Life span is variable, and patients have survived to adulthood. All identified patients have been visually impaired, with sensorineural hearing loss.

A progressive leukodystrophy, with variable age at onset, has been reported in a number of patients. This disorder results in loss of previously acquired skills, and, in most cases, progresses to a vegetative state and death. Unlike in X-linked adrenoleukodystrophy, the rate of progression has been more variable.

Clinical recognition of these disorders may present some uncertainty because of nonspecific abnormalities and phenotypic variability. Disorders of peroxisome biogenesis commonly manifest in the neonatal period, and patients come to attention because of hypotonia, seizures, or liver disease. Evaluation appropriately focuses on a search for cytogenetic abnormalities, acute treatable metabolic disorders, and structural liver disease. Later in childhood, patients often are mistakenly diagnosed as having cerebral palsy, X-linked adrenoleukodystrophy, mitochondrial disease, or lysosomal disorders.

All of the disorders in this group are inherited in an autosomal-recessive fashion, so it is important for genetic counseling that an accurate diagnosis is arrived at expeditiously. Carrier detection is possible only by DNA analysis if the molecular defect has been identified in the index case. Carrier detection is not possible by biochemical determination.

### Laboratory Diagnosis

The major diagnostic biochemical abnormality is the increased amount of very long-chain fatty acids, which are fatty acids with carbon chains of more than 22. They also are elevated in single-enzyme defects of peroxisomal  $\beta$ -oxidation, so their presence is nonspecific; therefore other studies are required for this diagnosis. Very long-chain fatty acid accumulation here is

due to the reduction of peroxisomal  $\beta$ -oxidation, which is greater in Zellweger syndrome than in milder forms (Wanders, 2014). Because the first two steps of plasmalogen synthesis are peroxisomal functions, a reduction of plasmalogen levels is noted in patients with peroxisome biogenesis defects. An age-related increase in the levels of phytanic acid occurs in all of the peroxisome biogenesis disorders.

With broader genetic tools available such as whole exome sequencing (WES) and other DNA-based panels, the older algorithms for diagnosis may be approaching the end of their utility, but because of the ability to rapidly get biochemical information this approach will be warranted where there is appropriate clinical suspicion.

### Prenatal Diagnosis

Cultured amniocytes or chorionic villus cells can be used to diagnose all of the disorders of peroxisome biogenesis. A variety of biochemical strategies have been used and focus on the type and degree of biochemical abnormality. Two independent techniques, the measurement of very long-chain fatty acid  $\beta$ -oxidation and plasmalogen synthesis, have demonstrated accurate diagnosis. Molecular genetic techniques may be used in families in which the mutation has been identified and preimplantation genetic diagnosis has been performed.

### Therapy

Because many of the abnormalities are already present in the affected fetus, potential for therapy is limited at present and likely to remain so. Treatment is primarily supportive, targeting liver dysfunction with vitamin K for prothrombin deficiency, providing nutrition often with tube feeding, and antiepileptic medication. In the milder phenotypes, rehabilitative approaches, including communication training and physical and occupational therapy, are helpful.

Attempts to normalize some of the biochemical abnormalities include oral ether lipid therapy and dietary restriction of very long-chain fatty acids or phytanic acid have not met with clinical improvement. Therapy with docosahexaenoic acid replaces low levels in plasma and red blood cells of patients with Zellweger spectrum disorder; however, it is ineffective in improving clinical function.

## DEFECTS OF SINGLE PEROXISOMAL ENZYMES

### Defects of Single Peroxisomal $\beta$ -Oxidation Enzymes

This is a broad and heterogeneous group of disorders and many are rare. However, this group includes X-linked adrenoleukodystrophy which is the most common peroxisomal disorder and will be discussed here.

### Adrenoleukodystrophy

The first clinical cases of what is known as X-linked adrenoleukodystrophy (ALD) were described in 1923 by Siemerling and Creutzfeldt (Moser et al., 2007). The X-linked mode of inheritance was suggested by Fanconi and associates. A key observation of characteristic lamellar lipid-soluble cytoplasmic inclusions in the adrenal cortical cells and brain macrophages of patients with childhood adrenoleukodystrophy was made by Powers and colleagues. Similar inclusions were observed in men with Addison disease and spastic paraparesis, and the related condition was named adrenomyeloneuropathy (AMN). Igarashi and associates defined the biochemical defect by demonstrating that the inclusions in the adrenal cortex and cerebral white matter consisted of cholesterol esters

with a striking excess of saturated unbranched fatty acids of 24- to 30-carbon chain length, of which C26:0 and C25:0 were the most abundant. This excess of very long-chain fatty acids in cultured skin fibroblasts, plasma, or red blood cells is the hallmark of the disorder and useful for diagnostic purposes.

### Biochemical and Molecular Basis

The peroxisomal  $\beta$ -oxidation pathway consists of four enzymatic steps (as outlined in Fig. 43-1). Before the substrates can enter this pathway, the acyl residues require activation by transfer of a coenzyme A. For very long-chain fatty acids entering the I-specific  $\beta$ -oxidation pathway, lignoceryl-CoA ligase (also referred to as lignoceryl-CoA synthetase) is the activating enzyme. Although this enzyme was originally thought to be the cause, it is known that the genetic basis for X-linked adrenoleukodystrophy is mutations of the ABCD1 gene, which encodes a PMP, an ATP-binding cassette protein; the gene for this protein is located on the X chromosome in the Xq28 region.

The protein is involved in the transport of appropriate fatty acids into the peroxisome and when this path is disrupted they continue to enter the elongation pathway. Multiple mutations in ABCD1 have been identified in patients with X-linked adrenoleukodystrophy, and no phenotype correlation has been identified. Several mouse models of X-linked adrenoleukodystrophy are now available, but to date none of the animals have manifested a cerebral phenotype.

### Clinical and Pathologic Features of X-Linked Adrenoleukodystrophy and Adrenomyeloneuropathy

One of the most intriguing aspects of ALD is the variation in presentations depending on age. All affected individuals demonstrate accumulation of very long-chain fatty acid, and molecular studies have confirmed ABCD1 gene mutations. Various phenotypes have been recognized as occurring within the same pedigree, so neither the genetic mutation nor the biochemical abnormality predicts the clinical presentation.

#### Childhood Cerebral Form of Adrenoleukodystrophy

The childhood cerebral variant is the most common and fulminant form of X-linked adrenoleukodystrophy. Affected boys are normal until 4 to 8 years of age, when they manifest behavior problems and failure in school as a result of rapid regression of auditory discrimination, spatial orientation, speech, and writing. Seizures occur in 30% of patients and, in rare instances, may be the initial sign. The magnetic resonance imaging (MRI) scan reveals parietooccipital white matter lesions (in 85% of patients) or frontal lesions (in 15%) at this stage, with contrast accumulation at the leading edge of the lesion (Fig. 43-5). Rapid clinical deterioration leads to spastic quadriplegia, swallowing difficulty, and visual loss, culminating in a vegetative state usually within 2 years of the initial signs and symptoms. Although males come to medical attention because of the neurologic deficits, impaired adrenal function is seen in the majority of boys at the time of diagnosis.

#### Adolescent Cerebral Form of Adrenoleukodystrophy

Patients with the adolescent cerebral form of adrenoleukodystrophy manifest signs and symptoms of cerebral involvement, as described previously, between 10 and 21 years of age.

### Adult Cerebral Form of Adrenoleukodystrophy

In the adult cerebral form of adrenoleukodystrophy, dementia, psychiatric disturbances, seizures, and spastic paraparesis develop after age 21. Patients may be misdiagnosed as having multiple sclerosis, brain tumor, or schizophrenia and demonstrate rapid deterioration similar to that in the childhood cerebral form. Therefore patients with these clinical presentations and adrenal insufficiency or leukodystrophy should be evaluated by plasma very long-chain fatty acids.

### Adrenomyeloneuropathy

The neurologic manifestations of adrenomyeloneuropathy (AMN), an adult form of adrenoleukodystrophy, consist of an insidious onset and slow progression of spastic paraparesis, impaired vibratory sense in the lower extremity, and bladder or bowel dysfunction. Onset is typically in the third decade of life. The primary pathology involves the spinal cord with loss of myelinated axons in the corticospinal tracts, nucleus gracilis, and dorsal spinocerebellar tracts. Sural and peroneal nerves reveal a loss of large and small myelinated fibers.

The development of cerebral demyelination has been seen in approximately 15% to 20% of men with adrenomyeloneuropathy. This pathologic change needs to be differentiated from long tract findings on MRI. Cerebral disease is similar in time course to the childhood form of the disease and leads to dementia, spasticity, blindness, and death. Approximately half of patients with adrenomyeloneuropathy appear to have some degree of cerebral involvement, with mild to moderate abnormalities noted on MRI in 46% (Fig. 43-5). These abnormalities consist most frequently of parietal-occipital white matter and optic radiation involvement.

Primary adrenal insufficiency or Addison disease precedes the onset of neurologic symptoms in 42% of patients; in some, this may occur 3 to 35 years earlier. Serum testosterone levels were abnormally low in 22% of our patients, and early onset sexual dysfunction occurred in one-third.

### Addison Disease Only

The diagnosis of adrenoleukodystrophy with Addison disease only includes the patients who have isolated primary adrenal dysfunction disease in the absence of neurologic signs and symptoms and is more common than was previously recognized. This is not surprising because there is no correlation between adrenal and neurologic dysfunction, so males may come to attention in childhood with adrenal insufficiency and develop neurologic issues decades later. Recognition of these patients is vital for genetic counseling and to monitor for the development of adrenomyeloneuropathy or cerebral symptoms later on.

### Asymptomatic Patients With the Biochemical Defect of Adrenoleukodystrophy

In asymptomatic patients with the biochemical defect of adrenoleukodystrophy, diagnosis may be accomplished by measurement of plasma very long-chain fatty acids during screening tests of relatives of symptomatic patients. These persons may be of any age and is clearly a function of age. All newborn males are unaffected, and this population appears to decline with age. Whether there are any truly asymptomatic individuals in midadult life is unknown. The elevation of very long-chain fatty acid levels in these males is comparable with that in severely affected family members.

**Figure 43-5. Magnetic resonance imaging (MRI) studies in adrenoleukodystrophy.** **A**, Typical alteration of the blood–brain barrier at the edge of the demyelinated lesion in childhood adrenoleukodystrophy demonstrated on gadolinium-enhanced MRI. **B**, The discrete but continuous auditory pathway involvement from the lateral lemniscus in the pons to the medial geniculate bodies at the midbrain level to the temporal cortex can be seen. MRI permits precise correlation between the location of the lesion and cognitive deficits; the findings may explain the early auditory comprehension deficiency seen in childhood adrenoleukodystrophy. **C**, MRI study of the spine in X-linked adrenoleukodystrophy. Views in axial (left) and lateral (right) planes demonstrate cord atrophy, particularly in the thoracic regions.

## Symptomatic Heterozygotes

Between 10% and 20% of the women who are carriers for the adrenoleukodystrophy gene manifest myelopathy resembling that in adrenomyeloneuropathy between the third and fifth decades of life. Long tract signs and diminished vibration sense in the legs are present in two-thirds of the patients, although only 25% complain of symptoms. Approximately 14% have severe spinal involvement requiring assistance with ambulation, and 5% have dementia. In contrast with males, adrenal insufficiency rarely occurs in these women.

In the past, elevation of very long-chain fatty acids in plasma allowed identification of 85% of obligate heterozygotes, but this assay missed 15% of them. Mutation analysis is essential for the accurate identification of females at risk.

## Pathogenesis of Adrenoleukodystrophy

The main biochemical defect is the striking excess of very long-chain fatty acids, which accumulate in the cholesterol ester fraction, primarily in the adrenal gland and cerebral white matter. The accumulation of very long-chain fatty acids in X-linked adrenoleukodystrophy is not as severe as in disorders of peroxisome biogenesis or single-peroxisomal  $\beta$ -oxidation enzyme defects. The resultant accumulation does lead to a variety of issues with membrane dysfunction including issues with red blood cell microviscosity, altered response of adrenal cells to adrenocorticotropic hormone, and other issues with steroid production.

The pathogenesis of the nervous system lesion has been more difficult to discern. It has been presumed that elevation of very long-chain fatty acids results in the axonopathy seen in patients with adrenomyeloneuropathy and in women who are carriers. It is not clear, however, why rapid, inflammatory demyelination affecting the cerebral white matter tracts develops in certain persons. The levels of very long-chain fatty acids in plasma or skin fibroblasts or the capacity to metabolize very long-chain fatty acids in cultured fibroblasts do not differ in males with the childhood form from those in men with adrenomyeloneuropathy or other forms. No correlation exists between severity of the neurologic disease and levels of very long-chain fatty acids. These observations have led to the conclusion that very long-chain fatty acid excess alone is not sufficient to explain cerebral demyelination and that other factors must play a role in the phenotypic variability (Moser et al., 2005).

The presence of the perivascular lymphocytic infiltration in the white matter of the cerebral forms provides evidence of immunologic involvement as one additional factor. This is not seen in the adrenal gland or other leukodystrophies. The pattern seen is that of a cellular immune response in the central nervous system, and the collective evidence implies that an immunologic mechanism contributes to the rapid progression of white matter lesions, possibly in response to the altered lipid composition in brain of patients with adrenoleukodystrophy (Mahmood et al., 2007).

Recent studies have demonstrated a shift in the production of reactive oxygen species, evidence of mitochondrial dysfunction, and activation of low levels of chronic inflammation in all forms of ALD. It has also been shown that at least one inciting factor is the elevation in very long-chain fatty acids. Further studies in this area may identify factors that contribute to the pathogenesis of the nervous system lesions.

## Therapy for Adrenoleukodystrophy

Therapy for ALD depends on what manifestations the individual is presenting with; it should also be emphasized that therapy continues to evolve. Adrenal insufficiency should be

treated with steroid replacement with increased doses at times of physiologic stress.

The utility of therapies to lower very long-chain fatty acids remains uncertain. Although dietary restriction alone will not lower very long-chain fatty acids, the addition of monounsaturated fatty acids does lower plasma levels of saturated fatty acids. Dietary therapy with the use of glyceryl trierucate, sometimes referred to as Lorenzo's oil, does not alter the course of rapidly progressive childhood cerebral disease. The role in AMN remains unknown, but the results in open studies have not been impressive. In one open study, it was shown that the use of glyceryl trierucate lowered the risk of developing childhood cerebral disease when started in asymptomatic boys (Moser et al., 2005). The usage of this therapy, unfortunately, remains uncertain, and it must be emphasized requires a significant lifestyle change in the subject with unclear benefit.

Bone marrow transplant has been shown to be effective in boys with early cerebral disease as detected by MRI changes (Mahmood et al., 2007). In patients with more advanced disease, transplantation has not resulted in halting the course and may be associated with worsening of the neurologic status immediately after the procedure; therefore this procedure is not advised in those with neurologic findings.

Recently, gene therapy with a lentivirus vector has been successfully used in boys with early cerebral disease. This advancement in the field potentially offers additional avenues of treatment for many individuals who could not previously undergo transplantation.

In patients with advanced cerebral disease, neither dietary therapy nor bone marrow transplantation is effective. A variety of therapies including IVIG, cyclophosphamide immunosuppression, and high dose steroids do not arrest the rapid progression of the illness.

Males at risk for developing the childhood form of ALD (younger than 10 years of age) require appropriate monitoring. MRI should be performed on a yearly basis. Because MRI abnormalities become evident at least 12 months before onset of neurologic symptoms, periodic neurologic examination is not sufficient for monitoring these patients. Timely assessments are especially important because the best outcomes with bone marrow transplantation are in patients identified at an early stage of cerebral disease. Appropriate adrenal monitoring also is indicated in identified patients.

## Newborn Screening for XALD

A biochemical assay using tandem mass spectroscopy and the standard newborn blood spot has been developed and has been found to be highly sensitive and specific. This has recently been instituted in New York and may be incorporated in other state panels. If this is subsequently incorporated more broadly into newborn screening programs, it will most likely change the proportion of males coming to attention in the presymptomatic phase and will also improve their care and management.

## Current and Future Outlook

With expanding clinical phenotypes, peroxisomal disorders are now included as standard considerations in the differential diagnosis for a variety of neurologic findings in infants, children, and adults. As new peroxisomal functions are being identified, they have provided insight into mechanisms involving biogenesis of the organelle and control of protein import. Their vital role encompassing neuronal migration in fetal brain development through membrane integrity in the axons in adults is being appreciated. All of the disorders can be recognized by noninvasive biochemical and genetic tests,

providing valuable information for genetic counseling. These disorders may be severely debilitating or fatal, but therapeutic options are becoming available.

The term “neurotransmitter disorders” constitutes a broad and increasingly complex spectrum of neurologic conditions associated with defects in the production, transport, release, and reuptake of a variety of chemical compounds involved in neurotransmission. This chapter provides an overview of such disorders, with a primary emphasis on those associated with a dopamine or serotonin deficiency state.

Neurologic symptoms associated with dopamine deficiency are broad and range from extremely mild and subtle alterations in mood or gait to a classic exercise-induced dystonic gait abnormality and an infantile-onset parkinsonism syndrome. In recessive inborn errors of dopamine metabolism associated with tetrahydrobiopterin (BH4) deficiencies, neurologic symptoms are often more severe and accompanied by hyperphenylalaninemia, which can be detected on newborn screening. Associated serotonin deficiency is present in most of these disorders. Even when these disorders are ascertained by newborn screening, repletion of neurotransmitter precursors may not be sufficient, resulting in global developmental impairment, fluctuating tone abnormalities, eye movement abnormalities, encephalopathy, ataxia, and seizures. Diseases related to dysfunction of other neurotransmitter systems (i.e., gamma-aminobutyric acid [GABA], glutamate, and glycine, among others) are more difficult to characterize in humans; however, manifestations of these disorders are equally as diverse as in monoaminergic systems, including seizures, ataxia, hypotonia, oculomotor dyspraxia, and developmental delay.

Screening for neurotransmitter-related disorders occurs primarily by recognition of key neurologic symptoms, though overlap with other disorders with shared features can make accurate identification and diagnosis of these disorders challenging. The routine availability of increasingly more sophisticated diagnostic tools, including cerebrospinal fluid neurotransmitter metabolite studies, cerebrospinal fluid and urine pterin studies, neuroimaging studies, phenylalanine loading studies, enzymatic assays in blood cells or skin fibroblasts, and molecular studies, have facilitated the diagnosis and treatment of patients with monoaminergic neurotransmitter abnormalities.

For ease of classification, neurotransmitter-related disorders can be divided into five groups:

1. Monoaminergic neurotransmitter deficiency states with hyperphenylalaninemia
2. Monoaminergic neurotransmitter deficiency states without hyperphenylalaninemia
3. Amino acid neurotransmitter dysmetabolism
4. Secondary neurotransmitter deficiency states
5. Undefined neurotransmitter deficiency states (Table 44-1)

## MONOAMINERGIC NEUROTRANSMITTER DEFICIENCY STATES WITH HYPERPHENYLALANINEMIA

### Overview

The neurotransmitter deficiency in infants in this group arises as a result of defects in BH4 metabolism (Fig. 44-1). Patients

are usually identified by elevated phenylalanine levels on newborn screening, as BH4 is required for phenylalanine hydroxylation in the liver. The accompanying neurotransmitter deficiency results from the lack of BH4, an obligatory cofactor required for the synthesis of catecholamines and serotonin. Although most academic biochemical genetics clinics that monitor children with phenylketonuria systematically perform the additional studies required to diagnose this group of disorders, children occasionally are not identified until they have progressive neurologic symptoms or clear evidence of developmental delay despite a phenylalanine-restricted diet, prompting the earlier designation of “atypical phenylketonuria.” Importantly, newborn screening before an adequate interval of protein intake can lead to a false-negative result. 6-Pyruvoyltetrahydropterinsynthase deficiency results in inadequate BH4 synthesis; dihydropteridine reductase deficiency results in decreased regeneration of BH4 from dihydrobiopterin (see Fig. 44-1). Both are autosomal-recessive disorders in which hyperphenylalaninemia results from a deficiency of BH4. Because of the involvement of BH4 in catecholamine and serotonin synthesis, such infants also have a manifest deficiency of neurotransmitter metabolites in addition to hyperphenylalaninemia. Other conditions in this category include autosomal-recessive guanosine triphosphate cyclohydrolase (GTPCH) deficiency and primapterinuria (Table 44-2).

### Role of BH4 in the Central Nervous System

Because BH4 is required for the hydroxylation of aromatic amino acids, its importance in the central nervous system (CNS) becomes immediately apparent, as catecholamine and serotonin synthesis require tyrosine and tryptophan. A BH4-dependent process can be strongly suspected when plasma phenylalanine levels return to normal after BH supplementation. The greater requirement of tyrosine hydroxylase for BH4 in comparison with tryptophan hydroxylase may explain the more severe impairment in the catecholaminergic system compared with the serotonergic system.

### 6-Pyruvoyltetrahydropterin Synthase Deficiency

6-Pyruvoyltetrahydropterin synthase catalyzes the elimination of inorganic triphosphate from dihydroneopterin triphosphate to form 6-pyruvoyltetrahydropterin. Patients have elevated neopterin to biopterin ratios in urine and plasma. Reduced 6-pyruvoyltetrahydropterin synthase activity can be documented in red blood cells. In the classic form of the disorder, patients have reduced catecholamine and serotonin metabolites and an increased neopterin to biopterin level in cerebrospinal fluid. Patients are usually detected by newborn screening, as with phenylketonurics, and demonstrate progressive neurologic involvement in the first few months of life, including extrapyramidal signs, axial and truncal hypotonia, hypokinesia, feeding difficulties, choreoathetotic or dystonic limb movements, and autonomic symptoms. Many of these patients, despite early diagnosis and supplementation with

**TABLE 44-1** Primary Monoaminergic Neurotransmitter Deficiency Disorders

Disorder	Phenotypic Features	Locus	Inheritance
<b>ELEVATED PLASMA PHENYLALANINE</b>			
6-Pyruvoyltetrahydropterin synthase deficiency*	Encephalopathy, dystonia, spasticity, axial hypotonia, autonomic symptoms, oculogyric crises, seizures	11q22.3–23.3	AR
Dihydropteridine reductase deficiency*		4p15.31	AR
GTP cyclohydrolase deficiency*		14q22.1–22.2	AR
Primapterinuria	Benign hyperphenylalaninemia	10q22	AR
<b>NORMAL PLASMA PHENYLALANINE</b>			
GTP cyclohydrolase deficiency*	Exercise-induced dystonia, gait disorder, writer's cramp, restless leg syndrome, tremor	14q22.1–22.2	AD
GTP cyclohydrolase deficiency*	Dystonia, spasticity, torticollis, axial hypotonia, limb rigidity, autonomic symptoms, psychomotor retardation, oculogyric crises	7p11	AR
Sepiapterin reductase deficiency*	Parkinsonian symptoms, psychomotor retardation, behavioral disturbances	2p14p12	AR
Tyrosine hydroxylase deficiency*	Gait disturbance, infantile parkinsonism, dystonia, speech delay	11p15.5	AR
Tryptophan hydroxylase deficiency*	Ataxia, speech delay, hypotonia, psychomotor retardation	11p15.3	AR
Dopamine b-hydroxylase deficiency*	Orthostatic hypotension, lethargy, ptosis	9q34	
Monoamine oxidase A deficiency	Mild mental retardation, tendency to violent or aggressive behavior	Xp11.23	XR
Dopamine Transporter Deficiency*	Hyperkinetic movement disorder progressing to parkinsonism dystonia	5p15.33	AR
Vesicular Monoamine Transporter2 Deficiency*	Mixed hyperkinetic and hypokinetic movement disorder, oculogyric crises, dysautonomia, developmental delay, behavioral and sleep disturbances	10q25.3	AR

\*Disorder associated with a dopamine deficiency state.

AD, autosomal-dominant; AR, autosomal-recessive; GTP, guanosine triphosphate; XR, X-linked recessive.

(With permission from Hyland, K., 2007. *Inherited disorders affecting dopamine and serotonin: Critical neurotransmitters derived from aromatic amino acids. J Nutr* 137, 1568–1572S.)

BH<sub>4</sub> and neurotransmitter precursors, continue to manifest delay in development. A “peripheral” form of the disorder is associated with nearly one-third of known mutations with the human PTS gene and is characterized by normal central neurotransmitter levels and less significant or transient hyperphenylalaninemia. Patients with the peripheral form have an excellent prognosis for normal neurologic development, provided the hyperphenylalaninemia is corrected by diet or BH<sub>4</sub> administration.

## Dihydropteridine Reductase Deficiency

Dihydropteridine reductase deficiency manifests in a variety of phenotypes, all with hyperphenylalaninemia. The clinical presentation is similar to that of central 6-pyruvoyltetrahydropterin synthase deficiency. Without folic acid to restore methyltetrahydrofolate status in the CNS, these patients can have progressive calcification of the basal ganglia and subcortical regions, despite treatment with BH<sub>4</sub> and

neurotransmitter precursors. Diagnosis can be confirmed by the pattern of urine pterins and documentation of abnormal dihydropteridine reductase activity in skin fibroblasts. Results of phenylalanine loading tests are abnormal, and phenylalanine status improves or returns to normal with BH4 supplementation. Cerebrospinal fluid neurotransmitter and pterin analysis reveals reduced concentrations of homovanillic acid and 5-hydroxyindoleacetic acid, decreased or normal BH4 levels, and elevated dihydrobiopterin levels.

### Autosomal-Recessive Guanosine Triphosphate Cyclohydrolase Deficiency

Patients with the autosomal-recessive form of GTPCH deficiency (in contrast to autosomal-dominant dopa-responsive dystonia) present similarly to patients with dihydropteridine reductase deficiency and 6-pyruvoyltetrahydropterin synthase deficiency with severe global developmental impairment, marked axial hypotonia, eye movement abnormalities, limb hypertonia, convulsions, and autonomic symptoms. GTPCH activity is absent in blood cells, liver, and skin fibroblasts. Cerebrospinal fluid neurotransmitter metabolite analysis reveals low homovanillic acid, 5-hydroxyindoleacetic acid, neopterin, and biopterin levels.

### Pterin-4a-Carbinolamine Dehydratase Deficiency (Primapterinuria)

Pterin-4a-carbinolamine dehydratase deficiency, or primapterinuria, causes mild hyperphenylalaninemia these infants are usually identified on newborn screening but generally have a benign course with normal development (Thöny and Blau, 2006).

## MONOAMINERGIC NEUROTRANSMITTER DEFICIENCY STATES WITHOUT HYPERPHENYLALANINEMIA

### Overview

Neurotransmitter deficiency disorders not associated with hyperphenylalaninemia span a complex clinical spectrum. The lack of newborn screening and increasingly diverse phenotypes make these disorders challenging to recognize. Excepting autosomal-dominant dopa-responsive dystonia and monoamine oxidase a deficiency, these disorders are inherited

in an autosomal-recessive fashion. Heterozygous carriers very rarely have a discernible phenotype.

### Segawa Disease or Autosomal-Dominant Dopa-Responsive Dystonia

The best-described and most widely identified entity among this group of disorders is autosomal-dominant dopa-responsive dystonia caused by GTPCH deficiency, or Segawa disease. Patients with a classic presentation of exercise-induced dystonia are easily recognized; however, the diagnosis should also be considered in patients with spastic diplegia, particularly with diurnal variation, as well as in more atypical presentations resulting from incomplete penetrance such as writer's cramp, asymmetric limb dystonia, tremor, or restless leg-type symptoms. Patients often benefit greatly from directed treatment of the associated dopamine deficiency state and clinical response to L-DOPA/carbidopa may aid in diagnosis.

Cerebrospinal fluid neurotransmitter metabolite (low homovanillic acid, normal or low 5-hydroxyindoleacetic acid, and reduced BH4) and pterin studies as well as phenylalanine loading can be helpful in confirming the diagnosis in these patients and can help characterize the degree of associated dopamine and serotonin deficiency. GTPCH activity can be measured in skin fibroblasts. Urine biopterin levels are low.

### Aromatic L-Amino Acid Decarboxylase or Dopa-Decarboxylase Deficiency

Aromatic L-amino acid decarboxylase is a pyridoxine-dependent enzyme that decarboxylates L-DOPA and 5-hydroxytryptophan to make dopamine and serotonin, respectively. Patients with this disorder typically present in the first few months of life with dystonia or intermittent limb spasticity, axial and truncal hypotonia, oculogyric crises, autonomic symptoms, and ptosis.

Cerebrospinal fluid neurotransmitter metabolites demonstrate a characteristic pattern: low homovanillic acid and 5-hydroxyindoleacetic acid levels; markedly elevated 3-O-methyldopa, 5-hydroxytryptophan, and L-DOPA; and normal biopterin and neopterin levels. Plasma L-DOPA is markedly elevated. Urine catecholamines may be reduced or elevated, specifically with vanillic acid, despite normal preliminary organic acid results (Fig. 44-2).

Although some children benefit in terms of the underlying movement disorder, treatment is complex, and these patients

**Figure 44-2.** Episodic neurologic manifestations in aromatic L-amino acid decarboxylase deficiency. **A,** Ocular convergence spasm, ptosis, and orofacial dystonia. **B,** Torticollis and limb dystonia. **C,** Torticollis and limb rigidity.

are vulnerable to an array of medication-related side effects. Overall clinical outcomes in aromatic L-amino acid decarboxylase deficiency have remained poor, though emerging gene therapies may hold promise.

### Sepiapterin Reductase Deficiency

Sepiapterin reductase catalyzes the (NADP) reduction of carbonyl derivatives, including pteridines, and plays an important role in BH4 biosynthesis. It is likely that low dihydrofolate reductase activity in the brain allows accumulation of dihydrobiopterin that inhibits tyrosine and tryptophan hydroxylases and uncouples neuronal nitric oxide synthase, leading to neurotransmitter deficiency and neuronal cell death. Thus identification of low cerebrospinal fluid neurotransmitter levels and the presence of elevated cerebrospinal fluid dihydrobiopterin are essential, and the diagnosis can be confirmed with low skin fibroblast enzyme activity or sequencing of the SPR gene.

Few patients have been described. In the largest published series, motor delay, axial hypotonia, language delay, diurnal fluctuation of symptoms, dystonia, sleep benefit, weakness, oculogyric crises, dysarthria, parkinsonian signs, hyperreflexia, and psychiatric of behavioral signs were observed in more than half of the 38 patients surveyed. Other significant neurologic manifestations included autonomic disturbances, eye movement abnormalities, chorea, ataxia, dysphagia, hyporeflexia, seizures, and myoclonus. In all cases receiving treatment, significant motor improvement resulted from low-dose L-DOPA/carbidopa.

### Tyrosine Hydroxylase Deficiency or Autosomal-Recessive Dopa-Responsive Dystonia

Tyrosine hydroxylase deficiency, sometimes referred to as autosomal-recessive Segawa disease, displays diverse phenotypes that can be classified as mild, moderate, or severe. Mild cases may demonstrate clumsy gait, toe-walking, tight heel cords, or abnormal posturing that may worsen at the end of the day and may progress with age. Attention or articulation difficulties are sometimes seen. All children with mild symptoms are readily treated with medication. Moderately affected cases demonstrate an abnormal gait often with dystonic posturing with stressed gait, sometimes accompanied by ataxic, spasticity, speech delay, involuntary eye movement problems (brief upward eye-rolling movements with stress or fatigue), or frank oculogyric crises. Most have an excellent response to treatment, but full benefit may take many months. In the most severe cases, referred to as the infantile Parkinson's disease variant, children are severely disabled and affected from early infancy, demonstrating muscle tightness and rigidity, arching, tremor and poor muscle control, and involuntary eye movements. Ptosis, speech delay, feeding difficulty, and constipation are also common. Less commonly, there are children with generalized low tone, with poor head control and inability to sit unsupported. They often demonstrate torticollis. Dysautonomia can occur, frequently during illness. Severe cases are more difficult to treat, often requiring multiple medications and being unusually vulnerable to side effects of dopaminergic agonists or precursors. Response may be slow, with some continued benefit during months to years. Some cases show persistent mental retardation, encephalopathy, and motor disability despite of treatment.

Cerebrospinal fluid concentration of homovanillic acid is low whereas 5-hydroxyindoleacetic acid, neopterin, and biopterin are normal. Phenylalanine loading studies are normal, and enzymatic assays for confirmation of a suspected

diagnosis are not presently available, making confirmation by molecular testing is extremely helpful. A recent analysis has identified mostly missense and compound heterozygous TH mutations, consistent with prior reports of autosomal recessive inheritance.

Patients variably respond to L-DOPA/carbidopa, and some have complete reversal of symptoms. The exception to this is the patient with the severe infantile parkinsonism form, who typically tolerates L-DOPA poorly. Addition of dopamine agonists such as selegiline or anticholinergic agents such as trihexyphenidyl can provide significant benefit and help promote the gradual ongoing attainment of motor skills and ability to ambulate independently, but such achievements may occur over years, rather than months or weeks, in the most severely affected patients (Marecos et al., 2014).

### Tryptophan Hydroxylase Deficiency

Tryptophan hydroxylase catalyzes the BH4-dependent hydroxylation of tryptophan to 5-hydroxytryptophan, which is then decarboxylated to form serotonin. Tryptophan hydroxylase expression is limited to certain cells in the CNS and periphery. Although clinically suspected, no confirmed cases have yet been identified.

### Dopamine B-Hydroxylase Deficiency

Dopamine b-hydroxylase converts dopamine to norepinephrine. Patients with severe deficiency cannot synthesize norepinephrine, epinephrine, and octopamine in CNS or peripheral autonomic neurons. Dopamine acts as a false neurotransmitter for noradrenergic neurons. Neonates with dopamine b-hydroxylase deficiency can have episodic hypothermia, hypoglycemia, and hypotension, leading to early death. Survivors do fairly well until late childhood, when overwhelming orthostatic hypotension profoundly limits their activities (Robertson et al., 1991).

Most patients have been identified as young adults. Observation of severe orthostatic hypotension in a patient whose plasma norepinephrine/dopamine ratio is much less than 1 supports the diagnosis. Orthostatic hypotension, particularly after exercise, and ptosis are constant features. General lethargy and lassitude improve dramatically, and blood pressure becomes normal with treatment with D,L-threo-dihydroxyphenylserine, a synthetic amino acid that is converted to norepinephrine by aromatic L-amino acid decarboxylase.

Patients may undergo personality change, becoming more "aggressive" with treatment.

### Monoamine Oxidase Deficiency

Monoamine oxidase is a mitochondrial enzyme involved in the catabolism of biogenic amines. Monoamine oxidase A, the primary type in fibroblasts, preferentially degrades serotonin and norepinephrine. Monoamine oxidase B, the primary type in platelets and in the brain, preferentially degrades phenylethylamine and benzylamine. These enzymes are critical in the neuronal metabolism of catecholamine and indoleamine neurotransmitters. The genes are closely linked on the X chromosome, near the Norrie's disease locus, and only affected boys have been identified to date.

### Monoamine Oxidase A Deficiency

Brunner described a family with an X-linked nondysmorphic mild mental retardation and a tendency to severe aggressive or violent behavior and urine studies consistent with marked disturbance of monoamine metabolism (Brunner et al., 1993). No additional patients have been identified to date.

## Monoamine Oxidase B Deficiency

Isolated monoamine oxidase B deficiency has not yet been reported in a patient. Two brothers with a microdeletion, including the Norrie locus and monoamine oxidase B, however, had features consistent with Norrie disease alone. These patients had neither abnormal behavior nor mental retardation, leading the authors to conclude that monoamine oxidase A plays a more significant role than does monoamine oxidase B in the metabolism of biogenic amines, and monoamine oxidase B deficiency alone may have a primarily neurochemical phenotype: that of increased phenylethylamine in urine (Lenders et al., 1996).

## Monoamine Oxidase A and B Deficiency

A small number of cases of MAO A and B deficiency (with intact Norrie locus) have been reported, all male. Affected individual's demonstrated episodic hypotonia, intellectual disability and stereotyped movements (Saito et al. 2014).

## Dopamine Transporter Deficiency

The presynaptic dopamine transporter (DAT) encoded by SLC6A3 modulates the intensity and duration of dopaminergic signaling by synaptic dopamine reuptake. Individuals with dopamine transporter deficiency syndrome classically present with a hyperkinetic movement disorder of infantile onset that progresses to parkinsonism dystonia and characteristic elevated CSF homovanillic acid to 5-hydroxyindoleacetic acid (HV to 5-HIAA). Inheritance has been consistent with an autosomal recessive pattern. Treatment generally involves ropinirole, L-dopa, and/or selegiline therapy, but most cases are refractory to medical or surgical management (Marecos et al., 2014).

## Vesicular Monoamine Transporter 2 Deficiency

A syndrome of mixed hyperkinetic and hypokinetic movement disorder with oculogyric crises, dysautonomia, developmental delay, behavioral and sleep disturbances with no CSF neurotransmitter deficiency has been described in a single family. Affected individuals additionally demonstrate elevated urine 5-HIAA, HVA, and decreased urine norepinephrine and dopamine and were found to carry single family has been described with homozygous missense mutations in SLC18A2, the gene encoding the vesicular monoamine transporter 2. Treatment with pramipexole improved dopamine-related symptoms markedly, and to a lesser extent, other symptoms (Marecos et al., 2014).

## DISORDERS OF AMINO ACID NEUROTRANSMITTERS

### Overview

Amino acid neurotransmitters are the main inhibitory and excitatory messengers in the nervous system; however, few have been implicated in human disease. GABA and glycine-related disorders are best studied yet incompletely understood. Glycine has ubiquitous function and both excitatory and inhibitory properties. Glycine encephalopathy, formerly referred to as nonketotic hyperglycinemia, will be touched on briefly, as more extensive review occurs elsewhere in this text. Disorders of GABA degradation will also be reviewed (Fig. 44-3), with specific emphasis on succinic semialdehyde dehydrogenase deficiency, the most common and best characterized.

## Gamma-Aminobutyric Acid Transaminase Deficiency

GABA is the major inhibitory neurotransmitter of the brain, derived primarily from glutamate, the major excitatory neurotransmitter. The first step of the GABA degradation pathway involves GABA transaminase, which removes an amino group from GABA and adds it to alpha-ketoglutarate, thus replenishing glutamate and reestablishing the closed loop system known as the GABA shunt. GABA transaminase deficiency is a rare, autosomal-recessive disorder characterized by abnormal development, seizures, and high levels of CSF GABA beta-alanine, both of which are also elevated in serum. Cases to date have presented with neonatal seizures, lethargy, hypotonia, hyperreflexia, developmental retardation, and high pitched cry, all with poor outcomes (Definitive diagnosis can be made by measurement enzyme activity in various cell types [Parviz et al., 2014]).

## Succinic Semialdehyde Dehydrogenase Deficiency

Succinic semialdehyde dehydrogenase deficiency is an autosomal-recessive inborn error of metabolism associated with a defect in the metabolism of GABA. Phenotypic features range from nonspecific global developmental delay and hypotonia to ataxia, severe mental retardation, visual impairment, and seizures. Somewhat uniquely among neurotransmitter-related disorders, disease course is not intermittent or episodic. Neuropsychiatric symptoms (i.e., sleep disorders, inattention, hyperactivity, obsessive-compulsive disorder, and anxiety) are prominent. MRI is commonly abnormal. Urine organic acid screening to detect elevated 4-hydroxybutyric acid is the most easily available screening strategy, but GABA levels in cerebrospinal fluid and urine are also elevated. Treatment is generally symptomatic and targeted at seizure management (Lapalme-Remis et al., 2015).

## Secondary Neurotransmitter Deficiency States

Menkes disease is an X-linked recessive disorder in which multiple copper-dependent enzymes can be secondarily affected, including dopamine b-hydroxylase, leading to secondary autonomic involvement and norepinephrine deficiency (Kaler et al., 2008).

Hyperreflexia, or "startle disease," is a heterogeneous disorder caused by defects in the  $\alpha 1$  subunit of the glycine receptor occurring in autosomal-dominant and autosomal-recessive forms, characterized by stimulus-sensitive myoclonus. Transient hypertonia and hypokinesia in infancy in some families with the disorder has led to the designation "stiff baby syndrome." Dubowitz and colleagues described an infant with classic startle disease, with markedly decreased cerebrospinal fluid GABA levels (Dubowitz et al., 1992). Infants with hyperreflexia have higher than expected rates of sudden infant death syndrome. An exaggerated startle response persists throughout life; sudden, acoustic or tactile stimuli can precipitate a brief attack of intense rigidity with falling. Dramatic improvement of symptoms occurs in most patients with clonazepam.

Neurodegenerative disorders are sometimes associated with reduced neurotransmitter metabolites. Such abnormalities have been seen in patients with leukodystrophy and progressive encephalopathy phenotypes in which a primary defect in neurotransmitter or pterin metabolism could not be identified but who still may benefit from directed treatment of the underlying neurotransmitter deficiency.

