower-twitch motor units are recruited first, followed by fast twitch as demands increase. The rate of discharge of motor neurons also influences the amount of force generated.

The neuromuscular junction is a specialized region of the axon terminus and sarcolemma, separated by a synaptic cleft (Fig. 135-10). The area on the muscle is the end plate and is located near the center of the muscle. The synaptic knob is the unmyelinated terminal dilatation of the nerve axon and contains synaptic vesicles of acetylcholine. Depolarization of the nerve terminus opens voltage-gated calcium channels at the synaptic knob, inducing a calcium-mediated exocytosis of acetylcholine-containing vesicles. The Lambert-Eaton myasthenic syndrome results from autoantibodies directed against

**Figure 135-9. Longitudinal anatomy of the myelinated axon.** A contiguous axon is surrounded by Schwann cell basal lamina, cell membrane, and cytoplasm; tightly packed concentric layers of Schwann cell membrane comprise the myelin sheath. Pockets of residual Schwann cell cytoplasm are present within the internode, the Schmidt-Lanterman cleft. In the node of Ranvier, the myelin sheath is interrupted, allowing for saltatory nerve conduction.

these voltage-gated calcium channels (Chapter 145). Acetylcholine is synthesized from acetyl coenzyme A and choline and is stored in a reserve compartment. The process of vesicle formation, fusion, and release is a complex system involving many proteins (Martyn et al., 2009).

Acetylcholine combines with acetylcholine receptors concentrated on the tops of the junctional folds of the postsynaptic membrane of the muscle sarcolemma. The acetylcholine receptor is a transmembrane glycoprotein, composed of four subunits: fetal  $\alpha$ ,  $\beta$ ,  $\delta$ , and  $\gamma$ ; postnatally the  $\gamma$  isoform is replaced by  $\epsilon$ . The acetylcholine receptor

monomer contains two acetylcholine-binding sites and the cation-specific channel, whose opening is regulated. The acetylcholine receptors are anchored to dystrophin-related protein complexes and connected to the cytoskeleton by dystroglycans and sarcoglycan protein complexes. Congenital myasthenic syndromes (CMS) are a heterogeneous group of disorders in which inherited defects in the neuromuscular junction result in pathologic muscle fatigability (Chapter 144). The majority of these syndromes result from postsynaptic defects, most commonly involving abnormalities of the acetylcholine receptor. Myasthenia gravis is caused by antibodies to

receptor proteins. Fetal akinesia (Escobar syndrome) can occur from maternal antibodies directed against the fetal  $\gamma$  subunit. Binding of two acetylcholine molecules with the  $\alpha$  subunits of the receptor causes a conformational change, opening the center of the receptor for a few milliseconds and increasing the permeability of the sarcolemma to sodium and potassium and localized membrane depolarization. Numerous depolarization events (miniature end-plate potentials) are required to reach the threshold for a propagated sarcolemmal depolarization and resultant myofiber contraction. Interference with the release of acetylcholine or a reduction in the number of receptors lessens the likelihood of successful neuromuscular transmission.

# 136 Laboratory Assessment of the Child with Suspected Neuromuscular Disorders

Peter B. Kang and Eugenio Mercuri

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Knowledge of pediatric neuromuscular disease through the nineteenth century was largely limited to observations of cohorts of children with similar clinical histories and physical examination findings. The most famous of these observations are the descriptions of the disease that became known as Duchenne muscular dystrophy, with lumbar lordosis, calf pseudohypertrophy, toe-walking, a waddling gait, and the Gowers sign. In retrospect, reports from the first half of the nineteenth century, predating Guillaume-Benjamin-Amand Duchenne's and William Gowers's famous papers, describe the same disease. Duchenne is credited with developing the first muscle biopsy technique in the late nineteenth century; this testing modality has been refined since then, with respect to both acquisition of samples and muscle specimen analysis.

The first half of the twentieth century was marked by the development of clinical electromyography testing, using an oscilloscope, along with nerve conduction studies. Reliable laboratory testing to delineate neuromuscular diseases arose in the mid-twentieth century when the muscle enzymes creatine kinase and aldolase were found to be consistently and dramatically elevated in Duchenne muscular dystrophy.

The cloning of dystrophin as the causative gene for Duchenne muscular dystrophy in 1986 (Monaco et al., 1986) and the identification of the corresponding protein the following year marked the beginning of a revolution in neuromuscular disease and the broader fields of clinical medicine and biomedical science. A steady stream of genetic discoveries for a broad array of inherited neuromuscular diseases followed, transforming the care of diseases such as muscular dystrophy, congenital myopathy, myotonic dystrophy, metabolic myopathies, congenital myasthenic syndrome, Charcot-Marie-Tooth disease, and spinal muscular atrophy. Multiple causative genes have been identified for all of these diseases, revealing an astounding richness in their genetic landscape. In 2001 the full human genome was sequenced for the first time, leading to an explosion of novel approaches to genetic sequencing and upending diagnostic algorithms for pediatric neuromuscular disease. Tests that may be useful for neuromuscular diagnostic evaluations vary significantly depending on the age of the patient (Table 136-1).

## LABORATORY CHEMISTRIES AND SEROLOGIES

A routine blood test to screen for muscular dystrophy was not available until the middle of the twentieth century when serum creatine kinase (CK) levels were found to be consistently elevated in patients with clinical diagnoses of muscular dystrophy. Serum aldolase levels were similarly described to be elevated in such individuals and were described first, although CK is more specific for muscle tissue and is currently the most widely used serum biomarker to screen for a variety

of neuromuscular diseases (Table 136-2). Serum CK levels may decrease over time in patients with Duchenne muscular dystrophy as muscle tissue is progressively replaced by connective tissue. It is not as well known that three serum transaminases most commonly associated with the liver, alanine aminotransferase (ALT), aspartate aminotransferase (AST), and lactate dehydrogenase (LDH), are also found in smaller amounts in skeletal muscle tissue. In muscle disease, elevations of serum CK and aldolase are typically much more elevated than those of ALT, AST, and LDH. The differences are consistent enough that mathematical formulas have been generated to describe ratios among some of these laboratory values in Duchenne and Becker muscular dystrophy (McMillan, Gregas, Darras, and Kang, 2011). Some patients with muscular dystrophy, especially milder forms such as Becker muscular dystrophy, are initially ascertained by mild elevations of the transaminases, and unfortunately, a small number of these children undergo extensive hepatic evaluations, including liver biopsy, before the possibility of muscular dystrophy is considered. In some cases where transaminases are more dramatically elevated than the serum CK level, the possibility of a glycogenosis should be considered. It is important to remind general pediatricians and pediatric subspecialists, especially pediatric gastroenterologists, of this association to shorten the diagnostic odyssey that some of these children encounter. In juvenile dermatomyositis, the LDH may be elevated when the CK and aldolase are normal.

The interpretation of serum CK levels can be confusing. Elevations in Duchenne muscular dystrophy are not subtle, typically rising above 10,000 U/L (normal values vary by laboratory and are generally less than 240 U/L), and on occasion may exceed 100,000 U/L. As a rule of thumb, CK levels are grossly elevated in muscular dystrophies, whereas congenital myopathies display mild or no elevations. There are exceptions to this rule because serum CK levels may be normal or only mildly elevated in muscle diseases such as facioscapulo-humeral muscular dystrophy (FSHD) and certain forms of congenital muscular dystrophy, such as Ullrich congenital muscular dystrophy or SEPNI-related myopathies. Mild elevations of serum CK levels may also be found in nonmuscle diseases, the most prominent example being spinal muscular atrophy, which has been associated with normal levels and elevations as high as 1000 U/L. Mild elevations may also be incidental findings that cannot be tied to objective evidence for a neuromuscular disease.

The diagnostic uncertainty surrounding mild elevations in serum CK levels has implications for newborn screening for neuromuscular disease, an active topic of research, pilot studies, and implementation in some states, including New York and Ohio. Serum CK levels can be checked in dried blood spot samples. Newborn screening now has practical implications for a number of inherited neuromuscular diseases as potential therapeutic compounds are in human clinical trials, and the first new treatment for Duchenne muscular dystrophy was approved by the U.S. Food and

**TABLE 136-1** Workup to Be Considered for Suspected Neuromuscular Disease in Various Age Groups

	Neonate	Infant	Child	Adolescent
Systemic evaluation	Sepsis, HIE		Lead	
Basic laboratory	CK, Mg <sup>++</sup> , thyroid	CK, thyroid, vitamin B <sub>6</sub> , B <sub>12</sub> , E		
Specialized laboratory	AChR antibodies	Botulinum toxin		
Radiographs	CXR for thin ribs			
Imaging	Muscle U/S (brain MRI)	Muscle U/S, muscle MRI (brain MRI)		
EMG, NCS	+	+	+	+
Edrophonium test	+	+	+	+
Muscle biopsy	+	+	+	+
Genetic testing	Targeted genetic tests and NMD genetic testing panels (targeted genetic tests may include those for Prader-Willi syndrome, myotonic dystrophy, and SMA)	Targeted genetic tests and NMD genetic testing panels		

Neonates are typically defined as those individuals in the first month of life, infants as being those in the first year of life, children as being older than infants but prepubertal, and adolescents as being peri- and postpubertal. Not all tests apply to all circumstances. For example, brain MRI would only be applicable in circumstances, such as suspected cases of certain subtypes of congenital muscular dystrophy. AChR, acetylcholine receptor; CK, creatine kinase; CXR, chest x-ray; EMG, electromyogram; HIE, hypoxic-ischemic encephalopathy; MRI, magnetic resonance imaging; NMD, neuromuscular disease; SMA, spinal muscular atrophy; U/S, ultrasound.

**TABLE 136-2** Serum CK Levels Typically Found in Pediatric Neuromuscular Diseases

Disease	CK level	
Spinal muscular atrophy	Normal to 5x ULN, rarely 9x ULN	Limb-girdle muscular dystrophy type 2 (autosomal recessive) LGMD2A ( <i>CAPN3</i> ) 6 to 84x ULN LGMD2B ( <i>DYSF</i> ) 2 to 150x ULN LGMD2C ( <i>SGCG</i> ) 8 to 150x ULN LGMD2D ( <i>SGCA</i> ) 4 to 100x ULN LGMD2E ( <i>SGCB</i> ) 3 to 209x ULN LGMD2F ( <i>SGCD</i> ) 5 to 60x ULN LGMD2G ( <i>TCAP</i> ) 1.2 to 17.5x ULN LGMD2H ( <i>TRIM32</i> ) 1.4 to 24.5x ULN LGMD2I ( <i>FKRP</i> ) 3 to 60x ULN LGMD2J ( <i>TTN</i> ) 1.5 to 17x ULN LGMD2K ( <i>POMT1</i> ) 20 to 40x ULN LGMD2L ( <i>ANO5</i> ) 6 to 57x ULN LGMD2M ( <i>FKTN</i> ) 6.7 to 343x ULN LGMD2N ( <i>POMT2</i> ) 8.6 to 22x ULN LGMD2O ( <i>POMGNT1</i> ) 28 to 68x ULN LGMD2Q ( <i>PLEC</i> ) 19 to 29x ULN
Charcot-Marie-Tooth disease	Normal	
Guillain-Barré syndrome	Normal	
CIDP	Normal	
Congenital myasthenic syndrome	Normal	
Neonatal myasthenia gravis	Normal	
Juvenile myasthenia gravis	Normal	
Dystrophinopathy		
Duchenne muscular dystrophy (DMD)	28 to 350x ULN and above (< 10 years)	
Becker muscular dystrophy (BMD)	Normal to 40x ULN (> 10 years) 6 to 115x ULN	FSHD1 Normal to 3.8x ULN
Congenital muscular dystrophy		FSHD2 3 to 4x ULN
Collagenopathy		
Ullrich CMD	Normal to 2x ULN	
Bethlem myopathy	Normal to 7x ULN	
Merosinopathy ( <i>LAMA2</i> deficiency)	Normal to 125x ULN	
Dystroglycanopathy		
Walker-Warburg syndrome	4 to 260x ULN	
Muscle-eye-brain disease	4 to 28x ULN	
Fukuyama CMD	Normal to 15x ULN	
Limb-girdle muscular dystrophy type 1 (autosomal dominant)		
LGMD1A ( <i>MYO7</i> )	1.6 to 9x ULN	Pompe disease Normal to 15x ULN
LGMD1B ( <i>LMNA</i> )	Normal to moderately elevated	Myotonic dystrophy type 1 (DM1) Normal to 4x ULN
LGMD1C ( <i>CAV3</i> )	4 to 25x ULN	Juvenile dermatomyositis Normal to 100x ULN
LGMD1D ( <i>DNAJB6</i> )	Normal to 10x ULN	Juvenile polymyositis Normal to 35x ULN
LGMD1E ( <i>DES</i> )	Normal to 2x ULN	Viral myositis Normal to 59x ULN
LGMD1F ( <i>TNPO3</i> )	Normal to 20x ULN	

CIDP, chronic inflammatory demyelinating polyradiculoneuropathy; CMD, congenital muscular dystrophy; FSHD, facioscapulohumeral muscular dystrophy; LGMD, limb-girdle muscular dystrophy; ULN, upper limit of normal.

Drug Administration (FDA) in 2016. The potential false-positive rate and difficulties interpreting mild serum CK levels should be considered as newborn screening programs are rolled out because pediatric neurologists will begin seeing infants with positive screening results. A pilot study of newborn screening in DMD demonstrated high sensitivity and low false-positive rates when the serum CK was over 2000 U/L (Mendell et al., 2012).

Screening serum and urine tests are also available for some metabolic muscle diseases. These include lactate and pyruvate for mitochondrial disease and the serum carnitine panel, serum acylcarnitine panel, and urine acylglycine panel for other metabolic myopathies. The measurement and interpretation of lactate and pyruvate are often difficult. Serum lactate levels may be artifactually elevated if a child is upset during phlebotomy or if a tourniquet is used, and thus mild to moderate elevations do not necessarily indicate the presence of a mitochondrial disorder. Lactate and pyruvate levels measured in cerebrospinal fluid tend to be more reliable but are more invasive to obtain. A third means of quantifying lactate levels is magnetic resonance spectroscopy (MRS), which can detect elevated lactate in selected regions of the brain.

Serum chemistries and serologies may be useful in several acquired neuromuscular disorders, including inflammatory myopathies. If a child is suspected of having dermatomyositis or polymyositis, serum testing for general inflammatory markers and more specific antibody titers may contribute to the diagnostic evaluation. A serum antibody that is specific for dermatomyositis is Jo-1. This topic is discussed in more detail in Chapter 150.

Antibody titers can be very helpful in the diagnostic evaluation of a child with suspected neonatal or juvenile myasthenia gravis (Chiang, Darras, and Kang, 2009). The classic and most commonly elevated antibody titers for myasthenia gravis in both children and adults are the acetylcholine binding, blocking, and modulating antibodies, which are found in about half of children with ocular myasthenia and the majority of children with generalized myasthenia (Liew et al., 2014). Binding antibodies attach to portions of the receptor aside from the acetylcholine binding site, blocking antibodies prevent attachment of acetylcholine to the receptor, and modulating antibodies cross-link acetylcholine receptors with subsequent degradation. Because acetylcholine receptor antibodies were the first to be identified in association with myasthenia and are so commonly found, patients without these laboratory abnormalities are referred to as having “seronegative” myasthenia gravis. This is to some extent a misnomer because this patient subpopulation is also likely to harbor elevated antibody titers of various types. The most well known of these is the muscle-specific kinase (MuSK) antibody, which is often detected in seronegative adult myasthenia gravis and less frequently in seronegative juvenile myasthenia gravis (Liew et al., 2014). Important therapeutic considerations in MuSK antibody-positive myasthenia gravis are that this subtype of disease tends to be less responsive to cholinesterase inhibitors, which are often first-line therapies for myasthenia gravis, and that the literature regarding the efficacy of thymectomy, although to some extent supportive, is somewhat more conflicted than for acetylcholine receptor antibody-positive cases. A third category of antibody for myasthenia gravis is the antistriated muscle or antititin antibody. In adults, elevations of this antibody are usually seen in conjunction with elevations of acetylcholine receptor antibodies and are associated with a higher incidence of thymoma. In children, elevated antistriated muscle/antititin antibody titers may be found in isolation and do not seem to be associated as consistently with thymoma (Liew et al., 2014). This topic is discussed further in Chapter 145.

With respect to inflammatory neuropathies, serum antiganglioside antibodies are useful for selected subtypes. Anti-GQ1b antibodies may be elevated in the Miller-Fisher variant of Guillain-Barré syndrome, whereas anti-GM1 antibodies are sometimes elevated in chronic inflammatory demyelinating polyradiculoneuropathy (CIDP). However, antibody elevations are less consistently recorded in affected children, especially those with CIDP.

Cerebrospinal fluid analysis is useful in selected situations, most prominently for the evaluation of suspected inflammatory neuropathies such as Guillain-Barré syndrome and chronic inflammatory demyelinating polyradiculoneuropathy (CIDP). The classic finding of cytoalbuminologic dissociation (elevated protein without pleocytosis) supports the diagnosis of an inflammatory neuropathy and is likely caused by the radicular involvement that is often seen in these disorders. However, it is important to remember that cytoalbuminologic dissociation may also be seen in inherited neuropathies, which may be an important consideration for more chronic and indolent presentations.