Periods of hypoxia or ischemia can lead to secondary deficiencies of serotonin and dopamine.

## UNDEFINED NEUROTRANSMITTER DEFICIENCY STATES

Increasingly, with more widespread testing of cerebrospinal fluid neurotransmitter metabolites, patients are being identified with documented neurotransmitter deficiency states that do not fit easily into any of the preceding diagnostic categories, and the nature of their underlying defects remains unknown. These include patients with a wide variety of movement disorder phenotypes, encephalopathy, or seizures. Additional studies are needed to determine the precise defects affecting neurotransmitter levels and to ascertain whether they are primary or secondary.

## APPROACH TO TREATMENT IN PATIENTS WITH NEUROTRANSMITTER DEFICIENCY STATES

Because patients with neurotransmitter deficiency disorders caused by tyrosine hydroxylase or BH4 deficiency have been deficient for prolonged periods before treatment, they can be extremely sensitive to initiation of neurotransmitter precursors. Starting with extremely conservative dosages, increasing the dosage slowly during weeks or months, and ensuring that peripheral aromatic L-amino acid decarboxylase is fully blocked by providing ample carbidopa can make the transition to treatment much easier. The rate or degree to which children respond depends on a variety of factors, including age at diagnosis, specific disorder and mutation, presence or absence of associated hyperphenylalaninemia, and presence or absence of central BH4 deficiency. In general, optimism about improvement is warranted.

Institution of neurotransmitter precursor treatment may lead to new problems, such as intermittent dyskinesia related to a peak dose effect, changes in appetite, gastroesophageal reflux, diarrhea, and constipation. These problems, greatest in the first few weeks of institution of treatment, tend to improve with time. With regard to replacement of L-DOPA, use of a slow-release form of the medication may theoretically be ideal. However, such formulations are dosed, not for use in children, but for use in adults with Parkinson's disease. In addition, dividing standard dosage forms marketed for adults makes adequate dosing in infants and young children a significant challenge. Thus ideal dosage forms may need to be formulated in compounded preparations, rather than through commercially marketed dosage preparations. Support for parents and children during this often difficult period of transition from initiation of treatment to adjustment of medications is critical because these patients will likely require neurotransmitter precursor replacement throughout their lifetimes.

In a disorder such as aromatic L-amino acid decarboxylase deficiency, in which direct receptor agonists may be indicated, only adult formulations of these often-potent medications are available, making the use of compounding necessary. Giving more frequent and lower doses throughout the day may be necessary in some children.

Although patients with primary neurotransmitter deficiency states are more likely to respond optimally to treatment, patients with secondary neurotransmitter deficiency may have some symptomatic benefit from directed treatment of their underlying neurotransmitter deficiency state.

## NEUROLOGIC DISORDERS CHARACTERIZED BY EXCESS NEUROTRANSMITTER LEVELS

### Glycine Encephalopathy

Glycine encephalopathy, formerly referred to as nonketotic hyperglycinemia, is a heterogeneous disorder associated with insufficient activity of various components of the mitochondrial glycine cleavage system. The enzyme system for cleavage of glycine is composed of four protein components: P protein, a pyridoxal phosphate-dependent glycine decarboxylase; H protein, a lipoic acid-containing protein; T protein, a tetrahydrofolate-requiring enzyme; and L protein, a lipoamide dehydrogenase. Nonketotic hyperglycinemia may be caused by a defect in any one of these enzymes. It is an autosomal-recessive disorder with several reported phenotypes, including the classic severe neonatal form, an infantile variant, a mild-episodic childhood variant, a late-onset form, and a benign reversible form.

Most patients described to date have the neonatal and most severe phenotype, likely because it is the most distinctive phenotype. These patients present shortly after birth with lethargy, encephalopathy, hypotonia, myoclonic jerks, and apnea. EEG generally reveals a burst-suppression pattern. Those who survive the neonatal period generally develop intractable seizures and profound mental retardation. Patients with the infantile form have seizures and variable cognitive impairment after a short period of apparently normal development. In the mild, episodic form, patients typically present some time after infancy with mild psychomotor retardation and may manifest episodes of delirium, chorea, and vertical gaze palsy during febrile illness. In the late-onset form, children present with progressive spastic diplegia and optic atrophy. They generally do not have seizures, and intellectual function is preserved. Diagnosis is best made by documenting an increased cerebrospinal fluid to plasma glycine ratio. At present, confirmation of diagnosis requires enzyme analysis in liver or transformed lymphoblasts. Treatment with dextromethorphan and sodium benzoate has led to variable improvement in seizure control and behavioral problems in some patients. It is additionally advisable to avoid valproate, as it may increase serum and CSF glycine levels (Hoover-Fong JE et al., 2004).

The disorders referred to as phakomatoses are notable for their dysplastic nature and tendency to form tumors in various organs, particularly the nervous system. Some of these conditions have been referred to as “neurocutaneous disorders” because of the frequent involvement of the skin in addition to the nervous system. Cutaneous features are not present in all phakomatoses, however (e.g., von Hippel-Lindau syndrome), and many include features outside the skin and nervous system (Table 45-1 summarizes the phakomatoses).

## THE NEUROFIBROMATOSES

The neurofibromatoses consist of three distinct disorders: NF1 (Ferner and Gutmann, 2013), NF2 (Lloyd and Evans, 2013), and schwannomatosis (Plotkin et al, 2013).

### Neurofibromatosis Type 1

Neurofibromatosis type 1 (NF1) is transmitted as an autosomal-dominant trait and is notable for its great variability of expression. It can involve not only the peripheral and central nervous systems, but also the skin, bone, endocrine, gastrointestinal, and vascular systems. Diagnostic criteria for NF1 are presented in Box 45-2.

#### Clinical Characteristics

In NF1, the usual presenting signs are cutaneous manifestations. Skin changes include café-au-lait macules, cutaneous neurofibromas, nevus anemicus, patchy and diffuse areas of hyperpigmentation, and juvenile xanthogranulomas. Six or more café-au-lait macules measuring at least 5 mm across before puberty or 15 mm after puberty constitute one diagnostic criterion for NF1. Individuals with mutation in the SPRED1 gene may also present with multiple café-au-lait macules, skinfold freckles, and macrocephaly but do not develop neurofibromas or other tumor-related NF1 complications. This condition is referred to as Legius syndrome. Usually the second sign to appear is skinfold freckling. Freckles begin in the inguinal region in children at 3 to 4 years of age and eventually appear in the axillae, at the base of the neck, and in the inframammary region in females.

Cutaneous neurofibromas are a prominent finding in NF1 and are located in or adjacent to the dermis. They are discrete, soft or firm papules, ranging in size from a few millimeters to several centimeters, can be flat, sessile, or pedunculated, and can be readily impressed into the skin below. Neurofibromas can develop at any time and in any location, and may affect any component of the peripheral nervous system, from the dorsal root ganglion to the terminal nerve twigs. Plexiform neurofibromas represent tumors involving a longitudinal section of nerve or multiple branches of a major nerve. Near the surface of the body they can cause thickening and hypertrophy of the skin and soft tissues. They may occur deeper in the body and be detected only by imaging. Tumors of the orbit

or limbs can cause major physical deformity. Plexiform neurofibromas can be congenital lesions, often growing rapidly in the early years of life; they then may remain quiescent for long periods of time or grow unpredictably. The tumors are easily visualized by magnetic resonance imaging (MRI), and display a characteristic “target sign.” Neurofibromas originating at the dorsal roots may grow in a dumbbell shape and invade the spinal canal, sometimes causing spinal cord compression. The gastrointestinal tract can also be affected by growth of neurofibromas or ganglioneuromas causing intestinal obstruction or bleeding.

Ophthalmologic features of NF1 include Lisch nodules, glaucoma, and optic glioma. Iris Lisch nodules are melanocytic hamartomas that are highly specific to NF1. Optic pathway gliomas are found in approximately 15% of patients. Most are asymptomatic, but these tumors can manifest with decreased visual acuity, visual field defects, or precocious puberty. Visual symptoms do not necessarily correlate with the size or growth of the tumor radiographically. The glioma can involve the optic nerves, chiasm, optic radiations, and hypothalamus; it may manifest rarely as the diencephalic syndrome of infancy or more commonly with precocious puberty. Optic gliomas are pilocytic astrocytomas, but usually are slow-growing.

Aside from optic gliomas, astrocytomas of the cerebrum, brainstem, and cerebellum are the most common intracranial tumors encountered in NF1. Malignant peripheral nerve sheath tumor occurs in 8% to 13% of affected persons. These manifest with pain or sudden growth, usually within a preexisting plexiform neurofibroma. Various other neoplastic disorders occur more frequently in patients with NF1 than in the general population, including leukemia, especially juvenile myelomonocytic leukemia and pheochromocytoma.

Macrocephaly and short stature are common in NF1 and scoliosis has been reported to occur in 10% to 40% of patients. Bowing of the tibia, fibula, and other long bones can be present in early life, with occurrence of spontaneous fractures at the junction of the middle and distal thirds of the bone shaft, resulting in pseudarthrosis. Nonossifying fibromas may occur and can present with pain or fracture.

Children with NF1 manifest an increased frequency of migraine, and these may be associated with features of abdominal pain, nausea, and vomiting. Constipation has also been reported at increased frequency in affected children.

Approximately 50% of patients have learning disabilities, with no specific pattern unique to those with NF1. Both verbal and nonverbal disabilities occur, as well as attention-deficit disorder, hypotonia, and expressive and language problems. Those with attention deficit disorder do tend to respond to stimulant medication. Problems with motor coordination and balance are also seen, and correlate with the presence of other neurocognitive dysfunctions. Children with NF1 may also have problems with sleep. Fewer than 10% have severe intellectual disability, and most of these patients have large deletions of the NF1 gene. There is also an increased frequency of symptoms consistent with autism spectrum disorders.

**BOX 45-2** Diagnostic Criteria for Neurofibromatosis 1

- Six or more café-au-lait macules more than 5 mm in greatest diameter in prepubertal children, and more than 15 mm in greatest diameter in postpubertal children
- Two or more neurofibromas of any type or one plexiform neuroma
- Freckling in the axillary or inguinal regions
- Optic pathway glioma
- Two or more Lisch nodules (iris hamartomas)
- A distinctive osseous lesion, such as sphenoid dysplasia or thinning of long bone cortex, with or without pseudarthrosis
- Diagnosis of NF1 in a first-degree relative (parent, sibling, or offspring) according to foregoing criteria

(Modified from: Stumpf, D., 1988. Consensus development conference of neurofibromatosis. *Arch Neurol* 45, 575–578; Gutmann, D.H., et al., 197. The diagnostic evaluation and multidisciplinary management of neurofibromatosis 1 and neurofibromatosis 2. *JAMA* 278, 51–57.)

Seizures occur in approximately 6–10% of patients, are often focal, and may be associated with structural changes in the brain.

Vascular anomalies in NF1 can occur in peripheral or cerebral vessels and include regions of intimal proliferation and fibromuscular changes in small arteries. Renal artery stenosis can lead to hypertension in children, and involvement of other vessels can cause vascular insufficiency or hemorrhage as a result of arterial wall dissection. Stenosis of the internal carotid artery can lead to moyamoya disease and stroke, although lesions often are asymptomatic. Surgical revascularization has been shown to be effective in prevention of ischemic episodes in instances of internal carotid stenosis.

### Pathology

Neurofibromas consist of a mixture of cell types, including Schwann cells, fibroblasts, perineurial cells, and mast cells. In plexiform neurofibromas, the pathologic process extends across multiple nerve fascicles instead of occurring at a focal site in a nerve and may extend across branches of a larger nerve. Malignant peripheral nerve sheath tumor manifests as a malignant tumor of Schwann cell origin, although sometimes rhabdoid elements are present in such tumors. Most, if not all, of these neoplasms arise from preexisting tumors, usually plexiform neurofibromas.

### Genetics

NF1, inherited as an autosomal-dominant trait, has an estimated prevalence of 1 in 3000 in all populations; about half of cases are new mutations. The NF1 gene is located at 17q11.2 and encodes a 3818-amino-acid protein referred to as neurofibromin. The protein includes a functional GTPase-activating protein (GAP) domain that regulates conversion of RAS-guanosine triphosphate to Ras-guanosine diphosphate. Neurofibromin functions as a tumor suppressor gene with respect to neurofibroma formation. Transformation to malignancy requires additional genetic changes, such as mutation of p53.

NF1 exhibits a wide range of variability of expression and complete penetrance. Mutations are widely scattered across the gene and include a wide variety of mutational mechanisms. Approximately 50% of cases of NF1 occur sporadically, as a result of a new mutation of the NF1 gene. Because of the high penetrance of the disorder, unaffected parents of a sporadically affected child have a low risk of recurrence, barring the rare instance of germline mosaicism. Somatic mosaicism

for NF1 may manifest with segmental distribution of features. Genetic testing for diagnosis of NF1 is available on a clinical basis. The discovery of mutation in the SPRED1 gene accounting for patients with multiple café-au-lait spots but lacking other features of NF1 (referred to as “Legius syndrome”) and provides additional rationale for genetic testing in young children with multiple café-au-lait spots. The majority of mutations in children with multiple café-au-lait spots are found in the NF1 gene, making it cost-effective to begin with NF1 testing, followed by SPRED1 testing if no NF1 mutation is found.

### Management

Treatment of patients with neurofibromatosis is symptomatic. Affected persons should be followed on a regular basis by a physician who is familiar with the disorder to recognize treatable complications early and to provide anticipatory guidance and counseling. Genetic counseling should be provided. Controversy surrounds the use of imaging, especially MRI, in screening patients with NF1. Most of the lesions that will be identified are not amenable to treatment, so such testing may create needless anxiety and risks associated with sedation. The value of the “baseline” examination is questionable because most of the lesions of NF1 are slow-growing and will be followed both clinically and by imaging once they come to attention. Current consensus guidelines do not recommend routine imaging, although care should be individualized for specific clinical needs (Gutmann et al., 1997).

Neurofibromas of the peripheral nerves need not be removed unless they are subject to repeated irritation and trauma or develop signs of malignant change. Some plexiform neuromas can be removed for cosmetic reasons, although complete resection is difficult and regrowth is common. Malignant tumors are managed with appropriate surgical measures and often radiation therapy and chemotherapy. Optic gliomas tend to behave in an indolent manner and therefore are followed clinically without treatment in asymptomatic children. Symptomatic tumors most often are treated with chemotherapy; radiation therapy may be associated with second malignant tumors or moyamoya disease. Malignant peripheral nerve sheath tumors tend to be highly malignant, so early diagnosis is essential. Patients with unexplained pain or growth of a neurofibroma should be evaluated, with consideration of biopsy. Positron emission tomography (PET) scanning may be helpful in distinguishing a malignant peripheral nerve sheath tumor from plexiform neurofibroma.

Clinical trials of drugs to treat specific complications are ongoing but no definitive medical therapy has been identified.

## Neurofibromatosis Type 2

### Clinical Characteristics and Pathology

Diagnostic criteria for NF2 are presented in [Box 45-3](#). The defining feature of NF2 is the occurrence of bilateral vestibular schwannomas. Vestibular schwannomas commonly present with tinnitus and/or hearing loss, and may cause problems with balance. Audiology and auditory brainstem-evoked response testing can be helpful, but definitive diagnosis is based on MRI findings. Schwannomas can occur along any other cranial nerve, the fifth being most common after the eighth. Schwannomas also may occur along spinal nerves, with the potential for causing radiculopathy or cord compression, or along peripheral nerves. In some patients, a polyneuropathy develops as a result of Schwann cell proliferation around peripheral nerves. Dermal schwannomas appear as plaque-like lesions, often with associated hair growth. Café-au-lait

**BOX 45-3** Diagnostic Criteria for Neurofibromatosis 2**CONFIRMED NF2\***

- Bilateral vestibular schwannomas  
or
- A first-degree relative with NF2  
and either
- Unilateral vestibular schwannoma before age 30 years  
or any two of
- Meningioma, schwannoma, ependymoma, juvenile lens  
opacity

**PRESUMPTIVE NF2**

- Unilateral vestibular schwannoma before age 30 years and at  
least one of: meningioma, schwannoma, ependymoma,  
juvenile lens opacity
- or
- Two or more meningiomas and unilateral vestibular  
schwannoma before age 30 years or at least one of:  
meningioma, schwannoma, ependymoma, juvenile lens  
opacity

**MANCHESTER CRITERIA†**

- Bilateral vestibular schwannomas  
or
- A first-degree relative with NF2  
and either
- Unilateral vestibular schwannoma or any two of: meningioma,  
schwannoma, ependymoma, neurofibroma, posterior  
subcapsular lenticular opacity
- or
- Unilateral vestibular schwannoma and any two of:  
meningioma, schwannoma, ependymoma, neurofibroma,  
posterior subcapsular lenticular opacity
- or

macules may occur but are not a reliable indicator of NF2, unlike in NF1. Other central nervous system tumors associated with NF2 are meningiomas and ependymomas. Virtually the entire NF2 phenotype is characterized by proliferative lesions; the one exception is the occurrence of posterior subcapsular cataracts or cortical wedge opacities.

## Genetics

NF2 is transmitted as an autosomal-dominant trait with complete penetrance and variable expression. Prevalence is estimated at approximately 1 in 60,000, and birth incidence at 1 in 30,000. Approximately half of cases occur sporadically as a result of new mutation. The NF2 gene was mapped to chromosome 22, and the responsible gene is variously referred to as schwannomin or merlin. Merlin is a cytoskeletal protein that appears to play a role in the control of cell growth in tissues. Schwannomas are clonal tumors, and the NF2 gene acts as a tumor suppressor in formation of these tumors, as well as other NF2-associated tumors. Genetic testing for NF2 is available for diagnostic purposes. Some genotype-phenotype

correlations have been identified; missense or splicing mutations tend to predict milder disease than do mutations that lead to protein truncation. Somatic mosaicism for NF2 mutation may produce localized disease or ameliorate disease severity.

## Management

Patients benefit from multidisciplinary care at a center with experience in dealing with the varied manifestations of the disorder. Management of tumors associated with NF2 is primarily surgical. Timing of surgery and the decision to treat one or both vestibular tumors depends on tumor size, degree of hearing loss, and involvement of other cranial nerves or compression of the brainstem. Stereotactic radiosurgery is also used for the treatment of vestibular schwannomas, although there may be an increased risk of malignancy in residual tumor. Use of auditory brainstem implants can be helpful in some patients in restoring some hearing due to tumor progression or surgery.

Treatment with the vascular endothelial growth factor (VEGF) inhibitor bevacizumab have shown promising results in reduction in size of vestibular schwannomas and improvement of hearing. Meningiomas are less likely to respond to bevacizumab treatment. Reduction in tumor size in some patients and improvement in hearing has also been observed with lapatinib treatment.

## Schwannomatosis

Schwannomatosis is a more recently recognized entity, characterized only by the occurrence of schwannomas on cranial and spinal nerves other than the vestibular nerve. It often presents with pain or nerve compression. Diagnostic criteria are provided in Box 45-4. Schwannomatosis is transmitted as a dominant trait with incomplete penetrance. About 10% of cases are familial; the remainder are sporadic, presumably due to new mutation or incomplete penetrance. The first gene found to be responsible for the disorder is *SMARCB1* and encodes a protein component of a chromatin remodeling complex. It is located on chromosome 22 near the NF2 locus but is distinct from that locus. Although schwannomas are the hallmark feature, meningiomas may also occur in some families with *SMARCB1* mutation. Mutation of *SMARCB1* do not account for all cases of schwannomatosis. A second gene, *LZTR1* has been found to account for some cases of schwannomatosis without germline *SMARCB1* mutation. Schwannomas in schwannomatosis patients with germline mutation of either *SMARCB1* or *LZTR1* have, in addition, mutation of NF2 on the same copy of chromosome 22 and loss of NF2 and either *SMARCB1* or *LZTR1* on the other chromosome. Not all cases of schwannomatosis are associated with loss of heterozygosity on chromosome 22, indicating that still other genes are involved.

Treatment of schwannomatosis is surgical. There is one report of a favorable response to bevacizumab, though no additional studies of the use of this drug have been reported to date.

## TUBEROUS SCLEROSIS COMPLEX (TSC)

Tuberous sclerosis complex is a disorder of autosomal-dominant inheritance that affects multiple organ systems, resulting in manifold clinical expressions. TSC is currently recognized as one of the most common single-gene disorders seen in children and adults, with an estimated incidence of 1 in 5800 live births. The first description of tuberous sclerosis complex was by von Recklinghausen, who described a newborn

**BOX 45-4** Diagnostic Criteria for Schwannomatosis**MOLECULAR DIAGNOSIS:**

Two or more pathologically proved schwannomas or meningiomas AND genetic studies of at least two tumors with loss of heterozygosity (LOH) for chromosome 22 and two different NF2 mutations; if there is a common SMARCB1 mutation, this defines SMARCB1-associated schwannomatosis  
Or

One pathologically proved schwannoma or meningioma AND germline SMARCB1 pathogenic mutation

**CLINICAL DIAGNOSIS:**

\* Two or more nonintradermal schwannomas, one with pathological confirmation, including no bilateral vestibular schwannoma by high-quality MRI (detailed study of internal auditory canal with slices no more than 3mm thick). Recognize that some mosaic NF2 patients will be included in this diagnosis at a young age and that some schwannomatosis patients have been reported to have unilateral vestibular schwannomas or multiple meningiomas.

\* One pathologically confirmed schwannoma or intracranial meningioma AND affected first-degree relative

\* Consider as possible diagnosis if there are two or more nonintradermal tumors but none has been pathologically proven to be a schwannoma; the occurrence of chronic pain in association with the tumor(s) increase the likelihood of schwannomatosis

Patients with the following characteristics do not fulfill diagnosis for schwannomatosis:

\* Germline pathogenic NF2 mutation

\* Fulfill diagnostic criteria for NF2

\* First-degree relative with NF2

\* Schwannomas in previous field of radiation therapy only

**BOX 45-5** Diagnostic Criteria for Tuberous Sclerosis Complex**MAJOR FEATURES**

- Hypomelanotic macules ( $\geq 3$ , at least 5-mm diameter)
- Angiofibromas ( $\geq 3$ ) or fibrous cephalic plaque
- Ungual fibromas ( $\geq 2$ )
- Shagreen patch
- Multiple retinal hamartomas
- Cortical dysplasias\*
- Subependymal nodules
- Subependymal giant cell astrocytoma
- Cardiac rhabdomyoma
- Lymphangiomyomatosis (LAM)<sup>†</sup>
- Angiomyolipomas ( $\geq 2$ )<sup>†</sup>

**MINOR FEATURES**

- "Confetti" skin lesions
- Dental enamel pits ( $>3$ )
- Intraoral fibromas ( $\geq 2$ )
- Retinal achromic patch
- Multiple renal cysts
- Nonrenal hamartomas

**DIAGNOSTIC CERTAINTY CRITERIA****Definite TSC**

- 2 major features or
- 1 major feature + 2 or more minor features
- Identification of a known pathogenic mutation in TSC1 or TSC2

**Probable TSC**

- 1 major feature or
- 2 or more minor features

\*Includes tubers and cerebral white matter radial migration lines.

<sup>†</sup>A combination of the two major clinical features (LAM and angiomyolipomas) without other features does not meet criteria for a definite diagnosis.

Tuberous Sclerosis Complex Diagnostic Criteria Update: Recommendations of the 2012 International Tuberous Sclerosis Complex Consensus Conference, Pediatr Neurol. 2013; 49(4): 243–254.)*

who had died of respiratory distress and was found at post-mortem examination to have multiple cardiac tumors and a "great number of cerebral scleroses." Bourneville usually is credited with the first detailed description of the cerebral manifestations of the disease, describing "sclérose tubéreuse," indicating the superficial resemblance of the lesions of a potato. He attached no significance to the facial skin rash of his first patient, calling it acne rosacea, but he and Brissard believed that the renal tumors and cerebral scleroses were associated findings. Facial angiofibromas, previously referred to as adenoma sebaceum, were independently described in several reports, but Vogt emphasized the association of adenoma sebaceum and the cerebral scleroses described by Bourneville. He also described a "classic" triad of clinical features comprising mental retardation, intractable epilepsy, and adenoma sebaceum, which is now known to be present in less than one-third of patients with TSC.

**Clinical Characteristics**

Diagnostic criteria are provided in [Box 45-5](#). The clinical presentation of TSC depends on the age of the patient, the organs involved, and the severity of involvement. Of importance, both the brain and the skin have more than one major criterion for diagnosis; therefore a diagnosis of definite tuberous sclerosis complex can be based on skin findings alone, or on neuroimaging findings alone.

Epilepsy is the most common presenting symptom in tuberous sclerosis complex and also is the most common medical disorder. In up to 80% to 90% of persons with TSC, seizures will develop during their lifetime, with the onset most frequently in childhood. A majority of children with TSC have the onset of seizures during the first year of life, and approximately one-third develop infantile spasms. Almost all seizure types can be seen in persons with tuberous sclerosis complex, including tonic, clonic, tonic-clonic, atonic, myoclonic, atypical absence, partial, and complex partial. Only "pure" absence seizures are not observed.

Infantile spasms will develop in approximately one-third of children with TSC, although some reports suggest an incidence as high as 75%. TSC is thought to be the most common single cause of infantile spasms, and in some series, 25% of symptomatic infantile spasms are secondary to TSC. Partial complex seizures precede infantile spasms in approximately one-third of patients with tuberous sclerosis complex in whom infantile spasms develop. A strong association between the presence of infantile spasms in tuberous sclerosis complex and subsequent developmental impairment has been noted, although children with tuberous sclerosis complex and infantile spasms can have a normal cognitive outcome.

The electroencephalogram (EEG) in infantile spasms associated with TSC often demonstrates hypsarrhythmia or modified hypsarrhythmia. It is important to realize, however, that the EEG, although usually abnormal, frequently does not have the features of hypsarrhythmia; in some series, up to 70% of children with tuberous sclerosis complex and infantile spasms did not have the characteristics of hypsarrhythmia. Several reports have characterized the EEG patterns of persons with TSC and have found a high incidence of abnormalities, including diffuse slowing and epileptiform features.

TSC is associated with a wide range of cognitive and behavioral manifestations. Approximately one-half of persons with TSC have normal intelligence, whereas the other half have some degree of cognitive impairment, ranging from mild learning disabilities to severe mental retardation. A bimodal distribution of cognitive abilities is evident, with affected persons falling into a severely cognitively impaired group or a group with normal intelligence. Risk factors for cognitive impairment include a history of infantile spasms, intractable epilepsy, and a mutation in the TSC2 gene. Persons with TSC, particularly those with cognitive impairment, also are at high risk for developmental disorders. Autistic spectrum disorders affect up to 50% of persons with tuberous sclerosis complex, and attention-deficit hyperactivity and related disorders also are common, affecting approximately 50% of the patients. During adolescence and adulthood, anxiety disorders, depression, or mood disorders develop in a majority of patients with TSC.

Cutaneous manifestations are found in up to 96% of patients with TSC. Angiofibroma, the skin manifestation initially described in the disorder as adenoma sebaceum, typically appears between the ages of 1 and 4 years and can progress through childhood and adolescence. These lesions typically are pink or red papules that appear in patches or in a butterfly distribution on or about the nose, cheeks, and chin (Fig. 45-10).

Hypopigmented, oval, or leaf-shaped macules, ranging from a few millimeters to several centimeters in length and scattered over the trunk and limbs, are commonly seen. The lesions often are apparent at birth and can appear more prominent during the first several years of life. In fair-skinned

**Figure 45-10.** Typical angiofibroma in an adult with tuberous sclerosis complex. (Courtesy of Dr. TN Darling, Uniformed Services University of Health Sciences, Bethesda, MD.)

persons, visualization of these hypopigmented spots is facilitated by using a Wood's light. At least three types of hypopigmented macules occur: polygonal (similar to a thumbprint) is the most frequent shape (0.5 to 2 cm); an ash leaf-shaped hypopigmented macule is characteristic but is not the most common shape (1 to 12 cm); and a confetti-shaped arrangement of multiple, tiny white macules (1 to 3 mm) (Fig. 45-11). Histologic assessment of the hypopigmented spots usually demonstrates a normal number of melanocytes, and on electron microscopy, a reduction in the number, diameter, and melanization of melanosomes in the melanocytes from the white macule is seen. If hypopigmented macules occur on the scalp, the affected person will have poliosis, or a patch of gray or white hair.

Another skin manifestation currently considered a major criterion for clinical diagnosis of TSC is the shagreen patch, a connective tissue hamartoma that is distributed asymmetrically on the dorsal body surfaces, particularly on the lumbosacral skin (Fig. 45-12). In a majority of the cases, the shagreen patch is characterized by multiple and small areas of connective tissue hamartoma, ranging in size from a few millimeters to 1 cm. Present from birth, the shagreen patch is more easily identified as the child grows. Subungual or periungual fibromas (Koenen tumors) are present in at least 20% of patients and usually first appear during adolescence, although they can be seen earlier. These typically involve the toes more often than the fingers (Fig. 45-13). Oral fibromas or papillomas occur in about 10% of patients and usually are found on the anterior aspect of the gingiva. Dental enamel pits have been found in all adult patients with TSC, compared with 7% of controls.

The kidneys are frequently affected in persons with TSC, and after neurologic manifestations, renal involvement is the most common cause of morbidity and mortality. The two main types of renal lesions are angiomyolipoma and renal cysts. Angiomyolipoma are present in up to 80% of patients with TSC and can develop in either childhood or adulthood. Persons with TSC can have multiple small angiomyolipomas on the surface of the kidneys, throughout the kidney, or one or more larger lesions. The larger lesions are considered to be at greater risk of becoming symptomatic, particularly when they reach 4 to 6 cm in size. They can produce nonspecific complaints such as flank pain, but they also carry a risk of potentially life-threatening hemorrhage from rupture of dysplastic, aneurysmal blood vessels in the angiomyolipoma. Renal cysts are seen in fewer than 20% of persons with tuberous sclerosis complex and are rarely, if ever, symptomatic. Polycystic kidney disease occurs in 3% to 5% of patients with tuberous sclerosis complex and, when present, usually reflects a contiguous gene syndrome, because the polycystic kidney disease gene is adjacent to the TSC2-tuberin gene on chromosome 16.

The cardiac manifestation, rhabdomyoma, is seen in 50% to 60% of persons with TSC. Typically, rhabdomyomas, which can frequently be detected prenatally, are maximal at birth and early childhood and undergo spontaneous regression during the first few years of life. If symptomatic, they result in outflow tract obstruction or valve dysfunction. If the lesions involve the cardiac conduction system, they can predispose the patient to dysrhythmias not only in infancy and childhood, but also throughout life.

Pulmonary involvement includes lymphangioleiomyomatosis, multifocal micronodular pneumocyte hyperplasia, and pulmonary cysts. Although multifocal micronodular pneumocyte hyperplasia is seen fairly commonly in both men and women with tuberous sclerosis complex, lymphangioleiomyomatosis is thought to occur almost exclusively in women. Although lymphangioleiomyomatosis was once thought to be quite rare, affecting less than 1% of women, recent studies

have found such abnormalities in up to 40% of women with, many of whom are asymptomatic.

Retinal hamartomas are relatively common, affecting at least 50% of patients, although typically they are not clinically significant. A nodular (mulberry) tumor can be seen on or about the optic nerve head, and round or oval gray-yellow glial patches can be central or peripheral. The large retinal tumors can be cystic. Papilledema is not present, except in those patients with an intracranial mass lesion that obstructs the normal circulation of the cerebrospinal fluid, resulting in increased intracranial pressure.

Hamartomas also can be found in other organ systems, including stomach, intestine, colon, pancreas, and liver. Hepatic angiomyolipoma and cysts have been reported in up to 24% of persons with and are thought to be asymptomatic and nonprogressive. Sclerotic and hypertrophic lesions of bone often can be seen, although these typically are not symptomatic.

### Clinical Laboratory Testing

Due to multiorgan involvement in TSC, a variety of clinical testing is recommended both at time of diagnosis and subsequently, to monitor for involvement and allow appropriate intervention (Table 45-2).

MRI and also computed tomography (CT), are important in confirming the diagnosis of TSC, demonstrating cortical tubers, subependymal nodules (Fig. 45-14), and subependymal giant cell tumors (Fig. 45-15). Brain MRI is the preferred imaging modality, because it allows better delineation of cortical tubers and other cortical abnormalities, such as radial migration lines. The imaging characteristics of tubers change with age, related to myelination state. In neonates, tubers appear hyperintense on T1 sequences and hypointense on T2. With increasing age, tubers appear isointense on T1 and hyperintense on T2. In addition to T1-weighted and T2-weighted MRI sequences, fluid-attenuated inversion recovery (FLAIR) sequences appear most useful for identifying tubers and other cortical and subcortical abnormalities. Both CT and MRI can identify subependymal nodules; calcification of the nodules is apparent on CT scan. Development of subependymal nodules into subependymal giant cell tumors occurs in 5% to 10% of persons with TSC; yearly neuroimaging is until the age of 20 years.

### Pathology

TSC is a multisystem disorder of cellular migration, proliferation, and differentiation, resulting in the development of hamartias and hamartomas. The major pathologic features in the brain include cortical tubers, subependymal nodules, and subependymal giant cell tumors. Cortical tubers are found in the cortex and subcortical white matter, typically located at the gray-white junction. They vary widely in size and distribution among patients with TSC and may extend centrally in a linear or wedge-shaped zone spanning the full thickness from the ventricular wall to the cortical surface. Histologically, tubers consist of dysplastic, hypomyelinated aggregates of abnormal glial and neural elements, with glia-derived cells and astrocytes predominating. A distinguishing feature of cortical tubers is the giant cell, an enlarged, bizarre-appearing neuron or large cells with both neuronal and glial characteristics. Many children with TSC may experience learning difficulties, as a result of mental retardation or autistic spectrum disorders. Risk factors include early seizure onset, infantile spasms, and an intractable seizure disorder. Correlation between the severity of cognitive deficits and epilepsy with tuber burden is thought

probable, although the data are limited. Distinct from cortical tubers, subependymal nodules do have growth potential and are located around the wall of the lateral ventricle, consisting of astrocytes arising from the subependymal zone and protruding into the ventricles. Subependymal nodules most commonly occur at the caudothalamic groove in the vicinity of the foramen of Monro, and it is thought that they arise from remnants of the germinal matrix in that region.

### Genetics

TSC is transmitted as an autosomal-dominant trait with variable penetrance and an estimated incidence of 1 in 5800 live births worldwide. Wide phenotypic variability of clinical manifestations and severity has been noted, even within families having the same mutation. Currently, no known effect of paternal or maternal age or of birth order on disease phenotype has been recognized. Approximately two-thirds of cases are sporadic and the result of apparent spontaneous mutations. Both somatic and germline mosaicism have been described in many patients.

Two genes, TSC1 and TSC2, have been identified for tuberous sclerosis complex. A disease causing mutation in one of these two genes can be identified in approximately 85% of persons with definite tuberous sclerosis complex according to current criteria. TSC1 located at 9q34; it was cloned in 1997, and the protein product, hamartin, was identified and characterized. The TSC2 gene is located on 16p13 and encodes a protein referred to as tuberin.

Tuberin and hamartin interact with one another and function as tumor suppressor molecules. Loss of heterozygosity has been identified in hamartomas from persons with TSC1 and TSC2 mutations, particularly in kidney and lung tissue, but less commonly in cortical tubers or subependymal giant cell astrocytomas. Tuberin has GTPase-activating properties, similar to the NF1 protein product. Hamartin and tuberin are components of the mammalian target of rapamycin (mTOR) pathway, which is involved in many functions, including regulation of cell size. In vivo, it appears that tuberin can be phosphorylated by Akt, at least in part regulating its activity. In normal cells, the tuberin/hamartin complex acts as an inhibitor of mTOR activity. On growth factor stimulation or other stimuli, tuberin is phosphorylated by Akt, which leads to the inactivation of inhibitory activity of TSC1/TSC2 and resultant cell growth. In cells containing mutations affecting the function of hamartin or tuberin, mTOR and S6 kinase activities are significantly increased, and cell growth is no longer regulated by the PI3-kinase-TSC1/TSC2 signaling pathway, which is thought to lead to the development of hamartoma.

### Management

TSC affects most organ systems, and management and treatment recommendations vary according to organ manifestations (Table 45-2). Affected persons, both children and adults, should be managed with regular follow-up evaluations by a physician who is familiar with tuberous sclerosis complex, to recognize treatable manifestations early and to provide anticipatory guidance and counseling.

With regard to neurologic manifestations, management focuses on treatment of epilepsy and behavioral disorders and on identification of learning disabilities. Treatment of epilepsy in TSC is similar to that for partial epilepsies resulting from other causes and includes antiepileptic medications, the vagus nerve stimulator, and the ketogenic diet. Vigabatrin is particularly effective in treating infantile spasms in patients with tuberous sclerosis complex. Epilepsy surgery has a very

important role in the management of patients who have pharmacoresistant epilepsy.

Rapamycin, an mTOR antagonist, has been shown to reduce the size of subependymal giant cell tumors and renal angiomyolipoma in tuberous sclerosis complex and may also reduce the progression of pulmonary lymphangiomyomatosis. In animal models of TSC, rapamycin has also been shown to prevent epilepsy if given prenatally and to improve cognitive deficits. Ongoing multicenter trials are evaluating the role of rapamycin and other mTOR antagonists in the management of TSC. One rapamycin-like drug, everolimus, is FDA approved for treatment of progressive subependymal giant cell astrocytoma or renal angiomyolipoma.

## VON HIPPEL-LINDAU DISEASE (VHL)

Von Hippel-Lindau disease is inherited as an autosomal-dominant trait and is characterized by retinal, cerebellar, and spinal hemangioblastomas, cystic tumors of the pancreas, kidney, and epididymis, renal cell carcinoma, endolymphatic sac tumors, and, in some families, pheochromocytoma (Maher et al., 2011).

### Clinical Characteristics

Retinal hemangioblastoma is one of the earliest manifestations of the disease. The early retinal lesion has the appearance of an aneurysmal dilatation of a peripheral retinal vessel; typically, tortuous vessels later manifest, with an arteriovenous pair leading to small, elevated retinal lesions. These lesions commonly are located in the retinal periphery and can easily be overlooked unless careful ophthalmoscopy is performed. Fluorescein angiography is helpful in demonstrating the lesion.

Although they usually affect the cerebellum, central nervous system hemangioblastomas sometimes are found in the medulla and spinal cord; they rarely occur in the cerebral hemispheres. The tumor usually is found in patients after the third decade of life but has been reported to occur rarely in children; initial symptoms and signs are those of a space-occupying lesion of the posterior fossa.

A variety of renal lesions has been found in VHL, including benign cysts, hemangiomas, adenomas, and malignant hypernephromas. Cystic lesions vary in size, ranging from a few millimeters to several centimeters across, and, although they can occur unilaterally, these lesions are more often bilateral and multiple. Renal cell carcinoma is a prominent cause of morbidity and mortality, occurring with a frequency next to that of the retinal and cerebellar hemangioblastoma.

Cystic lesions can also occur in the pancreas, adrenal gland, and epididymis. Other organs less commonly affected with cystic changes include the liver, spleen, and lung. Endolymphatic sac tumors associated with VHL can cause hearing loss. Pheochromocytomas occur more often in patients with von VHL than in the general population and tend to cluster in certain families.

The retinal hemangioblastoma diagnosis usually is established by careful ophthalmoscopy with fluorescein retinal angiography, revealing the vascular characteristics of the lesions. Cranial MRI scans demonstrate the cerebellar hemangioblastoma or those tumors affecting the medulla and spinal cord. Intraabdominal cystic lesions can be visualized by CT, MRI, or ultrasonography. Other laboratory studies that can assist in diagnosis include erythrocyte count and hematocrit determination, which can be elevated in patients with cerebellar hemangioblastoma or renal carcinoma because of the increased erythropoietin activity of the cyst fluid.

### Pathology

The tumors usually are well circumscribed, can be solid or cystic, and usually are found in the paramedial aspect of the cerebellar cortex. Characteristic microscopic features include large numbers of thin-walled, closely packed blood vessels lined by plump endothelial cells; the cells are separated by large, pale cells and incorporated in the elaborate network of reticulin fibers.