## NERVE CONDUCTION STUDIES AND ELECTROMYOGRAPHY

Peripheral electrodiagnostic testing, consisting of nerve conduction studies and electromyography, was first developed in the 1940s. It continues to be an important test modality for the diagnosis of certain types of peripheral nervous system disorders in the pediatric population (Karakis, Liew, Darras, Jones, and Kang, 2014). Diagnostic categories that may be characterized in this manner include anterior horn cell diseases (spinal muscular atrophy, polio), neuropathies (Charcot-Marie-Tooth disease, inflammatory neuropathies), disorders of the neuromuscular junction (myasthenia gravis, congenital myasthenic syndrome, botulism), and myopathies (congenital myopathies, dystrophies, myotonias and myositis). The one major neuromuscular disease category for which electrodiagnostic testing is typically no longer useful is muscular dystrophy because significantly elevated serum CK levels, especially if associated with abnormal results on muscle ultrasound, will nowadays justify immediate genetic testing. However, electrodiagnostic testing remains useful even in some cases of muscular dystrophy because some subtypes do not yield dramatic elevations of serum CK levels and present differently than other forms. Facioscapulohumeral muscular dystrophy is one example.

Technical considerations abound in the conduct of pediatric nerve conduction studies and electromyography, ranging from potential distress to the patient to electrode placement to differences in normal values. When performed by an electromyographer who is experienced and comfortable with children, these studies are often surprisingly well tolerated by the majority of children without the use of analgesia, conscious sedation, or general anesthesia. Toddlers are typically the most challenging and are more likely than infants or older children to require conscious sedation or general anesthesia. One important practical consideration when general anesthesia is used is that certain drugs, especially propofol, obliterate F-wave responses, and thus these factors should be taken into account when planning and interpreting electrodiagnostic testing in such settings. Electrode placement may be more challenging in infants and younger children because of the smaller extremity sizes. Surface electrodes may need to be trimmed in certain situations, and smaller-sized ring electrodes may be helpful for some sensory studies. Standard distances are impractical for infants and younger children. One specific consideration is that sural sensory responses are

typically difficult to record in infants; the medial plantar response is more consistently obtainable in this age group. Normal ranges for latencies, amplitudes, and conduction velocities vary by age. Two general rules are helpful to remember: newborn nerve conduction velocities are typically half the values of those found in older children and adults, and nerve conduction study parameters reach adult values by the age of 3 to 5 years.

The electrodiagnostic approach to disorders of the neuromuscular junction merits particular attention. Repetitive stimulation testing, a variant of a motor nerve conduction study, is as useful in children as in adults, but it is often more difficult for young children to remain still for this delicate test than adults. If there is a high index of suspicion for a disorder of the neuromuscular junction and the child has difficulty with this testing modality, conscious sedation or general anesthesia may be justified depending on what other supportive data are available. Single-fiber electromyography is a specialized form of electromyography that is especially useful in diagnosing disorders of the neuromuscular junction. The core measurement in single-fiber electromyography is the difference in latencies between the potentials generated by two different muscle fibers from the same motor unit. In disorders of the neuromuscular junction, the latencies are more volatile, leading to increased "jitter." Traditional single-fiber electromyography requires that the patient be extremely compliant with the gentle activation of the muscle being tested; ideally, only a single motor unit would be activated at a time. As one can imagine, this degree of subtle motor control cannot realistically be expected of many children. Thus a variant of this test, called stimulated single-fiber electromyography, was developed, and it is especially useful in children (Tidswell and Pitt, 2007; Pitt, 2008). Instead of requiring voluntary motor activation, this variant makes use of a monopolar stimulating electrode to activate individual motor units with small electrical currents. Accurate recordings are possible with ordinary concentric electrodes. In skilled hands, this test has a high degree of accuracy.

## MOTOR UNIT NUMBER ESTIMATION

One of the great difficulties in assessing motor neuron disease is the impracticality of sampling motor neurons, either via biopsy or imaging techniques, to measure the progression of these disease processes in clinical and research settings. Functional motor testing is a key component of such assessments, but there is a need for complementary neurophysiological measures. The motor unit number estimate is an approach developed in the 1970s that makes use of a variant of nerve conduction studies to stimulate and estimate the size and number of individual motor units in a given peripheral nerve. The currents used are much lower than in traditional motor nerve conduction studies, and the motor unit amplitudes are measured in  $\mu\text{V}$  rather than mV, on the same scale as sensory nerve action potentials. Several specific techniques have been developed to collect relevant data and calculate the motor unit size. Motor unit number estimation was initially applied to the study of amyotrophic lateral sclerosis, polio, and Duchenne muscular dystrophy. In recent years, it has gained increased attention as a potential outcome measure for spinal muscular atrophy in children. Several clinical studies have validated its longitudinal reliability in this setting, and intriguing observations were made in a natural history study that involved this modality. Motor unit number estimation is currently used primarily as a biomarker to track outcomes in longitudinal clinical studies, but it may have future diagnostic applications.

## ELECTRICAL IMPEDANCE MYOGRAPHY

Electrical impedance myography is an emerging technique that shows a great deal of promise as a tool to assess the severity of various neuromuscular disorders. It is likely to play a role as an outcome measure for human clinical trials and may eventually have diagnostic applications as well. Its chief virtues are that it is noninvasive and painless, making use of high-frequency, low-intensity electrical currents that are not perceptible by humans; thus, this approach could be especially useful in the pediatric population. As in traditional nerve conduction studies, current is administered, and voltage is measured using surface electrodes. One study demonstrated that electrical impedance myography could distinguish between spinal muscular atrophy types 2 and 3 and between individuals affected and unaffected by spinal muscular atrophy in general, indicating that this tool has a high potential to serve as an outcome measure for spinal muscular atrophy clinical trials. Electrical impedance myography and skeletal muscle ultrasound also appear to be complementary measures that could be used in clinical trial settings.

## IMAGING STUDIES

Skeletal muscle imaging via ultrasonography and magnetic resonance imaging (MRI) techniques has become increasingly sophisticated over the years. Both technologies have advantages in various circumstances. Ultrasound technology was first applied to monitoring for cardiac complications in Duchenne muscular dystrophy in the 1970s. The possibility of using sonographic studies of skeletal muscle for primary diagnostic purposes in muscular dystrophy, congenital myopathy, myotonic dystrophy, and spinal muscular atrophy was subsequently examined in the 1980s. Muscle ultrasound was also explored as a means of carrier detection for Duchenne muscular dystrophy and Becker muscular dystrophy. One of the great advantages of muscle ultrasound is that it is a noninvasive technique that can be easily used in infants and children, providing evidence for muscle disease, seen as increased echogenicity with scarce or no visualization of the underlying bone structures. This information can be very useful at the time of deciding on further diagnostic evaluations in children with minimal clinical signs or mildly elevated CK levels without any weakness. The increased echogenicity pattern differs from the one observed in spinal muscular atrophy, which displays a denervation pattern characterized by an increased ratio between subcutaneous tissue and the muscle belly and often a granular pattern in the muscle. As investigators and clinicians gained greater experience with this testing modality, they were able to associate different ultrasound patterns with specific neuromuscular diseases, including congenital muscular dystrophy.

During much of the 1990s, as causative genes for various type of neuromuscular diseases were discovered in rapid succession, skeletal muscle ultrasound was given less attention as a diagnostic modality. However, in the 2000s, it became clear that genetic analysis in isolation would often not be sufficient to clarify the diagnosis for various neuromuscular disorders, especially as genotype–phenotype correlations became more complicated than initially expected. As a result, ultrasonography of skeletal muscles as a diagnostic tool underwent a renaissance, and reference ranges for children were established in greater detail. Currently, skeletal muscle ultrasound is used in a number of centers as a diagnostic tool that helps narrow the differential diagnosis for neuromuscular disorders in children. By examining several muscles, one can assess which are involved and those that are relatively spared. Collectively, this montage can suggest a specific disorder, for example, sparing of the rectus femoris in *RYR1*-related central core

myopathy. This technique can be implemented with minimal training. Some studies suggest that skeletal muscle ultrasound may hold promise as a longitudinal outcome measure for human clinical trials.

The potential of applying MRI techniques to the study of skeletal muscle began to be explored in the 1980s, initially for Duchenne muscular dystrophy, followed by other diseases. As in other tissues, this testing modality has the capacity to show even greater morphologic detail than ultrasound in skeletal muscle, allowing for an analysis of the extent and type of involvement of individual muscles. Thus with skeletal muscle MRI studies, detailed portfolios of patterns of muscle involvement may be constructed. A number of disease-specific patterns have been identified in neuromuscular disorders such as myotonic dystrophy, Emery-Dreifuss muscular dystrophy, Ullrich congenital muscular dystrophy, facioscapulohumeral muscular dystrophy, Miyoshi myopathy, and Becker and limb-girdle muscular dystrophies. This has proven to be important to guide genetic testing, especially for muscle disorders with overlapping clinical phenotypes, such as muscular dystrophies with rigidity of the spine (Mercuri et al., 2010) and congenital myopathy subtypes that are associated with mutations in several genes. Short scanner protocols help make this testing modality more accessible to children. MRI findings correlate well with muscle histologic abnormalities. Skeletal muscle MRI is showing increasing promise as a noninvasive outcome measure in clinical trials of new therapies for muscular dystrophy. Longitudinal changes in fat content, for example, are correlated with muscle function changes in boys with DMD.

The use of nerve imaging to aid in the diagnosis of neuropathies has gained more attention recently. Nerve ultrasound data and magnetic resonance neurography can help with the diagnosis of chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) and aid in the detection of nerve entrapment.

Brain imaging does not typically contribute to the diagnostic evaluation of many neuromuscular disorders. The most prominent exceptions to this rule lie among several subtypes of congenital muscular dystrophy. Merosin-deficient congenital muscular dystrophy is classically accompanied by diffuse, symmetric white-matter lesions on MRI. The classic dystroglycanopathies are usually accompanied by striking structural brain abnormalities that overlap among subtypes. These range from isolated cerebellar structural abnormalities that often include hypoplasia or cysts to prominent supratentorial abnormalities that include cortical pachygyria, polymicrogyria, and hypoplasia of the corpus callosum, as observed in Fukuyama congenital muscular dystrophy or muscle-eye-brain disease. One of the most severe cortical malformations, lissencephaly, is a classic finding in Walker-Warburg syndrome.

## GENETIC TESTING

The inherited basis of many neuromuscular diseases was strongly suspected for many years, but the tools to investigate such connections did not exist until the late twentieth century. The invention of DNA sequencing in 1970s and the polymerase chain reaction in the 1980s paved the way for the landmark cloning of the dystrophin gene in 1986 and the identification of the dystrophin protein in 1987. Since then, dozens of causative genes for muscular dystrophy and other inherited neuromuscular diseases have been identified. The potential for improved diagnosis is vast, and has been augmented further by the sequencing of the complete human genome at the turn of the millennium and the subsequent development of high-throughput next-generation sequencing technologies. The most widely used next-generation sequencing technique

for clinical applications currently is targeted sequence capture, in which a selection of genes is sequenced based on the putative disease phenotype. Next-generation sequencing can be especially helpful in diagnosing disease categories in which the number of causative genes is especially abundant, such as limb-girdle muscular dystrophy, congenital muscular dystrophy, and congenital myopathy. This technique has also helped with the identification of novel muscle disease genes such as *MEGF10* and its newly identified phenotype, EMARDD, and the identification of novel genotype–phenotype correlations for previously described disease genes. Whole-exome sequencing is offered by some test facilities for clinical use; whole-genome sequencing currently is primarily used in research settings, but it may have greater clinical applicability in the future.

However, the proliferation of causative genes and genetic test modalities has generated increasing confusion among physicians and other health-care providers regarding the best approach to genetic diagnosis in children with neuromuscular diseases. It is important to remember that newer technologies such as next-generation sequencing are currently most accurate with respect to detecting single-nucleotide changes and small insertions and deletions (called “indels”) up to about 10 nucleotides in length. Larger mutations may sometimes be detected but not with the consistency that is seen with some of the older genetic technologies. Some of the most common inherited neuromuscular disorders may be missed by next-generation sequencing in its current forms because of the nature of the mutations involved. Examples of such diseases include Charcot-Marie-Tooth disease type 1A (duplication of the *PMP22* gene), Duchenne muscular dystrophy and Becker muscular dystrophy (frequently caused by single- or multiple-exon deletions), facioscapulohumeral muscular dystrophy type 1 (caused in part by contraction of the D4Z4 macrosatellite region on 4q35), and myotonic dystrophy types 1 and 2 (caused by trinucleotide repeat expansions in *DMPK* and quadruplet repeat expansions in *ZNF9*, respectively). All of these neuromuscular diseases are caused by large genetic mutations. Many of the older genetic test modalities will retain pockets of applicability for some time to come.

The delivery and accessibility of genetic testing are also changing rapidly. For example, 23andMe has gained a great deal of attention with its efforts to market its genetic testing products directly to consumers. After extensive discussions and what turned out to be a temporary cease and desist order, the U.S. Food and Drug Administration recently approved the use of 23andMe’s product to screen for Bloom syndrome. This is certainly a harbinger of a time to come when many individuals will obtain genetic testing of various types and then come to the physician with a report in hand, requesting an interpretation.

## CONCLUSIONS

Major advances in the diagnosis of neuromuscular disease were separated by long intervals in the nineteenth century and the first half of the twentieth century. The pace of discovery has accelerated since then and shows no signs of slowing down. The early years of the 21st century have brought a wealth of diagnostic tools that are being applied to neuromuscular disorders, including increasingly sophisticated genetic testing and noninvasive muscle imaging and electrophysiological techniques. These complement an array of established diagnostic test modalities that still play an important role in the diagnostic evaluation of children with suspected neuromuscular disease. As a result, the test options available have become abundant and sometimes confusing. There is, unfortunately, no single diagnostic test that can provide subtype- and

mutation-specific information for all, or even the majority, of such patients. Thus a good history and physical examination remain central to the evaluation of these children, and a basic working knowledge of the information provided by old and new diagnostic tests will be critical to navigating the diagnostic odyssey in the future.

# 137 Clinical Assessment of Pediatric Neuromuscular Disorders

Richard S. Finkel

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Pediatric neuromuscular disorders are common and present significant diagnostic and therapeutic challenges for physicians responsible for their care. In addition, the families of affected children are confronted with much uncertainty about their child's condition and how to optimize their child's potential. The combined efforts of multiple specialists are often required to evaluate and manage such children to optimize their potential and quality of life.

This chapter presents an overview of the clinical assessment of the neonate, infant, child, and adolescent with a suspected or known neuromuscular disorder. Other chapters review the general principles of the neurologic examination (Chapters 1 to 5), muscle and nerve development (Chapter 135), laboratory assessment of neuromuscular disorders (Chapter 136), disease-specific information (Chapters 138 to 151), and management of children with neuromuscular disorders (Chapter 153).

## DEFINITION, CLASSIFICATION, AND EPIDEMIOLOGY OF PEDIATRIC NEUROMUSCULAR DISORDERS

**Definition.** Neuromuscular disorders are characterized by the anatomic localization of the pathology within the motor unit, which consists of the motor neuron within the ventral horn of the spinal cord and brainstem motor nuclei, peripheral nerve, neuromuscular junction and muscle. Peripheral neuropathies are further characterized as involving the motor, sensory, and/or autonomic modalities, and by their distribution into focal, multifocal or generalized disorders. Muscle disorders are subdivided into six categories based upon histopathology:

1. Dystrophies (degenerative disorders of the muscle fiber)
2. Congenital myopathies (structural abnormality of the muscle fiber or extracellular collagen matrix)
3. Metabolic disorders affecting muscle (storage diseases, energy processing disorders)
4. Mitochondrial diseases (disordered energy generation or utilization)
5. Inflammatory myopathies (idiopathic)
6. Infectious myositis (bacterial, viral, protozoan)

Myopathies and dystrophies are genetically based disorders that can be further characterized by the subcellular localization of a mutant protein within the contractile apparatus, dystrophin-associated complex in the sarcolemmal membrane, nuclear envelope, or the extracellular matrix. Myotonic disorders are characterized by clinical features and the related abnormal ion channel. [Table 137-1](#) lists the more common pediatric neuromuscular disorders and is organized based upon these anatomic, pathophysiologic, and genetic principles. A more comprehensive compendium, Gene Table of Neuromuscular Disorders, can be accessed online at <http://www.musclegenetable.fr>.

**Epidemiology.** The combined prevalence of neuromuscular disorders among children and adults was initially estimated in 1991 at 1 in 3500 individuals and 1 in 3000 in children. See the [Table 137-2](#) for additional information.

The most commonly encountered pediatric neuromuscular disorders, in descending order of prevalence, are Duchenne muscular dystrophy, Charcot-Marie-Tooth disease (i.e., hereditary motor and sensory neuropathies), congenital myopathies, myotonic dystrophy, other myopathies, spinal muscular atrophies, mitochondrial encephalomyopathies, congenital muscular dystrophies, nondystrophic myotonias, unclassifiable disorders, Becker muscular dystrophy, and metabolic myopathies. Remaining disorders all have much lower prevalence.