### Genetics

VHL disease is inherited as an autosomal-dominant trait. The birth incidence is about 1 in 36,000 persons, and point prevalence has been estimated at 1 in 91,000. Penetrance is nearly complete on careful evaluation. The gene is located on 3p25–26, and encodes a protein that regulates a cellular system that senses and responds to hypoxia. The VHL gene functions as a tumor suppressor; hence, homozygous mutation occurs in tumors, leading to loss of function and constitutive activation of the hypoxia-sensing pathway. Genetic testing is available and has revealed that specific mutations tend to be found in families with von Hippel-Lindau disease associated with pheochromocytoma. VHL disease has been subdivided into type 1, in which all of the manifestations may be present except for pheochromocytoma, and type 2, which includes the full set of features. Type 2 is further divided into 2A (pheochromocytoma and other manifestations, but not renal cell carcinoma), 2B (all features), and 2C (isolated pheochromocytoma).

### Management

Affected individuals should be provided a program of surveillance to insure early recognition of treatable complications. Recommendations of the VHL Family Alliance are provided in Table 45-3. Retinal hemangioblastomas should be carefully followed by serial ophthalmologic evaluations when the lesions are small. If, however, visual loss or retinal detachment occurs, the lesions can be treated by either laser photocoagulation or cryocoagulation. Central nervous systems lesions are usually treated surgically or with stereotactic radiation therapy. Medical therapy for the various complications of VHL is currently under investigation.

## STURGE-WEBER SYNDROME (ENCEPHALOFACIAL ANGIOMATOSIS) (SWS)

Sturge-Weber syndrome is characterized by presence of a facial angioma (port-wine stain, or nevus flammeus) and an ipsilateral leptomeningeal angioma; it has an incidence currently estimated at 1 case in 20,000 to 50,000 persons. Schirmer initially described a patient with a facial vascular nevus who had associated buphthalmos, but he did not mention the central nervous system lesion. Sturge initially described this syndrome by providing the clinical findings of a 6-year-old girl with a facial nevus who also had angiomas of the lips, gingiva, palate, floor of the mouth, uvula, and pharynx. The child had buphthalmos and was hemiparetic, and Sturge suggested that she had a similar vascular nevus of the underlying brain. Not until 1897, however, did Kalischer perform the first neuropathologic study of a patient with similar findings, demonstrating that Sturge's initial contention of cerebral involvement by vascular nevus was correct. Associated intracranial calcification was later described by Weber.

## Clinical Characteristics

SWS, which occurs sporadically, is characterized by angiomas involving the leptomeninges and ipsilateral skin of the face, typically in the ophthalmic (V1) and maxillary (V2) distributions of the trigeminal nerve. It can extend to other facial areas, including the lips, gingiva, palate, tongue, pharynx, and larynx. The neck, trunk, and extremities also can be involved, either ipsilaterally or contralaterally to the facial angioma. The angioma also can involve the nasopharynx, mucous membrane, and ocular choroidal membrane, resulting in glaucoma in approximately 25% of patients (Fig. 45-17). Additional ocular findings include iridic heterochromia, strabismus, optic atrophy, and dilated retinal veins. In the brain, the associated ipsilateral leptomeningeal angioma most commonly involves the parietal and occipital regions, but also may involve the temporal region and, on occasion, can affect both hemispheres. Dimitri reported that these patients had intracranial calcifications observed on the skull radiographs and described the typical serpentine "tram-track sign" of calcific intracranial densities.

Neurologic manifestations vary and depend on location and extent of the leptomeningeal angioma. Seizures occur in 75% to 90% of patients with SWS and may be refractory to treatment. It is hypothesized that the seizure activity results from cortical irritability caused by the leptomeningeal angioma, resulting in regional hypoxia, ischemia, and gliosis, although associated cortical dysgenesis also may be involved. Seizure manifestations are primarily partial motor (40%), although some patients can have primary or secondary generalized tonic-clonic (20%) and both partial and generalized seizures (40%). Other types of seizure activity occur less frequently. Unfortunately, refractory epilepsy develops in a significant number of patients with Sturge-Weber syndrome, ranging in series from 11% to 83%. Surgical procedures, including focal cortical resection, hemispherectomy, and corpus callosotomy, should be considered if seizure activity proves medically intractable.

Persons with SWS also are at risk for hemiparesis contralateral to the leptomeningeal angioma, seen in approximately 33% of patients. The hemiparesis can result from ischemia with venous occlusion and thrombosis due in part to venous congestion resulting from failure of cortical vein development. Transient weakness also may result from seizure activity and may become more severe and less transient with recurrent seizure activity. Leptomeningeal venous angiomas can arise in the absence of any facial angioma; although secondary cerebral signs and symptoms similar to those of SWS can occur, these patients are more appropriately considered to have leptomeningeal angiomatosis.

Persons with SWS also are at risk for developmental delay and mental retardation (50% to 60%) and are more likely in those with bilateral leptomeningeal involvement and in those with a history of seizures. Headaches also are common, occurring in up to 60% of affected persons, and are thought to be secondary to the vascular abnormalities, giving symptoms consistent with migraine. EEG studies document decreased amplitude and frequency of electrocerebral activity over the affected hemisphere. Diffuse, multiple, and independent spike foci commonly are present.

Hemianopsia in young patients also is difficult to determine but is believed to occur in about one-quarter to one-half of patients. About one-third of patients have glaucoma, and approximately half of these have buphthalmos ipsilateral to the facial angioma. Glaucoma can be unilateral or bilateral, regardless of whether the facial angioma is bilateral.

Intracranial calcification is evident on radiographs in 90% of adult patients. Calcifications uncommonly are present at

birth but are manifest in virtually all patients by the end of the second decade of life. The intracranial calcifications typically assume a linear, parallel configuration ("tram-track sign"), or a convoluted pattern most commonly seen in the parietal or parietooccipital regions (Fig. 45-18). Cranial CT and MRI scans are complementary in evaluating the cerebral changes of SWS, in that the MRI demonstrates thickened cortex, decreased convolutions, and abnormal white matter, whereas cranial CT scans demonstrate more definitively the characteristic calcification. Cranial MRI scans (T2-weighted images) reveal smaller, nonspecific foci of hypointense signal. Gadolinium enhancement may reveal pial angioma, thereby allowing early diagnosis of SWS before calcification.

Cerebral angiography discloses decreased cerebral venous drainage with dilatation of the deep cerebral veins. Various other vascular abnormalities have been demonstrated in approximately one-third of patients and include thrombotic lesions, dural venous sinus abnormalities, and arteriovenous malformations. PET provides a sensitive measure of the extent of cerebral metabolic impairment. Serial PET scans in children with SWS can be useful and, when used with other neuroimaging studies, document the progression of the disease.

## Pathology

SWS is thought to be caused by the presence of residual embryonal blood vessels and their secondary effects on surrounding tissues. During development, a vascular plexus develops around the cephalic portion of the neural tube, under the ectoderm that subsequently becomes facial skin. This plexus forms during the sixth week of gestation and regresses at approximately the ninth week. It is thought that failure of this regression results in residual vascular tissue, subsequently forming the angiomas of the leptomeninges, face, and ipsilateral eye. Neuropathologic studies have demonstrated thickened, hypervascularized leptomeninges that involve the occipital, parietal, or temporoparietal region primarily (Fig. 45-19). These meningeal vessels generally are small and tortuous and rarely enter the underlying brain substance. Calcific deposits are present in the walls of some small cerebral vessels but more commonly are found in the outer pyramidal and molecular cortical layers. Biochemical assays have demonstrated increased calcium content of the gray and white matter, with normal iron content. The pathophysiology of the deposition of intracerebral calcium is not well understood.

## Management

Treatment for the neurologic manifestations of SWS includes management of seizure activity and headaches. Approximately 50% of children with seizures achieve control with administration of appropriate antiepileptic drugs. Those patients with seizure disorders refractory to medical treatment should be carefully considered for epilepsy surgery with resection of the affected lobe(s) or hemispherectomy. Rochkind and colleagues reported that seizure control after surgery was better in those patients who received antiepileptic drugs. Aspirin therapy may reduce the incidence of stroke-like episodes and is typically used in individuals with either recurrent vascular events or progressive neurologic deficits. Treatment options for the facial angioma include laser therapy using various pulsed-dye lasers, as well as pulsed-light sources, and other laser therapies. The current recommendation is to begin treatment as early as possible; infants have received treatment during the first week of life. Treatment of glaucoma, if present, consists of control of intraocular pressure, to prevent optic nerve injury, by

medical or surgical intervention. The management of patients with SWS requires the skill of an attentive physician, psychologist, and social worker.

### MAFFUCCI SYNDROME

Maffucci syndrome is a rare congenital disease characterized by multiple enchondromas with secondary hemangiomas, phlebolithiasis, and malformations of bone. Occasionally, associated skin changes, including patches of vitiligo, café-au-lait spots, and other hyperpigmented patches and nevi, are seen. A related disorder, Ollier disease, is characterized by multiple enchondromas without hemangiomas. Both are sporadic and have been found to be due to somatic mosaicism of IDH1 or IDH2 genes. No single treatment plan exists, because each patient must be individually managed.

### EPIDERMAL NEVUS SYNDROME

Epidermal nevus syndrome is a heterogeneous group of disorders characterized by patchy cutaneous hamartomatous lesions, central nervous system abnormalities, and various other manifestations (Table 45-4) (Happle, 2010a; Happle, 2010b). Most of these disorders occur sporadically and are highly variable in their presentation. Central nervous system manifestations include unilateral lissencephaly, a paucity of white matter, excessive and heterotopic gray matter, apparent schizencephaly, unilateral colpocephaly, and hemimegalencephaly. Associated neurologic abnormalities include intellectual disability and convulsive disorders. Cortical resection has been helpful in some instances, but no other definitive treatment exists.

The patchy manifestations of these disorders have suggested the possibility that they result from somatic mosaicism; this has been demonstrated in some instances of PTEN hamartoma syndrome, in which mosaicism for PTEN has been found. In the past, these patients were erroneously described as having Proteus syndrome, but it is now known that Proteus syndrome results from mosaic mutations in AKT1.

### PARRY-ROMBERG SYNDROME (FACIAL HEMIATROPHY)

Parry-Romberg syndrome, which typically has onset between 5 and 15 years of age, is characterized by a progressive ipsilateral loss of facial soft tissue, cartilage, and bone. This tissue loss usually involves the tissues between the nose and nasolabial fold or above the maxilla, but progresses to affect most of the ipsilateral face during the ensuing years. The tongue, the gums, and the soft palate may also become involved. The eyelashes, eyebrows, and hair on the involved side can be affected, and ipsilateral blanching of the hair or alopecia can occur. Progression of this atrophic process generally lasts between 2 and 10 years and is believed to cease by the end of the second or beginning of the third decade of life. In addition to atrophy of the facial tissues, various other neurologic deficits have been reported, including recurrent headaches, trigeminal neuralgia, ipsilateral Horner syndrome, contralateral partial seizures, and hemiparesis. Moreover, an unusual association of the syndrome with multiple benign tumors has been described. Scleroderma and lipodystrophy must be clinically differentiated from this disease. Cranial imaging can be normal or document cerebral atrophy, encephalomalacia, and abnormal T2 signal intensities. No typical or consistent neuropathologic findings have been reported. No specific treatment for the syndrome exists; however, various reconstructive surgical procedures, often using grafts of autogenous fat after

disease stabilizes, can result in reasonably good cosmetic results.

### NEUROCUTANEOUS MELANOSIS

Neurocutaneous melanosis is a rare, nonfamilial, embryonic, neuroectodermal dysplasia characterized by abnormally pigmented cutaneous areas (e.g., giant hairy pigmented nevi, multiple hyperpigmented cutaneous nevi, large congenital melanocytic nevi) and leptomeningeal melanosis (Gerami and Paller, 2013). Diagnosis is usually made in infants and children younger than 2 years of age; however, the condition is present at birth. No gender predilection exists. All patients have areas of abnormal skin hyperpigmentation, the most common pattern of which is multiple giant hairy pigmented nevi. Giant hairy nevi usually have a "bathing suit" or cape-shaped distribution. The presence of multiple satellite lesions, large size, and midline location for pigmented lesions are predictive of neurologic involvement. Mosaicism for specific mutations in the NRAS oncogene have been identified as the underlying cause of this disorder. This suggests the possible use of drugs that block RAS signaling in therapy.

The clinical presentation of neurocutaneous melanosis depends on the location and extent of involvement of this leptomeningeal lesion. Hydrocephalus is commonly encountered because of cerebrospinal fluid pathway obstruction in the basilar cisterns, the arachnoid villi over the cerebral hemispheric convexities, or both, and intraspinal melanotic arachnoid cyst, lipoma, and intraspinal lipoma have been described as obstructed. Association with Dandy-Walker malformation has been reported. Behavioral abnormalities and recurring seizures can occur, as well as cranial nerve dysfunction and signs of spinal cord and root involvement. Attempts to treat hydrocephalus by a shunting procedure are palliative. There is a risk of melanoma.

### KLIPEL-TRÉNAUNAY-WEBER SYNDROME (KTW)

Klippel-Trénaunay-Weber syndrome initially was believed to be characterized only by cutaneous and/or subcutaneous hemangiomas, varicosities, and hypertrophy of the soft tissues and bone of a limb. Additional associated anomalies later recognized included macrocephaly; hydrocephalus; lymphangiomas; hemangiomas of the trunk, intestine, and bladder; and abnormalities of the digits. KTW usually occurs sporadically. Another disorder associated with vascular malformations as well as skeletal anomalies, lipomatous overgrowth, and epidermal nevi, referred to as CLOVES syndrome, is associated with mosaic PIK3CA mutations.

Limb hypertrophy usually is apparent at birth. Lymphedema can be present. An inordinately progressive growth of the affected body part eventually occurs, leading to the development of various other abnormalities. Abnormal growth of one leg, for example, can result in a pelvic tilt and scoliosis, but the patient's overall height is not significantly changed. The legs are affected more commonly than the arms. Additional abnormalities include megalocornea, glaucoma, iridic heterochromia, syndactyly, polydactyly, macrodactyly, and clinodactyly. Hemangiomas of the tongue, pharynx, larynx, and bladder have been described, and labial and scrotal lesions are common. Macrocephaly often is present, and seizures and mental retardation have been reported.

Any treatment plan for these patients must be individualized and requires a multidisciplinary team. Nonsurgical management involves compression of the involved limb. MRI or CT venography can be performed if any vascular surgical

procedure is contemplated. Some vascular lesions can be treated with cryotherapy, laser therapy, or sclerotherapy, whereas others can be surgically removed. An osteotomy or epiphyseal stapling procedure can occasionally benefit patients with limb hypertrophy, but limb amputations may be required in others.

### INCONTINENTIA PIGMENTI (BLOCH-SULZBERGER SYNDROME)

Incontinentia pigmenti is transmitted as an X-linked dominant trait, predominantly affecting females. Most hemizygous males apparently die in utero. The gene responsible for disorder is *IKBKKG/NEMO*, which regulates nuclear factor kappa b signaling. Most mutations lead to loss of function with the most common, accounting for 78% of cases, an intragenic deletion involving exons 4 to 10. The syndrome is characterized by various hyperpigmented skin lesions that can be apparent at birth and by commonly associated abnormalities involving the central nervous system, eyes, hair, teeth, and bone (Minić et al., 2014).

The skin manifestations have been described as having three stages. The first stage typically is characterized by vesiculobullous lesions present at birth or during the first several weeks of life. These lesions appear in groups or in a linear distribution over the trunk and limbs, following the lines of Blaschko. A preponderance of eosinophils is found in the vesicular fluid, and the peripheral blood also can exhibit an eosinophilia. The lesions rupture, resulting in oozing and crusting, and can persist for months. The second stage is characterized by evolution into verrucous lesions beginning after the sixth week of life. The third stage typically is characterized by hyperpigmented brown or gray-brown macular lesions that follow the lines of Blaschko. These pigmented skin lesions usually become more prominent during the first few years of life and then gradually fade. The decrease of abnormal pigmentation may continue throughout adolescence, and in some patients the pigmentation can completely disappear.

One-third to one-half of patients have symptoms and signs of neurologic abnormalities manifested by developmental disability, corticospinal tract dysfunction, and seizures. Microcephaly and hydrocephaly may occur. Approximately one-third of patients have ocular abnormalities, including optic atrophy, papillitis, abnormal retinal pigmentation, nystagmus, strabismus, and cataracts. Visual loss occurs in about 8% of patients. The most common ocular abnormalities are retinal detachment and a fibrovascular retrolental membrane.

There are often associated ectodermal and skeletal anomalies. Skin changes include atrophic scarring and alopecia, and nails can be flat and thin, commonly with transverse ridges. Skeletal abnormalities include spina bifida, hemivertebrae, accessory ribs, and syndactyly. Delayed dentition, pegged teeth, and abnormal crown formation are also seen. Treatment remains symptomatic and supportive.

### INCONTINENTIA PIGMENTI ACHROMIANS (HYPOMELANOSIS OF ITO)

Incontinentia pigmenti achromians has been known as systemic achromic nevus and hypomelanosis of Ito (Pavone et al., 2015). Typical skin changes occur as hypopigmented lesions on any part of the head, trunk, or limbs, either unilaterally or bilaterally. The configuration of the hypopigmented lesions may manifest as linear streaks or whorls of hypopigmentation that follow the lines of Blaschko. The skin lesions are congenital. Multiple associated anomalies are common and can involve the central nervous system or the peripheral

nervous system, eyes, and bone. Common central nervous system abnormalities include mental retardation, language disabilities, seizures, and motor system dysfunction. Ocular abnormalities include strabismus, epicanthic folds, myopia, optic nerve hypoplasia, and hypopigmentation of the fundus; rarely, corneal asymmetry, pannus, and atrophic irides with irregular pupillary margins have been reported. Cataracts and retinal detachments also have been reported.

Characteristic histologic features of skin biopsy specimens include dyskeratosis, increased dermal mastocytes, and pilosebaceous abnormalities.

Hypomelanosis of Ito occurs sporadically and in many cases has been found to be associated with mosaicism for chromosomal abnormalities. The abnormal cells may be confined to the skin lesions and therefore are detected only by cytogenetic analysis of cultured fibroblasts obtained by skin biopsy. No single chromosome abnormality accounts for all cases; rather, it appears that the streaky hypopigmentation associated with the disorder, or sometimes patches of hyperpigmentation following Blaschko's lines, are the cutaneous manifestation of mosaicism for various genes or chromosomal regions.

### WYBURN-MASON SYNDROME (RETINOCEPHALIC ANGIOMATOSIS)

Although known as Bonnet-Dechaum-Blanc syndrome in Europe and as Wyburn-Mason syndrome in the United Kingdom and the United States, the condition is more appropriately called a retinocephalic vascular malformation (Fileta et al., 2014). The syndrome is thought to result from an embryonic abnormality in the development of the optic nerve pathway and related vessels from its origin in the mesencephalon all the way to the projection to the retina.

The intracranial vascular malformation usually is deep within the brain substance and can involve the mesencephalon, diencephalon, and basal ganglia, extending to the visual pathways and chiasm. Variable involvement of the cranial nerves occurs, including the third, sixth, seventh, and eighth nerves; nystagmus and Parinaud syndrome have been reported. Corticospinal tract dysfunction can be unilateral or bilateral, and some patients are ataxic. Approximately one-half of patients have vascular malformations that affect the palate, oral mucosa, maxilla, and mandible. Cutaneous lesions also can occur, manifesting as angiomas or punctate erythematous lesions.

The diagnosis of this syndrome is initially considered when the retinal vascular lesion is observed. Cranial CT and MRI scans clearly demonstrate arteriovenous malformation, but only cerebral angiography reliably delineates the extent of the lesion. No beneficial treatment method is currently available for this syndrome. The surgical removal of part or all of the extensive vascular malformation cannot be performed with any practical success, and the use of rigorous radiologic interventional techniques has been unsuccessful.

## Disorders of Vitamin Metabolism

Barbara Plecko and Robert Steinfeld

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Vitamins are essential nutritional compounds and work as cofactors of various enzymes. Vitamin deficiency disorders are seen in developing countries and in patients with chronic disease and can affect the central and/or peripheral nervous system, often in the context of a multisystem disease (Kumar, 2010). The vitamin supply of breastfed infants is directly related to maternal nutrition. Hypervitaminoses are seen in faddists and in cases of long-term overdose of vitamin supplements. Nutritional sources, cofactor function, age-dependent daily allowances, signs of deficiency, dosages for treatment of respective vitamin deficiencies, and signs of hypervitaminosis are given in Table 46-1.

In addition to nutritional disorders of vitamin metabolism, there is a growing number of inherited inborn errors of metabolism (IEMs) that affect specific steps of vitamin transport and processing or lead to selective vitamin inactivation. Rapid recognition and treatment of the underlying cause are warranted to avoid irreversible damage.

### THIAMINE (VITAMIN B<sub>1</sub>)

Thiamine is absorbed in the upper small intestine and is transported across cell membranes by two transporters, encoded by *SLC19A2* and *SLC19A3*. Within the cell, thiamine is phosphorylated to its active form, thiamine pyrophosphate (TPP), and works as a cofactor of the cytosolic transketolase. Another solute carrier, encoded by *SLC25A19*, imports TPP into mitochondria, where it finally acts as a cofactor of the pyruvate dehydrogenase complex, the branched chain keto-thiolase dehydrogenase, and the alpha-ketoglutarate dehydrogenase. Two diseases are linked to vitamin B<sub>1</sub> deficiency: beriberi and the more severe Wernicke's syndrome. Wernicke's disease is still one of the more frequently encountered vitamin deficiency syndromes, and in developed countries, it occurs in patients with severe chronic disorders, malnutrition, or chronic alcohol abuse. In infancy, thiamine deficiency has been reported with breastfeeding by thiamine-deficient mothers and in infants fed with soybean or other formulas in which the thiamine was presumably heat-inactivated during preparation. Infantile thiamine deficiency is characterized by a multisystem presentation, with vomiting, aphonia, abdominal distention, diarrhea, cyanosis, tachycardia, and convulsions. In less fulminant cases, infants have failure to thrive and developmental delay followed by edema, oliguria, constipation, cardiomegaly, and hepatomegaly. Cranial imaging may show signal hyperintensities in T2-weighted images localized in the periventricular gray matter around the third ventricle, sylvian aqueduct, fourth ventricle, and mammillary bodies.

Increased lactate in plasma or cerebrospinal fluid (CSF) and urinary excretion of less than 120 mg of thiamine per gram of creatinine would support the diagnosis. Clinical response to the administration of thiamine is the best confirmatory test. Oral administration of 10 to 50 mg of thiamine daily will reverse clinical symptoms in a few weeks. Serious life-threatening neurologic manifestations or congestive heart failure should be treated with the parenteral administration

of 5 to 20 mg of thiamine and may lead to severe long-term sequelae.

Genetic disorders affecting thiamine transport or activation present with surprisingly divergent symptoms and variable age (Brown, 2014).

### Rogers Syndrome

Rogers syndrome (Online Inheritance in Man [OMIM] 249270) is caused by autosomal-recessive mutations in the *SLC19A2* transporter and manifests with thiamine-responsive megaloblastic anemia, type 2 diabetes mellitus, and sensorineural deafness. Thiamine levels in plasma are normal, but the presence of sideroblasts in bone marrow suggests the diagnosis. Treatment consists of 25 to 75 mg of oral thiamine per day. Although most manifestations are thiamine responsive, hearing loss may be irreversible.

### Biotin- or Thiamine Responsive Basal Ganglia Disease

Biotin- or thiamine-responsive basal ganglia disease (BTBGD; OMIM 607483) is a panethnic, autosomal-recessive disease that is triggered by febrile infections, stress, or trauma. The typical onset is during early childhood, but onset can range from the neonatal period to adulthood. Major symptoms are subacute-onset encephalopathy, confusion, dystonia, ataxia, dysarthria, dysphagia, pyramidal tract signs, external ophthalmoplegia, and partial or generalized seizures. Episodes are followed by slow subtotal recovery and subsequent relapses. If left untreated the disease can lead to coma and, ultimately, death. T2-weighted magnetic resonance imaging (MRI) reveals bilateral signal intensities of the striatum in addition to cortical and subcortical lesions. Chronic changes include atrophy, necrosis, and gliosis (Ortigoza-Escobar et al., 2014).

BTBGD is caused by mutations in the *SLC19A3* gene, which encodes a thiamine transporter, and a rapidly growing phenotypic spectrum—from neonatal encephalopathy with lactic acidosis to seizures with generalized dystonia—has been described. The partial response to biotin is not fully understood to date. Routine metabolic testing is normal, with the exception of elevated lactic acid during the acute phase, but measurement of free thiamine in CSF may become a valuable diagnostic screening tool. Confirmation is by genetic analysis of the *SLC19A3* gene. Treatment consists of regular oral supplementation of thiamine, 300 to 900 mg/day. During subsequent exacerbation the usual thiamine dose may be doubled and given intravenously. An add-on of biotin, 5 to 10 mg/kg per day, may lead to faster recovery. Antipyretics are essential because fever may trigger decompensation.

### Thiamine Pyrophosphokinase Deficiency

Autosomal-recessive thiamine pyrophosphokinase deficiency (OMIM 606370) presents with a late-onset Leigh-like disease and basal ganglia changes on MRI. During acute episodes,

elevated blood and CSF lactate and enhanced excretion of  $\alpha$ -ketoglutarate are consistent findings. Thiamine pyrophosphate (TPP) concentrations in blood and muscle are reduced, and diagnosis is confirmed by sequencing of the *TPK1* gene. Thiamine supplementation at 100- to 200 mg/day was of limited benefit in symptomatic patients. Earlier intervention with doses around 500 mg/day may be associated with better prognosis.

### Amish Lethal Microcephaly and Bilateral Striatal Necrosis Resulting From *SLC25A19* Mutations

Amish lethal microcephaly and bilateral striatal necrosis (OMIM 607196) is caused by mutations in the *SLC25A19* gene, which encodes the transport of TPP into the mitochondria. The Amish founder mutation is associated with severe microcephaly at birth and a very short life span. Patients typically show excretion of  $\alpha$ -ketoglutarate and lactic acidosis during febrile infections. A few patients with different *SLC25A19* mutations have been described outside the Amish community; these patients presented with associated CNS malformation or bilateral striatal necrosis but a normal head circumference.

In addition to these primary defects in thiamine transport and activation, some enzyme defects may have a favorable response to thiamine administration. Among these are pyruvate dehydrogenase complex and pyruvate carboxylase deficiency and some forms of maple syrup urine disease.

### RIBOFLAVIN (VITAMIN B<sub>2</sub>)

Riboflavin is the precursor of the metabolically active forms flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD), which function as cofactors for at least 90 different flavin-dependent proteins (flavoproteins). Flavin-dependent enzymes catalyze oxidation–reduction processes in primary metabolic pathways such as the citric acid cycle,  $\beta$ -oxidation, and degradation of amino acids. Flavin-dependent proteins also play an important role in the biosynthesis or regulation of other essential cofactors and hormones, such as coenzyme A, coenzyme Q, heme, pyridoxal 5'-phosphate, folate, cobalamin, steroids, and thyroxine.

### Riboflavin Deficiency

Symptomatic riboflavin deficiency commonly occurs in association with deficiencies of other vitamins. Details are described in Table 46-1.

### Riboflavin-Dependent Enzymatic Reactions

At least 50 different deficiencies of flavoproteins have been associated with an inherited human disease. Because a significant proportion of mutations in flavoproteins affect the affinity to their cofactors, a supranormal intake of riboflavin can lead to functional rescue. Disorders that may respond to high riboflavin doses (100-300 mg) include deficiencies of multiple acyl-CoA dehydrogenase, dihydrolipoamide dehydrogenase, and acyl-CoA dehydrogenase-9 (Table 46-2).

### DISORDERS OF RIBOFLAVIN TRANSPORT

At least three distinct riboflavin transporters, *SLC52A1* through *SLC52A3*, are involved in riboflavin uptake via the human intestine. The relative contribution and role of these transporters are currently unclear, but deficiency of *SLC52A2* and *SLC52A3* is associated with genetic neuropathies.

### Riboflavin Deficiency

Haploinsufficiency of the *SLC52A1* riboflavin transporter has been reported with mild riboflavin deficiency (OMIM 615026) in a mother whose newborn child developed transient severe symptoms resembling clinical and biochemical features of multiple acyl-CoA dehydrogenase deficiency. Oral supplementation of 100 mg riboflavin per day rapidly normalized the biochemical parameters and clinical condition. The mother was treated with 50 mg of riboflavin per day.

### Riboflavin Transporter Deficiency Neuropathy

Type 1 riboflavin transporter deficiency neuropathy, also referred to as Brown–Vialeto–Van Laere syndrome-1 (BVVLS1) or Fazio–Londe disease (OMIM 211530), is an autosomal-recessive progressive neurologic disorder that is caused by mutations in the *SLC52A3* gene.

Type 2 riboflavin transporter deficiency neuropathy, also referred to as Brown–Vialeto–Van Laere syndrome-2 (BVVLS2; OMIM 614707) is an autosomal-recessive progressive neurologic disorder that is caused by mutations in the *SLC52A2* gene.

Both types of riboflavin transporter deficiency neuropathy are associated with very similar clinical features. More than two-thirds of patients carry pathogenic mutations in the *SLC52A3* gene. Onset of symptoms ranges from a few months of age to the early teenage years and rarely can occur in adulthood. Peripheral nerves are the main site of pathology, manifesting as motor, sensory, and cranial neuropathy, which can be proven by neurophysiological investigations. Cognition is usually preserved (Foley et al., 2014). The acylcarnitine profile in blood may show accumulation of short- and medium-chain (and sometimes long-chain) acylcarnitines in some but not all affected individuals.

Oral riboflavin supplementation starting from 10 mg/kg per day, divided into three single doses, is gradually increased to 50 mg/kg per day to establish the optimum individual dose. All treated patients have improved after the initiation of riboflavin therapy.

### NIACIN (VITAMIN B<sub>3</sub>)

Niacin (also nicotinic acid) and its active forms, the nicotinamides (NAD<sup>+</sup>), function in a variety of oxidation–reduction reactions and serve as main electron donors in the respiratory chain. Niacin deficiency occurs in alcoholics, in adolescents with anorexia nervosa, in individuals following dietary fads, and in patients infected with human immunodeficiency virus, most often confounded with other micronutrient deficiencies. Signs and symptoms of niacin deficiency are outlined in Table 46-1.

### NIACIN DEPENDENCY

Hartnup's disease (OMIM 234500) is caused by autosomal-recessive mutations of the neutral amino acid transporter *SLC6A19*. Low tryptophan levels lead to secondary niacin deficiency and Pellagra-like clinical features, which may improve after administration of 50 to 300 mg/day of NAD.

### VITAMIN B<sub>6</sub>

Vitamin B<sub>6</sub> is derived from the diet in different vitamers as pyridoxine, pyridoxal, or pyridoxamine and their phosphorylated esters (Fig. 46-1). Pyridox(am)ine 5'-phosphate is further oxidized to pyridoxal 5'-phosphate (PLP) by pyridox(am)ine

5'-phosphate oxidase (PNPO). PLP works as the active cofactor for more than 200 enzymatic reactions in amino acid and neurotransmitter synthesis and degradation. It is a cofactor of the glutamate decarboxylase and of the GABA transaminase and the aromatic acid decarboxylase. PLP thus plays a crucial role in brain metabolism. Some drugs (isoniazide, penicillamine, cycloserine, hydralazine, etc.) interact with pyridoxine and warrant preventive pyridoxine supplementation in dosages of 25 to 50 mg/day. Nutritional vitamin B<sub>6</sub> deficiency is rarely seen. Signs and symptoms are outlined in Table 46-1.

## Vitamin B<sub>6</sub> Deficiency, Dependency, and Responsiveness

In contrast to nutritional vitamin B<sub>6</sub> deficiency, dependency indicates a lifelong hyperphysiologic demand of pyridoxine or PLP as a result of different IEMs with autosomal-recessive inheritance, which cause reduced availability of PLP by different mechanisms (Table 46-3). In all entities, seizures are a hallmark of the disease. In addition, patients with classical homocystinuria, gyrate atrophy, or X-linked sideroblastic anemia can show pyridoxine response as a result of a chaperone effect. Vitamin B<sub>6</sub> responsiveness has also been described in single individuals with West syndrome or idiopathic epilepsy of unclear genetic background.

## Pyridoxine-Dependent Epilepsy

Pyridoxine-dependent epilepsy (PDE; OMIM 266100) is characterized by the onset of neonatal myoclonic or bilateral tonic-clonic seizures that are resistant to antiepileptic drugs and may evolve into status epilepticus. About 30% of patients have encephalopathic signs such as sleeplessness and irritability or show low Apgar scores. Late onset up to 3 years of age has been described. Electroencephalogram (EEG) findings can range from nonspecific slowing and discontinuity to focal discharges or, rarely, burst-suppression patterns. Neuroimaging may be normal or reveal a variety of unspecific changes. About 85% of patients show a prompt cessation of seizures after a single administration of pyridoxine (50-100 mg intravenously), followed by a stepwise normalization of the EEG. The first administration of pyridoxine can lead to prolonged apnea or a comatose state, and thus resuscitation equipment should be at hand. Approximately 15% of patients have an ambiguous clinical response to a single pyridoxine administration.

Therefore a pyridoxine trial with 30 mg/kg per day in two to three standard doses over 3 consecutive days is recommended. Some patients develop systemic signs that resolve upon specific treatment with pyridoxine (Stockler et al., 2011).

In 2006, antiquitin (*ALDH7A1*) deficiency was identified as the major molecular background of PDE (Fig. 46-2). Antiquitin encodes  $\alpha$ -amino adipic semialdehyde dehydrogenase, and its deficiency results in the accumulation of  $\alpha$ -amino adipic semialdehyde (AASA), which is in equilibrium with piperidine 6-carboxylate (P6C). P6C inactivates PLP and leads to a life-long hyperphysiologic pyridoxine demand. Elevated AASA in urine (plasma or CSF) serves as a reliable biomarker even when on pyridoxine. AASA is also elevated in molybdenum cofactor deficiency (MOCOD) and warrants simultaneous determination of urinary sulfocysteine to avoid false diagnoses. Infants with PDE are supplemented with pyridoxine at dosages of 20 to 30 mg/kg per day in two to three standard doses. Beyond infancy, usual total daily pyridoxine doses vary from 100 mg/day to 300 mg/day. In the case of febrile breakthrough seizures, doubling of the daily pyridoxine dose over 3 to 5 days is recommended in subsequent infections. Long-term pyridoxine dosages above 300 to 500 mg/day can cause (reversible) sensory neuropathy.

Approximately 75% of children with PDE show mild to moderate cognitive impairment. Future trials will show whether reduced formation of  $\alpha$ -AASA by a lysine-restricted diet or competitive inhibition of lysine uptake by high-dose arginine supplementation may lead to better outcome. In 2009, folinic acid-responsive seizures, a previously distinct entity of unknown molecular background, was shown to be allelic to antiquitin deficiency. Of note is that no patient on folinic acid monotherapy survived, but an add-on of folinic acid at dosages of 3 to 5 mg/kg per day has been beneficial in neonates with PDE and initial incomplete pyridoxine response.

A minority of PDE cases are caused by etiologies other than antiquitin deficiency, such as pyridoxine-responsive PNPO deficiency, hyperprolinemia type II, and severe neonatal hypophosphatasia. Recently, pyridoxine responsiveness has been described in severe forms of KCNQ2 deficiency.

## Pyridox(am)ine 5'-Phosphate Oxidase Deficiency

The clinical presentation of pyridox(am)ine 5'-phosphate oxidase (PNPO) deficiency (OMIM 610090) is indistinguishable from antiquitin deficiency, except for the higher rate of

**TABLE 46-3** Biomarkers of Vitamin B<sub>6</sub>-Dependent Epilepsies Resulting From Inborn Errors of Metabolism and Their Response to Treatment

IEM- and PLP-related mechanisms	Urine	Plasma	CSF	Response to Vitamin B <sub>6</sub>
PNPO deficiency Reduced PLP formation	Vanillactate*	↑ PM and PM/PA	↓ PLP <sup>o</sup> sek. NT changes*	Mainly to PLP, in certain mutations also pyridoxine
Congenital hypophosphatasia Reduced PLP uptake		↓ AP, ↓ Ph, ↑ Ca		To pyridoxine (or PLP)
Congenital hyperphosphatasia Reduced PLP uptake		↑ AP		Unknown
Antiquitin deficiency (PDE) PLP inactivation	↑ AASA and P6C	↑ AASA and P6C ↑ Pipecolic acid	↑ AASA ↓ PLP <sup>o</sup> sek. NT changes*	To pyridoxine (or PLP)
Hyperprolinemia II PLP inactivation	↑ Proline, P5C	↑ Proline, P5C		To pyridoxine (or PLP)

AP, alkaline phosphatase; AASA, alpha amino adipic acid; Ca, calcium; CSF, cerebrospinal fluid; IEM, inborn errors of metabolism; NT, neurotransmitter; PA, pyridoxic acid; PDE, pyridoxine-dependent epilepsy; P5C, pyrroline-5-carboxylate; Ph, phosphate; PLP, pyridoxal 5'-phosphate; PM, pyridoxamine; PNPO, pyridox(am)ine 5'-phosphate oxidase; P6C, piperidine-6-carboxylate.

\*Inconsistent findings.

**Figure 46-2.** Lysine degradation pathway. Antiquitin deficiency causes accumulation of alpha-amino adipic semialdehyde, which is in a non-enzymatic equilibrium with its cyclic form,  $\Delta^1$ -piperideine-6-carboxylate.  $\Delta^1$ -piperideine-6-carboxylate inactivates PLP by a Knoevenagel condensation.

prematurity observed in 60% of patients. The majority of infants have low Apgar scores and may require intubation. Myoclonic jerks and severe tonic-clonic convulsions are associated with a burst-suppression pattern in about 60% of cases. With the duration of symptoms, brain MRI may reveal white-matter changes and atrophy. In 2005 this disorder was found to be caused by mutations in the *PNPO* gene resulting in reduced PLP formation. Patients were initially characterized as being resistant to pyridoxine but dependent on PLP supplementation, but this paradigm has recently been contradicted by novel pyridoxine-responsive *PNPO* mutations. Surprisingly, some of these patients showed clear worsening of seizures when pyridoxine was replaced by PLP. In contrast to antiquitin deficiency, *PNPO* deficiency leads to severe systemic PLP deficiency with anemia and failure to thrive, and most patients die if untreated. Aside from secondary changes of

plasma and CSF amino acids and neurotransmitters or inconsistently elevated vanillactate in urine, *PNPO* lacks a specific biomarker (Mills et al., 2014).

Patients with classical *PNPO* deficiency need lifelong treatment with PLP (unlicensed outside of Asia), 30 to 60 mg/kg per day in four to six standard doses. To avoid oxidation, PLP should be dissolved immediately before oral administration. The first administration can cause severe apnea and coma, and thus resuscitation equipment should be at hand. Many patients are sensitive to exact dose intervals even during the night, and seizure recurrence is frequent. Because of potential PLP liver toxicity, transaminases should be monitored regularly, and the lowest effective dose should be used. Patients with pyridoxine-responsive *PNPO* mutations may be treated with pyridoxine alone. Residual seizures necessitate a switch to PLP, which can be successful if performed slowly.

## Hyperprolinemia Type II

Hyperprolinemia type II (OMIM 239510) is generally considered benign because only 50% of patients present with seizures, which often respond to common anticonvulsants. Hyperprolinemia type II is caused by a deficiency of  $\Delta^1$ -pyrroline-5-carboxylate dehydrogenase leading to the accumulation of  $\Delta^1$ -pyrroline-5-carboxylate (P5C), which inactivates PLP (Fig. 46-2). The diagnosis can be made by marked elevation of plasma proline and the presence of P5C in urine. The action of pyridoxine in this disorders is less clear.

## Congenital Hypophosphatasia

Congenital hypophosphatasia (OMIM 241500) is caused by deficient tissue-nonspecific alkaline phosphatase (TNSALP). In addition to its function in bone metabolism, TNSALP is responsible for the cellular uptake of PLP (Fig. 46-1). Patients with severe deficiency may thus present with pyridoxine-responsive neonatal seizures and burst-suppression pattern before recognition of the bone disease. The availability of enzyme replacement therapy will hopefully prevent the osteomalacia and early death associated with severe forms of the disease.

## Pyridoxine Versus PLP to Test for Vitamin B<sub>6</sub> Responsiveness

Neonates with seizures of unclear etiology who fail to respond to common anticonvulsants should receive a standardized pyridoxine trial with 30 mg/kg per day over 3 consecutive days. In responders, withdrawal is obsolete and is replaced by molecular workup according to the presence or absence of respective biomarkers. In case of failure, folinic acid, 3 to 5 mg/kg per day, might be added and pyridoxine switched to PLP, with monitoring of liver function tests from day 2. This suggestion is based on the relatively higher frequency of pyridoxine-responsive entities compared with classical PLP-dependent PNPO deficiency, the licensed drug status of pyridoxine in most developed countries, its availability as an IV drug, and the potential liver toxicity of high-dose PLP. Treatment effects have to be observed closely. Confirmation diagnosis in prospectively treated siblings of children affected by antiquitin or PNPO deficiency should be performed as quickly as possible.

## VITAMIN B<sub>12</sub> (COBALAMINE)

Vitamin B<sub>12</sub> (cobalamin; Cbl) is derived from animal food sources only and follows a complex mechanism of absorption, transport, and intracellular modification to finally act as one of the two active cofactors, methylcobalamin (MeCbl) for the recycling of homocysteine to methionine and adenosylcobalamin (AdoCbl) for the conversion of methylmalonyl-CoA to succinyl-CoA.

The estimated daily losses of Cbl are minute compared with body stores. Hence, even in the presence of severe malabsorption, 2 to 5 years may pass before Cbl deficiency develops.

## Cobalamin Deficiency

Infants of strictly vegan mothers are at special risk of developing nutritional Cbl deficiency. Rarer causes include intestinal bacterial overgrowth (e.g., *Helicobacter pylori*) or parasites (e.g., *Diphyllobothrium latum*), malabsorption as a result of intestinal disease, and inherited defects affecting absorption and trans-

port. B<sub>12</sub> deficiency also has been reported with exposure to anesthesia by nitrous oxide. Megaloblastic anemia and neurologic manifestations are the hallmarks of Cbl deficiency (Table 46-1), but they can occur irrespective of each other. Infants show a consistent pattern of irritability, failure to thrive, and simultaneous growth deceleration, apathy, and anorexia, accompanied by developmental regression. Severe cases may develop acute decompensation with metabolic acidosis, hyperammonemia, and coma. This is clearly distinct from manifestations later in life with glossitis, myelopathy, painful paresthesia, disturbed proprioception, dementia, and neuropsychiatric disorders. CNS symptoms may partly be attributable to secondary disruption of the folate cycle and low methionine levels. In infants, the main MRI abnormality, if present, is delayed myelination or supratentorial atrophy, which may reverse upon treatment.

The diagnosis of Cbl deficiency rests on a thorough history and measurement of biochemical parameters in plasma and urine. Severe deficiency requires injections of hydroxocobalamin (OHCbl), whereas oral treatment with (Cyano) Cbl is sufficient if intestinal absorption is intact. Dietary counseling is of utmost importance, especially in vegan families, and regular Cbl supplementation is the option of choice if dietary habits remain unchanged.

Symptoms of nutritional Cbl deficiency are reversible if recognized early. Treatment delay may result in poor cognitive outcome and microcephaly. Some infants showed a transient movement disorder consisting of tremor and myoclonus, particularly involving the face, tongue, and pharynx, which appeared 48 hours after the initiation of treatment with intramuscular cobalamin.

## Cobalamin Dependency

The genetic defects of Cbl metabolism can affect absorption, transport, cellular uptake, or intracellular processing. Hereditary intrinsic factor (IF) deficiency (OMIM 261000) and Imerslund–Graesbeck syndrome (OMIM 261100) lead to reduced intestinal absorption and poor renal reabsorption of Cbl and can manifest from infancy to adulthood with symptoms indistinguishable from those of nutritional Cbl deficiency. TC II deficiency (OMIM 275350) presents with additional symptoms of immunodeficiency and recurrent infections, glossitis, and oral ulcerations. Disorders of absorption lead to reduced Cbl plasma levels, whereas in TC II defects, the Cbl plasma concentrations are normal (Table 46-3). All disorders result in elevated concentrations of homocysteine and methylmalonic acid (MMA) in plasma and urine.

Disorders of intracellular Cbl processing can be classified into combined disorders of metCbl and AdoCbl metabolism, those with isolated metCbl deficiency, also called remethylation defects, and those with isolated adoCbl deficiency. The clinical picture and the presence of elevated homocysteine and MMA, alone or in combination, and the presence of anemia are important biomarkers to guide the molecular workup (Table 46-3).

## CblC, CbD-MMA/HC, CbF, and CblJ Deficiency (Combined Defects of Ado- and MetCbl)

The combined defects of Ado- and MetCbl include CblC (OMIM 609831), CbD-MMA/HC (OMIM 77410), CbF (OMIM 277380), and CblJ deficiency; CblC deficiency is by far the most severe and the most common. Most patients have an early onset during infancy, with feeding difficulties, failure to thrive, microcephaly, hypotonia, seizures, ataxia, megaloblastic

anemia or pancytopenia, and visual problems such as nystagmus or early-onset retinopathy. Acute symptoms in addition to chronic, such as thromboembolic vasculopathy, renal failure resulting from atypical hemolytic uremic syndrome (HUS), cardiomyopathy, or metabolic crisis with hyperammonemia and ketoacidosis, may occur. MRI reveals delayed myelination and global atrophy or hydrocephalus. Symptom severity seems to correlate with the reduction of methionine levels rather than with MMA or homocysteine concentrations. In late-onset cases, psychiatric problems and myelopathy prevail. The few patients described with CblF deficiency had a milder phenotype but suffered from recurrent infections. Treatment by regular injections of hydroxocobalamin up to 1 mg two to three times weekly, folic acid 5 to 20 mg/day, betaine at 100 mg/kg per day in four standard doses, and eventually supplementation of methionine improves acute manifestations, but cognitive outcome is often impaired.

### **CblE, CblG, and CblD-HC Deficiency (Defects of MetCbl; Remethylation Defects)**

Most patients with so-called remethylation defects, which include CblE, CblG, and CblD-HC deficiency, manifest in the first year of life with feeding difficulties, hypotonia, developmental delay, and megaloblastic anemia. Infection-related deterioration, thromboembolism, or late-onset disease may occur. Plasma homocysteine is elevated, whereas MMA excretion in urine is normal. Delayed diagnosis can lead to irreversible myelopathy with spastic paraparesis. Anemia may not be present in early phases of the disease. Treatment of isolated MetCbl defects is identical to the treatment of combined deficiencies, and responses can be excellent.

### **CblA-MMA, CblB-MMA, and CblD-MMA Deficiency (Defects of AdoCbl)**

CblA-MMA (OMIM 251100), CblB-MMA (OMIM 251110), and CblD-MMA (OMIM 277410 variant 2) deficiency cause isolated AdoCbl deficiency. Most patients present with acute metabolic decompensation and encephalopathy during early life, often triggered by febrile infections, with metabolic acidosis, variable hyperammonemia, and high MMA excretion but normal homocysteine (Table 46-3). In the acute phase, MRI may show bilateral T2-weighted basal ganglia hyperintensities or metabolic stroke. The neurologic manifestations range from acute extrapyramidal movement disorders or comatose state to more chronic presentations with hypotonia, developmental delay, or optic atrophy. Metabolic crises can lead to irreversible brain damage and need emergency treatment in metabolic centers. A considerable proportion of patients respond to parenteral administration of hydroxocobalamin, 1 mg twice weekly, whereas the remainder will need a protein-restricted diet.

### **TOCOPHEROL (VITAMIN E)**

Vitamin E, including alpha-tocopherol, is the generic term for a group of fat-soluble compounds that function as scavengers of free radicals and protect polyunsaturated fatty acids from oxidation. It is stored predominantly in adipose tissue. Blood levels reflect recent dietary intake and absorption rather than body stores. Nutritional vitamin E deficiency occurs predominantly in disorders associated with either chronic fat malabsorption (e.g., cystic fibrosis, celiac disease, chronic cholestatic hepatobiliary disorders, short bowel syndrome) or a deficiency of plasma lipoproteins (e.g., abetalipoproteinemia, Tangiers disease). Details are described in Table 46-1.

### **Disorders of Vitamin E Metabolism**

#### **Ataxia With Vitamin E Deficiency (= Familial Isolated Vitamin E Deficiency)**

Ataxia with vitamin E deficiency (AVED; OMIM 277460) is an autosomal-recessive neurologic disorder that is caused by mutations in the *TTPA* gene coding for the tocopherol transfer protein. Clinical signs comprise progressive spinocerebellar ataxia, areflexia, pyramidal tract lesion, loss of proprioception, retinopathy, ophthalmoplegia, mental retardation, cardiac arrhythmias, xanthelasma, and tendon xanthomas. Laboratory findings include extremely low vitamin E levels and high serum cholesterol, triglycerides, and beta-lipoprotein.

With daily alpha-tocopherol supplementation of 20 to 40 mg/kg po, plasma vitamin E levels will normalize and cognitive function rapidly improves; however, neurologic symptoms often show slow and incomplete recovery.

### **BIOTIN (VITAMIN H)**

Biotin is absorbed through the intestine by active transport mechanisms and serves as a cofactor for five carboxylation enzymes that are involved in carbohydrate, lipid, and amino acid metabolism: pyruvate carboxylase, acetyl-CoA carboxylase ( $\alpha$  and  $\beta$ ), propionyl-CoA carboxylase, and 3-methylcrotonyl carboxylase. Biotinidase is an important enzyme for the release of protein-bound biotin and for the recycling of biotin from biocytin, which is formed in the degradation of the carboxylases. Nutritional biotin deficiency is extremely rare.

### **Biotinidase Deficiency**

Because of its excellent treatability, biotinidase deficiency (OMIM 253260) is included in most newborn screening programs worldwide. Severe biotinidase deficiency (residual activity [RA] < 10%) presents in the first half year of life with hypotonia; tonic-clonic, myoclonic, and partial seizures or infantile spasms; skin rash; and alopecia. EEG findings vary from normal to burst suppression pattern or hypsarrhythmia. Brainstem auditory-evoked potentials (BAEPs) can show findings consistent with sensorineural hearing loss. MRI can show (reversible) diffuse white-matter changes, edema of the putamen and caudate nuclei, and varying degrees of cerebral atrophy with ventriculomegaly. If untreated, the disease can result in coma or death. Partial biotinidase deficiency (RA 10%-30%) manifests in older children with ataxia or spastic paraparesis, developmental delay, hearing loss, or optic atrophy. Metabolic ketoacidosis with an increased anion gap, elevated lactate, and abnormal analysis of organic acids is present in severely affected patients, whereas attenuated forms may only be detected by measurement of biotinidase activity in serum.

Symptomatic children with biotinidase deficiency improve when supplemented with 5 to 20 mg of oral biotin per day, irrespective of age and weight, and require lifelong treatment. Hearing loss and optic atrophy are usually not reversible.

### **Biotin-Dependent Holocarboxylase Synthetase Deficiency (Multiple Carboxylase Deficiency)**

Multiple carboxylase deficiency (OMIM 253270) is indistinguishable from biotinidase deficiency, but biotinidase activity in serum is normal, whereas the activity of various carboxylases is impaired. Patients are supplemented with higher doses of biotin, approximately 20 mg/day (Baumgartner, 2013).

## Biotin-Responsive Basal Ganglia Disease

See the section on [thiamine \(vitamin B<sub>1</sub>\)](#).

## FOLATE

Folates are essential micronutrients and derivatives of pteridine compounds. Three major folate coenzymes are involved in catalytic one-carbon-transfer reactions: 10-formyl-THF functions as formyl donor in the purine synthesis; 5,10-methylen-THF mediates the methyl transfer to dUMP; and 5-methyl-THF participates in the methylation of homocysteine (Fig. 46-3). The latter reaction is crucial for the synthesis of S-adenosyl-methionine (SAM), which represents the preferred methyl group donor in the majority of methylation pathways. Thus lack of folate coenzymes affects a multitude of metabolic routes and will eventually compromise the synthesis of nucleic acids, amino acids, neurotransmitters, and biomolecules that are essential for myelin formation. The dependency of the brain on the external supply of 5-methyl-THF can be explained by the low concentration of dihydrofolate reductase that is required to regenerate 5-methyl-THF (see Fig. 46-3).

A comparative summary of the characteristic laboratory findings of the folate pathway and transport disorders is illustrated in Table 46-3.

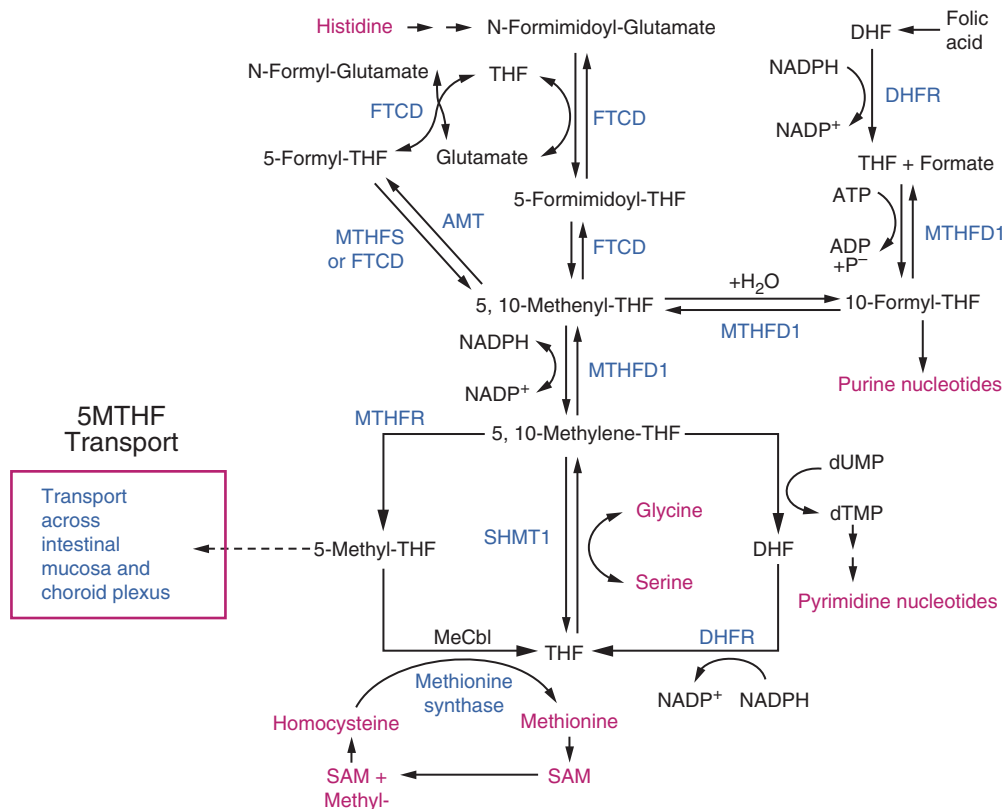

## Nutritional Folate Deficiency

Folate deficiency can be encountered along with multivitamin deficiencies or with increased folate requirements such as in pregnancy, lactation, prematurity, or diseases associated with abnormalities of folate absorption, use, or excretion. Drugs such as aminopterin, methotrexate, pyrimethamine, trimethoprim, and triamterene act as folate antagonists and produce folate deficiency by inhibiting dihydrofolate reductase, which is essential for the regeneration of tetrahydrofolate (see Fig. 46-3). Signs of deficiency and treatment are described in Table 46-1.

## DISORDERS OF FOLATE METABOLISM

### Dihydrofolate Reductase Deficiency

Dihydrofolate Reductase (DHFR) deficiency (OMIM 613839) has an autosomal-recessive inheritance pattern. As a consequence of DHFR deficiency, dihydrofolate accumulates and tetrahydrofolate diminishes, resulting in inhibition of pyrimidine and purine synthesis (see Fig. 46-3). DHFR is a major target of methotrexate, a commonly used chemotherapeutic for leukemias, and thus DHFR deficiency initially affects erythropoiesis and myelopoiesis but eventually may compromise cerebral folate supply and all THF-dependent reactions within the brain.

**Figure 46-3.** Schematic illustration of the folate metabolic pathways. The key metabolites histidine, serine, glycine, homocysteine, and methionine are highlighted in red. Enzymes are depicted in blue. Several enzymes are multifunctional, containing subdomains with distinct enzymatic activities. 5-methyl-THF is the major metabolite that is transported across the mucosa of the small intestine and the choroid plexus. AMT, aminomethyltransferase (EC 2.1.2.10); DHF, dihydrofolate; DHFR, dihydrofolate reductase (EC 1.5.1.3); FTCD, formiminotransferase (bifunctional enzyme, EC 2.1.2.5 + EC 4.3.1.4); MeCbl, methylcobalamin; MTHFD1, 5,10-methylenetetrahydrofolate dehydrogenase (trifunctional enzyme, EC 1.5.1.5 + EC 3.5.4.9 + EC 6.3.4.3); MTHFR, methylenetetrahydrofolate reductase (EC 1.5.1.20); MTHFS, 5,10-methenyltetrahydrofolate synthetase, 5-formyltetrahydrofolate cyclo-ligase (EC 6.3.3.2); SAH, S-adenosyl-homocysteine; SAM, S-adenosyl-methionine; SHMT, serine hydroxymethyltransferase (EC 2.1.2.1); THF, tetrahydrofolate.

All reported patients show infantile onset of symptoms comprising megaloblastic anemia, failure to thrive, and secondary microcephaly. Neurologic symptoms follow shortly and include profound developmental delay, central hypotonia with poor head control, inability to fix and follow, and frequent focal seizures. At later stages, learning difficulties and short episodes of involuntary blinking and winking may develop, eventually with impaired consciousness. The EEG may indicate atypical childhood absence epilepsy with eyelid myoclonia. Brain imaging demonstrates cerebellar and cerebral atrophy, thin corpus callosum, and poor myelination of white matter. Serum folate and plasma homocysteine concentrations are in the normal range (Table 46-4). However, there is a marked depletion of 5-methyl-THF in the CSF and a moderate decrease in tetrahydrobiopterin and neurotransmitter concentrations (homovanillic acid and 5-hydroxyindoleacetic acid) in the CSF.

Folic acid should be avoided in the treatment of DHFR deficiency because DHFR constitutes the only enzyme that catalyzes the conversion of folic acid to dihydrofolate. Infants should be promptly supplemented with 5 to 10 mg/kg body weight of oral folinic acid given daily as a single dose. Dosing for an affected individual should be adjusted to achieve a normal CSF concentration of 5-methyl-THF considering the age-dependent normal range.

### Methylenetetrahydrofolate Reductase Deficiency

Methylenetetrahydrofolate reductase (MTHFR) deficiency (OMIM 236250) has an autosomal-recessive inheritance pattern and is the most common inherited disorder of folate metabolism. MTHFR catalyzes the NADPH-dependent reduction of 5,10-methylene-THF to 5-methyl-THF, which in turn is required for the conversion of homocysteine to methionine (Fig. 46-3). The onset and severity of symptoms vary significantly but correlate with the degree of enzyme deficiency. The most common clinical finding in MTHFR deficiency is developmental delay, followed by motor and gait abnormalities, incoordination, cerebral seizures, paresthesias, stroke, muscular weakness, and psychiatric disturbances, including memory deficits. The majority of patients show EEG abnormalities, and about half of them develop microcephaly. In severe early-onset MTHFR deficiency, the infant may present with infantile spasms, developmental regression, and hydrocephalus.

Adult-onset MTHFR deficiency may manifest with the combination of progressive spastic paraparesis and polyneuropathy, variable behavioral changes, cognitive impairment, psychosis, seizures, and leukoencephalopathy. Other clinical signs may be quite variable, for example, marfanoid habitus resembling classical homocystinuria.

Betaine supplementation is the first choice in the treatment of MTHFR deficiency and improves the prognosis of severe MTHFR deficiency when initiated early. Patients should receive daily 100 mg/kg body weight per day (infants up to 250 mg/kg per day and older children up to 20 g/d) of oral betaine, divided in four single dosages. In case of psychomotor regression or epilepsy, the 5-methyl-THF concentrations in CSF should be monitored. Because of the limited folate transport across the blood-CSF barrier and the increased demand of choline for the biosynthesis of myelinated membranes, the concentration of 5-methyl-THF in the CSF is significantly reduced in most early-onset patients and roughly correlates with the severity of the neurologic symptoms in MTHFR deficiency.

In cases where betaine supplementation fails to achieve the aimed therapeutic effect, treatment with folinic acid or MTHF, riboflavin, methionine, pyridoxine, and cobalamin can be tried.

### MTHFD1-Encoded Enzyme Deficiency (Methylenetetrahydrofolate Dehydrogenase Deficiency)

The *MTHFD1* defect is inherited as an autosomal-recessive trait. In eukaryotes, the *MTHFD1* gene encodes a single cytoplasmic protein, a homodimer of 100-kD polypeptides, with three distinct enzymatic activities (Fig. 46-3).

All five reported patients presented with megaloblastic anemia in addition to leukopenia or signs of immune deficiency. Hyperhomocystinuria and mildly decreased synthesis of intracellular methylcobalamin in the presence of exogenous [<sup>57</sup>Co]cyanocobalamin were common findings. Cobalamin and folate levels in serum were within the normal range.

Three patients were treated with intramuscular hydroxocobalamin, oral folate or folinic acid, and oral betaine or thiamine. In one patient, 5-methyl-THF and methylcobalamin were later empirically added to the regimen at the age of 23 months. One patient had mild mental retardation at the age of 6 years, whereas two other patients had normal cognitive development.

**TABLE 46-4** Laboratory and Imaging Findings of Cobalamin or Folate Pathway and Transport Disorders

Disorder	Serum Folate	CSF 5MTHF	Blood Count	Plasma Homocysteine	Brain Imaging
FCTD deficiency	Normal	Low	Normal	Normal	No abnormalities reported
DHFR deficiency	Normal	Low	Macrocytic anemia	Normal	Hypomyelination, thin corpus callosum, brain atrophy
MTHFR deficiency	Normal	Low to normal	Normal	Increased	Periventricular demyelination
MTHFD1 deficiency	Normal	Low	Anemia	Increased	Bilateral small hippocampi, T2 signal changes in lobes
PCFT deficiency	Low	Low	Macrocytic anemia	Increased	Calcifications in the cortex or basal ganglia
CFT deficiency	Normal	Low	Normal	Normal	Hypomyelination, cerebellar (+ cerebral) atrophy
Methylcobalamin deficiency	High to normal	Normal	Macrocytic anemia	Increased	Thin corpus callosum, cortical atrophy, hypomyelination

CFT, cerebral folate transport; CSF, cerebrospinal fluid; DHFR, dihydrofolate reductase; FCTD, formiminotransferase; PCFT, proton-coupled folate transporter; MTHFD1, methylenetetrahydrofolate dehydrogenase-1; MTHFR, methylenetetrahydrofolate reductase.

## Formiminotransferase Deficiency

Formiminotransferase (= glutamate formimidoyltransferase, FTCD) deficiency (OMIM 229100) is an autosomal-recessive inherited disorder caused by mutations in the *FCTD* gene. FTCD catalyzes the formation of 5,10-methenyl-THF (Fig. 46-3) in the histidine degradation pathway. The clinical relevance of formiminotransferase deficiency is presently unclear. Patients carrying missense mutations in the *FCTD* gene show developmental or speech delay, muscular hypotonia, and breathing difficulties with late infantile onset. Additional findings are abnormal electroencephalograms and significantly increased urinary excretion of formiminoglutamate (FIGLU).

Because of the poor correlation between clinical phenotype, residual enzymatic activity, and biochemical findings, no specific treatment is currently recommended.

## DISORDERS OF FOLATE TRANSPORT

### Hereditary Folate Malabsorption

Hereditary folate malabsorption (HFM; OMIM 229050) is an autosomal-recessive inherited trait caused by mutations in the proton-coupled folate transporter (PCFT = SLC46A1), which cotransports folates together with protons. Affected individuals fail to absorb sufficient folates in the small intestine to match the daily requirements of about 0.4 mg. In addition, the frequent failure to correct 5-methyl-THF levels in CSF even under normalized plasma folate concentration indicates impaired folate transport across the blood-CSF barrier in a proportion of patients with HFM.

Patients may show poor feeding and failure to thrive during very early infancy. The folate deficiency results primarily in megaloblastic anemia but may develop into pancytopenia. Anemia may be normocytic in case of poor nutrition and/or concomitant iron deficiency and may be accompanied by diarrhea and/or oral mucositis. Infants with HFM may initially present with profound immunodeficiency, which includes humoral and cellular immunity and mimics severe combined immune deficiency (SCID). Neurologic signs may be part of the initial manifestation of HFM or may develop later and include developmental delay, cognitive and motor impairment, behavioral abnormalities, ataxia and other movement disorders, peripheral neuropathy, and seizures with onset in infancy or early childhood (Zhao et al., 2007). Calcifications in the cortex or basal ganglia have been reported for several individuals with HFM.

Serum folate concentrations are very low or even undetectable. Oral folate supplementation does not result in significant increase in serum folate concentration, and a single oral load of 5-formyl-THF (= folinic acid) shows no or little effect on serum folate concentration over a minimum of 4 hours. CSF 5-methyl-THF concentrations in affected individuals are frequently low (< 5 nM) and remain below the normal range even after correction of the serum folate concentration.

Treatment aims to prevent hematologic and immunologic defects and to optimize the psychomotor development of children (Diekman et al., 2014). Infants should immediately receive 10 to 20 mg/kg body weight of oral folinic acid given daily as a single dose. Dosing should be adjusted to achieve a normal CSF concentration of 5-methyl-THF considering the age-dependent normal range. In case of insufficient response to oral treatment, intramuscular injections of levofolinic acid, either daily 1 mg or 5 mg twice per week or, alternatively, intravenous injection of 50 to 100 mg of levofolinic acid should be tried.

## Cerebral Folate Transport Deficiency

Cerebral folate transport deficiency (CFTD; OMIM 613068) is an autosomal-recessive inherited disorder associated with mutations in the *FOLR1* gene, which encodes folate receptor alpha (FR $\alpha$ ). CFTD is characterized by the failure of FR $\alpha$ -mediated folate transport in the CSF that differentiates it from other types of cerebral folate deficiency (see Table 46-3). Folic acid possesses a very high affinity for FR $\alpha$  and thus may block 5-methyl-THF transport across the choroid plexus.

The most consistent clinical finding in CFTD is developmental regression, with onset typically before the age of 3 years. Short drop attacks resembling infantile spasms may precede frequent myoclonic epileptic seizures that are often resistant to antiepileptic medication. Ataxia, truncal hypotonia, and lower limb spasticity are frequent neurologic signs. Most patients appear to lose their social contact skills and develop an autistic-like behavior. Some patients present a milder phenotype with developmental delay, ataxia, and autistic features only (Grapp, 2012). Many patients become microcephalic in the course of the disease.

Brain imaging reveals delayed myelination, hypomyelination, and cerebellar and cerebral atrophy. Magnetic resonance (MR) spectroscopy indicates low concentration of inositol and choline in the cerebral white matter. Focal T2 hyperintensities of the white matter can be detected in cranial MR imaging at later stages of the disease. Slow background together with multifocal epileptiform activities are commonly found in the EEG.

Very low CSF concentrations of 5-methyl-THF are the biochemical hallmark of CFTD, and concentrations have been below 5 nM in all patients reported so far. Plasma folate concentrations of untreated patients are measured in the lower normal range, and intraerythrocytic folate concentration is typically normal.

Oral supplementation with 5 to 10 mg/kg of folinic acid results in normalization of cerebral choline and inositol and correction of 5-methyl-THF. In cases of incomplete clinical response, additional intravenous injections of 50 to 100 mg folinic acid once per week should be considered. In selected patients, intrathecal administration of folinic acid may be beneficial. Early treatment is mandatory to achieve complete correction of clinical symptoms.

The important role that optimal early nutrition has in brain development has been stressed for years. Some authors have stated that nutrition may be the environmental variable with the widest range of effects on brain development. Diet is responsible for both the provision of substrates from which the brain is constructed and the energy required for its function. The central nervous system is most vulnerable to nutritional influence at the periods when growth, development, and plasticity are higher; in the case of human beings this extends from the beginning of the third trimester of pregnancy until 2 years of age. At age 2 years, the volume of the human brain has reached 80% to 90% of adult size (Isaacs, 2013). Between the 24th and 42nd weeks of gestation white- and gray-matter structures undergo a rapid increase in volume, with the cerebellum and cortical gray matter being the structures with highest growth rates. Although the brain initially grows rapidly, its development continues into the teenage years, raising the possibility that the nature of diet at later stages may also be influential.

The effects of malnutrition are based on the timing and magnitude of the nutrient deficit and on the brain's need for the particular nutrient at the time of the deficit. It is important to note that insults early in life when the brain is developing could have long-lasting effects.

### PROTEIN-CALORIE MALNUTRITION

Studies based on animal models at the beginning of the last century have demonstrated that undernutrition in early life has dramatic anatomic and biochemical effects on the brain. It seems that the primary effect of protein-calorie deprivation involves replication and growth of cells in those elements most actively proliferating during the insult, rather than cell destruction. Box 47-1 lists major neuropathologic abnormalities resulting from malnutrition described in animal experimental studies. Table 47-1 summarizes the most important nutrients required for brain growth during late fetal and neonatal brain development and the particular brain structure or function that they regulate.

The major aspects of the anatomic and biochemical changes associated with malnutrition in animals have been observed in malnourished children. Malnutrition during brain development leads to reduction in brain cells, number of synapses, dendritic arborization, and myelin production, which result in decreased brain size and macrostructure and alterations in neurotransmitter systems. The structures that are most affected are the hippocampus, cerebellum, and neocortex. All of these alterations are associated with delays in motor and cognitive functions, such as impaired school performance, decreased IQ scores, decreased memory, learning disorders, attention deficit disorders, and reduced social skills (Laus et al., 2011). A combination of intrauterine and extrauterine malnutrition has the greatest effect on brain structure composition and function.

The fetus takes the critical nutrients it needs irrespective of the nutritional status of the mother. This ensures proper delivery of substrates for growth. Only in extreme situations of nutrient deprivation is the placental transfer of nutrients

affected. Severe deficiencies in nutrition are widespread in developing countries, and there is evidence that these deficiencies affect brain structural maturation and long-term functioning of the brains of children, resulting in cognitive functional delays and permanent cognitive impairments. Maternal protein-calorie malnutrition can restrict uterine blood flow and growth of the uterus, placenta, and the fetus. Intrauterine growth restriction is associated with many adverse fetal and neonatal outcomes, including delayed neurologic development. After birth, stunting affects one third of children under age 5 years in low-income and middle-income countries. Ninety percent of the worldwide burden of child stunting is attributable to 36 countries. The highest prevalence of stunting occurs in central Africa and south-central Asia, with an approximate prevalence of 40%. Childhood stunting has been linked to poor mental development and school achievements as well as behavioral abnormalities (Laus et al., 2011). Whether some of these effects are reversible remains a matter of debate.

Optimal development of the fetal and infant brain depends on adequate maternal nutritional intake. Stunting early in life has been reported to have lasting effects on school performance and IQ scores up to the age of 15 years. Some other authors state that children can recover from an early nutritional insult and improve cognition. Nutrient deficiencies are more likely to occur in disadvantaged environments, which themselves have additional adverse effects on children's behavior and development. An unstimulating home environment could exacerbate the effects of malnutrition on neurologic development. The extent to which nutrition as an independent risk factor influences brain development and its future function is difficult to elucidate (Laus et al., 2011).

Neuroimaging techniques have shown that infants with intrauterine growth restriction that reflects a deficient prenatal nutrition have reduced total brain tissue volumes and reduced cortical gray and hippocampus volumes, compared with children with the same gestational age but appropriate intrauterine growth (Isaacs, 2013). Intrauterine growth restriction has been associated with lower IQ, academic underachievement, reduced social skills, and behavioral problems such as attention deficit and hyperactivity disorder. Although it seems clear that nutrition plays a role in the genesis of brain tissue abnormalities, the effects of other contributing factors, such as dysfunction of fetal-placental perfusion leading to hypoxia and acidosis in fetal circulation, cannot be excluded in these children (Von Beckerath et al., 2013).

Recent advances in perinatal and neonatal intensive care have led to an increase in the survival of preterm extremely low birth weight infants, although undernutrition occurs frequently during hospitalization in these infants. Undernutrition in extremely low birth weight infants is associated with extrauterine growth restriction and other adverse outcomes, such as bronchopulmonary dysplasia, sepsis, and neurodevelopmental impairment. Preterm infants with extremely low birth weight can encounter cognitive problems such as poorer school performance, behavioral and learning problems, and deficits in higher order neurocognitive functions. Studies in preterm infants have shown that those fed high nutrient

**BOX 47-1** Nutrition and Brain Development**EFFECTS OF MALNUTRITION ON THE DEVELOPING BRAIN**

- Reduction in brain volume
- Sparing of cortical neurons
- Increased cell packing
- Disruption of cortical pyramidal cells
- Reduction in cortical dendritic spines
- Decrease in width of cortical neurons
- Decreased dendritic branching in cortex
- Reduced number of cortical glial cells
- Reduced number of cortical synapses
- Reduced number of synaptic reactive zones

**EFFECTS OF RESTORING NUTRITION ON REVERSIBILITY OF BRAIN LESIONS**

- Increase in brain weight and volume: “catch-up” head growth
- Prolongation of period of mitotic activity
- Prolongation of period of protein synthesis
- Reversal of cell packing
- Reduced cortical glial cell density
- Persistence of reduced number of cortical dendrites and synaptic spines
- Persistence of reduced myelination
- Increase in number of mitochondria in neurons
- Increase in synaptic density

(Modified from Levitsky, D.A., Strupp, B.J., 1995. *Malnutrition and the brain: changing concepts, changing concerns. J. Nutr.* 125, 2212S.)

formulae have larger brain volumes and a better performance in intelligence tests.

The effects of breastfeeding have also been studied. Increasing the percentage of breast milk in the early diet of preterm infants increases the amount of white matter relative to gray and has also been associated with better performance in intelligence tests (Isaacs, 2013; Hsiao et al., 2014). Thus early administration of optimal postnatal nutrition can help to prevent neurodevelopmental impairment in preterm infants, but up to 75% of extremely premature infants do not receive the recommended nutrition and develop extrauterine growth retardation (Hsiao et al., 2014).

The limit of viability for preterm infants is around the 23rd to 24th week of gestation. Thus nutritional deficits in preterm infants will be introduced earlier during development compared with intrauterine growth restricted children. Therefore in preterm infants differences are observed mainly in the white matter, whereas intrauterine growth restricted children tend to show differences in gray matter structures (Isaacs, 2013). White-matter injury is the most common pattern of brain injury after preterm birth.

The third trimester of gestation is critical for brain development, especially for white-matter structures. During this period, preoligodendroglial progenitors differentiate to mature myelin-producing oligodendrocytes, axons develop and form connections, and neurons proliferate and migrate to the cortex and deep nuclear gray-matter structures. The main pathogenic mechanisms of white-matter injury are inflammation and ischemia. Both activate the microglia, which leads to release of free radicals and proinflammatory cytokines,

**TABLE 47-1** Important Nutrients During Late Fetal and Neonatal Brain Development

Nutrient	Brain Requirement for Nutrient	Described Brain Abnormalities or Disorders
Protein-energy	Cell proliferation, cell differentiation Synaptogenesis Growth factor synthesis	Global Cortex Hippocampus
Iron	Myelin Monoamine synthesis Neuronal and glial energy metabolism	White matter Striatal-frontal Hippocampal-frontal
Zinc	DNA synthesis Neurotransmitter release	Autonomic nervous system Hippocampus, cerebellum
Copper	Neurotransmitter synthesis, neuronal and glial energy metabolism, antioxidant activity	Cerebellum
LC-PUFAs	Synaptogenesis Myelin	Eye Cortex
Choline	Neurotransmitter synthesis DNA methylation Myelin synthesis	Global Hippocampus White matter
Iodine	Cerebral development Cerebellar development	Reduced brain weight, including cerebellum Reduced number of neurons in cerebrum, cerebellum, and brainstem Increased thickness of cerebellar external germinal layer Regional increases in neuronal density in cerebral hemisphere and decreased in synaptic counts visual cortex
Vitamin A	Regulation of gene and protein expression controlling neural growth and differentiation Regulation of patterning of neural tube development Modulation of neurogenesis, neural survival, and synaptic plasticity	Hydrocephalus Microcephaly Retinal and optic nerve defects
Vitamin B <sub>12</sub>	DNA synthesis Formation and maintenance of myelin sheaths Neurotransmitter synthesis	White-matter degenerative lesions in brain, spinal cord, and peripheral nerves Spinal cord posterior and lateral column involvement

LC-PUFAs, long-chain polyunsaturated fatty acids.

(Adapted from Georgieff, M.K., 2007. *Nutrition and the developing brain: nutrient priorities and measurement. Am. J. Clin. Nutr.* 85, 614S–620S.)

ultimately resulting in degeneration of preoligodendrocytes. As a consequence there is a failure in the differentiation of preoligodendrocytes into mature myelinating oligodendrocytes, and hypomyelination occurs.

Perinatal infection, which is frequent in preterm infants in intensive care units, has been recognized as an important risk factor for white-matter injury. Infection leads to systemic inflammation, and it is often associated with hemodynamic instability with reduced brain flow, which subsequently potentiates the two main pathogenic mechanisms of white-matter injury previously mentioned. Nutrition in preterm infants not only influences brain growth and maturation, but nutritional supplements that would reduce systemic infections and attenuate inflammation could also protect the brain against injury in this period of high vulnerability. There are some specific nutrients such as glutamine and probiotics that may be of interest as potential neuroprotective agents for preterm infants. Probiotics have shown to improve gut mucosal barrier integrity, regulate adequate bacterial colonization, enhance intestinal innate immune response, and modulate intestinal inflammation, which results in a reduction of necrotizing enterocolitis, bacterial translocation, and inflammation.

Although probiotics have failed to improve neurodevelopmental outcomes, they may attenuate white-matter injury because of a favorable alteration of the immune response, resulting in less inflammation (Hsiao et al., 2014). In addition, they may be able to produce beneficial effects through the recently described microbiome–gut–brain axis. The exact mechanisms by which the gut microbiome modulates brain development are not yet clear, but the immune system seems to play a key role. Glutamine supplementation has also been shown to reduce the risk of serious neonatal infections and systemic inflammation, thereby leading to a reduction of white-matter injury. The mechanism through which glutamine enteral supplementation exerts its effects is yet to be unraveled. The postulated benefits of these nutritional supplements warrant further investigation.

Studies have shown that animals may recover from periods of undernutrition. However, if stunting continues during the entire period of cell replication, there is a persistent reduction in cell numbers, irrespective of the diet subsequently provided. Evidence of recovery in humans is less direct. An adequate calorie and protein intake certainly ends the insult, but it is not clear whether supplements always improve brain function, as genetic and environmental factors play a role in the potential for recovery. Studies evaluating the relationship between nutrition and cognition that took into account the social environment demonstrated that both factors are significantly correlated with cognitive performance. In interventional studies, both treatments, nutrition, or psychosocial stimulation alone seem to improve cognition. Combined treatments are the most effective at preventing large losses of potential cognitive performance, however, with greater effect the earlier the treatment begins. Some authors have stated that malnourished children have less energy to explore their environment and take advantage of opportunities for social contacts and learning processes; thus an unstimulating home environment can exacerbate the effects of malnutrition.

There is evidence that in developing countries clinical deficiencies in nutrition affect the structure and long-term functioning of children's brains. These clinically evident deficiencies are less likely to occur in industrialized countries, where a balanced diet is generally available. In industrialized countries, special attention should be paid to preterm children and those with intrauterine restricted growth who are often nutritionally deprived during critical stages of brain development. Concern should also be focused on those children with malabsorption, metabolic diseases, or increased demands of

nutrients caused by underlying pathologies, as well as on those receiving vegan diets.

## MICRONUTRIENTS

There is widespread belief that micronutrient intake in industrialized countries is deficient because of changes in nutritional habits. Some studies conclude that in general average intake of nutrients is above reference nutrient intakes, but it is often marginal for some micronutrients, such as iron, folic acid, and vitamins D and B<sub>12</sub>. Whether such a marginal intake is a matter of concern remains under discussion. In industrialized countries, it is therefore necessary to distinguish those whose diets are deficient from those with minor inadequacies.

All nutrients are important for neuronal growth and development, but certain nutrients have greater effects on brain development than others do. Fetal and neonatal malnutrition can have global or circuit-specific effects on the developing brain given that some nutrients influence a specific brain area preferentially. Each of these nutrients has generated a wide range of research literature examining their relation with the brain.

## Minerals

### Iron

Iron deficiency is the most prevalent nutritional deficiency in the world. Over 30% of the world's population is anemic, and iron deficiency is the most common cause of anemia. It is prevalent not only in developing countries but also in industrialized countries, and children and women are the most commonly affected. This raises concern, as both isolated iron deficiency and iron deficiency anemia are thought to adversely influence neurodevelopment and behavior. Some of the consequences of developmental delay associated with iron deficiency are decreased motor development, lower IQ, and difficulties with learning and memory. Furthermore, the adverse effects of iron deficiency occurring in the first 6 to 12 months of life are likely to persist even if iron intake is subsequently normalized. In older children, iron deficiency has been related with poorer social-emotional development and problems of sustained attention, which can be reversed by an adequate supply of iron.