## EVALUATION OF THE CHILD WITH A SUSPECTED NEUROMUSCULAR DISORDER

As clinicians, we endeavor to establish a diagnosis in the neuromuscular patient similar to how we approach other neurologic patients. Sometimes, the diagnosis is obvious and needs only confirmation with a definitive test—for example, the classic infant with spinal muscular atrophy or the boy with Duchenne muscular dystrophy. More often a structured approach is needed to work through the diagnostic process. One such approach is described here and focuses specifically on the more common neuromuscular disorders in the pediatric population.

The clinician needs to address several aspects based upon the history and physical examination findings: presenting symptoms, age at symptom onset, gender, rate of progression, other organ system involvement, and family history. Collectively, these clinical features will enable the clinician to localize the lesion within the neuraxis, develop a differential diagnosis, and strategize a plan for further evaluation. [Figure 137-1](#) presents an algorithmic approach to diagnosing pediatric patients with a suspected neuromuscular disorder. Details on laboratory diagnostic testing can be found in Chapter 136. The [www.genetests.org](http://www.genetests.org) website is a compendium of genetic testing laboratories where testing for specific disorders or gene panels can be obtained.

## Localization and Classification

Neuromuscular disorders in each of the four domains of the motor unit can result from genetic or acquired etiologies. The differential diagnosis is often extensive. Having a structured approach sharpens the focus and reduces the diagnostic odyssey for the patient and family.

A fundamental goal of the history and physical examination in the neuromuscular patient is to localize the primary site of dysfunction within the motor unit. [Table 137-3](#) summarizes aspects of the examination that help localize the lesion. This, along with the age of onset, rate of progression, and relevant

**TABLE 137-1** Classification of Pediatric Neuromuscular Disorders

This schema is based upon localization within the motor unit with consideration of salient clinical features, electrophysiological findings (for peripheral nerve and neuromuscular junction disorders), muscle biopsy features, and genetic aspects for heritable disorders. The more commonly encountered pediatric disorders are listed here. A full listing of genetic neuromuscular disorders can be accessed on the <http://www.musclegenetable.fr>. Abbreviations used here are listed at the end of the chapter.

	<i>Disorder</i>	<i>Features</i>	<i>Gene</i>	<i>Protein</i>
<b>Acquired Etiology</b>		<b>Genetic Etiology</b>		
<b>Motor Neuron</b>				
Infection:	SMA		<i>SMN1</i>	Survival of motor neuron 1

medical and family history, aids in generating a differential diagnosis and plan for further assessment.

Neuromuscular disorders present with distinctive and age-related developmental features. Weakness is the cardinal feature of most neuromuscular disorders but may not be the initial or predominant symptom. Fixed weakness and related impairment need to be distinguished from fluctuating or intermittent weakness. Age at onset varies and may help to limit possible diagnoses.

Acquired disorders generally present with an acute or subacute onset and may progress rapidly, with loss of strength and decline in motor function, although genetically based disorders tend to present with a more indolent onset and subtle influence. Exceptions certainly occur; for example, spinal muscular atrophy (SMA) type 1 can present acutely similar to infantile botulism and chronic inflammatory demyelinating polyneuropathy (CIDP) may present in a chronic manner similar to Charcot-Marie-Tooth (CMT) inherited neuropathies. Motor impairment may be complicated by respiratory, cardiac, musculoskeletal, and nutritional compromise, with resultant morbidity, impaired independent functioning, and effect on survival.

## History

The history needs to capture aspects of the patient's onset of symptoms and signs, tempo of progression, effect on motor development, presence or absence of muscle pain or cramps, increased or decreased sensory symptoms, and coordination and balance issues. Related respiratory, cardiac, feeding/growth, and musculoskeletal issues need to be assessed carefully. It is important to inquire about the effect on the patient's independent functioning at home, at school, and in the community. A careful family history should always be explored. The review of systems should search for features of a systemic or genetic disease (Table 137-4 and Box 137-1). Abnormal laboratory chemistry findings (AST and ALT) may incidentally lead to a neuromuscular diagnosis. Measuring the gamma-glutamyl transferase (GGT) helps in eliminating a hepatic component.

Findings in the neonate that indicate prenatal onset include congenital torticollis, scoliosis, or multiple joint contractures. These findings are not specific for a neuromuscular disorder and may be seen in many conditions, including genetic syndromes and skeletal dysplasias. Some neonates

with congenital myopathies may have characteristic facies and ophthalmoplegia.

Signs and symptoms in the infant include hypotonia ("floppy baby"; see Chapter 138), delayed acquisition of motor milestones, dysphagia, failure to thrive, hypoventilation, and cardiomyopathy.

The child with a neuromuscular disorder typically presents with a plateau or slowing of progression in motor development. For example, the boy with Duchenne muscular dystrophy (DMD) may walk at a normal age or be slightly delayed but does not typically come to attention until abnormal running, difficulty climbing stairs, and poor jumping are recognized at age 3 to 4 years. Similarly, the child with SMA type 2 achieves sitting at a normal age and may achieve standing but fails to ambulate independently. An alert parent with CMT may identify the early signs of foot drop or cavus deformity in their similarly affected child.

Initial symptoms in the adolescent often include muscle fatigue and activity-related myalgias rather than weakness or a decline in motor function. Muscle stiffness or cramping should prompt consideration of a myotonic disorder or a metabolic disease. Although aching discomfort is common, frank pain is not typical in most neuromuscular disorders. Exceptions include myotonic dystrophy type 2 and the acute sensory presentation of Guillain-Barre syndrome.

Fluctuating or intermittent weakness is characteristic of disorders of neuromuscular transmission (e.g., myasthenia gravis), the congenital myasthenic syndromes, and different subtypes of periodic paralysis. Patients with primary orthopedic, arthritic, or chronic pain syndromes may present with intermittent deficits in motor function, especially impaired gait.

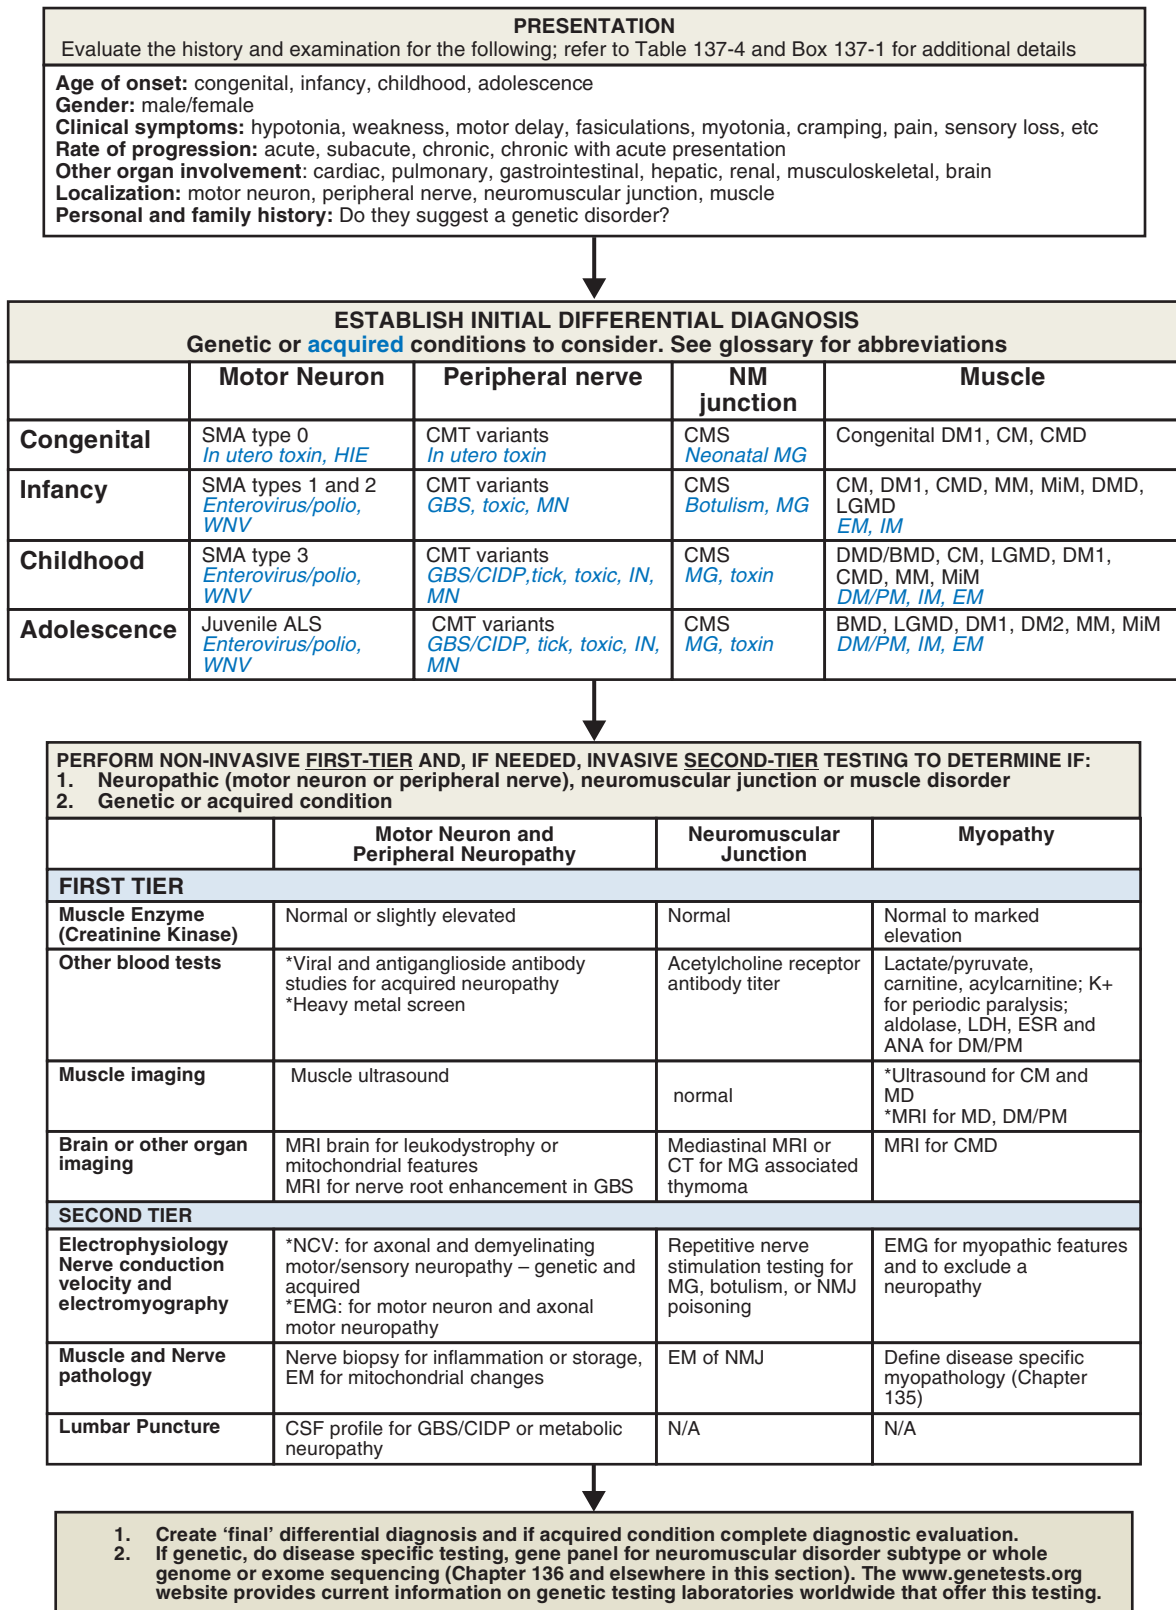

## Examination

The examination can be done in a structured manner to provide maximum information. It includes the following components and is discussed in depth in the online chapter.

**Inspection.** Assess posture, spontaneous motor activity, respiratory effort, and feeding.

**Muscle bulk and quality.** Examine for atrophy, hypertrophy, and fasciculation.

**Joint mobility and tone.** Examine for hypotonia or hypertonia and joint contractures. Joint hyperlaxity can be characterized using the Beighton score (Table 137-5A).

**Figure 137-1.** This algorithm presents a suggested pathway for the assessment of the pediatric patient with a suspected neuromuscular disorder.

Please refer to [Tables 137-1, 137-3, 137-4](#), [Box 137-1](#) and [Figure 137-2](#) for additional information.

**Assessment of muscle strength and weakness.** *Weakness* can be identified by formal testing of strength and by indirect assessment of motor impairment on functional testing. *Strength* is a composite of several physiologic elements of motor function: the magnitude, duration, velocity, and torque of muscle contraction.

Peak torque strength is most commonly evaluated using manual muscle testing (MMT). The British Medical Research Council (1941, revised 1943) developed the 0 to 5 "MRC" scale, which has since been expanded into a fuller 10-point version (1976) that is now commonly used by neurologists. Table 137-6 describes the MRC scale and two others in common use. It is generally agreed that grade 5- should not be used; the examiner should make a decision that the muscle is normally strong (5) or mildly weak (4+). Proper position is important for administering MMT correctly by assessing the patient in the following positions:

**Sitting:** shoulder abduction, elbow flexion and extension, wrist flexion and extension, fingers and thumb, hip flexion, knee extension, ankle dorsiflexion

**Supine:** neck flexion

**Prone:** neck extension, hip extension, knee flexion, ankle plantar flexion

**Side-lying:** hip abduction

The MRC scale focuses upon muscle groups that perform a particular joint motion (e.g., elbow flexion). The MRC scale is nonlinear. For example, on the MRC scale, there is a significant difference in power between a grade 5 (normal; "against strong pressure") and grade 4+ (mildest grade of weakness, "against moderate to strong pressure"); however, little change in power is noted among grades 3 "against gravity," 3+ ("against slight pressure"), and grade 4- ("against slight to moderate pressure.") None of the MMT methods specify the length of time required to achieve a particular grade. As such, only brief peak torque is typically measured.

Testing in children requires more subjective judgment as to what is normal for age and gender and usually can be assessed reliably by age 5 years. Testing in DMD has been shown to be reliable but more recently has been largely replaced by myometry and motor function testing, particularly in clinical trials. Myometry testing of strength has the benefit of being a linear scale and is typically used in a research setting. The most commonly used method is hand-held dynamometry of isometric strength.

After carefully examining the child for specific areas of weakness, it is important to consider the overall distribution in more general terms of proximal versus distal, and whether there is associated ptosis, ophthalmoparesis, facial, bulbar, neck, or trunk weakness (Fig. 137-2).

**Motor function testing.** This provides insight into the degree of functional motor impairment in addition to indicating indirectly the extent of weakness and fatigue. These tests need to be developmentally appropriate and should be performed quickly and without requiring special equipment.

(a) **Neonates and infants:** It is important to consider developmental features and distribution of hypotonia and weakness. A healthy premature infant will normally have low tone and limited strength, whereas similar findings in a 6-month-old infant are abnormal. It is useful to use a neonatal scoring scale such as the Hammersmith Infant Neurologic Examination, which can be serially administered.

It is helpful to note the infant's posture and degree of antigavity limb activity and breathing pattern in the supine position and to elicit further activity by stroking the limb or tickling the foot. Next, one should examine for torticollis and

**Figure 137-2.** Distribution of predominant muscle weakness in different types of muscular dystrophy. **A**, Duchenne and Becker. **B**, Emery-Dreifuss. **C**, Limb-girdle. **D**, Facioscapulohumeral. **E**, Distal. **F**, Oculopharyngeal. Shaded = affected areas. (With permission from Emery, AEH. *Fortnightly review: The muscular dystrophies*. *BMJ* 1998; 317:991-5.)

limb contractures and palpate the muscles for bulk and consistency. It also is helpful to examine whether the patient is capable of performing the following postural and elicited responses and note if there is related weakness, asymmetry, or fatigue during the maneuver (Table 137-7).

1. Perform the traction test with a slow pull to sit while holding the infant's hands; note neck flexion, shoulder fixation, elbow flexion, and hand grip.
2. Observe for the degree of head and neck control in sitting while supporting the infant at the upper thorax under the arms. The spine can also be examined for excessive kyphosis, scoliosis, or rigidity.
3. Next lift the infant upright and check for "slip-through" at the shoulder girdle.
4. Test for weight-bearing capacity in the lower extremities while the infant is held vertically in one hand by placing the other hand on the plantar surface of the feet and pushing up gently to elicit a hip and knee extension reflex.

5. This is followed by tipping the infant from a vertical to horizontal posture while holding the infant at the thorax and determining whether there is active neck extension. This can also be elicited by the Landau or Galant maneuvers (see online text).
6. In the infant over 9 months of age the parachute reflex should be performed—first to see if the arms extend and the open hands symmetrically extend and “plant” onto the examination table, followed by checking for the ability of the infant to support his/her full upper body weight, then to “wheelbarrow” along the examination table.

A variety of developmental and motor function scales have been used in weak infants and are summarized in the online chapter.

(b) **Child and adolescent:** In the older child and adolescent, clinical symptoms may develop more slowly and findings may be more subtle so a careful and systematic examination can be helpful in detecting motor or sensory abnormalities.