Brain tissue is overall rich in iron with concentrations differing according to brain region and stage of development. Some areas—like the cortex, hippocampus, and striatum—are more sensitive to iron deficiency than others. Iron accumulates in the brain during prenatal development. Given the poor bioavailability of iron in human milk, these iron stores in the brain are paramount in the first 6 months of life when infants are unable to regulate iron transport across the blood–brain barrier. Afterward, the brain is able to fully regulate iron entry into the brain even during periods of iron deficiency. The brain's need for and usage of iron does not end during the perinatal period and infancy; the adult brain still requires an adequate supply of iron (Radlowski and Johnson, 2013).

Studies in animals have shown that iron deficiency inhibits neurogenesis in the hippocampus, which provides a basis for behavioral deficits associated with perinatal iron deficiency. Iron homeostasis is critical for the expression of neurotrophic factors that support brain development. These neurotrophic factors influence not only neurogenesis but also neuronal morphology, dendritic outgrowth, and spine density and geometry, which are crucial for cell function. Iron deficiency also affects synaptic plasticity and severely affects myelination (Radlowski and Johnson, 2013). Moreover, iron is essential for neuronal metabolism and the enzymes involved in the

synthesis of some neurotransmitters, including serotonin, dopamine, and norepinephrine. Dopamine is important for regulating cognition and emotion, reward and pleasure, movement, and hormone release. Serotonin is highly implicated in neurodevelopmental disorders such as autism, anxiety, and depression (Radlowski and Johnson, 2013).

Although an unequivocal relationship between iron deficiency and neurologic development has yet to be established, it is important to prevent it. Preterm infants and those born to mothers with anemia, diabetes, hypertension with intra-uterine growth restriction, and multiple gestations are at risk of developing iron deficiency, as these circumstances lower fetal iron stores. Dietary recommendations for preterm infants are for an elemental iron intake of 2 to 4 mg/kg/day to a maximum of 15 mg/d by 1 month of age and extending through 12 months of age, with the exception of those who received multiple transfusions in which the need of iron supplementation should be assessed. Iron-fortified formulas provide sufficient iron to meet these requirements, but breastfed preterm infants should be supplemented. Healthy term infants usually have sufficient iron stores until 4 to 6 months of age, and the small amount of iron in human milk is enough for exclusively breastfed infants.

Exclusive breastfeeding after the age of 6 months is associated with an increased risk of iron deficiency anemia. Therefore, for exclusively breastfed term infants, supplementation of 1 mg/kg/day is recommended starting from the fourth month until an appropriate iron intake is achieved with complementary food. Term formula-fed infants do not need any dietary supplementation, as iron requirements can be met for the first 12 months by standard infant formulas containing 12 mg/L iron and the introduction of iron-containing complementary foods at 4 to 6 months. After this age, iron needs can be achieved by consumption of iron-rich foods. Only those children not receiving the recommended iron intake in the diet will require supplementation.

## Zinc

Zinc is an essential nutrient with multiple roles. It is involved in the activity of more than 200 enzymes and plays a fundamental role in the synthesis of proteins and nucleic acids. It is involved in gene expression, cellular division and development, and in the growth and function of many organs, including the central nervous system. Severe zinc deficiency during pregnancy has been associated with fetal losses and congenital malformations. Animal studies regarding the central nervous system have shown that zinc deficiency during early development results in adverse effects on brain structure and function. Zinc deficiency alters autonomic nervous system regulation and hippocampal and cerebellar development. There are no conclusive data on humans about the effects of zinc deficiency on neurologic development, but some studies have suggested an association with decreased cognitive and motor function as well as behavioral problems (Gogia and Sachdev, 2012).

Severe zinc deficiency is rare in humans, but mild to moderate depletion appears to be quite prevalent. In the last half of pregnancy when fetal growth is rapid, there is an additional need for 0.6 mg zinc daily. The United Nations International Children's Emergency Fund (UNICEF) recommends that all pregnant women in developing countries use multiple micro-nutrient supplements that include zinc.

## Iodine

Iodine deficiency is the leading preventable cause of mental retardation worldwide. Iodine is essential for the production of thyroid hormones, for normal growth, and for brain development. In chronic severe iodine deficiency, thyroid hormone

synthesis is reduced. A severe iodine deficiency during critical periods of brain development will result in irreversible brain damage and is associated with both physical and mental impairments. The most serious consequence of iodine deficiency is cretinism, which is characterized by severe, irreversible alterations in brain development resulting in profound mental retardation and neurologic signs including deafness, impaired language development, abnormal eye movements, and motor disorders.

Iodine deficiency early in life is associated with a loss of 6.9 to 10.2 IQ points in those who do not develop cretinism, which is estimated to be 5% to 15% of those noncretinous children with severe iodine deficiency (Bougma et al., 2013). Thyroid hormone-dependent neurodevelopment begins in the second half of the first trimester, but it is not until the beginning of the second trimester that the fetal thyroid begins to produce hormones. Even then, the reserves of the fetal gland are low, and it does not fully mature until birth. Thus the fetus is dependent on maternal production of thyroid hormones for brain development until birth. It is therefore important to keep an adequate intake of iodine during pregnancy, when a 50% increase in maternal intake is recommended to produce enough thyroid hormones to meet maternal and fetal requirements.

Adequate thyroid hormone for ongoing neurodevelopment remains critical after birth. Newborn intrathyroidal iodine stores are limited to approximately 300 µg, and thyroid hormone requirements for the developing infant are at their highest compared with subsequent growth periods. All this makes newborns and infants particularly vulnerable to iodine deficiency. Prevention of iodine deficiency by iodization of salt has helped to alleviate endemic cretinism, but attention is now turning to the adverse effects of moderate and mild iodine deficiency. In general, it seems that maternal thyroid metabolism can cope with mild iodine deficiency, such that the mother can sufficiently supply the infant with thyroid hormones. Although the developing brain is the most severely affected if iodine is deficient, chronic hypothyroidism also can have effects across all ages. Iodine deficiency has a negative effect on cognitive performance of school-age children, but supplementation of moderately iodine-deficient school children improves cognitive and motor functions, showing that the effects of iodine deficiency later in life are at least partially reversible.

Iodine deficiency is still one of the most common micro-nutrient deficiencies in the world. Iodine is naturally present in seawater and in the soil, and the iodine content of the soil determines its content in vegetables, milk, and eggs. Fish, seafood, and algae are good sources of iodine. Prevention of iodine deficiency is easily managed by iodization of salt, but it is still present in some regions of the world. Recommended dietary iodine intake in pregnant women is 250 µg/day. Whether routine iodine supplementation should be recommended to pregnant women in areas of mild-to-moderate iodine deficiency remains uncertain. Iodine requirements for newborns have been set at 15 µg/kg/day at term and 30 µg/kg/day for preterm infants. An intake of 130 µg/day is recommended during the second half of the first year of life.

Exclusively breastfed infants rely entirely on maternal iodine intake to meet their requirements. Commercially prepared formulas contain iodine, but its amount varies worldwide. In addition, iodized salt is discouraged in home-prepared complementary foods for infants. International organizations recommend the universal use of iodized salt to prevent iodine deficiency. In countries with severely iodine-deficient populations, single annual doses of iodized oil may be administered to lactating mothers or weaning infants as a strategy for achieving recommended iodine intakes.

## Vitamins

Vitamins are organic compounds required by mammals in small amounts to sustain normal metabolism. They must be supplied from exogenous sources because they cannot be synthesized endogenously. Nutritional vitamin deficiency remains a public health problem in developing countries and among the poor worldwide.

### Folate

Folic acid is a B vitamin that plays an important role in cell proliferation, brain cell repair, and appropriate epigenetic expression of the genome. Folate is believed to be involved in cell division by means of its influence on nucleic acid synthesis, which is necessary for DNA integrity and replication and amino acids synthesis. During pregnancy the rate of cell division increases dramatically, and folate demand increases beyond maternal requirements. It is therefore essential for growth and necessary for normal development of the fetal spine, brain, and skull, in particular during the first 4 weeks of pregnancy.

There is widespread evidence that both periconceptional folic acid supplementation and high maternal folate concentrations reduce the risk of neural tube defects, including spina bifida and anencephaly. These congenital malformations of the brain and spinal cord result from failure of normal developmental processes involving failure of the neural tube to close properly during the first trimester of gestation, in particular during the third and fourth week of pregnancy (Benton, 2012). The exact mechanism by which folate supplementation prevents neural tube defects remains unknown. Maternal folate levels have also been related to better performance of their children in tests assessing memory, reasoning, attention, and visual-spatial and verbal abilities. Little attention has been given to folate nutritional deficiency later in the course of pregnancy. Folic acid supplementation may also have beneficial effects on cognitive development and preventive effects on neurodevelopmental disorders such as language delay, autism spectrum disorders, and schizophrenia.

The main sources of folate in the diet are vegetables, legumes, and milk. Pregnant women are at risk for folate insufficiency because of the increased need of folate for rapid fetal growth, placental development, and enlargement of the uterus. Generally, reports on average dietary folate intake in pregnant or childbearing women all over the world show low folate intakes compared with the recommendation of 400 µg/day. Neural tube defects occur during the third and fourth week of pregnancy, before a mother becomes aware that she is pregnant. The risk is reduced when women take daily folic acid supplements 3 months before considering pregnancy and continuing up to the sixth week of pregnancy. These recommendations have led some countries to include folic acid food fortification, which has greatly reduced the incidence of spina bifida. Therefore all women of childbearing age are recommended to take a folic acid supplement of 400–800 µg/day, preferably at least a month before conceiving.

### Cobalamin (Vitamin B<sub>12</sub>)

Vitamin B<sub>12</sub> deficiency during pregnancy has been related to adverse fetal and neonatal outcomes such as neural tube defects and delayed defects, delayed myelination, or demyelination. There is evidence that decreased maternal serum levels of vitamin B<sub>12</sub> in humans are associated with an increased risk of neural tube defects, regardless of folic acid supplementation of the diet.

Most of the data regarding vitamin B<sub>12</sub> deficiency in infancy are from case studies of infants born to mothers who were not treated for pernicious anemia or infants who were exclusively breastfed by mothers on vegan or vegetarian diets. The deficiency results in irritability, anorexia, lethargy, and retarded neurodevelopment. Neuroimaging techniques have also shown severe brain atrophy and retarded myelination in vitamin B<sub>12</sub>-deprived children. After therapy, recovery has been reported to be variable, with recovery of brain structures but brain function remaining delayed in some children. Later in life, poorer measures of intelligence, memory, and frontal lobe function have been reported in adolescents who as children had received vegan diets and who subsequently ate omnivorous or vegetarian diets (Benton, 2012; Black, 2008).

The mechanisms underlying the action of vitamin B<sub>12</sub> are unclear. Cobalamin deficiency leads to functional folate deficiency because folate cannot be transformed into its active tetrahydrofolate form. Deficiency of folate and cobalamin results in similar biochemical effects; cobalamin deficiency may contribute this way to the development of neural tube defects. It is also involved in fatty acid metabolism and therefore the maintenance of periaxonal myelination, which occurs from midgestation through the second year of life and continues to and during puberty. It influences the speed of nerve conduction and may in this way influence cognitive development. Some other possible mechanisms include its role in the inflammatory process, altering the balance of neurotrophic and neurotoxic cytokines, affecting the S-adenosylmethionine:S-adenosylhomocysteine ratio, and increasing the accumulation of lactate in brain cells (Benton, 2012; Black, 2008).

Provision of vitamin B<sub>12</sub> is therefore essential for pregnant and breastfeeding mothers and infants. During pregnancy, serum vitamin B<sub>12</sub> concentrations in the mother decline, and they are concentrated in the placenta and transferred to the fetus down a concentration gradient, with newborn vitamin B<sub>12</sub> concentrations approximately double those of the mother. The total vitamin B<sub>12</sub> requirements of the fetus are estimated to be 50 µg, whereas maternal stores in well-nourished women are estimated at greater than 1000 µg. Thus body stores are adequate to meet fetal needs during gestation.

During pregnancy, vitamin B<sub>12</sub> is stored in the fetal liver, so that infants whose mothers are well supplied with vitamin B<sub>12</sub> are born with a supply sufficient for the first several months. An increased risk of vitamin B<sub>12</sub> deficiency is associated with dietary deficiencies with low consumption of animal-source foods, as occurs with strict vegan or vegetarian diets or alternatively with impaired B<sub>12</sub> vitamin absorption. The recommended dietary allowance (RDA) for vitamin B<sub>12</sub> in pregnancy is 2.6 µg/day, 0.2 µg/day greater than the RDA for nonpregnant women and adolescents.

### Vitamin D

Vitamin D has recently been considered a neurosteroid and is thought to have a role in brain development and function. The role of vitamin D in the brain is not yet known, but research in recent years has yielded considerable evidence supporting this hypothesis. The major metabolites of vitamin D are present in human cerebrospinal fluid, and the enzymes involved in the conversion of vitamin D are present in the brain. In addition, vitamin D receptors are expressed throughout the human brain. All these findings indicate that vitamin D, like other neurosteroids, may play a role in brain function. Vitamin D receptors appear early in the fetal brain and increase in number during gestation, which may indicate that vitamin D is involved in neurologic development (Benton, 2012).

It has been proposed, but not proven, that low levels of vitamin D during pregnancy and infancy could increase the

risk of neurodevelopmental disorders and psychiatric problems such as schizophrenia and autism.

Although it is found in some foods, exposure to sunlight is the greatest source of vitamin D. Changes in lifestyle, including less exposure to the sun and obesity, lead to vitamin D insufficiency in industrialized countries. The vitamin D RDA for women, including during pregnancy, has been recently established at 600 IU per day. Breastfed infants are at high risk of vitamin D deficiency because of the low levels of this vitamin in breast milk. Therefore all breastfed infants should receive a daily vitamin D supplement of 400 IU beginning in the first few days of life.

### Other Vitamins

Some other vitamins have been related to neurologic development, although evidence is still scarce and the possible mechanisms of action need to be elucidated.

Vitamin A is a member of the family of nuclear steroid transcription regulators, and as such, exerts transcriptional control over genes and proteins in different tissues, including genes that control neural differentiation, and plays an important role in neuromodulation. Retinoic acid is a signaling molecule in the brain of growing and adult animals, and retinoid receptors have been found in the hippocampus of rats, which plays a role in memory. Dietary vitamin A deficiency is globally one of the most common forms of malnutrition, with clinical manifestations including ocular disorders, immunosuppression, and impaired growth. It plays a critical role in visual function, and a deficiency continues to be a major cause of infantile blindness in some developing countries. The role of vitamin A on the human brain is poorly understood, but it has been suggested that it influences memory and sleep and plays a role in depression and Parkinson and Alzheimer diseases. The effects of vitamin A deficiency are more likely to be observed in developing than in industrialized countries, where variations in vitamin intake within the normal range may not have functional implications (Benton, 2012).

Thiamine (vitamin B<sub>1</sub>) has an important role in nerve conduction and the synthesis of the neurotransmitter acetylcholine. Studies in animals have noted that thiamine-dependent enzymes play an important role in establishing adult patterns of brain energy metabolism and myelin synthesis. Thiamine requirements are enhanced during pregnancy and lactation, especially in the third trimester when thiamine is preferentially taken up by the fetus. Data from a single study have related thiamine dietary supplementation in children with better intelligence scores, visual acuity, faster reaction times, and better memory. Thiamine deficiency during pregnancy has long-lasting consequences for cognitive development, but this effect has not been demonstrated for subclinical deficiencies (Benton, 2012). Clinical manifestations of dietary thiamine deficiency (beriberi) primarily affect the cardiovascular and nervous systems.

Pyridoxine (vitamin B<sub>6</sub>) is a coenzyme necessary for the production of various amino acid neurotransmitters, including serotonin and noradrenaline. Its deficiency has been associated with irritability, seizures, and peripheral neuropathy in children. Infantile seizures caused by dietary B<sub>6</sub> deficiency are rare and may be seen in developing countries. Furthermore, pyridoxine dependency has been recognized in some types of epilepsy and pediatric neurotransmitter diseases. Studies in animals have shown structural and functional impairments in the hippocampus in subjects that are prenatally vitamin B<sub>6</sub> deficient. Some other studies have reported an association between vitamin B<sub>6</sub> and autism, although recent reviews did not have conclusive results. The influence of vitamin B<sub>6</sub> supplementation during pregnancy on neurologic development

has been recently reviewed, but there is insufficient evidence at this time to recommend supplementation (Benton, 2012).

Choline is the precursor of the neurotransmitter acetylcholine, and it is a precursor for phospholipids that are constituents of cell membranes and the methyl donor betaine. Plasma levels of choline are high in the newborn, which suggests an important functional role. During pregnancy it is critical for brain development as it influences stem cell proliferation and apoptosis, thereby altering brain structure and function (Benton, 2012). Although it is accepted that choline plays a role in brain development, there is to date no evidence that adding choline to the diet improves cognitive development.

### Long-Chain Polyunsaturated Fatty Acids

The most frequently studied nutrients have been long-chain polyunsaturated fatty acids (LC-PUFA). LC-PUFA have important structural and metabolic functions in the human body. The two major LC-PUFA synthesized in the human body are docosahexaenoic acid (DHA) and arachidonic acid (AA). Mammals are unable to synthesize polyunsaturated fatty acids, thus their precursor essential fatty acids, linoleic acid (LA) and linolenic acid (ALA), must be obtained from the diet. The most abundant fatty acid in cell membranes is DHA. It is present in all organs but it is particularly abundant in neural tissues such as the brain and retina.

Lipids constitute approximately 50% to 60% of human brain dry weight; about 35% of the lipids are polyunsaturated fatty acids, and most of them are LC-PUFA. From the beginning of the third trimester of life to 2 years of postnatal age there is enrichment in the relative content of DHA in the brain. Fatty acids in the brain can either be taken up from the blood as preformed DHA or synthesized from ALA inside the brain. Several hypotheses have been proposed to explain the role of DHA in the brain, which in general can be divided into properties conferred by lipid-bound DHA in the membrane bilayer and those related to unesterified DHA. Changes in membrane DHA content can alter membrane physicochemical properties and also affect the signal transduction pathway and neurotransmission. The high proportion of DHA in neural membranes also raises the possibility that n-3 LC-PUFA deficiency may impair membrane biogenesis, influencing neurogenesis, neuronal migration, and outgrowth. Unesterified DHA has a role in regulating gene expression which is influencing stem cell differentiation to neurons and ion channel activity. It can also be further metabolized to neuroprotective metabolites in the brain, and it has been suggested that it has an important role in neurogenesis. Thus n-3 fatty acid deprivation may affect brain development at multiple levels, with the effects and potential for recovery differing depending on when the deficiency occurs.

The effects of LC-PUFA on neurodevelopment outcome have been widely studied. In premature births, the umbilical transfer of LC-PUFA is interrupted, thus preterm infants have lower LC-PUFA concentrations than full-term infants. The beneficial effects of adding LC-PUFA to preterm formulas have shown conflicting results with regard to neurodevelopment. Several studies have demonstrated improvements in electroretinogram activity, visual acuity, and short-term global developmental outcome, but recent meta-analysis has shown no clear long-term benefits for preterm infants receiving LC-PUFA supplemented formula on pooling results (Campoy et al., 2012).

However, an inappropriate supply of lipids in preterm infants has been reported to lead to biochemical deficiency of essential fatty acids, causing reduced body and brain weight (Hsiao et al., 2014). Meta-analysis of the effects of LC-PUFA in term infants or during pregnancy and early infancy

conclude that there is insufficient evidence to affirm that supplementation exerts a clear and consistent benefit (Campoy et al., 2012). Trials are normally conducted in developed countries with relatively healthy infants, thus they should receive adequate DHA transplacentally and in breast milk. The benefits of supplementation on neurodevelopment might be more pronounced in undernourished children. Furthermore, recent evidence shows that n-3 LC-PUFA supplementation is effective for improving behavioral problems such as attention deficit/hyperactivity disorder (Hsiao et al., 2014).

The main natural source of LA and ALA are vegetable oils, particularly safflower and corn oils. AA and DHA are not found in plants, but are synthesized by animals. Only small mammals accumulate a high proportion of them. Meat and eggs are rich sources of AA but not DHA. Marine food is rich in n-3 PUFA as algae are the primary producers of DHA and EPA in the ecosystem. Fish are therefore rich in DHA. Western diets are characterized by low n-3 fatty acids intakes and high amounts of n-6 fatty acids; as a result, EPA and DHA demands are not adequately supplied. The exclusion of fish and meat from the diet can result in very low intakes of DHA. Before birth, DHA is transported to the fetus from the mother across the placenta, and after birth the infant is provided with DHA in breast milk. Therefore pregnant and lactating mothers should receive an average DHA intake of at least 200 mg/day, which means a consumption of two servings of fish weekly.

It is unreasonable to expect that micronutrients examined in isolation will be associated with differences in cognitive functioning. Brain function is the result of millions of metabolic processes in which nutrients act in combination. Furthermore, a diet deficient in one component is also likely to be poor in others. A multivitamin and mineral approach is probably more beneficial in terms of cognitive development.

It is widely accepted that an insufficient intake of calories, proteins, and micronutrients at critical stages of brain development can produce irreversible changes in brain structure and consequently reduce cognitive capacity for life. There is

controversy concerning the effects of dietary supplementation in infants who are well fed, however; it is likely that only those children who are poorly nourished respond to nutritional interventions. Further research is necessary to address this question.

## INTRODUCTION

The neuronal ceroid lipofuscinosis (NCL) disorders are a group of genetically inherited lysosomal neurodegenerative diseases characterized by the intracellular accumulation of autofluorescent lipopigment storage material that causes progressive neurologic degeneration in all age groups. The clinical course includes progressive dementia, seizures, progressive visual failure (except in the adult-onset forms), and often movement abnormalities.

Collectively, these disorders are the most common cause of an inherited childhood neurodegenerative disease and are increasingly recognized in late-onset or adult-onset forms. Prevalence is estimated widely from 1.5 to 9 per million, and incidence, which varies among geographic ethnic regions, has been reported from 1.3 to 7 in 100,000 live births. The clinically relevant pathobiology affects primarily the central nervous system and may include, in variant fashion, cognitive failure (dementia, encephalopathy), seizures that often are myoclonic, movement abnormalities that are often ataxic or extrapyramidal in nature, and visual failure. Retinal degeneration and visual failure are rare in the adult forms of these diseases.

This group of genetic disorders has an autosomal recessive inheritance, except the rare autosomal dominant adult-onset disorder. Summaries of NCL disorder mutations and relationship to clinical features have been published.

## HISTORICAL CLINICAL CHARACTERIZATION

### Nomenclature

Historically, these disorders were characterized by clinical age of onset and pathologic hallmarks of lysosomal deposition. The individual disorders were initially given names honoring those who first identified the clinical spectrum in narrow ethnic populations and in reference to age of onset. The classic clinical distinction was therefore infantile (INCL), late-infantile (LINCL), juvenile (JNCL), and late-onset or adult (ANCL; Kufs). The terminology is confusing because it was established before many clinical variants or disorders were defined and before the identification of the etiologic genes. Classification by age of onset is still useful in clinical evaluation. Atypical forms with variable ages of onset are well described. Distinguishing these disorders by genetic etiology is now currently favored and serves the study of disease-specific pathobiology (Table 48-1).

The term "Batten disease" was originally used to honor the clinician that first recognized this disease in the juvenile-onset form. Although historically incorrect when applied to all the NCL disorders, this designation is a simple and practical one and has been universally adopted and accepted by family groups, private foundations, and U.S. government agencies.

## Clinical Description and Characterization

The first clinical description of NCL was that of the juvenile form in a small Norwegian family. This was soon followed by clinical and pathologic descriptions of familial cases within a larger population of so called "amaurotic family idiocy" by Batten, Vogt, Spielmeier, and Sjögren. A detailed historical summary of the lives and work of these early and seminal clinician researchers has been published.

Significant interfamilial variability in phenotype, in many of the early described NCL cases, gave challenge to a unifying classification. Originally, the NCL disorders were grouped among the sphingolipidosis and the more global clinical characterization as "amaurotic idiocy." The term "neuronal ceroid lipofuscinosis" was introduced by Zeman and Dyken in 1969, referencing primarily the common pathologic feature of these disorders. Earlier investigators had difficulty distinguishing whether these were single disorders or related ones. But by collection, observation, and report of familial cases, five types of NCLs were eventually clinically characterized: congenital, infantile, late infantile, juvenile, and adult onset.

The congenital form was first clinically described by Norman and Wood in 1941 and later associated with cathepsin D deficiency in congenital school-age or adult forms. This NCL has been designated CLN10 (CTSD).

The infantile form (INCL; CLN1; Santavuori-Haltia) was clinically described by Hagberg in 1968 and then by Haltia and Santavuori in 1973. Although originally described as infantile in onset, late-infantile, juvenile, and adult forms have been reported. The underlying cause of CLN1, palmitoyl protein thioesterase 1 deficiency, was identified by linkage and fine molecular mapping.

The classic late-infantile (LINCL; CLN2; Jansky-Bielschowsky) form was originally described in patients by Jansky in 1908 and Bielschowsky in 1913. Cases were reported throughout the 1970s with typical clinical presentation and disease course. The underlying cause of CLN2, tripeptidyl-peptidase deficiency, was identified by protein study. Clinical correlation with genotype has been reported, although the phenotype continues to be expanded. Other nonclassic late-infantile clinical disorders have been described, including variant late-infantile and early-juvenile forms due to defects in the CLN5 gene in patients first described clinically in 1991 and in CLN6, CLN7 (MFSD8), and CLN8. A possible CLN9 form has been described that is clinically similar to the juvenile form, although no unique associated genetic locus has been yet identified and the originally reported two sibships have been later shown to have CLN5 disease.

The classic juvenile form (JNCL; CLN3; Batten disease) is the most prevalent and characteristic of the NCL disorders. Juvenile, other than CLN3 disease, and early adult-onset forms have been recently characterized by clinical features and molecular gene identification. The adult-onset disorder, later

#few cases only

termed Kufs disease in honor of the early clinician who recognized this disorder in 1925, is an autosomal recessive form of early-onset dementia with seizures, with or without movement abnormalities, but without vision loss. An autosomal dominant adult-onset form (Kufs, Parry-type) was much later described. Sporadic late-onset cases have since been reported and collectively are grouped as Kufs disease. These include the autosomal dominant form CLN4 associated with DNAJC5, autosomal recessive CLN11 disease, associated with GRN mutations, and with phenotypic overlap with frontotemporal dementia (FTLD-GRN) and CLN12, also termed Kufor-Rakeb or PARK9, associated with mutation in the *ATP13A2* gene. Smith and colleagues also described a late-onset form of NCL, termed CLN13 and associated with mutation in *CTSF*. A late-onset form of CLN6 disease has also been described.

Molecular genetic technologies, studies in families, and sporadic cases eventually have led to a NCL disorder classification based on gene mutation (Table 48-1). Although this allows separation into distinct genotypes, there is much evidence that the NCL genes may participate in interrelated pathways and in an overlapping pathobiology. There is increasing recognition of a broad clinical phenotypic scope of each of these genetic forms, with reports of increased intrafamilial variability and of atypical cases. It is presumed that there are important epigenetic modulators to be identified that directly or indirectly affect clinical expression within any one of these genetically defined disorders.

In addition to observational clinical case and familial reports, formal assessment tools have been developed and validated. Published and utilized in clinical study are those for infantile and late-infantile forms, Hamburg scale, Weil-Cornell scale, and for juvenile CLN3 (UBDRS) scale. These are important instruments for the study of the natural history and for clinical trial efficacy measurements.

Although the classic clinical features, if all present, (encephalopathy/dementia, seizures, visual loss  $\pm$  movement disorder) clearly point to a NCL disorder, there is broad and important differential diagnosis which needs consideration. This may, in fact, account for the sometimes long delay in diagnosis. There are many NCL masqueraders particularly in the early stages of disease when only a single clinical feature is evident (Table 48-2).

## Molecular Genetics

Molecular genetic study of NCL-like patients has allowed for the identification of etiologic genes in clinically identified forms, including congenital, late-infantile, juvenile, and adult-onset. Currently 13 genetic loci are identified in association with human NCL disease (Table 48-1).

The first NCL genes were identified in 1995 for the infantile-onset form (INCL; CLN1), encoding the soluble lysosomal protein palmitoyl protein thioesterase 1 (PPT1) and the *CLN3* gene, responsible for the juvenile form (JNCL) reported by a NCL consortium. This was followed by identification of the late-infantile, classic form (CLINCL; CLN2) gene, encoding the soluble lysosomal protein tripeptidyl peptidase 1 (TPP1) in 1997. Variant late-infantile forms have subsequently been identified and include CLN5, CLN6, CLN7, CLN8, and CLN14 (KCTD7). The later has more commonly been described in association with progressive myoclonic epilepsy without documented NCL-like visual failure or pathologic inclusions. A primarily congenital-onset form CLN10 (CTSD) was identified although later onset cases have been described. The genetic etiology of late adult-onset NCL disorders has been identified among the cohort of both sporadic and familial cases by whole exome sequencing. Genetic loci include one autosomal dominant inherited form CLN4 (DNAJC5) reported simulta-

neously by a number of groups as well as in an autosomal recessive pattern in CLN11, CLN12, and CLN13. As there are cases that, by clinical history and pathologic features, appear to be NCL-like, it is presumed that more genetic loci will be identified in the future. Continued elaboration of a widening phenotypic spectrum, for many of these disorders, is also ongoing.

An updated mutation database of all NCL disorders is maintained at the University College of London by Sara Mole ([www.ucl.ac.uk/ncl](http://www.ucl.ac.uk/ncl)), and publication of mutation spectrum and phenotypic correlations has expanded our understanding of these disorders.

## Pathology

Early pathologic description of storage material in patient tissues documented an autofluorescent, waxy, dusky lipid accumulation in neuronal endosomes, reminiscent of the aging pigment lipofuscin. This led to the term neuronal ceroid lipofuscinosis being applied to these neurodegenerative disorders. By electron microscopy, these pathologic hallmarks are membrane-bound (lysosomal) inclusions most prominently seen in neurons but recognizable in many cell types. Common sites of biopsy and inclusion identification include the skin, conjunctiva, and/or rectal tissues. Inclusions can appear as granular osmophilic deposits (GRODs), curvilinear (CL), rectilinear (RL), or as more crystalline fingerprint bodies (FP) (Fig. 48-1). Unique to juvenile CLN3 disease are the vacuoles seen by EM in circulating lymphocytes. These ultrastructural crystalline structures have remained an important distinguishing feature of the NCL disorders. Identification of this storage material, by biopsy and EM, strongly suggests an NCL diagnosis. Unfortunately, peripheral tissue biopsy may be negative, as is particularly true in the late-onset forms of NCL. In many of these cases, however, central nervous system storage has been demonstrated. Lipopigment accumulation is presumed to alter lysosomal function, lead to autophagy disruption, and/or cellular oxidative damage.

Lysosomal storage of saposins A and D in CLN1 and subunit *c* of the mitochondrial ATP synthase in CLN2, CLN3, and adult-onset forms are most likely epiphenomenon, or secondary markers, and not disease-specific markers of the primary underlying molecular pathology. Neuronal loss in brain, predominantly in cerebral and cerebellar cortices, and retina, is also characteristic of the NCL disorders, although the underlying biology of this cell loss is not yet clear.

## Pathobiology

The pathobiologic details are still being elaborated. In the NCL disorders, there is protein deficiency, pathway blockade, and metabolic substrate accumulation, as well as downstream functional deficiencies and potentially detrimental cellular compensatory changes, which may lead to cellular pathobiology and the resultant clinical phenotypes. Active research is ongoing to elucidate the protein functions, the substrates and interacting partners of these proteins, the mechanisms of neuronal death, and the relationships between the various NCL proteins. Affected intracellular pathways involve at least the endosomal-lysosomal autophagy degradation pathways, the synaptic trafficking and function pathways, and the neuroinflammation/immune regulation pathways (Fig. 48-2).

CLN1 and CLN2 are caused by deficiency and metabolic block of the classic soluble lysosomal hydrolases PPT1 and TPP1, respectively. Mitochondrial abnormalities in the NCL disorders have also been described, including abnormal mitochondrial ATP synthase regulation, mitochondrial structural changes, and altered respiratory chain function, as well

as decreased cellular ATP production and neuronal survival in the context of oxidative stress. Mitochondrial dysfunction appears linked to cytoskeleton-mediated presynaptic inhibition in the homozygous CLN3 knockout mouse. Altered mitophagy as a result of NCL-defective autophagy or increased vulnerability to metabolic stress may play a role in the NCL cellular pathobiology associated with the increased oxidative stress and decreased neuronal survival seen in these disorders. Recently human induced pluripotent stem cells (iPSCs) models of CLN2 and CLN3 have been shown to have mitochondrial structural abnormalities, increase mitochondrial ATPase subunit *c*, in addition to abnormalities in structure and function seen in Golgi, ER, and endosomal-lysosomal compartments.

Altered biometal homeostasis and deregulation has also been noted in the NCL disorders. The cellular mechanisms, which may be a secondary phenomenon in the NCL disorders, have yet to be fully elaborated. CLN5 glycosylation defects have been noted and may be further evidence of the widespread and complex secondary cellular pathobiology. Current studies, focusing on the complex endosomal-lysosomal autophagy pathway, continue to highlight potential network disruptions in these disorders. Specific gene mutations may trigger distinct processes that converge on a common cellular pathway as has been shown in CLN6 and CLN3 murine models. Alternatively, there may be direct and specific interactions between these proteins as has been documented between CLN2, CLN3, and CLN5. These studies speak to the nonindependent nature of these pathways and serve to challenge or models of pathobiology and therapeutic intervention.

## NCL Models and Clinical Trials

Animal models, both naturally occurring and those produced by genetic technologies, have been utilized in the pathobiologic study of many of the NCL disorders. The spontaneous models include many large animals (dogs, sheep, cattle, cats, and goats). Even unicellular and simple animals have yielded NCL models, including those in yeast, *C. elegans* and *Drosophila*. The technologies for generating iPSCs lines from human fibroblasts and the techniques being developed that allow for reprogrammed cell-phenotypic differentiation have invaluable changed the ability to make human model systems for these disorders. Recent report of success in generating human iPSCs as models of CLN1 and CLN3 has been reported and allows for study of the endocytic pathway.

Therapeutic approaches to the NCL disorders have included enzyme replacement, gene and stem cell delivery, and pharmacologic therapies.

## Diagnosis

The diagnostic approach has changed through the years and will continue to evolve as panels and whole exome/whole genome technologies and bioinformatics improve. One approach to diagnose NCLs, based on the age of presentation, can be found on Figure 48-3. Skin biopsy is still useful when the initial screen for common CLN disorders is negative or when genetic testing is not as readily available as ultramicroscopic techniques. Sequential evaluation of NCL genes based on age of presentation was the common approach. However,

the introduction of panels, especially epilepsy panels, makes the latter more time and cost efficient. False negative assay results must be taken into consideration given current next-generation sequencing efficacy. As a general approach, when a patient presents with refractory epilepsy and/or signs/symptoms concerning for a NCL disorder, performing an epilepsy panel that has several NCL genes included is a good strategy. Current epilepsy panels in the United States involve more than 70 genes known to cause epilepsy, including almost all the NCL ones. If successful, this allows an expedited diagnosis of an NCL disorder (avoiding expensive sequential gene testing) or the identification of a non-NCL gene that explains and can guide treatment/counseling of the epilepsy of the patient. Whole exome sequencing (WES) will play an increasingly prominent role in NCL patient identification, particularly in atypical cases.

## CLN1 (PPT1; OMIM #256730)

### Clinical Description

The typical presentation is of an infantile onset disorder presenting at around 10 to 18 months of age and characterized by profound neurodevelopmental regression with motoric deterioration, seizures, and visual failure. The course of the disease is rapidly progressive and leads to an early vegetative state with prominent spasticity. The children usually die within the first 10 years of life.

There is often microcephaly that may have been evident at birth. Visual impairment can be seen at around 1 year of age and there is blindness by 2 years of age. Optic atrophy, thinned retinal vessels, and a discolored, brownish macula are seen funduscopically. Commonly, myoclonic jerks appear after the first year, and many develop generalized seizures. Hand-knitting movements similar to Rett syndrome are observed early but disappear by 2 years of age. At 3 years of age, children are bedridden, hypotonic, irritable, and spastic. At 5 years of age, severe flexion contractures, acne, hirsutism, and rarely, precocious puberty are observed. Children with CLN1 have hypothermia and bradycardia risk especially during anesthesia. Most children die between the ages of 7 and 13 years.

### Other Presentations

- Later presentation similar to the variant late-infantile onset. Onset is between 1.5 and 3 years. The main features are behavioral disturbances and cognitive decline. Myoclonic jerks are the most prominent paroxysmal phenomenon. Neurologic regression was associated with shrinkage of cortical structures.
- Juvenile form is similar to CLN3 but differs as learning problems present initially rather than visual problems and with regression of acquired skills at an earlier age. In a reported case, Behavioral problems followed by vision changes started at 6 years of age and was followed by isolated myoclonic jerks in arms. Seizures appeared at 17 years of age as well as ataxia and intermittent delusions. Another juvenile form presented in an 8-year-old boy with progressive vision loss followed by cognitive and behavior problems. No seizures have been reported.
- An adult presentation, starting after 18 years of age, has been described with mood changes and declining academic performance followed by vision changes (including visual hallucinations). Extrapyrarnidal syndrome (hypokinesia, bradykinesia, rigidity), an unstable flexed posture, and cerebellar ataxia has also been reported in two French

sisters. Frank seizures have not been reported up to now. Electroencephalography (EEG) showed generalized reduced activity without periodic abnormalities. The progression has been slow.

## Genetics and Pathology

The genetic defect is in the palmitoyl protein thioesterase 1 (PPT1) gene, which encodes a soluble lysosomal enzyme (PPT1). The function of this lysosomal thioesterase is to remove fatty acids attached in thioester linkages to cysteine residues in proteins. Proteins containing the fatty acylated cysteine residues are usually found at the inner plasma membrane leaflet. PPT1 is located in the lysosome and taken up in a mannose-6 phosphate-dependent manner. PPT1 has also been shown to be localized in synaptic vesicles in neurons. PPT1 deficiency has been implicated in the disruption of the lysosome-endosomal pathway and in other cellular processes, including endocytosis, vesicular trafficking, synaptic function, lipid metabolism, neural specification, and axon connectivity. PPT1 deficiency seems to be involved in cell susceptibility to apoptotic cell death, in abnormalities in the number, intracellular localization, pattern and morphology of mitochondria, as well as defects in the mitochondrial enzyme activities and adaptive energy metabolism. The accumulation of sphingolipid activator proteins A and D (SAPs) in storage cytosomes is probably a secondary phenomenon.

*Definitive Diagnosis:* PPT1 enzyme analysis with identification of confirmatory PPT1 mutations. For further details of diagnostic evaluation, see [Table 48-1](#) and [Figure 48-3](#).

## CLN2 (TPP1; OMIM #204500)

### Clinical Description

CLN2 disease, in its classic form, has an onset between 2 and 4 years of age with epilepsy being the initial symptom in most cases. Seizures can be generalized tonic-clonic, focal, absence, and/or myoclonic (most prominent in the face). Thereafter, there is decline in motor skills, often with ataxia and deterioration of speech and language. Sometimes slowing of developmental milestones is evident before the onset of seizures. Visual loss begins often by the fourth year of life and is slowly progressive. Some patients may retain some visual function during the first decade. An early hypotonia is replaced with severe spasticity with flexion contractures. Autoregulation of vascular tone is lost, resulting in mottled, cold hands and feet and hypothalamic involvement leads to temperature instability. Hyperthermia often leads to unnecessary fever evaluation for infectious cause. Copious secretions and shallow breathing due to poor chest wall excursions often lead to pneumonias. Most children are nonambulatory and mute by 5 years of age, totally dependent of caregivers and need g-tube support when swallowing becomes problematic. Sepsis and uncontrollable seizures are frequently the cause of death at the end of the first decade or in the early teens.

### Other Presentations

- An infantile form of CLN2 has been described with onset before the first year of life. In one case, the patient had microcephaly and hypotonia noted at the fourth month of life with impairment of motor and language abilities. By 4 years of life, the patient developed signs and symptoms of progressive myoclonic encephalopathy along with motor and cognitive deterioration.

- A slowly progressive autosomal recessive spinocerebellar ataxia with childhood onset, referred to as SCAR7 (OMIM #609270) has been described.
- A juvenile form of CLN2 disease has been described with disease onset between 6 and 10 years and a protracted phenotype. In one case epilepsy was absent.