1. **Standing:** Can the child stand securely? Is there a wide-based stance? Encourage the child to squat to pick up a toy and see if she/he can recover upright posture or needs to push off the thigh to do so (Gowers assist). Can a full squat and recovery then be accomplished? Ask the child to stand with feet together and with eyes closed (Romberg test). How well can the child jump?
2. **Gait:** Using the hallway is often useful. The toddler who recently achieved ambulation will walk with a flat-footed stance phase gait but, within a few months, should develop into a more mature heel strike-stance-toe push-off cadence. Watch for toe walking and, if present, examine the Achilles tendons for tightness or knee for hyperextension, crouched gait, hip waddle, exaggerated lumbar lordosis, or if any asymmetries are present. Then encourage walking on toes and heels and running and making a turn. Finally, evaluate a brief jog and then full run.
3. **Supine-to-stand test (Gowers maneuver):** Have the child lay supine and then ask to him/her to stand up quickly. By age 3 to 4 years, the normal child will do a sit up, push off the floor with one hand, then pop upright quickly. A child with proximal lower extremity weakness will roll over into the prone position, push up onto both hands and knees (quadruped), spread the legs apart, and lift up the buttocks before thrusting the trunk upright to standing posture. With more advanced weakness of the trunk and hip extensors, the child will push off the anterior thigh with one or both hands to achieve an upright position.
4. **Climbing stairs:** Toddlers climb stairs initially marking time (both feet on one step) and use one or both handrails. A normally developing child will climb stairs with a handrail by age 20 months and will alternate feet without a handrail ascending by age 44 months and descending by 68 months.

**General Motor Function Scales.** In patients with known weakness, upper limb function is often characterized using the Brooke scale and lower limb function with the Vignos scale (Table 137-9).

Many neuromuscular physicians semiquantify how the child runs, arises from supine to stand, and climbs stairs (Table 137-10). This allows for comparison to determine subtle changes and adaptation over time. This can be done informally or in a more structured way that is part of the timed testing (e.g., the North Star Ambulatory Assessment functional scale as described later in this chapter).

*Timed testing* of motor function is a practical and useful exercise that can be readily incorporated into the routine clinic evaluation of ambulatory children with neuromuscular disorder. The same three tests described previously are commonly employed: 10-meter run/walk, supine-to-stand time (Gowers maneuver), and the four-step climb. When performed serially at each clinic visit, timed tests provide a perspective that complements the patient's, the parents', the physical therapist's, and the physician's bedside assessment of strength. Changes in these timed tests are particularly useful in demonstrating a relative decline in function when no skill has actually been lost, referred to as the “plateau phase.” This phase is important to capture in DMD as it is commonly used as the time when initiation of glucocorticosteroid medication should be considered. These timed tests are also predictive of future loss of function. For example, greater than 7 seconds on the supine-to-stand test had an 80% predictive value for loss of ambulation within the next year.

The *6-minute walk test distance (6MWT)* was developed as a test for adults with cardiac and pulmonary disease. The 6MWT segued into the neuromuscular area initially in the study of adults with myotonic dystrophy and with late-onset Pompe disease, based upon the premise that it summates skeletal muscle, cardiac and respiratory aspects of motor disability. A 30-meter difference has been generally accepted to be clinically meaningful and has been used as the basis for determining a therapeutic response to an intervention in ambulant patients with neuromuscular disorders. As such, the 6MWT has been used as a primary outcome measure in several neuromuscular trials.

**Additional motor function scales.** These scales for older children and adolescents focus largely on lower extremity function (Table 137-11).

**Muscle stretch reflexes.** These “deep tendon reflexes” (DTRs) can be a challenge to obtain in infants and squirmy children. It is important to have the patient relaxed and to place the joint being testing under slight tension, to load the muscle spindles. This can be difficult in the child with hyperlaxity or who is resisting the examination. Distraction with toys or placing the child on the parent's lap is often useful. It is usually helpful to delay testing reflexes until near the end of the examination, as the child may become upset with the testing and make additional assessment more problematic. Asymmetry in limb tone and reflexes may occur in an infant with an active tonic neck reflex. Thus assessment should be performed with the head midline.

Reduced reflexes are typical of a neuromuscular disorder but are not a necessary finding early in the course of a myopathic or neuropathic disorder. In general, reflexes are reduced or absent in myopathies or dystrophies proportionate to the extent of weakness at that site. For example, the patellar reflex is reduced when there is quadriceps weakness. Similarly, acquired neuropathies such as chronic inflammatory demyelinating polyneuropathy (CIDP) will typically have a reduced Achilles tendon reflex when there is plantar flexion weakness. Generalized reduced or absent reflexes are typical of generalized myopathies/dystrophies or inherited neuropathies. Conditions such as myotonia congenita or periodic disorders without fixed weakness such as hypokalemic periodic paralysis will typically have normal reflexes.

Increased reflexes are usually indicative of an upper motor neuron disorder. One notable exception is acute motor axonal neuropathy (AMAN), a subtype of CIDP, in which lower limb hyperreflexia is often noted. A few beats of ankle clonus is normal in infants; significant asymmetry, however, may prompt a brain or spinal cord imaging study.

**Sensory testing.** This can be performed in the infant informally by tickle or gentle pinch to the toes. Applying a

cool tuning fork to the foot and observing for withdrawal from the stimulus works as well as a pin, and the parents will be less alarmed. More detailed testing is sometimes necessary such as when mapping out any dermatomal loss of sensation in an infant with brachial plexus palsy. The sharp end of a wooden cotton tipped ear swab snapped in half works well. Large fiber modalities are important to check when a peripheral neuropathy is suspected—for example, inherited and inflammatory neuropathies. Joint position and vibration sense involve the same size sensory nerves and share the same central pathway in the dorsal columns. The sensory findings, however, may be divergent in these patients, and both modalities should be evaluated. In the child and adolescent, the Romberg test, standing with feet together and eyes closed, is more reliable, quicker, and more engaging than joint position testing. Semiquantitative testing of vibration sensitivity can be performed using a Rydel tuning fork. When sensory deficits are identified distally, it is then necessary to evaluate the lower extremity more proximally and then to compare to the upper extremity. It also is important to search for asymmetry. In this way a length-dependent neuropathy can be characterized.

### Quality of Life and Disability Scales

Patient reported outcome (PRO) and Quality of Life (QOL) instruments serve an important role in identifying the effect of a disease and, potentially, an intervention to treat that disease. Ideally this is from the direct perspective of the patients. For younger children the parents complete a proxy for their child. Age specific questionnaires have been validated and include the PedsQL, a generic QOL scale that has been incorporated into pediatric neuromuscular trials to address aspects particular to children with DMD and SMA.

Abbreviations used in this chapter:

AIDP: Acute inflammatory demyelinating polyneuropathy (Guillain-Barre syndrome)  
 ALS: Amyotrophic lateral sclerosis  
 BMD: Becker muscular dystrophy  
 CIDP: Chronic inflammatory demyelinating polyneuropathy  
 CM: Congenital myopathy  
 CMD: Congenital muscular dystrophy  
 CMT: Charcot-Marie-Tooth inherited neuropathies  
 CMS: Congenital myasthenic syndrome  
 DM: Dermatomyositis  
 DM1: Myotonic dystrophy type 1  
 DM2: Myotonic dystrophy type 2  
 DMD: Duchenne muscular dystrophy  
 EDD: Emery-Dreifuss muscular dystrophy  
 EM: Endocrine-related myopathy, e.g., thyroid-related  
 FSHD: Facioscapulohumeral muscular dystrophy  
 GBS: Guillain-Barre Syndrome  
 IN: Infection-related neuropathyp e.g., Lyme disease  
 IM: Infection-related myopathy; e.g., influenza  
 LGMD: Limb-girdle muscular dystrophy  
 MiM: Mitochondrial myopathy  
 MD: Muscular dystrophy  
 MG: Myasthenia gravis  
 MM: Metabolic myopathy, e.g. Pompe disease  
 MN: Metabolic neuropathy, e.g. metachromatic leukodystrophy  
 PM: Polymyositis  
 SMA: Spinal muscular atrophy  
 WNV: West Nile virus

# 138 The Floppy Infant

Graeme A.M. Nimmo and Ronald D. Cohn

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## DEFINING HYPOTONIA

“The floppy infant” is an informal term for generalized hypotonia and is a presenting feature for a wide range of both systemic and neurologic disease. The pediatric neurologist is regularly requested to evaluate an infant with hypotonia, and it poses a particular diagnostic challenge owing to the extensive differential diagnosis. The list of disorders with presenting features, including hypotonia, has expanded rapidly in the genomic era and continues to grow. Although at present most of the conditions have few disease modifying treatments, diagnosis is essential as it provides both families and physicians with prognostic information and screening strategies for associated pathologies. It may also expose certain risks associated with known diagnosis; for example, individuals with RYR1 mutations may be at increased risk for malignant hyperthermia (Brislin and Therous, 2013). Furthermore, many of the diagnoses are genetic and have implications for living family members or future family planning.

Severe hypotonia usually presents in the neonatal period, but milder or slowly progressive pathologies may not come to a physician’s attention until the child fails to attain milestones in the latter part of the first or second years. In the neonatal period, the differential diagnosis must include hypoxic-ischemic injury, intraventricular hemorrhage, and systemic disease such as hypoglycemia, sepsis, and heart failure; these diagnoses are not discussed here. For the most part, the remaining conditions presenting in this period have an underlying genetic origin, but acquired causes that present in this age group are also discussed. Chapter 137 provides an approach to the older child with suspected neuromuscular disease.

## Muscle Tone

Muscle tone is defined as a skeletal muscle’s inherent resistance to passive movement. It is particularly important to differentiate this from muscle strength, which is a muscle’s maximum voluntary resistance to movement. Tone is controlled by the peripheral fusimotor system with input from the central nervous system (CNS). The afferent fibers detect muscle spindle stretch and subsequently direct the motor unit system to cause muscle contraction; this is reviewed in detail in Chapter 5. Failure of any component of the motor unit, from the anterior horn cell, motor neuron, neuromuscular junction, or the muscle itself, will result in hypotonia. Supraspinal input from the motor cortex, basal ganglia, striatum, red nucleus, and cerebellum is predominantly inhibitory in its interaction with fusimotor system. In older children and adults, disturbance of inhibitory pathways results in increased excitatory output with hypertonia and hyperreflexia. In contrast, disturbance to these pathways in infancy often presents with decreased muscle tone; but importantly, the reflex arc is the preserved. Hypotonia in infancy, therefore, may be caused by disorders affecting any level of the nervous system.

Some diagnoses may be established directly from history and examination, and confirmation with further testing, often

in the form of genetic testing, can be carried out immediately. On the other hand, many of the neuromuscular diagnoses may be more difficult to distinguish based on the initial clinical evaluation alone and require preliminary investigations to better characterize the disease and define a group of diagnoses. The first step in the determination of the cause of hypotonia is to localize the pathology.

## LOCALIZATION OF HYPOTONIA

As with other types of neurologic presentation, the first step in the approach to diagnosis is to localize the clinical findings to the site of pathology. Conditions that affect the central nervous system, and therefore supraspinal pathways, cause a clinical picture referred to as central hypotonia. The term peripheral hypotonia is used to describe the clinical features of an infant that presents with pathology affecting the motor neuron unit. The key differentiating feature is the presence or absence of weakness (Dubowitz, 1980).

Infants with a central cause for their hypotonia may present with other findings suggesting disorders involving the CNS: dysmorphic features, decreased level of consciousness, seizures, and may have evidence of brisk reflexes and clonus (Table 138-1). In an older child, there may be a history of developmental delay affecting both cognitive and motor domains.

Infants with peripheral hypotonia, in contrast, have a paucity of antigravity movements and may have myopathic facies but are generally alert and reach cognitive milestones appropriately. Fasciculations, muscle atrophy, and diminished reflexes are characteristic of this group. There are some exceptions in these divisions. Infants with myotonic dystrophy and congenital myopathies often do not have profound weakness. Many of the findings thought to be present in central hypotonia such as seizures and dysmorphic features are found in considerable proportions in both divisions. Nevertheless, the constellation of findings generally allows correct classification an estimated 80% of the time. It is also useful to think of a third group of pathologies that have both central and peripheral features and are referred to here as combined hypotonia. A practical algorithm guiding the approach to a neonate or infant with hypotonia is shown in Figure 138-1.

## HISTORY

Key components of the clinical examination confirm the presence of hypotonia, localizes its origins, and narrows the differential diagnosis. A careful and complete history is essential.

The pregnancy history should include corrected gestational age as infants may present with hypotonia secondary to premature gestational age alone. A history of maternal illnesses (particularly myasthenia gravis) and exposure to medications, drugs, and infection should be sought. Results of antenatal ultrasounds, specifically polyhydramnios and paucity of fetal movements, are characteristically seen in peripheral

**TABLE 138-1** Features Differentiating Central and Peripheral Hypotonia

Central	Peripheral
Developmental delay	Weakness with paucity of spontaneous movement
Normal CK <sup>a</sup>	Raised (or normal) CK
Decreased LOC	Alert
Increased DTRs, clonus	Decreased DTRs <sup>c</sup>
Seizures <sup>b</sup>	Muscle fasciculations
Dysmorphic facial features	Myopathic facies <sup>d</sup>
Microcephaly	Ophthalmoplegia Ptosis Bulbar dysfunction
Apneas, irregular respiration	Prolonged breathing difficulties, ventilator dependence
High pitched/unusual cry	Fatigable or weak cry
Multiple congenital abnormalities	History of polyhydramnios

<sup>a</sup>CK may be normally raised in the early neonatal period. <sup>b</sup>Seizures are common in patients with LAMA2-related congenital muscular dystrophy. <sup>c</sup>DTRs may be normal in patients with disorders affecting the neuromuscular junction. <sup>d</sup>Tented upper lip, dolichocephaly, long face, and high arched palate. CK, creatinine kinase; DTRs, deep tendon reflexes.

hypotonia, whereas evidence of congenital malformations may be more in line with a multisystem syndrome and a cause of central hypotonia.

Delivery history may uncover risk factors for hypoxic-ischemic injury (HIE), including maternal hypotension, breech extraction, cord prolapse, or placental abruption. HIE must be excluded as it is the most common cause for central hypotonia. Apgar scores and details surrounding resuscitation, if required, may be useful in order to further exclude birth asphyxia. Infants with HIE often present with an altered level of consciousness that gradually improves in the neonatal period. It is also not uncommon for the tone to improve over the first several months of life with evolution to hypertonia and spasticity within the first 2 to 3 months of life. Asphyxia has been observed in peripheral disorders. Details of resuscitation may be required to differentiate between these infants and those with severe diaphragmatic or bulbar muscle weakness of neuromuscular origin that may require early respiratory support.

Onset and progression of the hypotonia should be elucidated. Central hypotonia tends to improve with time, whereas peripheral hypotonia remains stable or progresses gradually. Rapid progression after an uncomplicated pregnancy, delivery, and neonatal course suggests an inborn error of metabolism. Infantile botulism may also present with progressive weakness and history of constipation, after an otherwise unremarkable neonatal course. It is important to exclude the consumption of honey or corn syrup if this diagnosis is suspected. Fluctuation in symptoms may be seen with congenital myasthenia syndromes or in LAMA2-related muscular dystrophy. Many infants with hypotonia will require respiratory support owing to the more complicated delivery, presence of apneas, bulbar dysfunction, or respiratory muscle weakness. However, prolonged intubation, defined by a length greater than 5 days, is more commonly seen in infants with peripheral causes. A feeding history may also be reveal bulbar dysfunction, resulting in choking or aspiration often seen—although not

exclusively—with peripheral hypotonia. Fatigue with feeding may be observed with myasthenic syndromes. Seizures have been traditionally associated with central causes, although have been reported in peripheral disorders particularly in LAMA2-related muscular dystrophies.

Developmental history should be obtained if the infant is of an appropriate age. Motor delay will often result secondary to the hypotonia, but cognitive delay is more common with central causes and myotonic dystrophy.

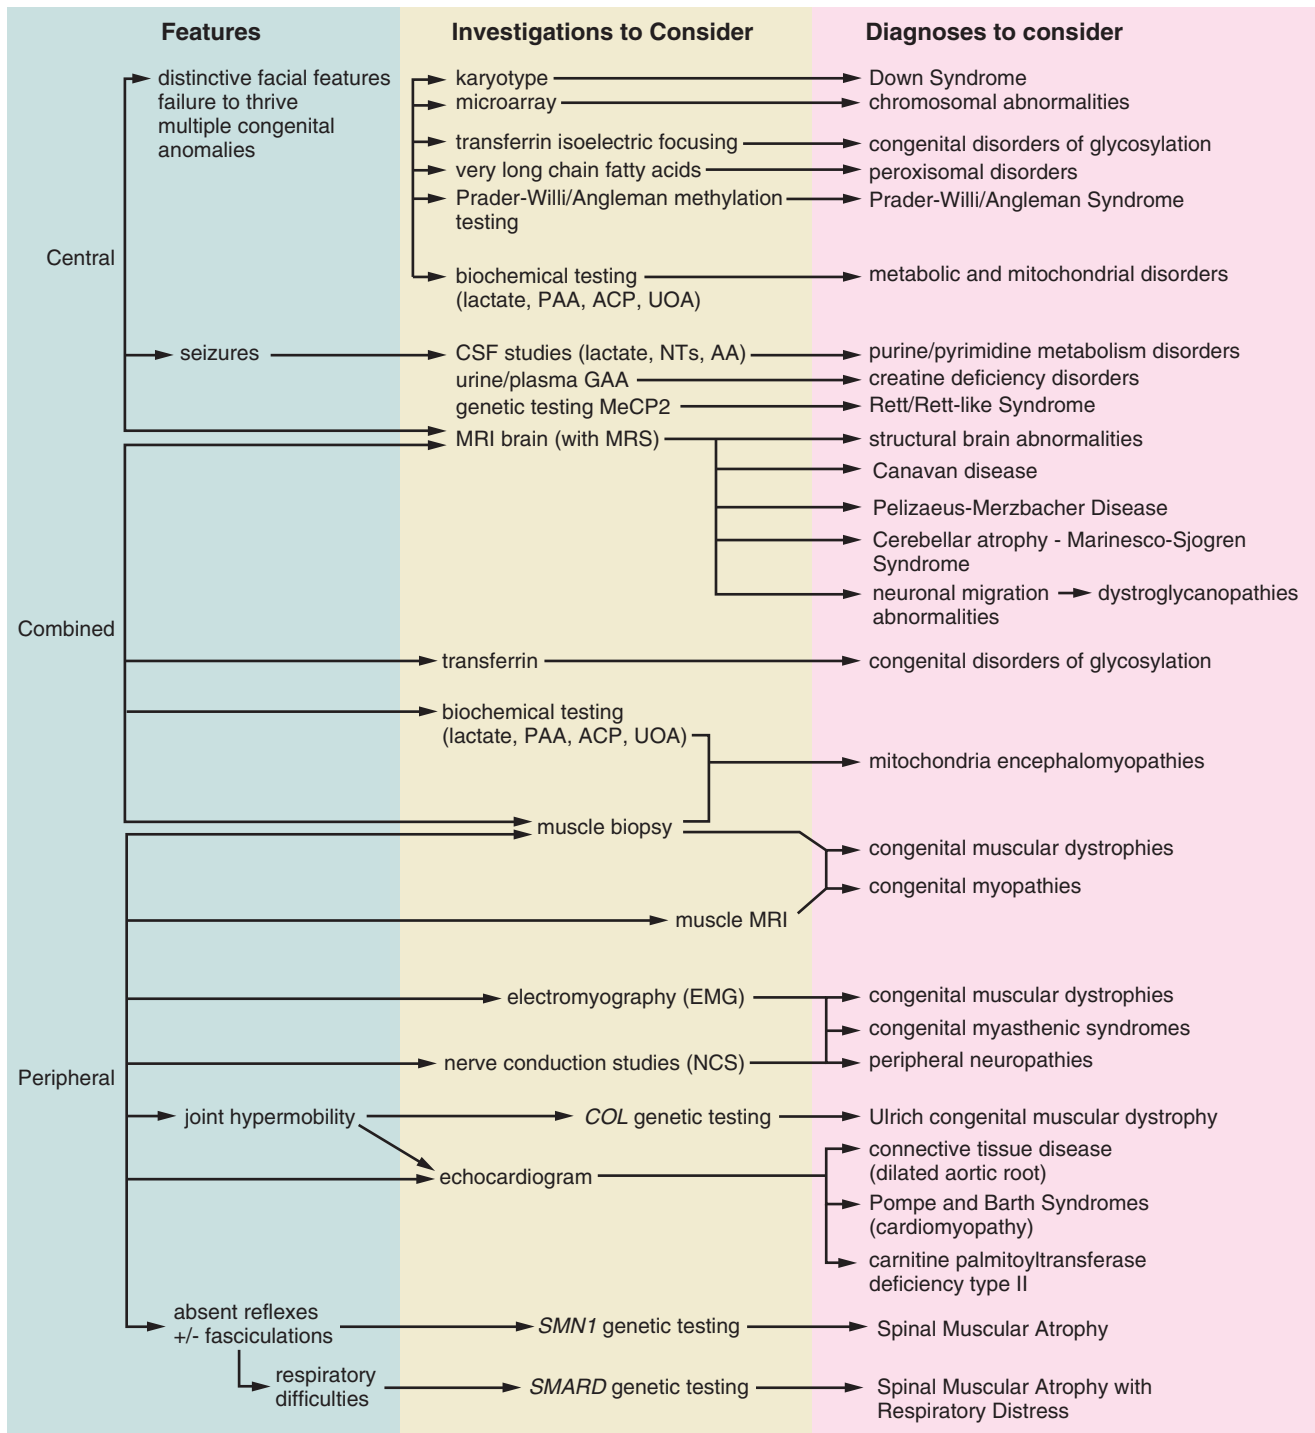

A detailed family history is essential. Certain conditions are more common in particular ethnicities; Ashkenazi Jews have a high carrier rate for familial dysautonomia and Canavan disease. The presence of consanguinity increases the likelihood of any recessive disease and is commonly reported with inborn errors of metabolism. Familial or maternal history of recurrent miscarriages points to a multisystem, and perhaps syndromic, disorder. Positive family history and details of known skeletal muscle disease, congenital abnormalities, developmental delay, and intellectual disability may also narrow the differential considerably. History of malignant hyperthermia may suggest a congenital myopathy. Maternal features of myotonic dystrophy should also be elicited, as these stable symptoms commonly go unrecognized: distal muscle weakness, intellectual disability, insulin resistance, cataracts, cardiomyopathy, and arrhythmias (Thornton, 2014). If a diagnosis of mitochondrial disease is being considered a positive history of less severe manifestations of exercise intolerance, migraine headache, diabetes mellitus, retinitis pigmentosum, and sensorineural hearing loss may be elicited, and may demonstrate a maternal inheritance pattern (DiMauro, 2013).

## EXAMINATION

Identifying an infant as hypotonic is typically difficult for an inexperienced examiner, and a number of unaffected infant examinations may need to be performed before more subtle decrease in tone can be appreciated. Reliable determination of hypotonia, particularly in the NICU setting, is often complicated because tone may be influenced by systemic illness, medication, level of alertness, and gestational age. The examiner will often need to perform serial examinations or defer an examination to a time when the infant is not acutely unwell.

The assumption of unusual postures by the hypotonic infant is often the first indication of decreased tone. Instead of the contracted posture of a healthy term infant, infants with hypotonia typically have flaccid extension of the arms and abduction of the legs of described as “frog-leg.” There are several maneuvers that are particularly useful for assessing tone in infants:

1. The **pull-to-sit** (or traction) test may be used to assess both axial tone and upper limb weakness. The supine infant is pulled by the hands to the sitting position with the examiner observing for head lag. Term neonates, until about 2 months, should have only mild head-lag. Infants usually resist this movement with flexion at the shoulder and elbow; this also gives the examiner an opportunity to assess strength in the upper limb.
2. The **scarf-sign** provides a measure of appendicular tone in the upper limb. To elicit this sign the supine infant’s hand is pulled toward the opposite shoulder and around the neck. The sign is positive for hypotonia if the elbow can be pulled across the midline.
3. Measurement of the **popliteal angle** is a more objective way to measure tone in the lower limb. In the supine position, the infant’s hip is flexed to the torso and the knee

**Figure 138-1. Hypotonia algorithm** (Adapted from Lisi, E.C., Cohn, R.D.,2011. Genetic evaluation of the pediatric patient with hypotonia: perspective from a hypotonia specialty clinic and review of the literature. *Dev Med Child Neurol* 53(7), 586–599.)

extended as far as possible. The angle between the thigh and the leg is the popliteal angle and should be less than 90 degrees in the term infant.

4. **Shoulder suspension** or vertical suspension test in which the infant is held under the shoulders in the vertical position assesses appendicular tone. A term neonate resists falling through the hands of the examiner.
5. For the **ventral suspension** test, the examiner holds the infant by the torso in a supine position. An infant with adequate tone is able to maintain both upper and lower limbs in flexed posture and, at least transiently, be able to hold their head higher than the horizontal.

The examiner should also get a subjective appreciation of appendicular tone as described in Chapter 5. Axial hypotonia with the relative preservation of peripheral tone should prompt consideration of metabolic disease. This particular pattern is also seen in the LMNA1 congenital muscular dystrophy and SPEN1-congenital myopathy (Bonnemann et al., 2014; North et al., 2014). The most common causes of severe hypotonia are Down syndrome, Prader-Willi syndrome, and centronuclear congenital myopathies.

Once the determination of hypotonia is confirmed, most of the useful information for this age group can be gathered by observation alone. Severe weakness that impairs an infant's spontaneous antigravity movement and appropriate withdrawal response is most likely secondary to a peripheral pathology. The presence or absence of weakness is the most reliable distinguishing feature between central and peripheral causes.

Particular attention should be placed on examining the infant's facial features. Distinctive features may point toward a specific syndromic diagnosis such as Down syndrome, Prader-Willi syndrome, Williams syndrome, or DiGeorge syndrome. Myopathic facies with marked facial weakness, open mouth, tending upper lip with additional dysmorphic features of dolichocephaly, long faces, and high arched palate suggest a severe form of congenital myopathy, myotonic dystrophy, or congenital myasthenic syndrome. Findings of ptosis and ophthalmoplegia should be noted as they are commonly seen in patients with congenital myopathies and congenital myasthenic syndromes. Isolated ophthalmoplegia is rare in neonates but may be associated with disorders of the mitochondrial respiratory chain.

Diaphragmatic breathing is common in the neonatal period; however, respiratory distress with in-drawing of the sternum may indicate intercostal muscle weakness of neuromuscular origin. Weak cry is also a consequence of respiratory muscle weakness, although high pitched or unusual cries are more in keeping with central etiologies. A fatigable cry is associated with myasthenia.

Joint contractures may also be observed in the context of weakness secondary to prolonged periods of decreased movement. Arthrogryposis may be present after fetal akinesia and are most commonly associated with congenital myopathies, congenital myasthenia, and spinal muscular atrophy (Wang et al., 2007). More localized contractures, including talipes equinovarus, may present with any of lower motor neuron etiologies but tend to be proximal in Collagen-VI-related congenital muscular dystrophy and distal in LAMA2-related congenital myopathy.

Reflexes are often unreliable in the newborn period, as they are often brisk or may be normally absent. In older infants, reflexes may be brisk in upper motor neuron lesions and absent or reduced in lower motor neuron lesions. Clonus, if present, may indicate an upper motor neuron lesion, but it must be kept in mind that up to six beats of clonus may be normal in neonates.

Finally, full examination of all other systems should be performed in order to identify any additional congenital abnormalities that may indicate a syndromic diagnosis.

## CENTRAL HYPOTONIA

Hypotonia in the absence of weakness is suggestive of disorders affecting the central nervous system. This suspicion is often further supported with findings of altered level of consciousness, dysmorphic features, major congenital anomalies, and/or the presence of seizures. The creatine kinase (CK) is normal.

The approach to an infant with central hypotonia should, as in all areas of medicine, be directed at identifying the most life-threatening and actionable diagnoses first with consideration of the most common etiologies next. It is therefore imperative that the general health of the infant be a part of the initial assessment. Both sepsis and severe congenital heart disease can cause a picture of central hypotonia. Hypoxic-ischemic injury accounts for approximately one-third of infants with hypotonia. Intraventricular hemorrhage accounts for a significant proportion of preterm neonates with hypotonia.

All infants presenting with hypotonia should have a CK level measured. Creatine kinase is not raised with CNS disease, but care must be taken in interpreting this in the early neonatal period as CK may be normally raised in the first few days of life. Magnetic resonance imaging of the brain should be obtained to identify structural abnormalities. Importantly, a cranial ultrasound or MRI may also identify abnormalities characteristic of HIE or IVH as reviewed in Chapter 19. Additional investigations based on the history and examination should be considered in order to identify and characterize any congenital abnormalities that may be a part of a particular syndrome. Further testing may include echocardiogram, abdominal ultrasound, ophthalmology assessment, and/or hearing testing. Biochemical testing for inborn errors of metabolism should be considered and include plasma amino acids, urine organic acids, acylcarnitine profile, glycosylation patterns, and lactate/pyruvate. Additional biochemical testing may be warranted with specific clinical findings suggestive of peroxisomal disorders, Smith-Lemli-Opitz syndrome, or in the presence of seizures as outlined in Figure 138-1.

The findings of multiple congenital abnormalities, dysmorphic facial features, or delay in cognitive milestones should prompt consideration of a syndromic diagnosis or chromosomal abnormalities, and involvement of a geneticist may be valuable. Depending on the clinical context, genetic tests may be indicated and include karyotype, microarray, fluorescence in situ hybridization (FISH), and/or methylation analysis (Watson et al., 2014). The more common diagnoses, including Down syndrome, Prader-Willi syndrome, and William syndrome, are listed in Table 138-2 with their distinguishing features.

## PERIPHERAL HYPOTONIA

Hypotonia with weakness suggests a disorder affecting the lower motor neuron. These infants are generally alert, and there are no signs of CNS involvement, although motor development may be delayed in older infants. Creatine kinase may or may not be raised.

Peripheral hypotonia is less common than that of central origin, accounting for approximately 20% of diagnosis in infants with hypotonia in the NICU. The most common causes are spinal muscular atrophy, myotonic dystrophy, and the congenital myopathies. Table 138-3 lists the most common disorders causing peripheral hypotonia and the associated

**TABLE 138-2** Distinguishing Features of Common Causes of Central Hypotonia

Diagnosis	Features Suggestive of Diagnosis
<b>Chromosomal abnormalities</b>	Dysmorphic facial features, multiple congenital abnormalities, microcephaly, macrocephaly, failure to thrive, delay in cognitive milestones, advanced maternal age, history of recurrent miscarriages, abnormal aneuploidy screening
<b>Down syndrome</b>	Flat facial profile, up slanting palpebral fissures, epicanthal folds, anomalous ears, transverse palmar crease, and fifth finger clinodactyly, endocardial cushion defects, duodenal atresia
<b>Prader-Willi syndrome</b>	Global developmental delay, distinctive facial features (bitemporal narrowing, almond shaped eyes, strabismus, thin upper lip, downturned upper lip), short stature, genital hypoplasia, failure to thrive in infancy with hyperphagia after 1 year if age
<b>Angelman syndrome</b>	Global developmental delay, acquired microcephaly, seizures, prognathism, skin hypopigmentation
<b>MeCP2-Spectrum disorders</b>	Acquired microcephaly, seizures, repetitive hand movements, regression, female predominant
<b>Williams syndrome</b>	Distinctive facial features (periobital fullness, hypertelorism, long philtrum, wide mouth, thin vermilion border, micrognathia), supraaortic stenosis, hypercalcemia
<b>Peroxisomal disorders</b>	Liver dysfunction, seizures, cataracts, retinal dystrophy, hearing loss, chondrodysplasia punctata, large anterior fontanelle, flat facial profile
<b>Smith-Lemli-Opitz</b>	Growth delay, global developmental delay, Y-shaped 2–3 toe syndactyly, cleft palate, cataracts, cardiac abnormalities, downslanting palpebral fissures, prominent epicanthal folds, anteverted nares
<b>Creatine Deficiency disorders</b>	Global developmental delay, seizures, delayed myelination

**TABLE 138-3** Distinguishing Features for Common Causes of Peripheral Hypotonia

Diagnosis	Features Suggestive of Diagnosis
<b>Spinal muscular atrophy</b>	Predominantly proximal weakness with relative preservation of facial movements, contractures, absent deep tendon reflexes, tongue fasciculations. SMARD presents with diaphragmatic and intercostal muscle weakness
<b>Congenital Myotonic dystrophy</b>	Facial diplegia with inverted-V shaped upper lip, weak cry, poor suck, maternal history of weakness, cataracts, type 2 diabetes, and contraction myotonia
<b>Congenital muscular dystrophies</b>	
LAMA2-CMD	Kyphoscoliosis, joint contractures, increased signal intensity of white matter with MRI
Collagen VI-deficient CMD (Ullrich CMD)	Distal hypermobility, proximal contractures, scoliosis
Dystroglycanopathies	Combined hypotonia, cobblestone lissencephaly, neuronal migration abnormalities, various ocular abnormalities
SEPN1-related CMD	Axial hypotonia, progressive spinal rigidity, and scoliosis
LMNA-related CMD	Weakness and contractures affecting the proximal upper limb and distal lower limb, cardiomyopathy
<b>Congenital myopathies</b>	Facial weakness with myopathic facies (ptosis, tented upper lip), dolichocephaly, long face, high arched palate, absent DTRs, family history of malignant hyperthermia, cardiomyopathy, orthopedic complications
Centronuclear myopathy	X-linked, severe weakness (no spontaneous movement, respiratory insufficiency), joint contractures, macrocephaly, arachnodactyly, cryptorchidism
<b>Congenital myasthenic syndromes</b>	Weak cry, poor suck, ptosis, facial weakness, occasional arthrogyriposis, fatigable weakness, exclude maternal history of myasthenia gravis
<b>Carnitine palmitoyltransferase deficiency type II</b>	Liver failure, cardiomyopathy, neuronal migration abnormalities, hypoketotic hypoglycemia
<b>Pompe disease</b>	Severe hypotonia, hypertrophic cardiomyopathy, hepatomegaly, shortened P-R interval on ECG
<b>Barth syndrome</b>	Cardiomyopathy, neutropenia, growth delay
<b>Polyneuropathies</b>	Distal weakness, sensory loss, decreased DTRs
Guillain-Barré syndrome	Progressive weakness after antecedent illness, DTRs reduced, elevated CSF protein, nerve root enhancement on MRI

Continued on following page

**TABLE 138-3** Distinguishing Features for Common Causes of Peripheral Hypotonia (Continued)

Hereditary motor and sensory neuropathies/ Charcot-Marie-Tooth disease spectrum	Wide range of presentation. Severe: arthrogryposis, respiratory distress, swallowing difficulties, slow nerve conduction velocities
Familial dysautonomia	Distinguishing features present later, high carrier frequency in Ashkenazi and Eastern European Jewish population
Infantile neuroaxonal dystrophy	Axial hypotonia, developmental regression, seizures, nystagmus, optic atrophy
Infant botulism	Hyporeflexia, constipation, respiratory distress, eye movement abnormalities, history of pica or honey
<b>Connective tissue disorders</b>	Mild hypotonia, hypermobility, aortic root dilatation
Marfan syndrome	scoliosis, pectus deformity, arachnodactyly, dolichostenomelia
Loeys-Dietz syndrome	Craniosynostosis, hypertelorism, cleft palate or bifid uvula, tortuous blood vessels
<b>Congenital disorders of glycosylation</b>	Central hypotonia and weakness, global developmental delay, dysmorphic features, inverted nipples, abnormal fat distribution
<b>Canavan disease</b>	Global developmental delay, macrocephaly, optic atrophy, seizures, spongy appearance of white matter, Ashkenazi Jewish ethnicity
<b>Marinesco-Sjögren syndrome</b>	Global developmental delay, cerebellar atrophy, ataxia, cataracts
<b>Mitochondrial respiratory chain diseases</b>	Central hypotonia or myopathy, exercise intolerance, seizures, migraines, ataxia, cardiomyopathy, ophthalmoplegia, sensorineural hearing loss, optic atrophy, hypothyroidism, diabetes mellitus, maternal family history of above
<b>Pelizaeus-Merzbacher disease</b>	X-linked, progressive peripheral and central hypotonia with evolution to spasticity, ataxia

features. Given the large number of etiologies and overlapping presentation, it may be impossible to make a diagnosis on clinical findings alone, and electromyography, nerve conduction studies, and/or muscle biopsy are often required. In the case in which maternal history of myotonic dystrophy or family history of specific neuromuscular disorder is present, it may be possible to avoid specific neuromuscular investigations and arrange for genetic testing in order to confirm the diagnosis. Certainly, some features, when present, are highly suggestive of specific diagnoses: tongue fasciculations in anterior horn cell disease, joint hypermobility in connective tissue disease or collagen VI-related CMD, and cardiac involvement in metabolic myopathies.