## Genetics and Pathology

CLN2 is caused by defects in a pepstatin-insensitive lysosomal tripeptidyl peptidase (TPP1) that normally removes tripeptides from the amino terminus of proteins. This protein is a soluble lysosomal hydrolase that is transported to the lysosome by a mannose 6-phosphate receptor mediated pathway. The *in vivo* substrates of this protein are not fully known, but TPP1 has been reported to initiate degradation of subunit *c* of the mitochondrial ATPase protein. In CLN2 human disease, the gene mutations are primarily missense ones. They are predicted, based on analysis of the CLN2 protein crystal structure, to disrupt folding and to lead to protein instability and degradation.

*Definitive Diagnosis:* TPP1 enzyme analysis with identification of confirmatory TPP1 pathologic mutations. For further details of diagnostic evaluation, see Table 48-1 and

 Figure 48-3.

## CLN3 (CLN3; OMIM #204200)

### Clinical Description

The juvenile form of NCL (JNCL), the most common form of this group of neurodegenerative disorders, is associated with mutations in the CLN3 gene. The first sign of the disease is decreased central vision caused by progressive retinal degeneration (retinitis pigmentosa) usually observed between 4 and 6 years of age. Initial clinical difficulties may be attributed to behavioral issues until the visual loss is recognized. These children are usually followed initially by ophthalmologists as normal children with retinitis pigmentosa who show better use of their peripheral vision. Patients become completely blind between 10 and 14 years of age but sometimes even later. Retinal findings can include macular retinal pigment epithelium atrophy, pigment stippling, bull's eye maculopathy, retinitis with the appearance of peripheral bone spicules, and variable disk pallor. Complete blindness is accompanied by a disturbed sleep-wake cycle and insomnia. There is slow cognitive regression that occurs during the initial years of this disorder. A subset of affected children may manifest difficult behavior between the ages of 7 and 9 years. There also can be a variety of behavioral symptoms, including anxiety, aggressive behavior, depression, and visual hallucinations. By at least 10 years of age, cognitive decline is noted. Epilepsy can start as early as 12 years of age, but usually seizures do not occur until 14 years of age. Seizures are primarily generalized tonic-clonic, but patients can also have focal and/or myoclonic seizures. Seizures are relatively easily to control until later stages of the disease. Speech is echolalic with perseveration of speech, and there is dysarthria usually after 15 years of age. Cogwheel rigidity is also present in the limbs, and patients walk with a stooped, shuffling gait reminiscent of patients with Parkinson disease. An intention tremor of variable severity is often observed. Patients generally plateau in their middle teens. A large number of patients become depressed and agitated, and a small number become aggressive and psychotic. Growth and physical maturity are not affected. Late-stage symptoms include drooling, difficulty swallowing, and weight loss. Temperature instability, with episodes of extreme hypothermia down to

92°F, alternating with hyperthermia, points to hypothalamic involvement. Some patients develop a cardiomyopathy or sick sinus syndrome with bradycardia. Most patients succumb in their early to mid-20s to seizures and cardiopulmonary arrest. A small number can survive into the fourth decade of life.

### Other Presentations

- Variant forms of CLN3 disease are associated with a slower disease progression. In some cases, there may be a long silent period after initial visual failure, and patients may remain free of additional neurologic deficits even for decades.
- A complex syndrome characterized by autophagic vacuolar myopathy (AVM), hypertrophic cardiomyopathy, pigmentary retinal degeneration, and epilepsy has been described associated with p.Gly165Glu mutation in CLN3.
- Cases of retinitis pigmentosa and cone-rod dystrophy have been associated with CLN3 mutations.

## Genetics and Pathology

A common 1.02-kb deletion accounts for 85% of disease alleles in the United States cohort and more than 93% of CLN3 cases carry at least one common 1.02-kb deletion allele. This suggests a founder effect. Deletion alleles are associated with production of prematurely truncated products. Compound heterozygous point mutation cases are rare. More than 60 mutations have been reported in the CLN3 gene.

CLN3 is an endosomal/lysosomal transmembrane protein that seems to play a pivotal role in the late endosomal/lysosomal membrane transport system. In neuronal cells, a substantial fraction of CLN3 is additionally targeted to neuronal extensions and synaptosomes in which it has been found to reside in early endosomes, presynaptic vesicles, and in so far unidentified vesicles. CLN3 is highly conserved across species. Proposed functions of CLN3 include a possible role in lysosomal acidification, membrane fusion, vesicular transport, autophagy, apoptosis, proteolipid modification, lipid metabolism, mitochondrial abnormalities, and neurotransmission. Furthermore, CLN3 has been shown to interact with CLN5. CLN3 also appears to play a role in the actin/myosin-associated functions and the microtubular system.

*Definitive Diagnosis:* Molecular testing for the common CLN3 deletion and, if necessary, full CLN3 coding region sequence analysis. For further details of diagnostic evaluation, see Table 48-1 and Figure 48-3. 

## CLN4 (DNAJC5; AUTOSOMAL DOMINANT KUF5; OMIM #162350)

DNAJC5 encodes cysteine-string protein alpha (CSF $\alpha$ ) and has been recently identified to cause adult-onset NCL disorder in five kindreds. These familial cases were previously well described with autosomal dominant inheritance.

### Clinical Description

Symptoms usually start during the fourth decade with myoclonic seizures, dementia, and movement abnormalities. Visual function is preserved. In the Czechoslovakian proband, onset was at 30 years of age with myoclonic epilepsy, generalized tonic-clonic seizures, progressive dementia associated with depression, and early death at 37 years of age. Brain pathology documented autofluorescent storage material and

GRODS by electron microscopy. Skin biopsy did not evidence storage by ultrastructural examination. In the reported Parry family, the proband carrying the *DNAJC5* mutation (p.L116del) had a clinical history of irritability and obsessive behavior in mid-20s, seizure onset by 32 years of age, followed by gradual loss of memory and an ataxic gait. Normal ophthalmologic examination was noted up to 34 years of age. Other family members were variably affected by a progressive seizure disorder, ataxic gait, and/or progressive dementia, typically starting in the 20 to 30s.

Extended clinical characterization in 19 affected patients from three families was reported. Variable features of generalized tonic-clonic seizures, myoclonus, ataxia, language dysfunction, and generalized dementia, parkinsonism, and early death were reported.

## Genetics and Pathology

Two human *DNAJC5* mutations have been reported to date, p.L115R and p.L116del. These mutations occur in a highly conserved cysteine-string domain of CSF $\alpha$ . By in silico analysis, the identified human *DNAJC5* mutation (p.L116del) has been shown to significantly decrease CSF $\alpha$  membrane binding and lead to intracellular missorting. There is also predicted possible effect on palmitoylation and aggregation propensity. Other studies also support this pathobiology, as the mutants are mistargeted and form palmitoylation-induced membrane-bound aggregates. How these perturbations lead to the neurodegeneration and clinical phenotype seen in CLN4 disease remains unknown.

**Definitive Diagnosis:** Pathologic mutation identified by molecular sequencing of *DNAJC5*. For further details of diagnostic evaluation, see [Table 48-1](#) and [Figure 48-3](#).

## CLN5 (CLN5; OMIM #256731)

### Clinical Description

CLN5 disease can present as a variant late-infantile NCL. The usual age of onset is between 3 and 7 years, but juvenile and adult-onset cases have also been reported (see later in this chapter). Patients usually present with slight motor clumsiness and hypotonia followed by learning problems. Visual failure and blindness may also be an early sign and by the age of 7 to 9 years, there is significant optic atrophy. Seizures usually appear about age 9. Myoclonus is frequently observed and can appear earlier and independent of generalized or focal seizures. Behavioral problems seem to be infrequent. Ataxia and athetosis can occur later. Children lose the ability to ambulate by about 10 years of age, and death occurs between the ages of 14 and 32 years.

### Other Presentations

- Juvenile onset: visual failure, loss of strength, and tremor in lower limbs starting between 4 and 9 years of age. Disease progression is relatively rapid evidencing behavioral changes, gradual loss of language, myoclonus and seizures, poorly responsive to valproate and clonazepam. There is then rapid progression with blindness and inability to ambulate. Behavioral disturbances and mental deterioration can also be presenting symptoms.
- Adult onset: One patient presented after 17 years of age with cognitive regression, followed by visual deterioration, seizures, and motor difficulties. Two Italian siblings presented in their mid-50s with difficulty walking, dysarthria, and progressive cognitive decline. They carried a homozygous mutation in CLN5.

- A congenital form presenting at 4 months of age has also been described.

## Genetics and Pathology

The mutation spectrum is wide but at least 50% of the mutations cause a premature termination codon through small deletions, small insertions, or nonsense changes. There are more than 30 mutations described at this time. Although relatively broad in nature, the clinical phenotype is similar in the different mutation and ethnic groups.

The CLN5 protein is a soluble lysosomal glycoprotein that is targeted to the lysosome after cleavage from a pro form. The *CLN5* gene expression differs between neurons and glia. High expression in microglia and the very early microglial activation in *CLN5* deficient mice suggest a role for CLN5 in microglial function. The function of CLN5 is unknown. It appears to interact with many NCL proteins including PPT1, TPP1, CLN3, CLN6, and CLN8. PPT1 and CLN5 bind F1-ATPase in vitro, suggesting mitochondrial involvement or defects in lipid transport. A defective sphingolipid transport has also been demonstrated in peritoneal macrophages of the *CLN5* knockout mouse. CLN5 is required for the recruitment of Rab7 and subsequently of the retromer complex required for endosome-to-Golgi trafficking.

**Definitive Diagnosis:** Demonstration of pathologic mutations in *CLN5*. For further details of diagnostic evaluation, see [Table 48-1](#) and [Figure 48-3](#).

## CLN6 (CLN6; OMIM #601780)

### Clinical Description

CLN6 disease presents as other late-infantile variant forms of NCL. The clinical features are similar to the classic late infantile form of NCL. However, a significant proportion of patients have a slightly later onset and a more protracted course with seizures, ataxia, and myoclonus as the leading symptoms. The age of clinical onset of disease is broad with usual range between 2 to 5 years of age. Initial clinical features include motor delay and cerebellar findings of dysarthria and ataxia. Seizures (including myoclonic jerks) start in more than 50% of patients before 5 years of age. Visual failure occurred early in 50% of patients. This disease is rapidly progressive to a vegetative state.

### Other Presentations

- Teenage-onset progressive myoclonus epilepsy: also associated with generalized tonic-clonic seizures and cognitive decline. No report of visual decline, motor weakness, movement disorders.
- Juvenile-onset cerebellar ataxia with seizures: Adolescents presented initially with action tremor, walking difficulty, and ataxia between 7 to 9 years of age. Dysarthria and nystagmus is also present. One patient had generalized tonic-clonic seizures. There was no blindness.
- Adult form: presenting from 16 to 62 years of age with a semiology consistent with Kufs type A or B. Type A patients usually present with seizures (progressive myoclonic and generalized tonic-clonic seizures) followed by dementia. Type B patients often present with dementia or psychosis with ataxia or other movement abnormalities. These patients have no vision changes.

## Genetics and Pathology

The *CLN6* gene encodes a nonglycosylated membrane protein that is localized to the ER. Although the gene encodes a

protein conserved among vertebrates, no functional or sequence homologies have been identified with other proteins. Biologic function and the human pathobiologic dysfunction are poorly understood. It has been postulated that CLN6 mediates selective transport of proteins or lipids that are essential for lysosomal function and acidification. The intracellular degradation of endocytosed proteins appear to be reduced which might be related to the finding of increased lysosomal pH in CLN6-defective fibroblasts. CLN6 also impairs both maturation and enzymatic activity of lysosomal hydrolases. In CLN6 disease, there is accumulation of autofluorescent lipopigments, subunit *c* of mitochondrial ATP synthase, free cholesterol and phosphosphingolipids and glycosphingolipids in lysosome derived storage bodies. CLN6 protein interacts with other proteins. It binds to CLN5 protein, and it interacts with the collapsing response mediator protein 2 (CRMP-2) that is involved in microtubule assembly and cytoskeletal dynamics during axonal outgrowth. CLN6 also appears to regulate genes involved in cholesterol homeostasis, extracellular matrix remodeling, cell signaling, and the immune/inflammatory responses. There have been more than 70 different mutations reported in the CLN6 gene.

**Definitive Diagnosis:** Identification of pathologic mutations in *CLN6* gene. For further details of diagnostic evaluation, see

 [Table 48-1](#) and [Figure 48-3](#).

## CLN7 (MFSD8; OMIM #610951)

### Clinical Description

This disorder was initially called the Turkish variant of late-infantile NCL as it was described in this ethnic group. It is now recognized to be panethnic as disease cases have been subsequently identified in many countries including Italy, Egypt, India, Croatia, Czech Republic, France, and Greece. This disease is hard to distinguish from other late infantile NCL forms (CLN2, CLN5, CLN6, or CLN8). Its onset is usually between 2 to 7 years of age. Initial symptoms are typically aggressive behavior and severe epilepsy in association with developmental regression. The clinical course is rapidly progressive with the appearance of myoclonus/clonic and nocturnal epilepsy, ataxia, dementia, and blindness. Some cases have presented with onset of visual failure and ataxia. There can be significant personality and behavioral changes as well as sleep disturbances. Rett-like onset and a clinical picture that includes midline stereotypic hands movements have been described. Death usually occurs in late childhood, but some patients survive until the second and third decade. Compared with classical CLN2 disease, CLN7 disease shows a somewhat later onset and a more severe seizure phenotype.

### Other Presentations:

- **Pure visual presentation:** It has been shown that heterozygous missense variant mutation p.Glu336Gln in the *MFSD8* gene is associated with nonsyndromic autosomal recessive macular dystrophy with central cone involvement. Affected individuals showed no other neurologic features typical for variant late-infantile NCL. Age of diagnosis ranged from 27 to 57 years.
- **Juvenile:** One case has been described. The patient presented with visual failure at age 11 and showed a protracted clinical course. Motor impairment and seizures developed at 24 and 25 years of age, respectively, followed by ataxia at 28 years of age. Mental and speech regression were noticed at 30 and 36 years. Patient was still alive at 43 years of age and wheelchair bound.

## Genetics and Pathology

The CLN7 protein is encoded by the *MFSD8* gene, which appears to be evolutionarily conserved. This protein is targeted to the lysosomes. Based on sequence homology analysis, CLN7 belongs to the major facilitator superfamily of transporters proteins and is presumed to function as a lysosomal membrane transporter. Its substrate specificity is not currently known. There have been more than 30 *MFSD8* mutations identified to date. Mutation analysis and biologic study seems to show that the primary consequence of the missense mutations is disturbed functional properties rather than altered subcellular localization.

**Definitive Diagnosis:** Genetic demonstration of pathologic mutations in *MFSD8*. For further details of diagnostic evaluation, see [Tables 48-1](#) and [Figure 48-3](#). 

## CLN8 (CLN8; OMIM #600143)

### Clinical Description

CLN8 disease was first recognized in the Finnish population in a childhood epilepsy syndrome, designated northern epilepsy (NE) or progressive epilepsy with mental retardation (EPMR), when neuropathologic studies identified cytoplasmic autofluorescent storage typical of a NCL-like disorder. Initial symptoms are short, frequent, and drug resistant generalized tonic-clonic seizures as well as focal seizures, with onset between 5 and 10 years of age, and cognitive decline. Seizures increase until puberty, when epileptic activity starts to decline but does not remit. Cognitive decline starts 2 to 5 years after the onset of seizures. Intellectual decline is most rapid before adulthood leading to mental retardation by the age of 30 at the latest. After 30 years of age, the patients have difficulties with equilibrium, and they walk slowly using broad-based, small steps. The speech becomes dysphasic in some patients. During childhood and puberty almost half of the patients also suffer from behavioral problems such as irritability, restlessness, disobedience, and inattentiveness. Retinal degeneration, a characteristic finding in NCL, has not been reported in EPMR. However, decreased visual acuity has been detected in some EPMR patients without any obvious ocular abnormality. Age at death varies from 17 years to late middle age, but some survive into the fifth decade.

CLN8 disease can present as typical late-infantile variant NCL, showing an earlier onset and more rapidly progressive disease course than EPMR. Symptoms usually start around 2 to 7 years of age with developmental delay (motor and language) and then onset of myoclonic seizures and ataxia. There is rapid disease progression after the onset of disease, and by the age of 8 to 10 years there is severe disability and worsening epilepsy. Focal and generalized seizures as well as absence seizures may evolve, and seizures can become very difficult to control. Frequently, there are behavioral problems. Spasticity, tremors, and extrapyramidal movement abnormalities are common. By 10 years of age, most of the children are wheelchair bound.

## Genetics and Pathology

Currently, there are more than 25 mutations in the CLN8 gene. The CLN8 protein is localized in the ER and the ER/Golgi intermediate compartment, and its normal function is unknown. An additional location outside of the ER has been suggested in polarized cells, including neurons. It has been postulated that the CLN8 protein may play a role in sensing, biosynthesis, and metabolism of lipids or protection of proteins from proteolysis as CLN8 is a member of the TLC

(TRAM-LAG1-CLN8) protein family. It is also thought that CLN8 protein may function as a protective sphingolipid sensor and/or in glycosphingolipid trafficking, in the synthesis and transport of lipids, vesicular/membrane trafficking, autophagy, and apoptosis.

**Definitive Diagnosis:** Identification of pathologic CLN8 mutations. For further details of diagnostic evaluation, see [Table 48-1](#) and [Figure 48-3](#).

## CLN10 (CTSD; OMIM #610127)

### Clinical Description

CLN10 disease seems, at this point, to be a rare disease. It has been primarily recognized as a congenital form of NCL, although severe late-infantile cases have been described. Clinically, these patients present at birth with microcephaly, respiratory failure, rigidity, and status epilepticus. Death occurs within hours to weeks after birth.

### Other Presentations:

- **Juvenile presentation:** A reported patient first showed neurodegenerative symptoms of ataxia and visual disturbances at early school age. The ocular fundus showed retinitis pigmentosa, and brain MRI revealed cerebral and cerebellar atrophy. The patient developed progressive cognitive decline, loss of speech, retinal atrophy, and loss of motor functions. By 17 years of age, she was wheelchair bound and severely mentally retarded. Another juvenile phenotype (8 to 15 years of age at presentation) was reported in two consanguineous pedigrees. Clinical features included ataxia, retinitis pigmentosa, cognitive decline, and, in one case, cardiomyopathy. All had distinctive muscle pathology (granulovacuolar material in angular atrophic fibers) in addition to GRODs.

### Genetics and Pathology

CLN10 disease is caused by CTSD mutations. The CTSD gene encodes the major lysosomal aspartic protease cathepsin D (CTSD). CTSD is transported to the lysosomes via a mannose-6-phosphate receptor-dependent and independent manner. CTSD is a lysosomal endopeptidase implicated in several specific physiologic functions, including proteolytic processing of selected polypeptides (hormones, growth factors, cytokines, and enzymes), presenting brain antigens, degradation of cytoskeletal proteins, regulation of autophagy, and apoptosis. CTSD has over 50 different interaction partners from various cellular compartments, suggesting involvement in multiple cellular functions. A number of substrates have been recognized *in vitro*, including prosaposin that can be cleaved into saposins A, B, C, and D. Saposins A and D are essential cofactors for some sphingolipid hydrolysis proteins. Currently there have been seven different CTSD mutations reported.

**Definitive Diagnosis:** CTSD enzyme analysis with identification of confirmatory CTSD pathologic mutations. For further details of diagnostic evaluation, see [Table 48-1](#) and [Figure 48-3](#).

## CLN11 (GRN; OMIM #614706)

### Clinical Description

A report of two siblings with an autosomal recessive late-onset neurodegenerative phenotype, lysosomal NCL-like inclusions, and homozygous progranulin (GRN) mutations established CLN11 as a variant phenotype-genotype from the loss-of-

function heterozygous GRN mutations seen in autosomal dominant frontotemporal lobar dementia (FTLD) with TAR DNA-binding protein-43 (TDP-43) inclusions (FTLD-TDP/GRN; OMIM #607485). The identification of NCL cases with GRN homozygous mutations suggests a link between a rare lysosomal disorder and a common late-onset neurodegenerative disease. It also points to potential lysosomal dysfunction in FTLD and highlights the pleiotropic effects of heterozygous/homozygous mutations in a single gene.

The clinical and neurophysiologic features of the CLN11 disorder, as represented by this familial case report and further reported by Canafoglia et al and associates include onset in third decade of a retinal dystrophy with optic atrophy, seizures, myoclonus, and ataxia. There was also evidence in some family members in their late 20s of relatively mild cognitive impairment characterized by borderline executive function difficulties and mild depression. Pathologic characteristics of NCL were identified in skin biopsy (vacuoles, fingerprint lysosomal inclusions). Retinal examination showed pigment epithelial dystrophy, vessel attenuation, and optic neuropathy. OCT showed retinal thinning and disruption of retinal pigment epithelium. ERG was absent in one sibling. EEG was abnormal in both siblings with moderate spike and wave discharges predominantly in the posterior regions against a normal background. VEP showed depressed cortical components and distorted waveforms with flash strobe. Brain MRI (age 22 years) showed severe cerebellar atrophy.

### Genetics and Pathology

Progranulin (PGRN) is a secreted growth factor involved in the regulation of a number of processes and plays an important role in central nervous system neurodegeneration. PGRN biologic activity is mediated through interactions with a number of proteins. Sortilin is a binding partner for PGRN on the cell surface of cortical neurons. PGRN-sortilin interaction regulates PGRN trafficking as sortilin facilitates endocytosis and delivers PGRN to lysosomes. PGRN is localized to late-endosomes and early lysosomes and appears to have a general role as an activator of lysosomal protein transport and, as such, is important in human pathobiology. PGRN is expressed in motor neurons and seems to promote neuronal survival. It has also been shown to protect against mutant TDP43 induced axonopathy. PGRN may even have an immune-regulatory function.

### FTLD Biology/Pathology

The FTLDs are the second most common cause of presenile dementia and, as a group, exhibit variant clinical phenotypes, variable penetrance, selective atrophy of the frontal and temporal brain regions, and variant pathologic characteristics. There is significant overlap with motor neuron disease/amyotrophic lateral sclerosis (FTD-ALS), atypical parkinsonian syndromes, progressive supranuclear palsy, and corticobasal syndromes. These diseases can also be classified by the predominant neuropathological protein that is identified, including FTLD-TDP in which TAR DNA-binding protein-43 is stored. It is within the category of tau- and alpha-synuclein-negative and ubiquitin- and TDP-43-positive cases that those with GRN mutations fall.

FTLD-TDP associated with GRN mutations make up about 20% of FTLD-TDP disorders and were first described in autosomal dominant kindreds in association with tau-negative and ubiquitin-positive deposition. GRN mutations were identified in two families with primary progressive aphasia. FTLD-TDP/GRN is now considered one of a spectrum of

TDP-43 proteinopathies, and a summary of mutations indicate that all reported to date are confirmed or predicted to lead to loss-of-function. This suggests haploinsufficiency as pathobiologic mechanism.

Clinically GRN-associated FTLT-DTP evidences phenotypic variability with a breadth of features including early behavioral abnormalities and executive function loss, dementia with loss of expressive language, or semantic language comprehension, with or without loss of motoric speech. Clinical features may show an overlap with amyotrophic lateral sclerosis, parkinsonism, or corticobasal syndrome. These cases are grouped into subtypes depending on the associated pathologic protein aggregates.

### NCL-FTLD Overlap

FTLD-TDP43/GRN may be a partial deficiency state, with risk of lysosomal dysfunction, whereas in the homozygous state, as seen in CLN11, may represent a more severe pathobiology and include, in addition to the executive dysfunction of FTLT, epilepsy and visual failure. This clinical and pathologic overlap raises the intriguing possibility that lysosomal dysfunction, whether primary or secondary, may be a general feature of neurodegeneration. Further study of the more common human disorder FTLT-DTP/GRN may shed light on the pathobiology of CLN11 and the NCL disorders more broadly.

*Definitive Diagnosis:* Identification of pathologic mutations in GRN. For further details of diagnostic evaluation, see [Table 48-1](#) and [Figure 48-3](#).

### CLN 12 (ATP13A2; AUTOSOMAL RECESSIVE KUFUS DISEASE; OMIM#610513)

#### Clinical Description

*ATP13A2* mutations were first associated in the very rare autosomal recessive juvenile parkinsonism with dementia phenotype (Kufor-Rakeb syndrome, PARK9, KRS, OMIM #606693) in 2006. After identification of *ATP13A2* (neuronal P-type ATPase gene) mutations in a dog model of late-onset NCL, a Belgian family previously reported as juvenile Parkinson disease (PD) and with typical NCL pathology, was studied by whole exome sequencing and a single homozygous mutation in *ATP13A2* was found. In this juvenile PD disorder, the clinical features include pyramidal degeneration, supranuclear gaze palsy, and severe dementia. Putaminal and caudate iron have been demonstrated and complex dystonic features noted in some cases. In the reported CLN12 Belgian family, learning difficulties were noted at about age 8 years. By age 11 to 13 years, there was unsteady gait. Over the next years, myoclonus and worsening ataxia, progressive extrapyramidal features with akinesia, and rigidity and speech difficulties were noted. The proband had severe myoclonus and unintelligible speech and was wheelchair bound by the age of 25 years. In addition to the pyramidal and extrapyramidal dysfunction, there were bulbar signs and evidence of gaze palsy with upgaze restriction. CNS pathologic study showed whorled lamellar inclusions typical of NCL in brain tissue, and there was lipopigment deposition in the retina. Other affected family members showed spinocerebellar ataxia, bulbar signs, extrapyramidal and pyramidal abnormalities, as well as dementia. No visual failure was apparent clinically. A sequence study of *ATP13A2* in 28 patients with adult-onset NCL, however, failed to identify pathologic variants. Further pathologic study of KRS patients is needed to confirm that KRS and CLN12 are allelic. This work highlights, however, the potential important paral-

els between NCL and parkinsonian disorders and suggests that lysosomal pathway disruption may lead to a more general neurodegenerative phenotype.

### Genetics and Pathology

*ATP13A2* is thought to be a lysosomal type 5 P-type ATPase with 10 predicted transmembrane domains. Lysosomal dysfunction in *ATP13A2* defective cells appears to impair  $\alpha$ -synuclein degradation and would presumably predispose to  $\alpha$ -synuclein accumulation and toxicity. There is a growing literature documenting lysosomal dysfunction in Parkinson disease (PD). A review of P-type transport ATPases in PD summarizes dysfunctional *ATP13A2* retention in the ER or other aberrant intracellular localization and function as well as reported evidence of impaired ATPase activity. *ATP13A2* has also been shown to maintain zinc homeostasis and promote  $\alpha$ -synuclein export via exosome, possibly by regulation of  $\alpha$ -synuclein-specific exosome biogenesis and to affect mitochondrial function. In animal models, a loss of *ATP13A2* leads to lipofuscin accumulation as seen in NCL disorders and  $\alpha$ -synuclein aggregation as seen in PD. A wide variety of *ATP13A2* interactors have been delineated, most of which appear to have roles in ER translocation, ER-Golgi trafficking, or vesicular transport. Further study of this interactome may yield additional understanding of the complex interactions in the endosomal-lysosomal pathway broadly important to both NCL and PD pathobiology.

*Definitive Diagnosis:* Identification of pathologic mutations by sequencing of *ATP13A2*. For further details of diagnostic evaluation, see [Table 48-1](#) and [Figure 48-3](#).

### CLN13 (CTSF, OMIM#615362)

#### Clinical Description

This is, as of yet, a rare identified cause of adult-onset NCL. Two Italian siblings were reported after linkage analysis and whole exome sequencing. Mutation in these siblings identified homozygous mutation in *CTSF* as in one other nonrelated patient. Clinical features were different in the two sisters. Whereas one presented at 20 years of age with cerebellar syndrome characterized by tremor, ataxia and dysarthria, the other patient did not show signs until 32 years of age with onset of a depression and cognitive decline. Seizures were noted in both later, and the younger sister then developed a progressive dementia associated with marked emotional lability and death at 42 years of age. The second sister showed cerebellar signs in later stages as well as pyramidal and extrapyramidal abnormalities and was bedridden by 51 years of age.

A recent familial case with apparent "pseudodominant" transmission has been reported in association with a homozygous *CTSF* splice mutation. Initial apparent autosomal dominant transmission raised question in this Kufs phenotype-expressing patients of possible DNAJC5 (CLN4) disease or PSEN1-related early onset Alzheimer disease. Careful history taking and family residence in a small village prompted consideration of potential autosomal recessive inheritance and molecular analysis that led to diagnosis. Clinical features in all reported family members documented presentation in third decade with tonic-clonic seizures followed by dementia in the third to fourth decade.

*CTSF* mutations include 4 missense, one splice, and one frame shift mutation. By structural modeling, these *CTSF* mutations were predicted to cause loss of *CTSF* enzymatic activity. It is less clear how a *CTSF* deficiency may lead to neurodegeneration and lysosomal storage.

## Genetics and Pathology

Human *CTSF* was cloned in 1998 and shown to be a member of a subgroup of the papain family of lysosomal cysteine proteases. *CTSF* is synthesized as an inactive preproenzyme and has been postulated to be targeted to the endosomal/lysosomal compartment via the mannose 6-phosphate receptor pathway, although original work had suggested that it did not contain the usual cathepsin-related signal sequence for lysosomal targeting and that it might be targeted to the lysosome via an N-terminal signal peptide-independent lysosomal targeting pathway. Recent work also suggests that *CTSF* may participate in an alternative lysosomal LIMP-2 trafficking pathway.

*Definitive Diagnosis:* Identification of pathologic mutation in the *CTSF* gene. For further details of diagnostic evaluation, see [Table 48-1](#) and [Figure 48-3](#).

## CLN14 (KCTD7; OMIM #611725)

### Clinical Description

More than 10 patients have been described to date. Mutations in the *KCTD7* gene are associated with an infantile form of NCL and infantile progressive myoclonus epilepsy.

The NCL form has been reported in two siblings who presented with seizures at 8 and 9 months of age. Seizures were myoclonic, precipitated or worsened by fevers and refractory to multiple anticonvulsive drugs. Normal development was until 18 months of age, followed by motor and speech regression. By 12 and 10 years of age, the patients had microcephaly, were nonverbal, and had no spontaneous motoric function. There was no response to visual threat and diminished pupillary light reflexes. One patient had mild, bilateral, optic atrophy. Brain imaging showed global cortical and cerebellar atrophy, and some loss of subcortical white matter. There was NCL-type storage in fibroblasts, neurons and eccrine secretory epithelial cells, and fingerprint and GRODs in approximately 15% of analyzed lymphocytes. Both patients died from complications of progressive disease in their mid teens.

In the infantile progressive myoclonus epilepsy presentation, the disease onset was under 5 years of age (range 10 months to 3 years), presenting with seizures and/or progressive mental and motor impairment with progressive psychomotor regression to severe mental and motor handicap within 2 years (range 1 to 22 months) after onset of seizures. Seizures were myoclonic, atonic, atypical absence, or/and tonic-clonic seizures. Ataxia also developed later and in one case was the presenting symptom. Retinal findings were normal. No lysosomal storage material compatible with NCL was detected in EM analysis of skin biopsies. In the group series of Kousi and colleagues, brain MRI was normal near disease onset in two patients, atrophic changes were seen in one patient, and nonspecific focal lesions were seen in a second patient (only in more advanced disease stages). EEG revealed prominent epileptiform activity with predominance in the posterior region. The patients were still living in 2012.

### Other Presentation

- Opsoclonus-myoclonus, ataxia-like syndrome: A patient presented with onset of myoclonus and ataxia by 13 months, and associated with abnormal opsoclonus-like eye movements at 16 months of age. Epileptic activity was seen on EEG 2 years later as well as two episodes of myoclonic seizures. At 4.5 years of age, the patient communicated but did not speak, had limited vocalizations, and understood

simple commands. He also had mild truncal ataxia and continuous myoclonus. Brain MRI and ophthalmologic evaluation were normal. A compound heterozygous missense mutation and large deletion in the *KCTD7* gene was reported.

## Genetics and Pathology

The *KCTD7* gene encodes the potassium channel tetramerization domain-containing protein 7. Currently there are at least eight mutations reported in this gene. *KCTD7* expression in the murine brain is strong in the mitral cells of the olfactory bulb, the dentate gyrus and CA1–CA3 hippocampal cells, the deep layers of the cerebral cortex, and the Purkinje cells of the mouse cerebellum. The *KCTD7* protein is located in the cytoplasm, with the highest expression near the nucleus and a partial localization at the plasma membrane. It has been shown that *KCTD7* overexpression in transfected primary cultures of murine neurons hyperpolarizes the cell membrane and reduces the excitability of transfected neurons in patch clamp experiments. Therefore mutations in *KCTD7* are consistent with a depolarizing resting membrane potential and increased excitability. It is hypothesized that *KCTD7* is required for the proper permeability of a nongated potassium channel that functions in a voltage range around the resting potential. *KCTD7* also associates with Cullin-3, suggesting that *KCTD7* could be part of an E3 ubiquitin ligase multiprotein complex.

*Definitive Diagnosis:* Diagnosis is made by finding mutations in the *KCTD7* gene. For further details of diagnostic evaluation, see [Table 48-1](#) and [Figure 48-3](#).

## Management and Treatment of NCL Disorders

Unfortunately, there is no cure for the NCL disorders, and management is mainly symptomatic for the range of clinical problems, including seizures, sleep-related problems, malnutrition, gastroesophageal reflux, pneumonia, sialorrhea, hyperactivity, behavior problems, psychosis, anxiety, spasticity, parkinsonian symptoms, and dystonia. A truthful discussion with the caregivers should include goals of care and when the moment is right code status to avoid sometimes unnecessary suffering for the patient and family. There should be surveillance for swallowing problems and microaspirations due to the risk of pneumonia/sepsis as well as x-ray surveillance of hip joints and spine when there is significant immobility or when the patient is wheelchair bound.

**Seizures.** It is one of the hallmark manifestations and can cause the most anxiety in the family. There is no single anticonvulsant medication that will work for all the NCL disorders. An anticonvulsant medication should be selected in discussion with the family and based on the stage of the disease, age of the affected individual, and quality of life assessment. A goal of complete control of seizures may be unrealistic in this disorder. A balance between number of seizures and sedation (which is one of the most common side effects of the anticonvulsant medications) should be discussed with the family and patient (if able to communicate).

In a survey of 60 patients with CLN3, one of the largest to date, lamotrigine and valproic acid showed relatively good seizure control in most patients. However, there was no rationale for the choice of these specific anticonvulsive drugs. Importantly, 54% of patients had refractory epilepsy requiring combination therapy by the middle second decade of age. The pathophysiology of epileptogenesis is poorly understood in NCL, and empiric trial of medication is common. Newer anticonvulsive medications may be more beneficial, but there are no studies in this respect for the

NCLs. Levetiracetam and clobazam should be considered (personal experience).

Benzodiazepines may be of benefit for seizures, anxiety, spasticity, and sleep difficulties. However, the main side effect is somnolence; therefore, again, a balance between symptoms and sedation is imperative. Trihexyphenidyl has been used to improve dystonia and sialorrhea. Antidepressants and antipsychotic agents are sometimes indicated for those with severe mood problems and/or aggression.

Unfortunately, most of the patients become bedridden and, because of swallowing dysfunction and aspiration, pneumonia is a risk. Patients with swallowing problems may benefit from placement of a gastric feeding tube.

Children with NCL disorders benefit from school attendance for socialization and stimulation, even late in the disease. This also affords respite for caregivers. Physical therapy, either at home or at school, is important to avoid painful contractures for the longest period of time possible. The use of augmentative therapies as visual failure occurs and even the teaching of Braille may help in education even for temporary benefit in the context of the progressive dementia. Quality of life assessment in these educational interventions is important. The use of digital tools (tablet, speech-assist devices) may help in communication.

**Genetic Counseling.** (This section is not meant to address all personal, cultural, or ethical issues that individuals may face or to substitute for consultation with genetics professional).

The NCL disorders are autosomal recessive with the exception of one form of adult disease (CLN4) that is autosomal dominant. Once a mutation has been identified in a patient, obtaining parental samples to confirm carrier status is recommended. This will allow family planning for the family as well as discussion with related family members of the risk of inheritance. Siblings of an affected patient have a 25% of being affected, 50% of being an asymptomatic carrier, and 25% of not being a carrier. When the sibling is underage, a discussion with the parents, taking into account current guidelines of national/international genetic associations, is of importance before presymptomatic genetic testing of a minor child. This is particularly controversial and more challenging when the proband has a later onset presentation, and there is a younger sibling. There are genetic guidelines that one should take into account along with the wishes of the family. Patients with infantile NCL, late-infantile NCL, and classic juvenile NCL do not reproduce. Very rarely, individuals with atypical juvenile NCL reproduce, but they are obligate carriers.

An autosomal dominant adult CLN individual has an affected parent. However, an AD adult-onset NCL may have the disorder due to a de novo mutation. Germline mosaicism can also be a cause of not finding a mutation in the parents of an affected individual. Of note, the family history of an affected individual may be negative due to failure to recognize the disorder in a family member, death before onset of symptoms, or late-onset of the disease.

## INTRODUCTION

Channelopathies are a group of genetically and phenotypically heterogeneous neurologic disorders that result from genetically determined defects in ion-channel function. These are considered heterogeneous because mutations in the same gene can cause different diseases and mutations in different genes can result in the same disease phenotype. Mutations of ion channels can alter the activation, ion selectivity, or inactivation of the mutated channel. Neurologic manifestations of channelopathies fall into several clinical phenotypes: epilepsy, pain, migraine, ataxia, movement disorders (all covered in this chapter; see [Table 49-1](#)), and muscle disorders (myotonia and weakness; covered in [Chapter 151](#)).

Ion channels are transmembrane glycoprotein pores that control the excitability of neurons and muscle cells by mediating the flow of charged ions in and out of cells. Channels are typically composed of different protein subunits, each encoded by a different gene. There are two major classes of ion channels: voltage-gated and ligand-gated. Voltage-gated ion channels are activated and inactivated by changes in membrane voltage and are identified according to the principal ion conducted through the channel (e.g., sodium, potassium, calcium, or chloride). Activation and opening of voltage-gated channels have different effects (depolarization, repolarization, or hyperpolarization of the cell membrane), depending on what ion they gate and that ion's charge, the electrochemical gradient for that ion (which determines in which direction the ion flows when the channel is opened), and where the channels are located on the cell. Sodium channel opening results in the generation of the action potential (i.e., depolarization). Opening of potassium channels repolarizes cell membranes after action potential firing and maintains the resting membrane potential. Calcium channels are important for the generation of muscle contraction, neurotransmitter release, and intracellular signaling via second messengers. Opening of voltage-gated chloride channels results in the hyperpolarization of cells.

Ligand-gated channels are heterogeneous complexes composed of multiple protein subunits that are activated by the binding of their respective agonists. Several ligand-gated channels are present in the peripheral and central nervous systems. Gamma-aminobutyric acid (GABA)<sub>A</sub> receptors mediate most of the fast synaptic inhibition in the brain beyond the fetal and early neonatal periods. They are anion selective and gate primarily chloride, which flows into the cell, causing hyperpolarization upon GABA<sub>A</sub> receptor activation. Glutamate is the primary excitatory neurotransmitter in the central nervous system and binds to three types of ligand-gated, cation-selective receptor channels: *N*-methyl-D-aspartate (NMDA),  $\alpha$ -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA), and kainate. Glutamate receptors gate either sodium only (most AMPA and all kainate receptors) or sodium and calcium (NMDA receptors and some subtypes of AMPA receptors). Nicotinic acetylcholine receptors are nonselective cation channels permeable to Na<sup>+</sup> and K<sup>+</sup>, and Ca<sup>2+</sup> in some subtypes; they are located on certain neurons and on the

postsynaptic side of the neuromuscular junction. Opening of nicotinic receptors causes depolarization of the plasma membrane and activation of voltage-gated ion channels that can affect the release of neurotransmitters and activate intracellular signaling cascades.

## EPILEPSY SYNDROMES

Ion channelopathies, involving sodium, potassium, and calcium channels, have been increasingly identified as an etiology of epilepsy. Ligand-gated channels such as GABA receptors and nicotinic receptors have also been implicated. Identifying these syndromes will likely lead to unique treatments for specific syndromes thus entering an era of precision medicine.