Raised serum creatine kinase (CK) suggests hypotonia of a peripheral origin; further supports hypotonia of peripheral origin; the most marked CK elevations are observed in patients with congenital muscular dystrophies. It is important to note that in all forms of peripheral pathologies, CK may be normal; therefore it is not possible to rule out peripheral hypotonia based on CK results alone. EMG and NCS may identify slowed conduction velocities seen in peripheral nerve pathologies, characteristic response to repetitive stimulation in congenital myasthenic syndromes, denervation consistent with an anterior horn cell disorder, myopathic features with muscle irritability suggesting Pompe disease, or myopathic changes with primary muscle disease. Muscle imaging by ultrasound or MRI, particularly of the thigh muscle, is an emerging modality for identification of specific patterns of muscle involvement observed in the congenital myopathies and congenital muscular dystrophies. Finally, biopsy is often required in order to demonstrate the characteristic histologic findings of congenital myopathies or dystrophic changes in the muscular dystrophies. When selecting a biopsy site, it is important to target muscles that are affected by weakness; information from EMG, ultrasound, and MRI are often useful for selecting a biopsy site involving affected muscle.

Information from the clinical presentation, family history, and investigations allows prioritization of genetic testing to

confirm a specific diagnosis. Because there is generally greater accessibility to genetic testing that is less invasive, muscle biopsy is sometimes bypassed, particularly if features of specific myopathy are present from the clinical examination or MRI findings. The route to direct genetic diagnosis with genetic testing does have some drawbacks. The first is the prolonged time required for the result to become available, which can be particularly problematic for families with a severe and unexpected presentation. Second, interpretation of genetic test results may be more complicated if precise diagnosis is unknown, particularly if the pathogenicity of the variant is not obvious or not consistent with the expected pattern of inheritance.

# 139 Genetic Disorders Affecting the Motor Neuron: Spinal Muscular Atrophy

Basil T. Darras, Umrao R. Monani, and Darryl C. De Vivo

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

In the early 1890s, the Austrian clinician Guido Werdnig at the University of Graz, Austria, and the German physician Johann Hoffmann in Heidelberg, Germany, described a neuromuscular disorder causing progressive muscular weakness associated with the loss of anterior horn cells in the spinal cord, with onset in infancy and early death. Together, their reports provide the first complete description of the severe form of spinal muscular atrophy (SMA), originally named Werdnig-Hoffmann disease. The SMAs have since been defined as a group of genetic disorders characterized by progressive muscle weakness and atrophy, associated with degeneration of spinal and, in the most severely affected patients, lower bulbar motor neurons. The most common of these forms, as well as the leading cause of infant mortality, is classic proximal SMA, which seems to be found in practically all populations but is diagnosed more frequently in infants and children, rather than in adults.

Genetic studies have found that classic SMA results from homozygous deletions or mutations involving the “survival of motor neuron” (*SMN*) gene. Two copies of the *SMN* gene, designated *SMN1* and *SMN2*, are present on each chromosome 5, forming an inverted duplication at locus 5q13 (Figure 139-1). The duplicated *SMN2* gene is differentiated from *SMN1* by 5 nucleotide changes that do not change amino acids. A single-nucleotide change in *SMN2* creates an exonic splicing suppressor in exon 7, leading to exclusion of exon 7 in most transcripts (Monani et al., 1999) and thus diminished production of the functional *SMN* protein. Patients with 5q proximal SMA harbor homozygous deletions or mutations involving exon 7 of the *SMN1* gene, but maintain at least 1 copy of *SMN2*.

## EPIDEMIOLOGY

The incidence of SMA has been estimated at 1 in 6000 to 11,000 live births or about 7.8 to 10 per 100,000 live births and at 4.1 per 100,000 live births for SMA type I. The estimated pan-ethnic disease frequency is approximately 1 in 11,000. The carrier frequency for mutations in the *SMN1* gene has been estimated from 1:38 to 1:70. It should be noted that, despite the high carrier frequency, the incidence of SMA is lower than expected. It has been postulated that this may reflect that some fetuses have a 0/0 *SMN1/SMN2* genotype (i.e., no *SMN* protein is present at all), which is known in other species to be embryonically lethal.

## CLINICAL CHARACTERISTICS

Though most patients with SMA have deletions or mutations involving the *SMN1* gene, a range of phenotypic severity permits division into four broad clinical subtypes. It is recognized that the subtypes represent a phenotypic continuum extending from the very severe, with onset *in utero*, to the very mild, with onset during adulthood; there is also a spectrum of severity within each of these groups (Table 139-1). For the

purposes of clinical classification, or of guidelines developed for standards of care, the “maximal functional status achieved” approach, which classifies type I patients as “nonsitters,” type II patients as “sitters,” and type III patients as “walkers,” has been used (Wang et al., 2007). Patients with a mild phenotype and onset during middle or late age are classified as type IV. The age at onset is also considered in the classification but because of potential overlap between subtypes and the difficulty in accurately determining the onset of symptoms, it has not been considered as the sole determinant of disease subtype.

## Type I SMA

After the initial description of infantile SMA by Werdnig and Hoffmann in the early 1890s and further descriptions made by Sylvestre in 1899 and Beevor in 1903, infantile or type I SMA was described again in detail, both clinically and pathologically, by Randolph Byers and Betty Banker at Boston Children’s Hospital in 1961. Patients with type I SMA, also known as Werdnig-Hoffmann disease, present between birth and 6 months of age. SMA type I has been further subdivided into 3 groups: type IA (or type 0 in certain reports) with onset *in utero* and presentation at birth, type IB with onset of symptoms before 3 months of age, and type IC with onset between 3 and 6 months of age. Infants with SMA type I have progressive proximal weakness that affects the legs more than the arms. They have poor head control, hypotonia that causes them to assume a “frog-leg” posture when lying and to “slip through” on vertical suspension, and areflexia. They are never able to sit (“nonsitters”) or roll over independently (see Table 139-1). There is also weakness of the intercostal muscles with relative sparing of the diaphragm, producing a bell-shaped chest and a pattern of paradoxical or “belly”-breathing. Infants with type I SMA also classically exhibit tongue fasciculations and eventually have difficulty swallowing, with failure to thrive and a risk for aspiration. Other cranial nerves are not as affected, although facial weakness does occur at later stages of the disease. Cognition is apparently normal, and they are often noted at diagnosis to have a bright, alert expression that contrasts with their generalized weakness. Infants with type I SMA usually develop respiratory failure by age 2 years, or much earlier, and in the past most did not survive past 2 years; however, there has been some increase in survival in recent years with the use of assisted ventilation (to be described in more detail in later sections) and other interventions (Darras et al., 2015). Prior natural history studies have reported shortened life span, with 68% mortality within 2 years and 82% by 4 years of age. The application of nutritional and respiratory interventions has reduced the mortality to approximately 30% at 2 years, but about half of the survivors are fully dependent on noninvasive ventilation. In a recent observational study, the median age at reaching the combined endpoint of requiring at least 16 hours/day of noninvasive ventilation or death was 13.5 months. Infants with two *SMN2* copies had

**Figure 139-1. Schematic diagram of human *SMN1* and *SMN2* genes on chromosome 5.** Patients with spinal muscular atrophy have deletions or mutations in both copies of *SMN1*. A C-to-T transition at position 840 of *SMN2* creates an exonic splicing suppressor (ESS) that leads to skipping of exon 7 during transcription and production of the truncated, nonfunctional SMN protein. However, a small amount (~10%) of full-length messenger RNA is produced from the *SMN2* gene, resulting in the functional, full-length SMN protein. AA, amino acids. **TABLE 139-1** Clinical Classification of Spinal Muscular Atrophy

SMA Type	Other Names	Age at Onset	Life Span	Highest Motor Milestone Achieved	Other Features	Proportion of Total SMA (%)
Type IA	Prenatal (type 0), congenital SMA, Werdnig-Hoffmann disease	Prenatal	<6 months	Mostly unable to achieve motor milestones	<ul style="list-style-type: none"> <li>Severe weakness at birth</li> <li>Profound hypotonia</li> <li>Facial diplegia</li> <li>Areflexia</li> <li>Early respiratory failure</li> <li>Joint contractures</li> </ul>	
Type IB	Werdnig-Hoffmann disease, severe SMA ("nonsitters")	Type IB (0–3 months)	<2 years without respiratory support	Never sits unsupported	<ul style="list-style-type: none"> <li>Weakness</li> <li>"Frog leg" posture, hypotonia</li> <li>Tongue fasciculations</li> <li>Hyporeflexia, areflexia</li> <li>Suck and swallow difficulties</li> <li>Respiratory failure</li> </ul>	60*
Type IC		Type IC (3–6 months)				
Type II	Intermediate SMA ("sitters"), Dubowitz disease	6–18 months	>2 years ~70% alive at 25 years of age	Sits independently, never walks independently	<ul style="list-style-type: none"> <li>Proximal weakness, hypotonia</li> <li>Postural hand tremor</li> <li>Hyporeflexia</li> <li>Average or above average intellectual skills by adolescence</li> <li>Scoliosis</li> </ul>	27
Type III	Kugelberg-Welander disease, mild SMA ("walkers")	>18 months	Almost normal	Stands and walks	<ul style="list-style-type: none"> <li>May have hand tremor</li> <li>Resembles muscular dystrophy</li> <li>CK often elevated 2-5X</li> </ul>	12
		Type IIIA (before 3 years)				
		Type IIIB (after 3 years)				
Type IV	Adult SMA	>21 years	Normal	Normal		1

\*Spinal muscular atrophy (SMA) types I, IA, IB, and IC all have a 60% proportion of total SMA.

(Modified with permission of Markowitz JA, Singh P, Darras BT. *Spinal muscular atrophy: a clinical and research update*. *Pediatr Neurol* 2012;46:1–12.)

greater morbidity and mortality than those with three copies. The need for nutritional support preceded that for ventilation support (Finkel et al., 2014).

It was previously believed that SMA is a purely motor neuron disorder. However, recent studies have shown that severe type I SMA can result in various organ manifestations, apart from spinal cord motor neurons such as brain, cardiac, vascular, and even sensory nerve involvement. Recent autopsy studies have shown increasing evidence of congenital heart disorders in severe SMA, with the most common association being hypoplastic left heart syndrome; however, this finding has not been confirmed and a chance of association has not been firmly excluded. Studies done on various mouse models have also found that severe SMN protein deficiency might present as vasculopathy. This was also noted in the case reports of two unrelated patients with severe SMA type I. Both these infants developed ulcerations and necroses of the fingers and toes. Autonomic dysfunction is thought to be the primary cause of this vasculopathy.

## Type II SMA

This intermediate form of SMA was first reported in 1893 at the University of Edinburgh, United Kingdom, and described again by Byers and Banker in 1961 and in detail by Dubowitz in 1964. Patients with type II SMA, also known as intermediate SMA or Dubowitz disease, are able to sit unsupported at some point ("sitters"), but are never able to stand alone or walk independently (see Table 139-1). The onset of symptoms is typically between 6 and 18 months of age. They have progressive proximal weakness affecting legs more than arms, hypotonia, and areflexia. They also develop progressive scoliosis, which, in combination with intercostal muscle weakness, results in significant restrictive lung disease as they grow older. They develop joint contractures and can have ankylosis of the mandible. They exhibit tremor, or polyminimyoconus, of the hands (Darras et al., 2015). Although their body mass index may be low (at the third percentile or less compared with normal children), this likely represents reduced muscle mass as the high-functioning, nonambulatory patients have a higher relative fat mass index and are at risk of becoming overweight. Cognition is normal and verbal intelligence may be above average. In a study done on 240 type II patients, survival rates were found to be 98.5% at 5 years and 68.5% at 25 years. Patients may live into the third decade, but life expectancy is shortened because of the risk of respiratory compromise (Darras et al., 2015).

## Type III SMA

In 1956, Kugelberg and Welander described a much milder form of SMA characterized by prolonged ambulation. Patients with type III SMA, also known as Kugelberg-Welander disease, are able to stand alone and walk at some point ("walkers"). The onset of symptoms occurs after the age of 18 months; it has further been subdivided into type IIIA (onset between 18 months and 3 years) and type IIIB (onset after 3 years). They have progressive proximal weakness affecting legs more than arms and may ultimately need to use a wheelchair, especially the IIIA group, but they generally develop little to no respiratory muscle weakness or severe scoliosis. Loss of ambulation increases the risk of these complications. They may have tremor or polyminimyoconus of the hands. Sometimes, the calves of these patients can be prominent and hence type III SMA can be confused with Becker muscular dystrophy. Creatine kinase levels are often elevated, usually no more than fivefold, and may lead to an erroneous evaluation for myopathy. EMG and nerve conduction testing is useful in this setting to indicate a neurogenic versus myopathic disorder and focus

appropriate further testing. Life expectancy is not significantly different compared with the normal population (see Table 139-1) (Darras et al., 2015).

There has been much debate about the appropriate classification of patients into these three types of SMA because, as mentioned, there are patients who within these categories exhibit phenotypes of differing severities. A classification system based on a continuous rather than discrete variable (e.g., SMA "Type 1.8" in the case of a less severely affected type I patient) has been proposed to better capture the clinical spectrum of these patients.

## Outliers

There are also patients who are outliers on either end of the phenotypic spectrum. As discussed above, an SMA "type IA" has been used to describe neonates who present with severe weakness and profound hypotonia, probably of prenatal onset, as well as with a history of decreased fetal movements. At the severe end of the type IA subgroup are infants born with severe contractures and no movements. Patients with this severe presentation, known as type 0, require ventilation support and do not attain any motor milestones. Other findings include areflexia, facial diplegia, atrial septal defects, and joint contractures. In SMA type IA, respiratory failure forms an important cause of morbidity and mortality, requiring noninvasive ventilation and endotracheal intubation at birth. Life expectancy is reduced and most of them are unable to survive beyond 6 months of age (see Table 139-1). Furthermore, arthrogryposis multiplex congenita (congenital joint contractures involving at least two regions of body) has been noted in SMA patients with *SMN1* gene deletions, and congenital axonal neuropathy involving motor and sensory nerves in conjunction with facial weakness, joint contractures, ophthalmoplegia, and respiratory failure at birth has been reported in three newborn siblings with deletions in the SMA chromosomal region.

A milder adult-onset SMA, or type IV SMA, has also been described with onset of symptoms after age 21 years and essentially normal life span. Most patients with the SMA type IA and IV phenotypes have homozygous deletions of exon 7 in *SMN1*, but as it will be discussed in the Genetics section, the *SMN2* copy number is usually only 1 in SMA type IA and 4 to 5 in SMA type IV.

## Other "Spinal Muscular Atrophies"

The non-5q13-associated spinal muscular atrophies are a heterogeneous group of motor neuron diseases associated with mutations in a variety of different genes (e.g., X-linked and autosomal-dominant or autosomal-recessive spinal muscular atrophies), distal or segmental spinal muscular atrophies or distal hereditary motor neuropathies. Patients with these disorders generally have some clinical characteristics that can help differentiate them from those with 5q13-associated or classic SMA.

## GENETICS

### The *SMN* Gene

Linkage analysis studies showed that all three forms of SMA map to chromosome 5q11.1-13.3. In 1995 Lefebvre et al. identified the *SMN* (survival of motor neuron) gene within this region, which was absent or interrupted in 98.6% of the patients in their group. The structure of this region is complex, with a large inverted duplication of a 500-kb element. This contains the *SMN1* gene, which is deleted or interrupted in patients with SMA and is evolutionarily older, in the telomeric portion of the region, and the *SMN2* gene, a duplication of

*SMN1* that differs from it by only five nucleotides, in the centromeric portion (see [Figure 139-1](#)). The critical difference between *SMN1* and *SMN2* is a C-to-T transition that creates an exon splicing suppressor in exon 7 of *SMN2*. Although this splice modulator change is translationally silent (i.e., it does not change the amino acid sequence), it affects the alternative splicing of the gene, so that exon 7 is spliced out of or excluded from most *SMN2* mRNA transcripts. This altered mRNA results in production of a truncated version of the SMN protein, which does not oligomerize efficiently and is degraded. Because exon 7 is not always spliced out of all *SMN2* mRNA, a small amount of full-length transcript and hence functional protein is produced by *SMN2*, but it yields only on average about 10% as much as that produced by *SMN1*. In patients with SMA both copies of the *SMN1* gene are deleted or disrupted, so the individual is left with only the small amount of SMN protein produced by the remaining copies of *SMN2*. The amount of the SMN protein is inversely correlated with the severity of disease.

About 95% to 98% of patients with SMA harbor deletions of the telomeric *SMN1* gene. The remainder have small intragenic mutations or have undergone gene conversions from *SMN1* to *SMN2*. De novo mutations occur at a rate of about 2%, which is relatively high, and explained by the fact that this region of chromosome 5 is unstable, containing not only the inverted repeat of *SMN1* and *SMN2*, but other surrounding low-copy-number repeats.

The number of copies of *SMN2* per chromosome 5 varies among normal individuals, and 10% to 15% of the population possess no copies of *SMN2*. Among patients with SMA, a clear correlation has been established between *SMN2* copy number and phenotypic severity. Feldkotter et al. in 2002 found that in their series 80% of patients with type I SMA had 1 or 2 copies of *SMN2*, 82% of patients with type II had 3 copies of *SMN2*, and 96% of patients with type III had 3 or 4 *SMN2* copies ([Figure 139-2](#)). Studies by Mailman et al. in 2002 and Arkblad et al. in 2009 found similar results (95% to 100% of type I patients had 1 or 2 copies of *SMN2*, and all type III patients had at least 3 copies of *SMN2*). However, this correlation is not so perfect as to permit the absolute prediction of clinical severity based on *SMN2* copy number, especially in the intermediate forms of the disease where there is some overlap (patients with three copies of *SMN2* have been described with all three phenotypes). One reason for the overlap is that not all copies of *SMN2* gene are equal; in terms of full-length SMN protein production, some copies probably

produce less and some more than 10% functional protein. In general, though, it can be said that a patient with 1 or 2 copies of *SMN2* is highly likely to present with SMA type IA, IB, or IC. Interestingly, unaffected family members with homozygous *SMN1* deletions and five copies of *SMN2* have been described, which suggests that *SMN2* copy number alone cannot be the sole modifying factor in disease severity, because there are patients with type III SMA who also have five copies of *SMN2*.

## Genetic Diagnosis

Genetic testing for SMA can be performed with PCR-based targeted mutation analysis using a restriction enzyme that digests exon 7. However, multiplex ligation probe amplification (MLPA) methodology is currently applied in most DNA diagnostic laboratories for deletion analysis of exon 7 of the *SMN1* gene in potential probands and carriers. This type of targeted mutation testing in conjunction with sequence analysis can also detect individuals who are compound heterozygotes with a deletion of exon 7 in 1 *SMN1* allele and an intragenic point mutation in the other allele. In such a case (approximately 2% to 5% of individuals with clinical diagnosis of SMA), sequence analysis of the *SMN* gene will detect the mutation; this sequence testing, however, will not detect exonic deletions or duplications ([Prior and Russman, 1993](#)), and will not determine whether the point mutation is in the *SMN1* gene or *SMN2* gene (if one of these genes is not deleted). Fortunately, certain point mutations have been described in more than 1 SMA patient already, and thus the detection of a previously reported mutation supports its pathogenicity and its location in the *SMN1* gene.

Carrier testing is feasible and accurate in the parents of patients with homozygous deletions of exon 7 or compound heterozygosity using a PCR-based dosage assay, known as “*SMN* gene dosage analysis.” It can also be performed using other techniques such as long-range PCR, MLPA, and chromosomal microarray (CMA) that includes this gene segment. Sequencing of the *SMN* gene will detect point mutations in nondeletion carriers. Rarely, carriers may have two copies of *SMN1* on one chromosome (both copies in *cis* orientation on one allele, a so-called “2 + 0 carrier”); the incidence of this genotype is about 4% of the general population. In the “2 + 0 carriers,” the SMA dosage carrier test will be falsely normal and thus one may need to pursue other methods such as family linkage analysis to identify the disease-associated

**Figure 139-2.** Frequency of patients with SMA types I, II, and III and *SMN2* copy numbers. In SMA type I, 80% of patients had 1 or 2 copies of *SMN2*, 82% of patients with type II had 3 copies of *SMN2*, and 96% of patients with type III carried 3 or 4 *SMN2* copies. (Modified with permission. This image was published in *American Journal of Human Genetics*, Volume 70, Feldkotter M et al., *Quantitative analyses of SMN1 and SMN2 based on based on real-time lightCycler PCR: fast and highly reliable carrier testing and prediction of severity of spinal muscular atrophy*, pages 358–368, copyright Elsevier [2002].)

genotype in families in which a deletion mutation has been transmitted more than once from a parent with two copies of the *SMN1* gene on gene dosage testing. Because of the occurrence of de novo mutations in 2% of patients with SMA, one of the parents may not be a carrier (Prior and Russman, 1993). So, in approximately 6% of parents of a child with SMA secondary to a homozygous *SMN1* deletion, *SMN1* gene dosage testing will be normal.

As mentioned in the introduction, a general correlation has been found between *SMN2* copy number and disease severity, and it is relatively straightforward to determine *SMN2* copy number in individual patients using various methodologies. However, this correlation is not so strict that the severity or type of disease can be reliably predicted based on copy number, and it is hence not advisable to offer families prognostic information based on *SMN2* copy number assays.

## Newborn Screening

The potential for newborn screening for SMA has been of great interest because the ideal time to initiate therapy would be before the initial degeneration of motor neurons, and newborn screening may help to identify presymptomatic individuals before the period of greatest motor neuron loss. A few pilot programs have been initiated in the United States.

## OTHER DIAGNOSTIC TESTS

In patients with SMA the serum creatine kinase may be 2- to 4-fold elevated, but not more than 10 times normal (Darras et al., 2015). Nerve conduction studies demonstrate normal sensory potentials, but may show diminished compound motor action potential amplitudes. Needle EMG in type II/III patients demonstrates a neurogenic pattern with high-amplitude, long-duration motor unit potentials with reduced recruitment pattern, indicating chronic partial reinnervation. Needle EMG in type I patients shows denervation changes but may not show evidence of reinnervation, as there may not have been enough SMN protein and/or time for this to occur yet. As will be discussed in more detail in the Pathology section, muscle biopsy in all types of SMA demonstrates a neurogenic pattern, with grouped atrophy; the small atrophic fibers are of both types (type 1 and type 2), whereas the large ones are always type 1 fibers. Although EMG continues to be used in the diagnosis of SMA in selected atypical cases, the use of muscle biopsy has become essentially obsolete.

## MOLECULAR FUNCTION OF SMN

SMN is a 38-kDa protein found in all cells, located in both the cytoplasm and in the nucleus, where it localizes to structures known as Gemini or Cajal bodies, or simply “gems”; therefore, its expression is ubiquitous. In patient fibroblasts, the number of gems correlates with SMA severity. SMN is also localized in motor neuron axons. The SMN protein in conjunction with several Gemin proteins forms an SMN complex whose chaperone function facilitates the assembly of spliceosomal small nuclear ribonucleoprotein particles (snRNPs), essential components of the spliceosome complex, and hence plays a critical role in pre-mRNA splicing. The SMN protein may also be essential in assisting arginine methylation of some splicing-related proteins, transporting axonal mRNAs in motor neurons and perhaps in other processes in muscle and neuromuscular junction. The role of the SMN protein in axonal mRNA trafficking and mRNA splicing may explain the selective vulnerability of spinal cord motor neurons to decreased SMN protein; although not the only ones, these neurons have long axons and many targets, particularly in large muscles, and thus may be very dependent on axonal

mRNA transport. Further, they may be extremely vulnerable to the mRNA splicing defect. Nevertheless, it continues to be unclear whether a splicing defect caused by SMN protein deficiency, disruption of an additional axonal SMN function, perturbation of an unknown function, or a combination of the above is responsible for the pathogenesis of SMA. The complete absence of the SMN protein in cells is embryonic lethal in mice and other organisms. The reason why motor neurons are specifically vulnerable to partial SMN deficiency is unclear.

Patients with SMA also appear to have structural and physiologic abnormalities of the neuromuscular junction. Kong et al. showed that in severely affected SMA mice, before anterior horn cell death and/or axonal degeneration there is synaptic dysfunction at the neuromuscular junction in the form of decreased synaptic vesicle density at motor terminals, reduced quantal content, and slowed maturation of the acetylcholine receptor with prolonged retention of fetal characteristics. Kariya et al. also demonstrated structural and functional abnormalities at the level of the neuromuscular junction that precede overt symptoms in mice, as well as structural abnormalities in the neuromuscular junctions of humans with SMA, and hence proposed that SMA may be a “synaptopathy” (Kariya et al., 2008). Based on this concept and the electrophysiologic data suggesting dysfunction of the neuromuscular junction in patients with SMA types II and III, treatment approaches directed toward enhancing neuromuscular transmission may also be beneficial to patients with SMA.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of 5q SMA is listed in Box 139-1. This box also lists the non-5q SMAs, which are discussed in further detail in Chapter 140.

## THE PATHOLOGY OF SMA

SMA is characterized by spinal motor neuron loss and skeletal muscle atrophy. However, a precise understanding of how the cellular pathology of the disease evolves over its course continues to be handicapped by a paucity of suitable patient material. Our current appreciation of SMA pathophysiology stems largely from analyses of autopsy material, reflecting pathology at the end of the disease. Analyses of early disease pathology have relied mostly on murine models. Still, from the current studies, certain key findings emerge. These, almost invariably, include a profound loss of the large anterior horn cells of the spinal cord. More infrequently, motor neurons are found mispositioned. Anterior horn motor neurons that remain often appear swollen or chromatolytic, containing phosphorylated neurofilaments, ribosomes, and vesicles.

Considering the degeneration of the spinal motor neurons, an expected pathologic characteristic is neurogenic atrophy of the skeletal muscles. Muscle from severely (type I) affected patients typically consists of a sea of small, rounded, atrophic fibers within which are sometimes seen islands of one or more large hypertrophic cells. In some instances, the atrophic fibers also appear immature with centrally rather than peripherally located nuclei, giving the appearance of a myopathic condition.

Even though SMA has historically been described as a disease characterized by motor neuron cell body loss, more recent data suggest that the earliest pathologic effects of reduced SMN are observed distally, at the neuromuscular junctions (Kariya et al., 2008). This early pathology that affects the pre- and postsynapse was first observed in mouse models of the disease and has now been confirmed in human samples as well (Kariya et al., 2008).

**BOX 139-1** Differential Diagnosis of 5q Spinal Muscular Atrophy**SPINAL CORD DISORDERS**

Neoplasms (SMA types I, II, III)  
Other myelopathies (SMA types I, II, III)

**OTHER MOTOR NEURON DISORDERS**

SMARD1 (SMA type I)  
Juvenile muscular atrophy of distal upper extremity (Hirayama disease)  
Fazio-Londe disease, Brown-Vialetto-van Laere syndrome  
Other non-5q SMAs (SMA types I, II, III)  
Juvenile ALS (SMA types I, II, III)

**NEUROPATHIES**

Congenital hypomyelinating or axonal neuropathies (SMA types I, II)  
Hereditary motor and sensory neuropathies (SMA types I, II, III)  
CIDP (SMA types II, III)

**NEUROMUSCULAR JUNCTION DISORDERS**

Botulism (SMA type I)  
Congenital myasthenic syndromes (SMA types I, II, III)  
Lambert-Eaton myasthenic syndrome (SMA type III)  
Autoimmune myasthenia gravis (SMA types II, III)

**MYOPATHIES**

Congenital myopathies (SMA types I, II, III)  
Congenital myotonic dystrophy (SMA type I)  
Congenital muscular dystrophies (SMA types I, II)  
Muscular dystrophies (DMD/BMD, LGMD) (SMA type III)  
Mitochondrial myopathies (SMA types I, II, III)  
Acid maltase/Pompe disease (SMA types I, II, III)  
Other metabolic myopathies (SMA types I, II, III)  
Inflammatory myopathies (SMA type III)  
Channelopathies (SMA type III)

**OTHER DISORDERS**

Chromosomal abnormalities (SMA types I, II, III)  
Prader-Willi syndrome (SMA type III)  
Central nervous system abnormalities (SMA types I, II, III)  
Hexosaminidase A deficiency (SMA types III, IV)

ALS, amyotrophic lateral sclerosis; BMD, Becker muscular dystrophy; CIDP, chronic inflammatory polyneuropathy; DMD, Duchenne muscular dystrophy; LGMD, limb-girdle muscular dystrophy; SMARD1, spinal muscular atrophy with respiratory distress 1.

**TREATMENT**

Currently, there is no cure for SMA. However, despite the presence of homozygous deletions of *SMN1* in the majority of patients with SMA, the unique structure of the 5q11.1-13.3 inverted duplication provides potential therapeutic targets. There has been great interest in identifying agents that can increase the amount of the full-length SMN protein by upregulating expression of the *SMN2* gene or promoting inclusion of exon 7. Researchers are also actively exploring several other approaches to treatment.

**Clinical Trials in SMA: Therapeutics**

SMA is a unique “translational” disease because of the presence of the *SMN2* gene, which is a well-validated target for therapeutic interventions. The status of therapeutics development is shown in Table 139-4. The effort on therapeutics is

**TABLE 139-4** Status of Therapeutics Development in Spinal Muscular Atrophy

(With permission of Lippincott Williams and Wilkins/Wolters Kluwer Health: Singh P, Liew WK, Darras BT. Current advances in drug development in spinal muscular atrophy. *Curr Opin Pediatr* 2013;25:682–688.)

directed toward finding pharmaceutical compounds that can upregulate *SMN2* expression or affect other modifying genes to produce more functional SMN protein.

**Agents That Upregulate *SMN2* Gene Expression and Promote Exon 7 Inclusion****Small Molecules**

A class of drugs known as histone deacetylase inhibitors (HDACIs) has been investigated extensively as potential therapeutic agents in SMA (Singh et al., 2013; Darras et al., 2015). Histones, which are core proteins in chromatin, play a role in epigenetic regulation of gene expression via their acetylation status. Several compounds that are HDACIs have been shown to increase full-length *SMN2* transcript levels in cell lines from patients, usually by activating the human *SMN2* promoter, enhancing transcription, and correcting the splicing pattern. Clinical trials of HDACIs, phenylbutyrate, and valproic acid have shown no difference in motor function scores compared with the placebo group in a nonambulatory cohort of type II SMA.

A proprietary small molecule developed by PTC Therapeutics, Inc., extends the life expectancy of the *SMNΔ7* severe mouse model from 14 days to more than 6 months. Along with the quinazoline derivatives, this compound is further developed for clinical trials in humans. The distinct advantage of these small molecules is that they can cross the blood-brain barrier (BBB).

The FDA-approved drug hydroxyurea, a non-HDACI, was identified in the course of drug screens using cell lines from SMA patients to increase the amount of full-length *SMN*

transcript and protein in vitro. However, a small pilot study of hydroxyurea at 3 different doses for 8 weeks in 33 type II and III patients showed no statistically significant benefit. A randomized, double-blind, placebo-controlled trial failed to show any improvement over an 18-month period.

Albuterol, a beta-adrenergic agonist, was evaluated in a pilot study of 13 SMA type II and III patients because of its reported positive effect on muscle strength in healthy individuals. At 6 months a significant improvement was noted in myometry, FVC, and DEXA scores, but there was no significant change in Medical Research Council strength score. Another pilot study of 23 SMA type II patients treated with salbutamol (a form of albuterol) for 12 months showed improved functional scores on the HFMS after 6 and 12 months, but this was not a placebo-controlled study and must be interpreted with caution (Pane et al., 2008). On an in vitro level, salbutamol has been shown to increase full-length SMN mRNA, SMN protein, and gem numbers by promoting inclusion of exon 7. The response was directly proportional to SMN2 gene copy number. This finding prompts further interest in exploring the effects of beta agonists on SMA with randomized controlled trials.