### Dravet Syndrome

#### Clinical Features

Dravet syndrome has a classic presentation in most cases. Children begin to have seizures in the first year of life, typically in the setting of fever and characterized by prolonged seizures with hemiconvulsions. Alternating laterality of seizures can occur with each event, and seizures often evolve into status epilepticus. In the second year of life, other seizure types begin to emerge, including absence, myoclonic, and generalized tonic-clonic seizures, and partial seizures that now occur without fever. Tonic seizures are rare and, if they do occur, tend to be brief and nocturnal. Photo-induced seizures occur in some of these children, and self-induced seizures have been reported. Throughout childhood, elevated body temperature and anticonvulsants that are sodium channel blockers (e.g., carbamazepine, phenytoin, fosphenytoin, oxcarbazepine, and lamotrigine) exacerbate seizures. Seizure control is rarely attained. Episodes of status are common, including "obtundation status" ([Brunklaus and Zuberi, 2014](#)). The phenotype of the clinical seizure and electrographic correlation may not be congruent, making seizure classification difficult ([Kim et al., 2014](#)).

Development of the affected child is universally normal in the first year of life. As seizure types become more varied and more frequent, there is cessation of developmental progress, which can be misinterpreted as developmental regression. Moderate to severe intellectual impairment is present in many children, and the degree of cognitive impairment is somewhat associated with seizure control ([Wolff, Casse-Perrot, and Dravet, 2006](#)). Hyperactivity and autistic traits present in the toddler years. As children enter into adolescence, hyperkinetic behavior tends to improve and is replaced with overall slowed behavior.

Not all children with Dravet syndrome present with classic features, as described earlier. Myoclonic seizures need not be present for a diagnosis to be made. These seemingly less affected children continue to be exquisitely sensitive to temperature and sodium channel-blocking anticonvulsants. In some cases these features may suggest the diagnosis. Recently this syndrome was recognized in a large percentage of children

(11 of 14) presenting with seizures and encephalopathy after receiving vaccines (vaccine encephalopathy) (Berkovic et al., 2006).

### Genetics/Pathophysiology

Mutations in the sodium channel gene *SCN1A* are found in approximately 80% of children with a clinical diagnosis of Dravet syndrome. Most have a de novo mutation, although some of the families have a higher-than-expected history of febrile seizures.

There remains equipoise regarding how *SCN1A* mutations are predicted to cause a loss of sodium channel function, logically a cause of hypoexcitability of individual neurons, could lead to network hyperexcitability and, consequently, seizures. Some research suggests that this seeming contradiction can be explained by the selective loss of *SCN1A* expression and decreased sodium channel function only in inhibitory interneurons (Yu et al., 2006), causing inhibitory dysfunction and secondary hyperexcitability. Other recent studies suggest that loss of *SCN1A* occurs more broadly and may result in compensatory increases in other sodium channels that produce a net increase in sodium channel currents leading to hyperexcitability (Liu et al., 2013).

### Clinical Laboratory Tests

Electroencephalogram (EEG) findings are typically normal in the first year of life, but evolve to demonstrate generalized and multifocal abnormalities. A photoconvulsive response can be seen, and diffuse background slowing can become more prominent as children age. No characteristic pattern is diagnostic of Dravet syndrome, as is seen in Lennox–Gastaut or Doose syndrome; in fact, there can be some overlap between these syndromes and Dravet syndrome, making accurate diagnosis challenging. Magnetic resonance imaging (MRI) in patients with Dravet syndrome is usually without any focal

abnormalities (Striano et al., 2007). Genetic testing is appropriate in patients suspected to have Dravet syndrome. Early diagnosis avoids extensive and expensive metabolic testing and inadvertent exacerbation of seizures by certain medications, and provides prognostic information for the family.

### Treatment

Seizure control is the primary treatment goal in this disorder. Medications that block the sodium channel exacerbate seizures and should be avoided in most patients (Guerrini et al., 1998). Topiramate, valproic acid, benzodiazepines, and levetiracetam have proven helpful. Combination therapy with stiripentol, clobazam, and either Depakote or topiramate has been reported to be more effective than other combinations of medication (Chiron et al., 2000). Acetazolamide has not been shown to be beneficial. A recent report suggests that verapamil, a calcium channel blocker, may be helpful, but more research is required (Iannetti et al., 2009). Fenfluramine was also successful in a small cohort and requires further study (Ceulemans et al., 2012). Nonpharmacologic treatments, such as vagal nerve stimulation or ketogenic diet, have been useful in some patients. Anecdotal reports in the media suggest that cannabidiol (CBD), a component of marijuana, may reduce seizures in some children, although a retrospective case series found that artisanal CBD oils did not result in a substantial reduction in seizures in most children (Press and Chapman, 2015). Clinical trials of pharmaceutical-grade CBD products are now under way.

Avoidance of hot temperatures, both environmental and elevated body temperature, has been used by many families to reduce seizures. Because of the severity of the cognitive impairment, appropriate support must be initiated for the family. Medications for behavioral issues may also be necessary (see Chapters 59 and 60). Cardiac surveillance may also be indicated, given laboratory models of cardiac dysfunction (Auerbach et al., 2013). Because there is a high rate of

sudden unexplained death in this patient population, counseling should be provided.

## Generalized Epilepsy with Febrile Seizures Plus

### Clinical Features

Generalized epilepsy with febrile seizures plus (GEFS+) is a familial epilepsy syndrome characterized by febrile seizures in childhood in several generations of family members, often with continuation of febrile seizures into adulthood. In addition, afebrile seizures are often present. Seizure types include generalized tonic-clonic, myoclonic, absence, and atonic seizures. There is variable penetrance of seizures in these familial cohorts. Phenotype also varies among family members. Seizure resolution often occurs by age 12. The majority of these patients have normal development and intelligence.

### Genetics/Pathophysiology

*SCN1B* mutations were first reported in a large family cohort (Wallace et al., 1998). Mutations in other sodium channels—*SCN1A* (Escayg et al., 2000) and *SCN2A* (Sugawara et al., 2001)—have been found subsequently. The majority of these have been point mutations. In patients with *SCN1A* mutations, a difference in phenotype from GEFS+ and Dravet syndrome can often be predicted, given the location of the mutation (distance from the pore) and alteration in transcription of the gene. Sodium channel mutations do not account for all of the mutations in GEFS+; there also have been reports of mutations identified in two GABA<sub>A</sub>-receptor subunit genes, *GABRG2* and *GABRD* (gamma 2 and delta subunits) (Harkin et al., 2002).

### Treatment

There has been little published discussion of the treatment of these syndromes. For patients with sodium channel mutations, avoidance of sodium channel blockers is wise. Treatment when necessary with broad-spectrum anticonvulsants is thought to be useful. Avoidance of temperature changes and routine use of fever control measures may be of some benefit.

## Benign Familial Neonatal Seizures

### Clinical Features

Benign familial neonatal seizures are an autosomal-dominant epilepsy presenting with seizures in the first or second week of life, most commonly starting on day of life 2 or 3, resolving within weeks to months. Most seizures have stopped at 4 to 5 months of life. Seizures are usually multifocal clonic seizures or focal seizures. The feature suggesting this entity is the presence of similar seizures in parents and first-degree relatives, occurring at the same age. Development is characteristically normal during this time period, and after seizures stop. Fifteen percent of children will develop epilepsy later in life, usually in childhood or as a young adult. Some children progress to medically refractory epilepsy with encephalopathy (Steinlein, Conrad, and Weidner, 2007).

### Genetics/Pathophysiology

Mutations in potassium channels *KCNQ2* (Singh et al., 1998; Biervert et al., 1998) and *KCNQ3* (Charlier et al., 1998) (found on chromosomes 20 and 8, respectively) have been reported in families with benign neonatal seizures. The age specificity of the seizures in this disorder is thought to emanate from brain developmental changes during the neonatal period, when potassium channels play a critical role in

inhibition that is rapidly replaced by the action of GABA receptors over the first several months of life.

### Clinical Laboratory Tests

EEG generally demonstrates normal interictal features, although at the time of seizure there is an electrographic correlate. MRI is expected to be normal. Other causes of seizures, such as neonatal infection and metabolic abnormalities, should be excluded.

## KCNQ2 Encephalopathy

### Clinical Features

*KCNQ2* encephalopathy presents in the first days of life with poorly controlled seizures, which may resolve within the first year of life, but with residual and often profound intellectual impairment. This syndrome has been increasingly recognized as a severe neonatal encephalopathy and can have an overlapping phenotype with Ohtahara syndrome and West syndrome. Seizures are tonic and focal in nature, with some children having myoclonic seizures and infantile spasms. Autonomic changes can be an associated feature with seizures and may include apnea and bradycardia. Most children have EEG findings of a burst-suppression pattern that resolves and is replaced with diffuse slowing and multifocal epileptiform discharges. MRI findings have been reported in several cohorts, and although not universal, many will have thinning of the corpus callosum, frontal lobe atrophy, and nonspecific white-matter findings.

Seizures often resolve in the first year of life. Varying degrees of intellectual delay are present, ranging from mild to severe (Weckhuysen et al., 2013).

### Genetic/Pathophysiology

De novo mutations in *KCNQ2* have been reported. Similar mutations rarely have been present in children with benign familial neonatal seizures. Mutations are present in highly conserved areas, leading to loss of function.

### Treatment

Some children have responded to carbamazepine and other sodium (Na) channel blockers. One child is reported to have had cessation of seizures with retigabine (Barrese et al., 2010). This treatment requires more research, but may be promising.

## Developmental Delay, Epilepsy, and Neonatal Diabetes

Developmental delay, epilepsy, and neonatal diabetes (DEND) is a rare syndrome, presenting with neonatal diabetes, developmental delay, seizures, and mild dysmorphic features, and has been associated with a mutation in the *KCNJ11* gene that encodes for a subunit of the adenosine triphosphate (ATP)-sensitive potassium channel. This channel is found on pancreatic islet cells and in neurons. Neonates with this disorder usually present with diabetes and subsequently develop seizures and global intellectual impairment. Dysmorphic features, including downturned mouth, bilateral ptosis, prominent metopic suture, and contractures, have also been described (Gloyn et al., 2004). Infantile spasms can present in some children (Bahi-Buisson et al., 2007), in addition to other seizure types, such as tonic-clonic and myoclonic seizures. Seizures have been refractory to traditional antiseizure medications. In contrast, patients are responsive to treatment with sulfonylurea medications, such as glibenclamide, leading to

improvement in the effects of diabetes, developmental outcomes, and seizure frequency and effects.

## Other Genetic Generalized Epilepsies

### Autosomal-Dominant Nocturnal Frontal Lobe Epilepsy

Autosomal-dominant nocturnal frontal lobe epilepsy is a familial epilepsy characterized by frontal lobe seizures that typically occur at night and phenotypically present as arousal from sleep with bizarre hypermotor behaviors, such as spinning, thrashing, and rocking. Seizures can be numerous. Nicotinic receptor mutations have been found in many of these familial cohorts (Steinlein et al., 1995), although there are several families for which no gene mutation has been identified. These ligand-gated receptors allow sodium and potassium to cross the cell membrane. Many patients are responsive to carbamazepine and phenytoin.

### Benign Familial Infantile–Neonatal Seizures

Benign familial infantile–neonatal seizures is an epilepsy syndrome that has been described as being similar to benign neonatal seizures, but it occurs at a slightly older age. Mutations have been found in a sodium channel, *SCN2A1*, in some cohorts (Herlenius et al., 2007).

### Childhood Absence Epilepsy

Childhood absence epilepsy has been linked to mutations in GABA receptors (*GABRA1* and *GABRG2*) (Baulac et al., 2001; Wallace et al., 2001) and chloride channels (*CLCN2*). Mutations have also been described in a calcium channel, *CACNA1H*. The families with *CLCN2* also had members with generalized tonic-clonic seizures on awakening and juvenile myoclonic epilepsy (Baykan et al., 2004).

### Juvenile Myoclonic Epilepsy

Juvenile myoclonic epilepsy is a seizure disorder that usually presents in adolescents with myoclonic seizures that are more likely to occur in the early morning after awakening, and generalized tonic-clonic seizures that also tend to occur in the morning hours. Several gene mutations have been found in these patients, although the majority of patients have yet to have an underlying etiology determined. It appears that, similar to childhood absence epilepsy, this is likely a polygenic disorder. Channels that have been identified include GABA receptors (*GABRA1* and *GABRD*) (Cossette et al., 2002), calcium channels (*CACNB4*) (Escayg et al., 2000), and chloride channels (*CLCN2*) (Baykan et al., 2004). In addition, a gene that is not a direct channel gene but enhances calcium influx into the cell and can stimulate programmed cell death (*EFHC1*) (Suzuki et al., 2004) has also been identified as being involved in this epilepsy syndrome.

## FAMILIAL PAIN SYNDROMES

Several pain syndromes have been associated with sodium channel mutations. This is not surprising, as sodium channels are located on spinal sensory neurons in the dorsal root ganglion (Bennett and Woods, 2014).

### Clinical Features

**Inherited Erythromelalgia, Primary Erythermalgia.** Inherited erythromelalgia (IEM), or primary erythermalgia, is a pain syndrome characterized by episodes of redness and swelling of the hands and feet, associated with burning pain. These episodes can be triggered by mild warmth or exercise.

Erythema can become constant, and edema may be associated (Drenth and Waxman, 2007; Cook-Norris et al., 2012). Age of onset can vary from childhood to adulthood, and can be familial or sporadic (Drenth et al., 2008; Han et al., 2009), with about 15% being familial and having autosomal-dominant inheritance.

**Paroxysmal Extreme Pain Disorder.** Paroxysmal extreme pain disorder (PEPD), formerly called familial rectal pain, is characterized by episodic severe pain, which commonly occurs in the perirectal region but can also involve the genitals, limbs, and face, especially the periorbital region. Stimulation of the region by bowel movements, contact in the perianal region, eating, or sudden changes in temperature can induce pain episodes. Flushing, harlequin skin changes, pupillary abnormalities, and cardiac abnormalities can occur at the time of the pain episode. Tonic episodes that are nonepileptic in nature can occur with the pain episodes and are secondary to the intense severity of the pain. Weakness has been present with pain in the limbs, lasting up to 24 hours after the pain has resolved. Constipation is a common problem because the episodes are induced by passing stool. Symptoms have been reported as early as at the time of delivery, and occurrence in utero is suspected (Fertleman et al., 2007).

**Congenital Indifference to Pain.** Congenital indifference to pain (CIP) is a syndrome characterized by insensitivity to pain and, in some cases, loss of smell. A more severe form has been reported that is associated with anhidrosis; intellectual delay and hypotonia may be present in these children. Individuals with anhidrosis can experience episodes of hyperthermia that can be life-threatening if not recognized. Awareness of a stimulus is present, but pain is not experienced in relation to the stimulus. Because of this altered response to pain, fractures, burns, and other significant injuries can go unnoticed. Fractures, foot injuries, and injuries to the fingertips may be present for several days without awareness of injury. Individuals can differentiate between hot and cold, but lack the ability to determine whether a temperature is extreme enough to cause injury. Signs of peripheral neuropathy on clinical examination or neurophysiological testing and autonomic nervous system abnormalities are lacking (Golshani et al., 2014).

### Genetics/Pathophysiology

Mutations in *SCN9A*, a sodium channel, have been associated with IEM, PEPD, and CIP. Mutations thought to lead to hyperexcitability of the sodium channel have been identified in IEM and PEPD. Mutations in IEM allow the channel to be activated by smaller-than-normal depolarizations, and the channel remains open longer after activation (Drenth et al., 2005). Mutations in PEPD lead to prolonged action potentials and repetitive neuronal firing when stimulated (Jarecki et al., 2008). Mutations in this same channel that lead to loss of function are associated with CIP (Goldberg et al., 2007; Nilsen et al., 2009). The alteration of function created by the mutation leads to different phenotypes and different pain syndromes.

### Treatment

Treatment for IEM, including use of sodium channel blockers, has not been very effective, although there have been reports of some relief with lidocaine, mexiletine (Choi et al., 2009), and carbamazepine (Fischer et al., 2009). Recently a pilot study of an Na channel antagonist demonstrated some benefit, although further studies are needed (Goldberg et al., 2012). Response to medications may vary with different mutations. Carbamazepine has been helpful in treating PEPD, but topiramate and gabapentin have not.

Congenital indifference to pain does not have a specific treatment, but patients need to be observed carefully for occult injuries, including fractures, joint injuries, and burns, in addition to mouth and hand injuries. Establishing a daily routine to monitor for injuries is important.

## MIGRAINE AND ATAXIA SYNDROMES

### Familial Hemiplegic Migraines

#### Clinical Features

Familial hemiplegic migraine often presents in the first or second decade of life with severe headache, often unilateral, and is associated with unilateral weakness typically lasting 24 hours or, rarely, several days. Extreme symptoms of prolonged duration (30 days) and coma are rare, as are seizures during hemiplegia. The clinical presentation can be less impressive with unilateral paresthesia and hemianopsia (Roth et al., 2014). Ataxia and dysarthria have been reported between attacks, or for a short duration while recovering from an attack. Family members also have occasionally had a prior diagnosis of benign paroxysmal torticollis of infancy (Giffin et al., 2002), although this is rare, and it is unclear whether this is or is not related to the gene mutation. Diagnostic criteria established by the International Headache Society include migraine with aura with motor weakness and at least one first- or second-degree relative with similar symptoms. Genetic information allows for further subtyping.

Headaches can have features of basilar migraine, including vertigo, visual symptoms, tinnitus, dysarthria, and ataxia. Some patients have been reported to have progressive ataxia later in life (Terwindt et al., 1998). In addition, cognitive impairment has been noted in affected patients (Marchioni et al., 1995).

#### Genetics/Pathophysiology

Genetic etiology has been linked to a calcium channel mutation (*CACNA1A*) (Stam et al., 2008); people with mutations of this gene are more likely to have ataxia and coma, and to be more prone to delayed cerebral edema after minor head injury (Terwindt et al., 1998; Kors et al., 2001; Stam et al., 2009). Mutations in *CACNA1A* (FHM1) also have been reported in patients with alternating hemiplegia of childhood, which phenotypically has some overlap with hemiplegic migraine (de Vries et al., 2008), and in patients with episodic ataxia type 2 (see following discussion) and spinocerebellar ataxia type 6. Mutations in *ATP1A2* (FHM2), *SCN1A* (FHM3), and *PRRT2* (Riant et al., 2012) also have been found in some patients with this clinical syndrome (De Fusco et al., 2003; Dichgans and Markus, 2005).

#### Clinical Laboratory Tests

MRI findings are not pathognomonic, but cerebellar atrophy (Terwindt et al., 1998), particularly in the superior cerebellar vermis, has been reported. Magnetic resonance (MR) spectroscopy of this region has demonstrated metabolic abnormalities consistent with neuron loss (Dichgans and Markus, 2005). EEGs during events can demonstrate slowing in the affected hemisphere, and mild asymmetries with minimal unilateral slowing have been noted on EEGs performed between episodes (Marchioni et al., 1995).

#### Treatment

Most commonly, patients are treated with acetazolamide, calcium channel blockers such as verapamil, or a trial of other standard migraine prophylactic drugs (tricyclic antidepressants,

beta blockers). Limited correlation exists between drug response and hemiplegic migraine type. There have been reports of the use of valproic acid and lamotrigine in FHM2 with good response, (Pelzer et al., 2014), and corticosteroids (Sanchez-Albisua et al., 2013); further study is needed.

### Episodic Ataxia

#### Clinical Features

This disorder is characterized by intermittent periods of ataxia (see also Chapter 91). There are two commonly described disorders: episodic ataxia type 1 and type 2. Phenotypic presentation differs slightly in each case, allowing clinical separation.

Episodic ataxia type 1 is characterized by frequent, brief episodes of ataxia, involving ataxic gait and slurred speech, precipitated by strong emotional outbursts, sudden movements, and exercise. Episodes can last several seconds to minutes in duration and can occur several times a day. In addition, there usually is evidence of muscle hyperexcitability manifested by the presence of myokymia, both clinically and electrographically. Some family members have reported seizures and isolated myotonia (Graves et al., 2014).

Episodic ataxia type 2 primarily involves truncal ataxia, with more prolonged periods of ataxia lasting hours to days. Eye movement abnormalities are sometimes present. Episodes can be induced by stress or exercise. Myokymia is rare. Some patients can have subtle, slowly progressive cerebellar features. Cerebellar atrophy has been reported. Migraine symptoms can be present in both types of episodic ataxia, but are more common in type 2; migraine symptoms may have many features consistent with basilar migraine, including vertigo, nausea, and occipital pain (Nachbauer et al., 2014).

#### Genetics/Pathophysiology

Both disorders are inherited in an autosomal-dominant fashion, with incomplete penetrance. Type 1 has been associated with point mutations in *KCNA1* (Lassche et al., 2014; Browne et al., 1994). This is a potassium channel that has no intervening introns. Episodic ataxia type 2 has been linked to mutations in *CACNA1A* (a calcium channel). Mutations that interfere with splicing or lead to a premature stop have been linked to the episodic ataxia type 2 phenotype (van den Maagdenberg et al., 2002).

#### Clinical Laboratory Tests

Electromyography (EMG) is helpful with episodic ataxia type 1 in identifying and/or confirming myokymia. MRI also may be useful, especially in episodic ataxia type 2, and should be performed to rule out other underlying etiologies of ataxia. Cerebellar vermis atrophy has been reported in episodic ataxia type 2.

#### Treatment

Acetazolamide and carbamazepine have both been reported to lead to reduction in the frequency and severity of events.

### Spinocerebellar Ataxia

#### Clinical Features

Several progressive ataxias have been described and reported as resulting from a variety of etiologies (see Chapter 92). Channelopathies are responsible for one subtype, now called spinocerebellar ataxia type 6. This type presents as a slowly progressive cerebellar degeneration, with ataxia, dysmetria,

and other cerebellar signs as prominent clinical features. Spasticity and cranial neuropathies are not prominent. There can be some overlap with episodic ataxia type 2, with episodes of truncal ataxia lasting for several hours to days and often precipitated by stress or exertion. There also may be some features associated with basilar migraine or familial hemiplegic migraine.

### Genetics/Pathophysiology

Spinocerebellar ataxia type 6 has been reported to be associated with triplet repeats in the *CACNA1A* gene (Zhuchenko et al., 1997). Unlike the gene changes associated with other triplet-repeat disorders, mutations in *SCA6* seem to be relatively stable, and the expansion is smaller than that typically seen in association with an abnormal phenotype. It is unclear if symptoms are related to channel dysfunction or the cytotoxic effects of the repeat, as is seen in other diseases. The overlap between these phenotypes suggests that there is a pathologic role in the abnormal function of the calcium channel. Mutations in this gene also have been reported in cohorts with familial hemiplegic migraine, which usually have point mutations. Cohorts with episodic ataxia type 2 also have been reported to have mutations in this gene that often lead to splicing errors or premature stops.

### Clinical Laboratory Tests

MRI is helpful because many patients with symptomatic episodic ataxia will have cerebellar atrophy.

### Treatment

Supportive treatment is recommended. Patients with episodes of headaches may be helped by the treatments outlined for the episodic ataxias and familial migraine syndromes.

## GENERAL CONCEPTIONS AND CONSIDERATIONS WHEN APPROACHING A CHILD WITH SUSPECTED DEVELOPMENTAL DISABILITIES

Child development, a general term relating to neurologic and psychological growth and development of a human being from birth to adulthood, is a continuum starting in the prenatal period and extending throughout life, with close and inevitable interaction with the environment. Perceiving development as a series of milestones gained in a stepwise fashion in various categories—though practical in the clinical setting—belies the complex concept of its very essence: an integrative process, in which each aspect interacts with all others, leading the individual from utter helplessness to independence, adaptive social skills, and emotional integrity.

The traditional concept of development relates to six domains: gross motor, fine motor, receptive language, expressive language, problem-solving, and social-adaptive skills.

Neuromuscular assessment can be performed as early as 20 weeks of gestation (Ballard et al., 1991). Term newborns already exhibit relation to the environment, and maladaptive patterns of behavior can be identified. Several assessment tools exist (i.e., Brazelton Neonatal Behavioral Assessment Scale) for birth up to 2 months of age. The scale relates to four aspects of early development: regulation of the autonomic system, of the motor system, of the state of alertness in response to various stimuli, and primary communicative skills.

The first 2 years of life are the most striking developmentally. Hence, the various estimation tools used (mentioned in section on approach to the evaluation of a child with NDD) regard development in 3-month intervals. Toddlers are commonly assessed in 6-month intervals and by school age, a yearly evaluation of a neurotypically developing child is customary. By then, focus shifts from the “classical” developmental benchmarks to academic skills as reflected by the child’s achievements at school.

*Delay* refers to a lag in one or more—and occasionally all—aspects of development. *Global developmental delay* (GDD) is a common term used at an early age to describe what might later turn out to be intellectual disability (ID). *Dissociation* regards a discrepancy between different developmental domains. This is typically seen in children with cerebral palsy, who struggle to gain gross motor milestones but do not necessarily display difficulties with language acquisition. *Dissociation* might be used to describe a difference in the extent of delay in two or more fields, for example, significant language delay along with mild motor delay, as is often seen in children diagnosed with autism spectrum disorder (ASD). *Deviance* is a term used to describe an abnormal sequence of development, usually “skipping” milestones that might indicate a

hidden pathology (Accardo et al., 2008). For instance, pushing to stand without crawling might indicate hypertonicity of the lower limbs. The “cocktail-party chatter” typical of William syndrome represents another deviance pattern, in which expressive language appears more elaborate than receptive abilities.

The developmental trajectory observed over time serves as yet another clue to the underlying pathology leading to developmental disabilities. Early delay with later catch-up is typical of preterm infants, with catch-up occasionally continuing into adolescence. On the contrary, normal gain of early milestones with difficulties emerging later on up to possible loss of already acquired skills denotes investigation of a possible metabolic or neurodegenerative disorder. A continuous GDD with a stable yet below age-average learning curve suggests a future ID and might warrant a genetic workup (Moeschler et al., 2014).

## Spectrum of Neurodevelopmental Disabilities

In its broadest sense, the term *neurodevelopmental disabilities* can include a wide range of disorders with significant overlap and varying causes (Box 50-1). These include conditions that affect motor, sensory, cognitive, language, and executive functions, and social and behavioral disorders. Typical conditions included within this designation include cerebral palsy, GDD, ID, attention-deficit/hyperactivity disorder (ADHD), ASD, and learning disorders. Neurodevelopmental disabilities are related to abnormalities in central nervous system (CNS) development and may lead to lifelong functional impairment.

They are a heterogeneous group of disorders. They can be defined quantitatively based on results of developmental or neuropsychological assessments, or qualitatively by comparing an individual’s developmental profile to that of same-age peers (Shevell, 2010). Socioeconomic, racial, and ethnic factors may affect the timing of diagnosis. In ASD, for example, lower socioeconomic status and Hispanic ethnicity have been associated with a later age at first diagnosis.

The functional implications of neurodevelopmental disabilities are addressed in the World Health Organization’s International Classification of Functioning, Disability, and Health, which uses three components—body function and structure, activity, and participation—that help delineate the nature of an individual’s disability.

A key aspect of the evaluation of a child suspected of having a neurodevelopmental disability is the approach to establishing diagnoses. Accurate diagnoses help guide further investigation into causality, implementation of necessary services, family counseling, and anticipation of long-term

**BOX 50-1** Frequently Encountered Neurodevelopmental Disabilities

Attention-deficit/hyperactivity disorder  
 Autism spectrum disorder  
 Cerebral palsy  
 Communication disorders  
 Global developmental delay  
 Epilepsy  
 Hearing impairment  
 Intellectual disability  
 Learning disorders  
 Leukoencephalopathies  
 Neurogenetic disorders and inborn errors of metabolism  
 Neuromuscular disorders  
 Visual impairment

prognosis. Certain genetic disorders predispose children to neurodevelopmental disorders, as do other predisposing factors, including prematurity, neonatal encephalopathy, and socioeconomic status. It is now well recognized that individual patients can be affected by more than one neurodevelopmental disability.

## Overview and Scope of the Problem

These conditions exist at the intersection of the disciplines of neurology, psychiatry, developmental pediatrics, neurodevelopmental disabilities, and psychology, and may be evaluated by specialists in any or all of these fields. Features of neurodevelopmental disabilities highlight the overlap and interaction between the fields of neurology and psychiatry. With growing understanding of the genetics and neurophysiology underlying these conditions, neurologists in the future may be expected to manage conditions previously designated as psychiatric disorders. For example, Rett syndrome was listed as one of the pervasive developmental disorders in American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders—IV* (DSM-IV), but with the identification of MeCP2 as the cause of this syndrome, it has subsequently been considered a neurogenetic disorder and removed from the current edition of the DSM ([American Psychiatric Association, 2013](#)).

Neurodevelopmental disabilities can be diagnosed on the basis of practice parameters such as those released by the American Academy of Neurology/Child Neurology Society for Global Developmental Delay (Chapter 51) and ASD (Chapter 57), or by applying diagnostic criteria as detailed in the DSM-5 ([American Psychiatric Association, 2013](#)). In DSM-5, neurodevelopmental disorders are described as "disorders with onset in the developmental period, often before starting school, and that are characterized by a range of developmental deficits that impair normal functioning." They include ID (intellectual developmental disorder), communication disorders (language disorder, speech sound disorder, and childhood-onset fluency disorder), ASD, ADHD, specific learning disorder, and motor disorders (developmental coordination disorder, stereotypic movement disorder, and tic disorders). A formal classification system can be used, for example, with characterization of cerebral palsy by neurologic subtype or by gross motor skills (Chapter 97).

There is a need to consider children's diagnoses in a longitudinal manner. Children with diagnoses of GDD have a high likelihood of experiencing persistent developmental and func-

tional impairments at school age but not necessarily cognitive impairment. These conditions often persist throughout life, and affect adults' health issues as well as have an impact on employment status, social relationships, and activities of daily living.

One way to establish a diagnosis or diagnoses is to refer a child for developmental or neuropsychological evaluation (Chapter 10), which will quantitatively determine the child's level of function related to age expectations or qualitatively establish appropriate DSM diagnoses. Another, not mutually exclusive, approach is a diagnostic workup that may include neuroimaging, metabolic and genetic testing, and neurophysiology studies. Chromosomal microarray has been recommended as a first-line investigation for the etiology of ID and ASD, and ongoing research has explored the yield of more advanced genetic testing, including whole exome sequencing and whole genome sequencing. Identification of a genetic diagnosis for a child with ID or ASD can have a significant impact for a family on the care of the child and may lead to more refined treatments, in the case of dietary treatment and enzyme replacement for metabolic disorders or optimal anticonvulsant treatment in the cases of SCN1A or GLUT1. Recent investigations using animal models now imply that ID can be reversible through pharmacology interventions (Chapter 59) or appropriate learning or retraining paradigms.

The concept that epilepsy itself or the presence of an epilepsy syndrome can contribute to a child's cognitive and behavioral impairments has been explored extensively, and epileptic encephalopathy is addressed in the current classification system for epilepsy. In the absence of clinical evidence that raises concern for epilepsy, current practice parameters advise caution in carrying out electroencephalography in patients with GDD or ASD.

Population-based studies have indicated that 15% of children aged 3 to 17 years have a developmental disability on the basis of parent report. A recently published survey noted that there has been a 21% increase in disabilities related to neurodevelopmental or mental health conditions in the United States in the 2000s.

The breakdown among individual disabilities varies. GDD is estimated to affect 1% to 3% of children, whereas a prevalence rate of 7.66% was found for ID. The Centers for Disease Control (CDC)'s Autism and Developmental Disabilities Monitoring Network noted that the prevalence of cerebral palsy has ranged from 0.31% to 0.36% since 1996. ASD prevalence rates in the most recent CDC surveillance findings were at 1.4% among 8-year-olds. Among learning disorders, reading was reported to have 5.3% to 11.8% cumulative incidence rates, math incidence rates of 5.9% to 13.8%, and writing 6.9% to 14.7% cumulative incidence rates in a population-based birth cohort.

## Determinants and Risk Factors

The prime determinants of neurodevelopmental disabilities involve genetic and metabolic abnormalities and aberrant CNS development, prematurity, low birth weight, perinatal complications, chronic physical health conditions, exposure to environmental hazardous substances, compromised family functioning, and low-socioeconomic family background. Families of children with ADHD have been found to have higher rates of alcoholism, other drug abuse, depression, delinquency, and learning disabilities than controls. The concept of the broader autism phenotype addresses the higher incidence of social and communication symptoms and stereotypical behaviors in family members of children with ASD.

## Commonalities

Although diagnostic criteria and recommendations for workup and treatment of individual disabilities have been established, a number of common elements are shared among neurodevelopmental disability diagnoses. Individual children can have multiple neurodevelopmental diagnoses, and diagnoses may evolve over time, with the child initially diagnosed with GDD later identified as having a learning disorder.

For conditions that are diagnosed primarily by behavioral manifestations and through application of DSM-5 criteria, there is a notorious lack of biomarkers. Neuroimaging and electroencephalography tend to be unrevealing or nonspecific. The American Academy of Neurology/Child Neurology Society (AAN/CNS) practice parameter recommends neuroimaging as part of the diagnostic evaluation, but indicates that data are insufficient for a recommendation regarding the role of EEG in child with GDD in whom there is no clinical evidence of epilepsy. In ASD, nonspecific EEG abnormalities have been found in most children and there is a lack of evidence to support universal screening EEG without a clinical indication.

Children with neurodevelopmental disabilities are often found to have evidence of neurologic soft or subtle signs, such as mirror movements, synkinesis, clumsy finger movements, difficulties with balance, and motor persistence. These soft signs have been noted in patients with ADHD and ASD and have been followed longitudinally in cohorts of patients.

Beyond treatments for inborn errors of metabolism, medications are typically prescribed to treat specific behaviors in children with neurodevelopmental disabilities, including stimulants and nonstimulants for inattention, hyperactivity, and impulsivity; antipsychotics and nonstimulants for aggression and irritability; and selective serotonin reuptake inhibitors and related medications for anxiety and mood symptomatology. Physical, occupational, language, and educational therapies are prescribed to these children.

## Overlap in Neurodevelopment Disorders

Neurodevelopmental conditions are frequently seen in combination in particular patients. Gillberg has proposed the acronym *ESSENCE* (early symptomatic syndromes eliciting neurodevelopmental clinical examinations), to describe the coexistence of impairing symptoms that can be initially identified in the first few years of life. In his classification, the *ESSENCE* conditions affect general development, communication and language, social interrelatedness, motor coordination, attention, activity, behavior, mood, and sleep. Children who are diagnosed with a particular neurodevelopmental diagnosis at an early age may no longer meet criteria for the specific diagnosis as they age, but may ultimately receive another neurodevelopmental disorder diagnosis (Gillberg, 2010). Children with ASD often have coexisting problems that include ADHD, epilepsy, ID, learning disorder, oppositional defiant disorder, anxiety disorder, mood disorder, and obsessive compulsive disorder.

Recent genetic research has called into question the current categorical diagnostic algorithm used for neurodevelopmental disorders (NDDs) as delineated in DSM-5. Similar genetic findings have been identified in individuals with different neurodevelopmental diagnoses. For example, genetic changes at 16p11.2 that were initially associated with ASD have been found to be associated with developmental delay, ID, communication problems, abnormal head circumference, and psychiatric conditions, including schizophrenia and bipolar disease, and *SCN2A* mutations have been associated with ASD and epilepsy.

The National Institutes of Mental Health has addressed the difficulty of diagnostic classification by introducing the Research Domain Criteria project as a framework for ongoing research that characterizes psychiatric disorders as neurophysiological disorders with a basis in genetics, electrophysiology, and functional imaging.

## Approach to the Evaluation of a Child with Suspected Neurodevelopmental or Intellectual Disability

Many of the principles of evaluating children with a neurodevelopmental disorder are similar to evaluating any child with a neurologic disorder. These principles are covered extensively in Part I: Clinical Evaluation. However, there are few aspects of these that merit special attention for children with neurodevelopmental disorders.

### The Developmental History

Ascertaining a child's current developmental milestones is an important part of the evaluation of a child with a neurodevelopmental disorder. Given the limited amount of time during an office visit, it may sometimes be helpful to obtain reports of previous testing that has been performed in other settings, such as school or early intervention.

Another dimension of the developmental assessment is adaptive measures, which refer to the ability to perform activities of daily living. This is an important part of understanding the level of functional disability of a child and is a requirement for the diagnosis of ID in the DSM-5. The Vineland Adaptive Behavior Scale, Second Edition (Vineland-II) is the most commonly used measurement, and can be a helpful tool to identify a child's strengths, as well as areas that require more attention.

Assessing the pattern of a child's development is important in generating a differential diagnosis. Is there a concern for a developmental regression or a loss of developmental milestones? Is one area more affected than another? Children with isolated motor delays raise concern for neuromuscular disorders or cerebral palsy. Children with language delays may have difficulty with hearing or comprehension, or may have autism. Children with abnormal socialization may have autism or Rett syndrome, or may be suffering from the effects of trauma or neglect. Developmental problems that began during the school years can raise concern for ADHD, learning disabilities, or psychiatric issues, including anxiety or depression.

### Birth History

Medication and drug exposure during pregnancy may influence the child's development. Information about the child's delivery should include the need for perinatal resuscitation, postnatal respiratory support, or low Apgar scores which may all be indicators of neonatal hypoxic ischemic encephalopathy. Providers should be aware of the newborn hearing screen results and if there was any follow-up.

### Social History

Because there is a complex interplay between the family milieu and children with neurodevelopmental disorders, taking a social history is important. Children with neurodevelopmental disorders often require significant financial and emotional support, which places stress on the child as well as the family. Assessing the needs of these families is an important aspect of their care.

Psychosocial stressors in the home can manifest themselves in the child and appear to be consistent with a neurodevelopmental disorder. For example, a child who has suffered from trauma or neglect has abnormal socialization and can present with developmental delay. Exposure to adverse events can make a child more likely to have emotional dysregulation, heightened responses to perceived negative stimuli, and executive dysfunction. These children are at increased risk for developing disorders such as ADHD, anxiety, and depression. Children with neurodevelopmental disorders require a close assessment of their home environment to understand concomitant stressors and adverse exposures so that the child's well-being is preserved.

History should include assessment of the school environment. Children with neurodevelopmental disorders are more likely to have a significant number of missed days at school, have fewer friends than their peers, be bullied at school, and, in the case of children with special healthcare needs who required behavioral services, to bully other children. They participate less in extracurricular activities and are at risk for social isolation. Their happiness and level of inclusion at school should be an important aspect of the social history.

### Family History

The family history can give important clues to the etiology of the developmental disorders. ADHD and dyslexia have strong genetic aspects. Children suspected of having fragile X syndrome may have maternal relatives with anxiety or depression, autistic-like features, or ADHD.

### Physical Examination

One of the most important aspects of the evaluation of the child is observing his or her behavior in as unstructured an environment as possible, such as providing toys and opportunities for the child to play while the practitioner obtains the medical history from the caregiver. Through this, there are many aspects of a child that may not be apparent through history alone. For example, how does the child interact with the toys? Does the child mouth or lick the toys, or does he or she use them functionally? Does the child share his or her enjoyment with you or the examiner, or does the child prefer to keep to herself? How does the child interact with toys that he or she needs help with? Does the child look to his or her caregivers, or to you, for help, or does the child simply put the toy aside? Or does he or she become inconsolable? Is the child limited in any way by difficulties with coordination or motor functioning? As the examination proceeds, important things to note include the ability of the child to make eye contact and respond to his or her name, to follow directions with and without demonstration, and the level of engagement he or she has with you as the examiner.

For the older child, engaging him or her in conversation during the examination may be more revealing. Is the child able to hold a conversation with you, or does he or she have difficulty? Asking about social life and interests can be an important way to help engage. Adolescents, if developmentally appropriate, may be more easily examined alone, so that they may feel more comfortable sharing information with you.

For a child with neurodevelopmental disorders, special attention is made to the child's appearance to rule out any dysmorphic features, the skin examination to evaluate for neurocutaneous disorders (i.e., neurofibromatosis type I can be associated with learning disabilities and autism), and the eye examination to evaluate for evidence for genetic or metabolic abnormalities.

### Testing

Testing children with suspected neurodevelopmental disorder should take a highly individualized approach based on the concern. The initial evaluation will provide clues to the nature of what testing should be pursued. Children with an abnormal neurologic examination finding revealing focal deficits require neuroimaging. Neuroimaging is recommended for children with GDD, per the American Academy of Neurology guidelines.

For many children with neurodevelopmental disorders, the most important testing is a neuropsychological evaluation. For school-aged children, this can occur in the school setting. For children younger than 3 years, they are entitled to a developmental assessment through an early intervention program. Office-based screening tools may be helpful to guide the testing that needs to be done. For example, a Vanderbilt assessment is helpful not only for symptoms of ADHD, but also to screen for any comorbid behavioral difficulties, such as conduct disorder, oppositional defiant disorder, anxiety, and depression. Difficulties in school and activities of daily living are assessed. Identified problems can help guide the provider to refer the child for further testing to address academic performance or for behavioral therapy.