## Neuroprotective, SMN Protein Stabilization Agents

### Other Small Molecules

Riluzole and gabapentin, “the neuroprotective agents,” were studied to assess the effect on motor performance in SMA. Unfortunately, the results were not found encouraging or the studies were not adequate to show efficacy.

Olesoxime (TRO19622), a novel neuroprotective compound, has been tested in a randomized, multicenter, parallel-group, double-blind, placebo-controlled trial conducted in Europe. Preliminary results seem encouraging.

CK-2127107, a selective skeletal fast troponin activator slows down the rate of calcium release from troponin C and thus increases fast skeletal muscle contractility; a phase 2/3 study (CY 5021) in Type II and III SMA patients is currently in progress.

## Other Approaches

### SMN2 Splicing Modifiers

Drugs have been developed to modify splicing of the SMN2 gene to include exon 7 and increase the amount of full-length transcript and, consequently, the amount of normal SMN protein.

**Antisense Oligonucleotides.** Antisense oligonucleotides (ASOs) have been developed that block an intronic splicing suppressor element, which in turn prevents skipping of exon 7 (Burghes and McGovern, 2010). Hua et al. in their work on transgenic mice found these intronic splicing suppressors to be located in intron 7 as tandem motifs, namely, hnRNP A1/A2. Blocking of these motifs by ASOs enhanced exon 7 inclusion in the SMA mouse model. Similar work by Singh et al. demonstrated enhanced production of full-length SMN mRNA in fibroblasts from patients treated by ASOs. Periodic intracerebroventricular deliveries of ASOs in SMA mice models have been found to improve the motor phenotype. Phase I/II clinical trials and two randomized, double-blind, sham procedure controlled phase III trials demonstrated the safety, tolerability and clinical efficacy of multiple doses of ASO (nusinersen), which is delivered intrathecally into the subarachnoid space of SMA type I and type II patients. Spinraza (nusinersen) was approved by the US FDA in December, 2016, for treatment of all types of SMA and all ages. It is the first approved drug treatment for SMA.

**Small Molecule Drugs.** Orally delivered small molecule drugs that modulate splicing and promote inclusion of exon 7 are in early phase of clinical development: LMI070 and RG7916. These are listed in Table 139-4.

## Stem Cells

Interest in the use of stem cells also continues, both as potential treatment for SMA and for use in constructing model systems for therapeutics development. During the last few years, pluripotent stem cells with the capacity to differentiate into motor neurons that lacked SMN1 expression were induced from a type I SMA patient and his mother; this could serve as an important model system for testing of new compounds and eventually for stem cell approaches to the treatment of SMA.

## Gene Therapy

Among other therapeutic targets, gene therapy has shown potential in animal models. Foust et al. demonstrated that self-complementary adeno-associated virus 9 (scAAV9) could cross the BBB and infect approximately 60% of motor neurons when injected intravenously into neonatal mice. When injected systemically with scAAV9 engineered to carry the wild-type SMN gene expressed high levels of protein in multiple tissues, these mice derived remarkable therapeutic benefit, surviving in some instances to 12 months or more with no evidence of muscle weakness. Considering proof-of-concept studies demonstrating the ability of scAAV9 to penetrate the mature BBB and infect adult motor neurons, an SMN replacement clinical trial to treat SMA type I is currently underway at Nationwide Children’s Hospital and The Ohio State University, United States.

## CARE OF THE PATIENT WITH SMA

Patients with SMA and their families benefit greatly from a multidisciplinary approach to care. This approach involves members from neurology/neuromuscular medicine, orthopedics, physical and occupational therapy, pulmonology, nutrition, and gastroenterology. For severely affected patients with type I SMA, early involvement of the pediatric advanced care or palliative care team can provide parents with support and assistance in making decisions that are consonant with their values and help to maximize their child’s quality of life. In 2007 a Consensus Statement for Standard of Care in Spinal Muscular Atrophy was released by a multidisciplinary team regarding the current best recommendations for management of patients with SMA (Wang et al., 2007).

## Pulmonary

Respiratory failure is the major cause of mortality in patients at the more severe end of the disease spectrum, namely types I and II SMA. Infants with type I SMA have weak intercostal muscles with relatively preserved diaphragm strength, resulting in a bell-shaped chest, pectus excavatum, and in some cases underdevelopment of the lungs. Patients with type II SMA have weak intercostal muscles with scoliosis contributing to progressive restrictive lung disease. The restrictive lung disease results in insidious onset of sleep hypoventilation. Proper use of BiPAP, with correct pressure adjustments and mask placement, has no significant side effects on patient hemodynamics. There should also be a low threshold for the use of antibiotics during acute illnesses in these patients, because of the risk of pneumonia (Wang et al., 2007). Patients should be followed regularly by a pulmonologist experienced in caring for patients with neuromuscular diseases, with home visits by a home ventilation team if available.

## Gastrointestinal

Patients with type I SMA are extremely weak and hence tire during feedings, which can lead to failure to thrive and aspiration with recurrent respiratory infections. In a small retrospective study, Durkin et al. found that early laparoscopic Nissen fundoplication and gastrostomy in patients with type I SMA was associated with improved nutritional status in these patients, and also perhaps with a trend toward fewer long-term aspiration events. Lastly, patients with SMA are at risk of constipation, which can, if severe (especially in young type I patients), worsen reflux or even respiratory symptoms.

## Nutrition

Failure to thrive or growth failure is common in infants with type I SMA and in some severely affected type II patients. However, though many type II patients plot as having a “normal” body mass index (often as low as third percentile for a healthy child of their age), they may actually have excessive fat mass relative to their muscle mass. Clinically high functioning nonambulatory SMA patients (Hammersmith score  $\geq 12$ ) are at risk of becoming overweight. Hence close attention must be paid to nutritional status in patients with all types of SMA, and consultation with a dietician who is aware of these special concerns is vital.

## Orthopedic

Patients with SMA at the severe end of the disease spectrum require close orthopedic follow-up for the development of scoliosis and contractures. Surgical intervention for scoliosis is often required, and careful coordination of perioperative respiratory and nutritional support can help to minimize complications (Wang et al., 2007). With the advent of improved surgical techniques such as growing rods, the interventions are currently considered earlier in life. Fractures and hip subluxation are commonly seen in milder type II and type III SMA patients. Distal femur is the commonest fracture site followed by lower leg, ankle, and upper arm. Most of the fractures can be treated conservatively.

## Fatigue

Physiologic fatigue is a common complaint in milder SMA patients and can be measured by the decrement in distance walked from the first to sixth minute of the six-minute walk test (Montes et al., 2010). The mechanism(s) underlying fatigue in SMA remains to be elucidated, but it may be related at least in part to the neuromuscular junction defects described earlier. Anecdotal evidence suggests that albuterol PO in usual pediatric doses is an effective agent in the treatment of fatigue in SMA patients and thus it is frequently used; however, fatigue has not been studied directly in the conducted albuterol pilot studies that showed improvement in motor function (Pane et al., 2008).

## CONCLUSIONS

SMA is a chronic, inherited motor neuron disease for which there is no established treatment. Yet there is cause for optimism, as it is an area of active research, and knowledge about the molecular genetics and pathogenesis of SMA is ever increasing. Several groups are actively exploring pharmacologic treatments, whether through the use of approved drugs, identification of new agents via high-throughput screens, or development of novel pharmaceutical compounds. Standards of care have also been developed to optimize the long-term multidisciplinary management of patients with SMA. Although

it may seem at times that a treatment for SMA is far in the future, the advances made since the gene was identified in 1995 permit a modicum of hope to patients, their families, and those with the privilege to care for SMA patients.

### ANATOMY: THE ANTERIOR HORN CELLS OF THE SPINAL CORD

Anterior horn cells ( $\alpha$ -motor neurons), located in the anterior gray matter of the spinal cord, are found at every segment and are concentrated in the cervical and lumbosacral enlargements. Morphologic differentiation of the anterior horn cells is most evident from 12 to 14 weeks' gestation. There is a period of normal differentiation, followed by programmed cell death. Anterior horn cells are clustered into medial and lateral cell divisions (Figure 140-1). The medial group is subdivided into ventromedial and dorsomedial components. The ventromedial component innervates the superficial larger muscles, and the dorsomedial component innervates the small, deep muscles adjacent to the spine. The lateral cell mass is also subdivided into groups. The ventrolateral group innervates extensor muscles, and the centrodorsal group innervates flexor muscles. These groups of neurons are located in a relatively small region; therefore deleterious influences harm cells from more than one group and weakness may be widespread.

Motor neurons in the nuclei of brainstem cranial nerves are homologous to spinal cord anterior horn cells. Therefore pathologic mechanisms that compromise the cranial motor neurons may initiate symptoms and signs that mimic anterior horn cell dysfunction in the spinal cord. Muscular atrophy, severe weakness, and fasciculations without sensory deficit are signs of anterior horn cell disease. When sensory function is impaired in conjunction with anterior horn cell disease, dysfunction of adjacent tracts of the spinal cord or the peripheral nerves may be present.

### DIAGNOSTIC WORKUP

Disorders of the motor neuron typically result in flaccid weakness, hypotonia, and decreased reflexes, with varying degrees of atrophy depending on the chronicity of the disorder. Fasciculations may be present as well. Dysfunction of the motor neurons can result from acquired or hereditary etiologies. Therefore in any patient in whom this is a consideration, a thorough medical and family history, and detailed neurologic examination are crucial. If the child's history and physical suggest a motor neuron disorder, multiple tests can be performed for confirmation, including serum creatine kinase (CK) and electrophysiologic testing (electromyography and nerve conduction study [EMG/NCS]). The serum CK can be normal or mildly elevated, usually not more than three times the upper limit of normal, about 600 mg/dl. Electrodiagnostic studies show normal or near-normal sensory responses and normal motor conduction velocities, often with reduction in amplitudes of compound motor action potentials. Chronic and/or acute denervation may be recognized by electromyography. Motor unit number estimate is a more of a research tool that is reduced in disorders of affecting the motor neuron.

### HEREDITARY DISEASES AFFECTING SPINAL MOTOR NEURONS

Inherited motor neuron disease in childhood is most commonly caused by mutations of the *SMN1* gene on chromosome 5q13 (see Chapter 139). However, a small proportion (4%) of patients do not have a mutation or deletion of *SMN1*. The clinical and genetic heterogeneity of this group of disorders can be overwhelming, particularly as the number of new genes identified increases yearly (Table 140-1) (Pestronk, 2003; Peeters et al., 2014). Classifying them by distribution of weakness (proximal, distal, bulbar), inheritance pattern (autosomal dominant, autosomal recessive, or X-linked), and other associated manifestations can guide the diagnostic workup. A simplified algorithm to the approach to the diagnosis of motor neuron disease is presented in Figure 140-2 by distribution of weakness, that is, proximal (Figure 140-2A) or distal (Figure 140-2B) (Finsterer and Burgunder, 2014).

### SMA-like Motor Neuron Disorders

Children with SMA-like motor neuron disorders present with symmetric proximal muscle weakness, affecting legs more than arms. This pattern of weakness is similar to those with 5q-associated SMA. Weakness typically is rapidly progressive, with respiratory insufficiency usually resulting in the need for mechanical ventilation, followed by death.

Respiratory insufficiency may be the first clinical feature in patients with spinal muscular atrophy with respiratory distress (SMARD). In SMARD1, patients may have diaphragmatic paralysis with eventration of the diaphragm; the intercostal muscles are spared. Weakness and contractures occur first in the distal extremities. SMARD1 is caused by mutations of *IGHMBP2*. A new phenotype of SMARD2 with a similar clinical presentation has been associated with mutations of *LAS1L*.

As in 5q-associated SMA, the main features of early onset scapulothoracic SMA include progressive weakness of the extremities beginning at birth or early childhood. A characteristic feature of this subtype of SMA is vocal cord weakness with hoarseness and respiratory stridor. If this feature is present, mutations of *TRPV4* should be considered.

Arthrogryposis is an early feature in boys with X-linked SMA and arthrogryposis (XL-SMA, *UBA1* gene) but otherwise the presentation is similar to that of 5q-associated SMA. Contractures typically occur in the proximal joints and fingers. Respiratory insufficiency also occurs early and is progressive, with death occurring in most patients before the age of 2 years because of respiratory failure.

### Motor Neuron Disease With Central Nervous System Manifestations

The presence of predominant central nervous system (CNS) findings such as spasticity, movement disorders, and intellectual disability is unusual in 5q-associated SMA. Cerebellar findings such as ataxia, nystagmus, or oculomotor apraxia in infants with motor neuron disease should prompt an

**TABLE 140-1** Motor Neuron Disease Plus Syndromes

Clinical Patterns	Disease	Symptoms	Genes	Inheritance	Diagnostic Testing
SMA-like With proximal muscle weakness	DSMA1	Onset birth to 2 months Diaphragmatic paralysis with sparing of intercostal muscles Death or respiratory failure less than 3 months Severe distal weakness Distal SMA weakness at age 1 year with progression but variable onset of respiratory failure Occasional mild contractures of the knee and ankle	Immunoglobulin $\mu$ -binding protein 2 ( <i>IGHMBP2</i> ); 11q13.3	AR	Normal CK Eventration of diaphragm on chest x-ray Sural nerve: myelinated axon loss
	SMA with respiratory failure 2 (SMARD2)	Single patient Distal weakness at birth Early respiratory failure Fasciculations of tongue Mild contractures of fingers and toes	<i>LAS1L</i> ; Xq12	X-linked recessive	EMG localized to motor neuron
	SMA: scapuloperoneal	Onset: congenital childhood Legs only Proximal and distal contractures Nonprogressive Vocal cord paralysis in some	<i>TRPV4</i> ; 12q24.11	AD	Mildly elevated CK EMG/NC: normal CMAP and SNAPs; giant motor units on EMG
	X-linked SMA with arthrogryposis (XL-SMA, SMAX2)	Onset at birth or infancy Pattern of weakness similar to classic SMA Proximal and finger contractures Myopathic facies Respiratory insufficiency Dysmorphic features Death less than 2 years of age	<i>UBE1</i> ; Xp11.3	X-linked recessive	
With CNS manifestations Cerebellar hypoplasia	Pontocerebellar hypoplasia (PCH) type 1A	Onset birth to 6 months Hypotonia, weakness, distal symmetric polyneuropathy Ataxia, nystagmus Mild to severe contractures Microcephaly	<i>VRK1</i> ; 14q32	AR	Normal CK MRI brain: cerebellar hypoplasia or absence EMG/NCS: axonal sensorimotor polyneuropathy
	PCH2	Onset birth Progressive microcephaly Distal contractures Oculomotor apraxia	<i>EXOSC3</i> ; 9p13.2	AR	MRI brain: cerebellar atrophy, small brainstem and cortex EMG/NCS: axonal sensorimotor polyneuropathy
	PCH1C	Onset 2–4 months Severe weakness Spasticity Vision and hearing impairment Stepwise decline with illnesses	<i>EXOSC8</i> ; 13q13.3	AR	MRI brain: cerebellar hypoplasia Hypomyelination of lateral descending tracts
Movement disorders Dystonia	Leukoencephalopathy with dystonia and motor neuropathy	Onset: childhood to teens Dystonia Hypergonadotropic hypogonadism Azoospermia Saccadic eye movements Brisk reflexes in arms, diminished in legs Intention tremor, ataxia Hyposmia	<i>SCP2</i> ; 1p32.3	AR	MRI brain: hyperintensities in thalamus, “butterfly-like” lesions in pons, lesions in occipital regions
	Hexosaminidase A deficiency (Tay-Sachs disease), juvenile form	Onset: late teens to early adulthood Muscle atrophy, muscle cramping, fasciculations, proximal great than distal weakness Ataxia, dystonia, dysarthria	<i>HEXA</i> ; 15q23	AR	MRI brain: cerebellar atrophy EMG/NCS: axonal sensorimotor polyneuropathy, CRDs

**TABLE 140-1** Motor Neuron Disease Plus Syndromes (Continued)

Clinical Patterns	Disease	Symptoms	Genes	Inheritance	Diagnostic Testing
	Mitochondrial membrane protein associated neurodegeneration (MPAN; NBIA4)	Onset: 3–39 years Dysarthria Spasticity Dystonia, parkinsonism Progressive distal great than proximal weakness Optic atrophy, slow saccades Cognitive decline Psychiatric manifestations	<i>C19orf12</i> ; 19q12	AR	EMG/NCS: motor neuropathy Serum CK: high MRI: hypointensity of globus pallidus and substantia nigra; cerebellar atrophy
Spasticity	Achalasia-addisonism-alacrima (AAA) syndrome (Allgrove syndrome)	Onset: childhood GI: achalasia, feeding difficulties, xerostomia, fissured tongue Endocrine: adrenal insufficiency Skin: hyperpigmentation, excessive creases on palms and soles, hyperkeratosis Long thin face, long philtrum Eyes: alacrimia, optic atrophy, pupillary abnormalities Intellectual disability Autonomic dysfunction Spasticity	<i>AAAS</i> ; 12q13.13	AR	EMG/NCS: predominantly axonal motor neuropathy
Seizures	SMA with myoclonic epilepsy	Onset 3–5 years SMA-like with proximal weakness first in legs and then in arms Respiratory failure occurs later in course	<i>ASAH1</i> ; 8q22	AR	Normal CK EEG: subcortical myoclonic epileptiform activity, sensitive to hyperventilation EMG: chronic denervation