Many children with neurodevelopmental disorders are at risk for having comorbid emotional or behavioral disorders. There are many in-office tools that can be helpful to assess these children's risks. Children who have positive screens for behavioral or emotional disorders should be referred to other providers for further management.

### Multidisciplinary Approach to the Care of the Child with a Neurodevelopmental Disorder

Caring for children with neurodevelopmental disorders is often complex and requires a multidisciplinary approach to their care. Families of these children have significant financial stressors and difficulties with coordinating medical care. These patients often have numerous medical providers as well as a team of therapists and educators who are all working to care for them. An attentive medical provider can be instrumental in helping to assure that these children are able to access the care they need to support their disabilities. This section discusses the challenges facing these families.

Children with chronic emotional, behavioral, or developmental problems are more likely to have health conditions that affect their daily activities, as well as be uninsured or underinsured; have unmet healthcare needs; have difficulty obtaining referrals; have more missed days of school; and have at least \$1000 per year in out-of-pocket health-related expenses. These families have high levels of financial stress, including decreased levels of employment and high out-of-pocket costs (Kuo et al., 2013). High out-of-pocket costs are associated with the medical severity of the disorder as well as the need for mental health services in addition to medical services. Families of children with autism have the highest reported out-of-pocket costs. Children with special healthcare needs who have functional limitations have more difficulties accessing needed services and getting needed referrals.

Compared with healthy peers, children with neurodevelopmental disorders have significant challenges that can affect their quality of life. Children with ADHD, learning disabilities, and intellectual disabilities are all more likely to have a comorbid psychiatric disorder than their typically developing peers. A study by Klassen et al. reveals that children with ADHD have poorer measures on health-related quality of life than controls, including measures of mental health and

self-esteem. Children with ADHD and comorbid psychiatric disorders tend to fare worse on quality-of-life measures (Stein et al., 2011). Children with learning disabilities have an increased risk of comorbid psychiatric disorders and increased social difficulties with peers. Children with intellectual disabilities have a much higher likelihood of having an emotional disorder or psychiatric disorders than typically developing children. Children with autism face social isolation from peers and, as young adults, have a higher likelihood of social isolation than peers with another developmental disorder, including intellectual disabilities. Children with special healthcare needs who have emotional problems or functional limitations have worse school outcomes than children with special healthcare needs who don't have those problems. Families of children with a neurodevelopmental disorder and a comorbid emotional or behavioral disorder tend to fare poorly. A study of children with neurologic conditions and behavioral disorders indicated that families of children with both a neurologic disorder and a behavioral disorder had more unmet needs and reported greater dissatisfaction with care, care coordination, ability to obtain a referral, and to use other services. A study by Nageswaran et al. of children with developmental disabilities with comorbid mental health diagnoses found similar findings (American Academy of Pediatrics, 2005).

## DEFINITIONS

Global developmental delay (GDD) and intellectual disability (ID) are related, nonsynonymous terms with common and distinctive characteristics. They can be defined as early onset, chronic disorders with disturbance in the acquisition of cognitive, motor, language, or social skills, which has a significant and continuing impact on the developmental progress of an individual (Michelson et al., 2011).

The 2002 consensus definition of the American Association on Mental Retardation (AAMR; now known as the American Association on Intellectual and Developmental Disabilities [AAIDD]) defined ID as “characterized by a significant limitation both in intellectual functioning and in adaptive behavior as expressed in conceptual, social, practical, and adaptive skills.” This disability originates before the age of 18 and manifests with severe problems in the capacity to perform (i.e., impairment), ability to perform (i.e., activity limitations), and opportunity to function (i.e., participation restrictions).

For the young child, the term “global developmental delay” has emerged to describe a disturbance across a variety of developmental domains. The latest consensus definition used by the American Academy of Neurology (AAN) and the Child Neurology Society practice parameter statement defines GDD operationally as a significant delay in two or more developmental domains (e.g., gross/fine motor, cognitive, speech/language, personal/social, activities of daily living) (Michelson et al., 2011). Typically, if there is delay in two domains, this often implies delay across all domains.

Thus the definitions of ID and GDD reflect an approach to disability that emphasizes adaptive behaviors and contextual factors as opposed to a single objective measure.

## Epidemiology

Assuming a normal distribution of IQ scores (and that adaptive skills correlate closely with these more conventional metrics of intellectual ability), approximately 2.25% of individuals will have an IQ below 70 and a diagnosis of ID. Early population-based studies confirmed this theoretical estimate, documenting an overall rate of ID of 2%, with 1.5% having mild ID (IQ of 50–70) and 0.5% having moderate or severe ID (IQ of less than 50). Although the population studied and the instruments used can influence the rate of mild ID, they seem to have little effect on the rate of severe ID. Thus the prevalence rates for mild ID in 15 subsequent studies varied broadly from 5 to 80 cases per 1000 people, whereas the prevalence of severe ID varied only between 2.5 and 7 per 1000 (Leonard and Wen, 2002).

Many changes that affect the rate of mild ID can affect the overall numbers of persons with ID in the population (e.g., poor education, nutrition, tobacco or alcohol use, environmental toxins such as lead). Additional risk has been associated with low birth weight and maternal age. Paternal smoking also increases the risk of having children with ID. In addition, race and gender disparities have also been reported, with ID overrepresented by as much as 50% among African Americans

relative to the Caucasian population (thought to be influenced heavily by social context), and the male-to-female ratio was 1.4:1.0.

ID cases are often grouped by prenatal, perinatal, and postnatal causes. Prenatal causes include genetic syndromes and chromosomal disorders, central nervous system malformations, and maternal toxic or infectious causes. Perinatal conditions include birth asphyxia, stroke, and infection. Postnatal conditions include infection, toxins (e.g., lead), and injury, such as nonaccidental trauma. Simple public health measures (e.g., iodized salt, community-wide rubella vaccination, newborn screening) have prevented an estimated 15% of cases of ID in the industrial world. Currently the most common potentially preventable cause of ID in high-resource settings is fetal alcohol syndrome, whereas congenital hypothyroidism caused by maternal dietary iodine deficiency remains the most common preventable cause world-wide.

Using the above framework, over 60% of children with ID do not have identified causes. Among the causes identified, chromosomal defects are common, and Down syndrome is the single most common known chromosomal cause. The increasing widespread availability and application of chromosomal microarray (CMA; also referred to as array comparative genomic hybridization [CGH]) and whole-exome sequencing in the clinical setting will increase the percentage of attributable causes to these subtler genetic disruptions (Sherr et al., 2013).

Many individuals with ID are unable to become productive members of society and require institutionalized or group-home care. The economic costs are substantial, with one study showing the financial burden on society equal to the economic impact of stroke, heart disease, and cancer combined (Meerding et al., 1998). Another analysis estimates lifetime costs of more than \$1 million dollars per person with ID, which is more than that for cerebral palsy, hearing loss, or vision impairment.

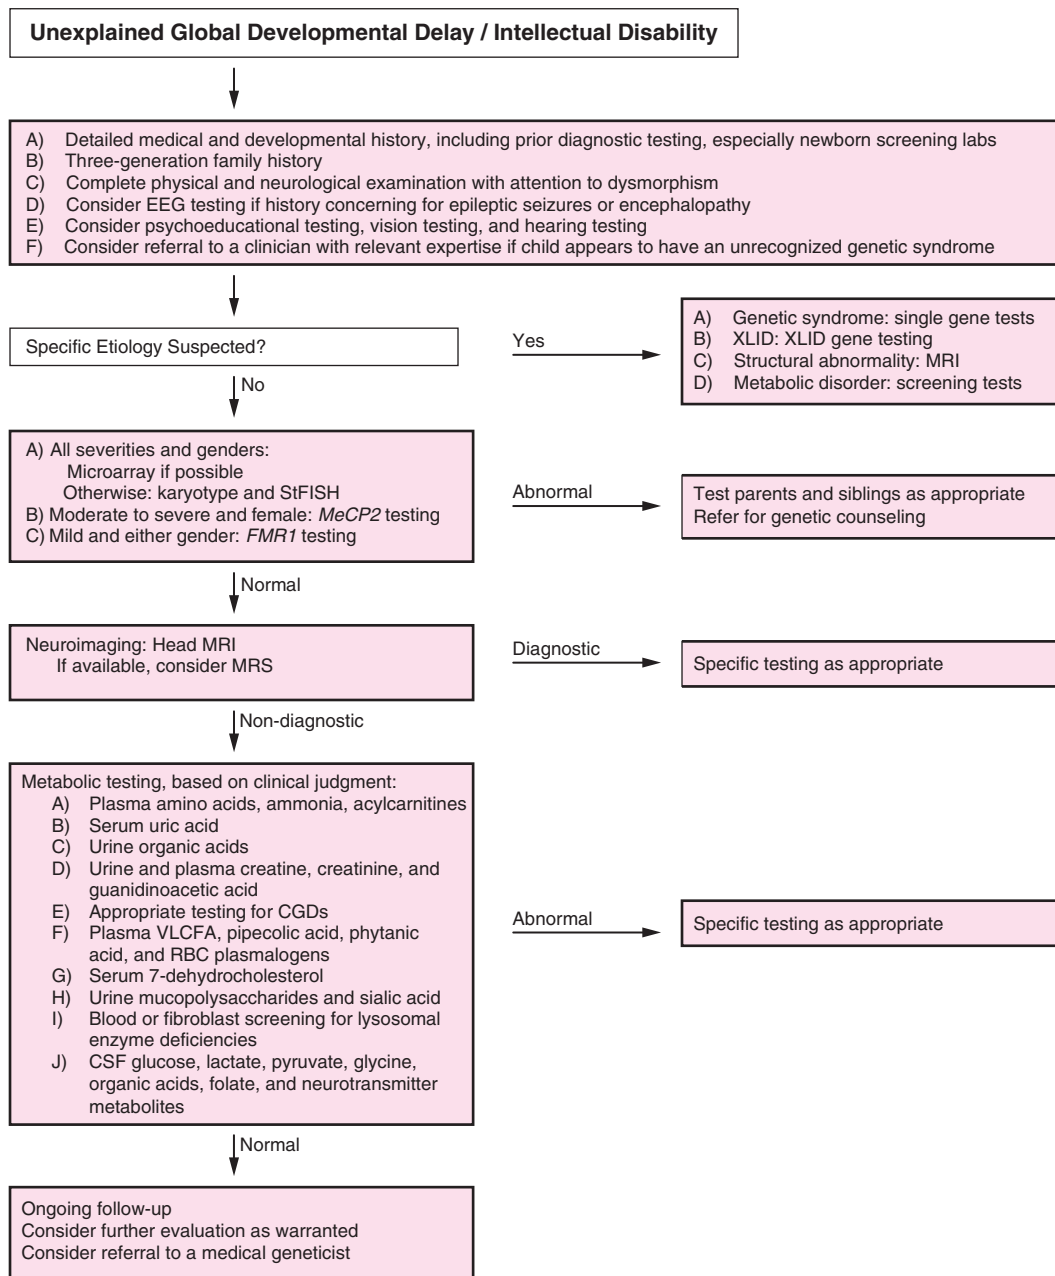

## DIAGNOSIS

### Definitions and Testing

Accurate diagnosis of GDD or ID is an essential precondition to proper management and service provision. Accurate diagnosis helps understand the specific medical and psychiatric complications, determine eligibility for service and support provision, aid in family counseling, and confirm legal recognition of disability. Multiple standardized, age-appropriate measures have been normed and validated on typically developing populations to assess intellectual function and adaptive behavioral skills.

### Advances in Diagnostic Testing

An approach to the diagnosis of ID/GDD can begin with the AAN practice parameter and evidence report for GDD (Figure 51-1) (Michelson et al., 2011). The recommendations incorporate a combination of broad screening tools and

**Figure 51-1. Algorithm for the evaluation of the child with unexplained global developmental delay or intellectual disability.** A detailed history, a complete physical examination, psychoeducational testing, and screening tests for visual and hearing deficits are recommended for all children with GDD/ID. EEG is recommended when there is concern about seizures or an epileptic encephalopathy. In children with features suggesting a specific etiology, genetic testing, neuroimaging, and metabolic testing may be useful for confirmation. For children without features suggesting a specific etiology, testing can be done in a stepwise or parallel manner for genetic abnormalities, structural brain abnormalities, and metabolic abnormalities. Although an extensive list of metabolic tests is provided in this algorithm, there is insufficient evidence to make specific recommendations as to which testing sequence would have the greatest diagnostic yield. The algorithm is explained in greater detail in the Clinical Context section of this guideline. This algorithm is based on data contained in an evidence-based review on this topic (Michelson et al., 2011). CGD, congenital disorder of glycosylation; CSF, cerebrospinal fluid; EEG, electroencephalogram; GDD, global developmental delay; ID, intellectual disability; MRI, magnetic resonance imaging; MRS, magnetic resonance spectroscopy; RBC, red blood cell; VLCFA, very long chain fatty acids; XLID, X-linked intellectual disability. (Report of the Quality Standards Subcommittee of the American Academy of Neurology and the Practice Committee of the Child Neurology Society. *Neurology* 2011.)

disease-specific testing based on a heightened pretest probability, given identifying clinical features. Correctly applied, *each individual disease-specific test* has a reasonable pretest probability (>1%) of diagnosis, whereas the more recently introduced broad-based genomic screening tools have a high pretest

probability (5% to 25%). The current algorithm begins with a complete clinical assessment. For patients in whom a specific diagnosis is considered, targeted testing is recommended. For the remaining patients a step-wise approach is recommended that begins with CMA followed by chromosomal karyotype

if that is negative. This recommendation reflects the capacity of CMA to detect clinically relevant chromosomal changes, and is also recommended by a consortium of clinical genetics laboratories (Miller et al., 2010; Michelson et al., 2011). Fragile X and meCP2 testing are examples of specific gene/syndrome approaches. However, if these tests are unrevealing, the algorithm recommends conducting brain magnetic resonance imaging (MRI; with single-proton spectroscopy, where available). If this approach is not diagnostic, comprehensive metabolic testing is then recommended (see Figure 51-1). As the yield of these diagnostic tools advances (a discussion of some recent advances, such as whole-exome sequencing, are expanded upon below), these algorithms will continue to change to reflect these technical improvements. Regardless, clinical judgment will always be tantamount.

### Genomic Microarray

Genomic microarray technology detects copy number changes in the genome, usually with a resolution of 30 kb or less. These platforms identify interstitial copy number variants (CNV). Studies done thus far confirm the importance of CNVs as a cause of neurodevelopmental disabilities, detecting many chromosomal changes not visible with high-resolution karyotyping. Many studies in autism, mental retardation, and cohorts with multiple congenital anomalies (who also have neurodevelopmental disabilities) show that many CNVs occur repetitively with the same chromosomal breakpoints and at a much higher frequency in affected individuals than in controls. Although in some cases the link between CNV and ID is well established, this determination is challenging or not possible when that genetic variation has never been reported previously, or its incidence in cases and controls is not well documented. To address etiology in these variants of unknown significance, the first step is to establish whether a documented copy number change is *de novo* or familial: determining the size of the CNV, knowing whether it is a deletion or duplication, and knowing the genes (and gene density) in the CNV. The establishment of publicly available and actively updated genotype–phenotype databases aids in the process of establishing pathogenicity of these less common CNV.

**Whole-Exome Sequencing:** As outlined previously, advances in genetic testing have driven much of the progress in understanding the causes of ID. For example, CMA give positive diagnostic yields of approximately 7% to 8%, above that seen via karyotypes (Sherr et al., 2013). Recent data highlight the diagnostic potential of whole-exome sequencing. Two recent studies from a combined 3000 families demonstrate a diagnostic rate of approximately 25%. When patients with developmental delay were specifically examined, the rate of identification increased to 36% to 40%, exceeding that seen for CMA or karyotypes. Most of these diagnoses resulted from *de novo* mutations in known genes, and in some cases either homozygous recessive (for consanguineous families) or compound heterozygous inherited mutations were causative. The rate of *de novo* mutations has been shown to correlate to paternal age and suggests that some of the increased incidence in neurodevelopmental disorders in developed countries can be explained by this societal change in parental age.

### Advances in Imaging

High-quality MRI has significantly advanced the ability to detect many brain malformations. Certain studies suggest that structural MRI is useful for detecting abnormalities in up to 50% of children with developmental delay, including the identification of polymicrogyria, pachygyria, lissencephaly, callosal agenesis, and periventricular nodular heterotopia, for

which genes are known to cause these syndromes. Proton MR spectroscopy measures the resonance of molecules in the brain, allowing the measurement of metabolism intermediates and helping in the diagnosis of mitochondrial disorders (lactate and pyruvate) or measuring creatine in disorders of creatine deficiency, potentially treatable forms of ID and GDD.

## ETIOLOGY

### General Considerations

The known specific causes of ID are too numerous to be listed here. The term “intellectual disability” returns more than 3000 entries in the Online Mendelian Inheritance in Man site alone, and this catalogs only identifiable genetic causes. As mentioned previously, ID usually is classified by prenatal, perinatal, postnatal, and undetermined causes. In most U.S.-based studies, the largest category of known primary causes is genetic or chromosomal (Leonard and Wen, 2002), with up to 75% of the known cases attributable to chromosomal aberrations. In contrast, in some regions of the world, cretinism (stunted physical growth and ID) from severe iodine deficiency occurs in up to 2% to 10% of the population of isolated communities. Mild mental impairment from iodine deficiency occurs five times more frequently than cretinism, making iodine deficiency the most common preventable cause of mental retardation. Treatment during the first trimester has a significant effect on the frequency of cretinism. In regions of mainland China with iodine deficiency, children score on average 10 IQ points less than cohorts in iodine-rich regions. This link between iodine deficiency and mental retardation has a strong genetic component, because alleles of the deiodinase type II gene and the ApoE4 allele confer a significantly greater risk of ID when the pregnant mother is iodine deficient. Despite the tremendous wealth of information about the causes of ID, the cause remains unknown in most individuals. Genetic and epidemiologic approaches likely will continue to make progress toward unraveling and treating these currently unelucidated causes.

### Genetic Causes

Both inherited and *de novo* mutations have been shown to be causative for ID and GDD, and the advances in clinical application of genetic tools have accelerated the rate of discovery of new causes.

### Fragile X Syndrome

Fragile X syndrome, caused by inactivation of the *FMR1* gene, has an estimated prevalence of 1 in 3000 males and is the most common inherited causes of ID. Expansion of the trinucleotide sequence CGG to more than 200 copies results in CpG methylation and inactivation of transcription of the *FMR1* gene. Patients have narrow and elongated faces, large protruding ears, macroorchidism in males, and joint hyperlaxity. Up to 50% of patients have ASD and 20% have epilepsy, and most have complex partial seizures. Carrier females and males with somatic mutations have a range of levels of intellectual impairment; studies demonstrate that the amount of the residual FMR protein detected in hair roots correlates well with IQ. Although previous studies suggested that premutation male carriers (55 to 200 repeats) were asymptomatic, later work has demonstrated that a range of symptoms are present in premutation carriers, including migraines, seizures, autism, and ID. Moreover, investigators have identified a progressive neurologic disorder, the fragile X-associated

tremor/ataxia syndrome (FXTAS) in premutation carriers. After the age of 50, primarily male patients present with intention tremor and cerebellar ataxia, and cognitive decline. This syndrome, which is unique to these premutation carriers, may result from an increase in expanded repeat *FMRI* mRNA that is consistent with a toxic “gain of function” mechanism. Although treatment still remains symptomatically based, investigators have shown that fragile X syndrome leads to an exaggerated activation through metabotropic glutamate receptors, and early clinical studies have tested compounds that inhibit this signaling. Although the initial results did not demonstrate enhanced outcomes, it is possible that a greater understanding of these mechanisms may lead to targeted therapies.

### Other X-Linked ID Conditions

The increased prevalence of ID in males and the relative ease of detecting familial transmission of X-chromosome mutations have led to the discovery of novel ID genes on the X chromosome. Since the early 1990s, more than 120 genes have been identified as causes of X-chromosome-linked syndromic and nonsyndromic ID (Table 51-4).

Mechanistically some of these genes work directly at the level of the synapse. For example, the protein family neuroligin on the postsynaptic membrane (with two X-linked neuroligin genes [*NLGN3* and *NLGN4*]), and its binding partner neurexin on the presynaptic side have been shown to promote synapse formation in vitro. Similarly, multiple genes that participate in signaling at the synapse through the small G protein RHO are mutated in many cases of X-linked ID: *GDI1*, *PAK3*, *OPHN1*, and *ARHGEF6*. There are also many genes without synaptic function that are well-established causes of ID, such as the genes *ARX* and *MECP2*. These genes can cause syndromic ID (as in patients with X-linked lissencephaly with ambiguous genitalia [XLAG] and Rett’s syndrome) and nonsyndromic ID, depending on the severity of the mutation. These observations demonstrate the complexity of understanding how genetic alteration causes mental retardation, what form it takes, and how genotype may correlate with phenotype.

## DE NOVO DOMINANT GDD AND ID

In addition to inherited cases of ID, there has also been significant strides in identifying genes that cause *de novo* dominant ID. The recent papers to detail the results of clinical exome sequencing report that, of the designated causative genes, nearly 1/3 of these were discovered in the last 18 months. At some point, the community of clinicians and investigators will begin to see a “saturation” for gene discovery, but that is still likely quite a ways off. Thus a specific listing of genes would be unproductive; however, there are many important themes that emerge:

1. The genetics of ID overlaps significantly with other neurodevelopmental disorders. This has been observed clinically, and was recently confirmed in cohorts of patients with *de novo* mutations demonstrating overlap between ID, ASD, epileptic encephalopathies, and schizophrenia causes.
2. Many genes have both syndromic and nonsyndromic presentations, depending on the severity and penetrance of the mutations.
3. Approximately 5% of patients will actually have two causative genes, suggesting that more complex disorders may be caused by these unexpected combinations.
4. Increasing the risk for *de novo* mutations by an older population contributes to this disease burden.
5. Postzygotic mutations play a significant role in these disorders in addition to germline mutations.

### Other Etiologic Considerations

Several questions arise when considering the causes of mental retardation that guide the clinician in evaluating patients and help the researcher focus on the underlying pathophysiology. What is the prevalence of any genetic cause for ID and how many genes can cause this disorder? Will cases of mild ID be caused by less severe mutations in these same, already-discovered genes or in a completely different subset? How many cases of ID will be found to be caused by genetic factors alone, environmental factors alone, or the interplay between the two, as has been demonstrated for iodine deficiency?

**TABLE 51-4** Genes Implicated in X-Linked Intellectual Disability

Gene	Function	Locus	Study
<b>Genes Primarily Implicated in Nonsyndromic Intellectual Disability</b>

## EVALUATION OF THE PATIENT

### History

The assessment of a child with suspected GDD or ID begins with a detailed history, including family history, mother's gestational history, perinatal history, birth, and early neonatal history.

The next component of history, history of present illness, includes the age at which the developmental concern became manifested to the caregiver and the timing of developmental milestones determined. The possibility of regression of previously acquired developmental skills should be specifically questioned, as this would mandate a different and more urgent approach to etiologic evaluation and follow-up. Current skill level in developmental domains and the degree of independence in activities of daily living must be documented. For the school-aged child, important points include scholastic history, with special reference to actual school and classroom placement, and the identification of the provision of any supplemental educational resources.

Coexisting medical problems, with particular reference to possible seizure disorders or feeding difficulties, should be questioned. Sleeping and problematic behaviors (e.g., aggressive, inappropriate, or self-injurious) may be particular concerns of the parents and are often underappreciated by health professionals. The medical history, including possible chronic medical conditions, prior hospital admissions, or surgical procedures, should be documented. Past and current medications prescribed, their indications, and their effects (beneficial or deleterious) must be assessed. The current social situation of the child and family must be carefully probed and the examiner must determine whether the patient has access to appropriate rehabilitation services. This approach should provide clear ideas regarding evidence of a static or progressive encephalopathy; the developmental and functional level; the timing of an underlying cause; a prioritized list of etiologic causes; the social or rehabilitation status of the affected child; and the possibility of associated medical or behavioral conditions meriting intervention.

### Physical Examination

The physical examination begins with careful observation of the child. The availability of a play area with appropriate toys, including paper, crayons, dolls, and representational toys, may allow for a nonintrusive assessment of developmental skills, behavior, and interaction with the surroundings and others. Much of the neurodevelopmental examination can take place during extended history-taking by observation alone. In the older child, language skills, both spontaneous and responsive, expressive and receptive, should be established, together with an understanding of simple cognitive concepts (i.e., size, shape, analogies, action, commonalities, numbers).

The general physical examination should specifically ascertain possible dysmorphology, hepatosplenomegaly, and markers of neurocutaneous disorders. The spine should be carefully inspected, including the sacral region, to look for dermal sinuses, hair tufts, or other subtle signs of spinal dysraphism. Height, weight, and occipitofrontal circumference should be obtained and plotted. In cases of microcephaly or macrocephaly, the parental occipitofrontal circumferences also should be obtained and plotted. The head shape and status of the anterior and posterior fontanels in the infant, together with the sutures, should be observed. Determination of the presence of any focal or asymmetric neurologic findings is the primary objective of the formal neurologic examination. Careful evaluation of vision, in addition to aiding in a definitive diagnostic process, is indicated to minimize the contribu-

tion of potentially correctable visual impairments to the burden of disability. Similarly, this approach applies to evaluating for possible gross auditory impairments in the office setting.

Within the clinical office setting, several test instruments exist for use as objective screening assessments of development during the first years of life (i.e., Denver Developmental Screening Test). These may be supplemented or complemented by the use of parent-based questionnaires (e.g., Child Developmental Inventory and Ages and Stages Questionnaire) that provide an aspect of objective developmental screening.

### Laboratory and Other Diagnostic Testing

Laboratory testing is directed at establishing the possible cause of the individual's delay or ID. Laboratory testing is undertaken in the spirit that the potential value of a definitive etiologic diagnosis from individual and familial perspectives may be substantial. Recent work has emphasized the delineation and diagnosis of nearly 90 treatable metabolic diseases associated with GDD or ID. Technologic advances, especially in the domains of genetic testing and neuroimaging, have improved diagnostic yield and precision, and will continue to improve with newer diagnostic tools. Aiding the formulation of a rational approach to laboratory investigations in this clinical population is the AAN practice parameter and updated evidence report (see [Figure 51-1](#)) ([Michelson et al., 2011](#)).

For the globally or intellectually delayed child without an apparent cause after history and physical examination, current recommendations would include CMA testing, followed, if clinically indicated, by high-resolution MRI. How and with what frequency whole-exome and whole-genome sequencing will be part of the standard clinical evaluation is not completely clear, but given the early success of this tool to aid in diagnosis, it is likely to be quickly incorporated into upcoming practice parameter revisions.

Electrophysiologic studies, such as electroencephalography, should be undertaken only in the situation of a suspected coexisting paroxysmal disorder or evidence of language regression or behavioral abnormalities suggestive of an epilepsy syndrome, such as Landau-Kleffner or electrical status epilepticus during slow-wave sleep. Visual- and auditory-evoked potentials are of use in assessing the integrity of the visual and auditory systems in the young, uncooperative child.

### Consultation

Concerns about the developmental and functional patterns highlighted at the time of specialty evaluation should prompt referrals to other health professionals with different but complementary expertise, permitting a multidisciplinary, comprehensive evaluation of the affected child. These health professionals represent genetics, occupational therapy, physical therapy, speech and language pathology, and psychology. Specific care needs, such as tube feeding, respite care, or financial difficulties, may prompt nursing or social service intervention. Vision and hearing screening is important because of the high frequency of potentially correctable primary sensory impairments in this population.

### MEDICAL MANAGEMENT OF COEXISTING CONDITIONS

With a greater drive to incorporate intellectually disabled individuals into the community comes a better awareness of the unique and challenging profile of their psychiatric and medical issues, and of how best to optimize their treatment to improve

quality of life and outcome for both the individual and family. These disorders, both psychiatric and medical, uniformly occur at a greater frequency in developmentally delayed and intellectually disabled children and youth compared with typically developing or cognitively able children. Psychiatric disorders encountered include anxiety, mood disorders, disruptive behaviors, inattention, and aggression. Medical issues include epilepsy, sleep disorders, sensory impairments, and feeding problems.

## OUTCOME AND PROGNOSIS

The vast majority of developmentally delayed or intellectually disabled children presently remain at home with the best caregivers possible—a loving, supportive, and nurturing family.

Longitudinal studies suggest continued intellectual development in those with mild or moderate delay, and the absence of such improvement in those with severe or profound ID. Functional attainment for the child with severe neurodevelopmental disability by age 6 typically represents the functional attainment with respect to ambulation, feeding, toileting, and self-hygiene achieved for the life span. As such, the pragmatic aims for education should be on short-term achievable goals that assist in improving functional capacity.

The transition to adult life can be challenging with issues related to living situations, limited access to entitlements, termination of educational options, sexuality, and employment (sheltered or supported), and the locus of medical care provision (i.e., pediatric to adult). Family involvement in transition planning is essential for the successful adjustment to adult life. Individuals with ID have had higher unemployment rates than the general population and a tendency for placement in segregated (i.e., sheltered) environments. Periodic, ongoing support often has been found to be a necessary precondition for continued employment.

The life expectancy of a child with mild to moderate ID who is in good general health without evidence of cardiopulmonary disease or severe epilepsy can be considered similar to that of the general pediatric population. Significant mobility limitations, lack of functional hand use, and feeding dependency (especially placement of a gastrostomy tube) limit life expectancy. However, a positive trend is evident, with life expectancy improving overall for those with ID, even for the most severely affected individuals.

## INTRODUCTION

Progressive encephalopathies (PE) are diseases that cause a gradual decline in cognitive and motor function over time. Toxic, infectious, inflammatory, and neoplastic disorders that can present in a subacute to chronic fashion must be considered in the evaluation of patients presenting with PE. This chapter will focus on the wide array of genetic and metabolic diseases that typically present with PE and pose several diagnostic challenges for clinicians.

One such challenge relates to the etiologies being individually rare and thus generally unfamiliar to clinicians. A second challenge relates to the phenotypic variability of genetic disorders. Many inborn errors of metabolism (IEM) caused by mutations in genes for critical enzymes, for example, have a "classic" and severe presentation related to complete enzyme deficiency (i.e., neonatal encephalopathy with multiorgan failure) but can be milder and even subtle with later presentation (i.e., psychiatric changes in adulthood) owing to increasing degrees of residual enzymatic function.

## DEFINITION

There is no accepted definition of the term "progressive encephalopathy," and it has been used interchangeably with such terms as "neurodegenerative disorder," "neurodegenerative encephalopathy," and "progressive intellectual and neurologic deterioration." We use the term PE in this chapter to refer to disorders that cause progressive central nervous system (CNS) injury and loss of function, affecting multiple domains (i.e., cognitive, affective, psychomotor, social, perceptual, and linguistic).

## EPIDEMIOLOGY

A few surveillance studies have informed our sense of the overall incidence of PE in various regions of the world. Two studies from Norway reported incidence rates of 0.6 per 1000 person years. Etiologies were most often metabolic (66%) or neurodegenerative (32%), but 20% of cases remained unclassified. A decreasing incidence was seen with age, with cases distributed among neonates (0 to 4 weeks, 32.1%); infants (1 to 12 months, 39.3%); and juveniles (6 to 12 years, 4.8%), with none seen in late juveniles (6 to 12 years, 4.8%) and late juveniles (older than 12 years, 0%). Far more neonatal onset cases were metabolic (46%) than neurodegenerative (7%) in nature.

A related study from the same investigators examined survival rates and prognostic factors for survival among these patients. Overall, 37% of the patients suffered early death, and the cumulative probabilities for survival were 81% at 1 year and 66% at 10 years. Neonatal onset of symptoms and a metabolic versus neurodegenerative etiology were risk factors for mortality. The 10 year survival rate for children with metabolic diseases (58%) was significantly poorer than that of children with neurodegenerative diseases (87.5%). Much of what has been published regarding these disorders has been retrospec-

tive and focuses on individual conditions, providing little basis for a discussion of their collective epidemiology.

## ETIOLOGY

Most genetic causes of PE are due to either an IEM or a neurodegenerative disorder (ND). Chapters 23, 26, 32, 48, 50, and 99 provide overviews of many of the conditions that can present with PE. Chapters 23, 26, 48, 50, and 99 provide overviews of many of the conditions that can present with a progressive encephalopathy. The IEMs are themselves frequently divided into three groups, based on pathophysiology. In the first group are those disorders in which symptoms of acute or chronic intoxication are caused by the intracellular and extracellular (and thus measurable in blood, urine, and/or cerebrospinal fluid) accumulation of the compounds proximal to the defective enzyme. Examples include errors of amino acid metabolism (e.g., phenylketonuria and maple syrup urine disease), organic acidemias (e.g., methylmalonic aciduria and propionic acidemia), urea cycle disorders (e.g., ornithine transcarbamylase deficiency and argininemia), disorders of carbohydrate metabolism (e.g., galactosemia and hereditary fructose intolerance), disorders of metal transport (e.g., Wilson disease and Menkes disease), and disorders of porphyrin metabolism. Because the placenta acts to maintain homeostasis of small molecules that can cross its capillaries, these disorders are, overall, less likely to cause embryonic toxicity and more likely to present in infancy and childhood after a symptom-free period whose length depends in part on the degree of enzyme deficiency. Other circumstances such as fever, illness, and dietary changes can also influence the timing and severity of symptoms.

The second group of IEMs is comprised of those disorders in which symptoms are due, at least in part, to the inability of the brain and other organs to produce or utilize sufficient energy for normal function. Energy deficiency can result from defective function of the mitochondria, including defects of pyruvate transport and modification, the Krebs cycle enzymes, the fatty acid oxidation enzymes, and the respiratory chain enzymes that allow for aerobic metabolism. Energy deficiency can also result from defects in cytoplasmic enzymes such as those responsible for glycogen synthesis, glycolysis and gluconeogenesis; insulin secretion and responsiveness; creatine synthesis and transport; and the pentose phosphate pathway. It is not uncommon for children with IEMs causing energy defects to present with congenital dysmorphism or cerebral dysgenesis.

Disorders in the third group of IEMs are typically thought of as storage disorders, in which incompletely catabolized complex molecules accumulate within neuronal and extraneuronal tissues and cause progressive neurologic symptoms and somatic changes. Examples include mucopolysaccharidoses, oligosaccharidoses, and lysosomal storage disorders. Some authors expand this third group to include disorders of complex molecule synthesis and breakdown that result in a loss of function without measurably abnormal storage such as

peroxisomal disorders, congenital disorders of glycosylation, and disorders of cholesterol biosynthesis.

Nonmetabolic genetic causes of PE associated with progressive neuronal loss, usually demonstrable as atrophy on neuroimaging, are classified as neurodegenerative disorders (ND). The description and recognition of NDs were previously based purely on clinical features. However, the past decades have seen the elucidation of a genetic basis for most and a pathophysiologic basis for many. NDs of as yet unclear pathophysiology are sometimes categorized based on whether they affect the brain homogeneously (diffuse encephalopathies) or preferentially affecting the cerebral cortex (poliodystrophies), the cerebral white matter (leukodystrophies), the basal ganglia (corencephalopathies), or the cerebellum, brainstem, and spinal cord (spinocerebellar diseases).

An early study of the incidence of PE at two large academic centers in the United States found 341 pediatric cases with one of more than 50 different CNS disorders among 1218 hospital admissions over the course of 10 years (Table 52-1). Although

72% of the cases were found to have genetic or metabolic disorders, the study also included a significant number of cases with isolated lower motor neuron syndromes and cases attributable to acquired injuries from infections, immunologic disorders, refractory epilepsy, chronic environmental insults, nutritional deficiencies, and iatrogenic factors. Data from another study are summarized in Table 52-2.

After the initial description in 1996 of 10 cases of new variant Creutzfeldt-Jakob disease (nvCJD) affecting young adults in the United Kingdom, several countries instituted prospective surveillance programs to collect data on patients with PE to better identify additional cases of nvCJD. Although these studies have relied on reports from pediatricians and have been unable to describe absolute incidence or prevalence figures, they have reported relative prevalences within their areas. The first report from the surveillance done in the United Kingdom collected and analyzed pediatric cases of progressive intellectual and neurologic deterioration over a 5-year span. Of the 798 cases collected, 577 (72%) had a confirmed

**TABLE 52-2** Diagnoses in 66 Cases of PE

Disease	N (%)
Metachromatic leukodystrophy	14 (21%)
Adrenoleukodystrophy	11 (16%)
Subacute sclerosing panencephalitis (SSPE)	8 (12%)
Wilson disease	6 (9.8%)
Friedreich ataxia	5 (7.5%)
Lipidosis	4 (6%)
Gaucher disease	3 (4.5%)
Alexander disease	2 (3%)
Pantothenate kinase associated neurodegeneration	2 (3%)
Multiple sclerosis	1 (1.5%)
Ataxia telangiectasia	1 (1.5%)
Unknown etiology	6 (9.8%)

(Adapted from Pierre, G., 2013. Neurodegenerative disorders and metabolic disease. *Arch Dis Child* 98(8), 618–624.)

diagnosis. Higher prevalence rates were seen in populations with higher rates of consanguineous marriage. Updates of the study reported 147 different confirmed diagnoses in 1114 (42%) of the 2636 patients. In total, six of the children were found to have confirmed or probable nvCJD.

A survey-based study conducted in Australia identified 230 cases of childhood PE in a 2-year period, with 134 patients having Rett syndrome, 20 having a lysosomal storage disorder, 16 having a leukodystrophy, and 15 having a mitochondrial disease. The previously described Norwegian study gathered cases of pediatric PE over an 18-year period from the area's single children's hospital and from the national diagnostic laboratory for metabolic diseases. The authors excluded patients with diseases in which cognitive impairment was either atypical (e.g., spinocerebellar ataxia and spinal muscular atrophy) or typically seen only late in the course (multiple sclerosis). In addition, unlike the studies already discussed, this study excluded disorders such as regressive autism and Rett syndrome, in which intellectual deterioration may be seen early in the course but typically stabilizes. As mentioned, the authors reported a total of 84 cases of PE, of which they classified two-thirds as metabolic, one-third as neurodegenerative, and two cases, both due to HIV/AIDS, as infectious. The authors found an increased (seven-fold) risk of PE in children born within communities with higher rates of consanguineous unions. They further estimated that avoidance of consanguineous marriage would decrease the incidence of PE by 30 to 50%.

## DIAGNOSTIC EVALUATION

When PE is suspected, a timely evaluation that results in a specific diagnosis can be of great value. It is not uncommon for the child neurologist to uncover clinical features of a progressive process in a patient who is referred for developmental delay or autism. In this regard, a key element in the evaluation of global developmental delay (GDD) or intellectual disability (ID) is a second visit to ensure that the child's condition is nonprogressive. The diagnostic yield for evaluating children with PE is far less well studied than the yield of evaluations of children with GDD or ID. Nevertheless, it is even more urgent that children with PE undergo a comprehensive diagnostic evaluation.

Although specific treatments are available for only a minority of the diseases responsible for PE, an etiologic diagnosis has many other direct benefits (Chapter 59), including the ability to:

1. Relieve caregivers of anxiety and uncertainty when specific information about inheritance and prognosis can be given
2. Empower caregivers to become involved in support groups, advocacy, and research networks
3. Limit further diagnostic testing, which may be costly (in time and money) or invasive
4. Prevent recurrences in family members through carrier screening and prenatal testing, when available
5. Improve understanding of
  - a. Available treatments
  - b. Long-term prognosis
  - c. Associated coexistent conditions
  - d. Recurrence risk and mode of inheritance

In all cases, the diagnostic tests employed should be tailored to the presentation of the child and, in most cases, testing should proceed from least to most invasive. Consideration should be given to the early identification or exclusion of all potentially treatable causes of the patient's symptoms.

## HISTORY

### Developmental History

Every child suspected of having a neurodevelopmental disorder should undergo a thorough clinical evaluation that includes a detailed medical and developmental history, family history, and review of systems and detailed physical and neurologic examinations. The clinical features most suggestive of a PE—the gradual loss of previously acquired skills and the gradual emergence of neurologic signs and symptoms after a period of normal development—are more readily observed when they are of later onset and when they progress more rapidly. In this regard, a key element in the evaluation of GDD or ID is a second visit to ensure that the child's condition is nonprogressive. A combination of late but rapid deterioration is not common to most disorders but can occur. The features of PE are more difficult to recognize when the progression is very slow or when the onset is so early that even initial development is clearly abnormal. A number of children initially given a diagnosis of cerebral palsy (CP) due to a presumed remote brain injury were later found to have an IEM or ND. This experience suggests that children with a diagnosis of CP should undergo further evaluation when there is no definite history of a preceding injury, when there is a family history of neurologic symptoms or of parental consanguinity, or if there is an inadequately explained oculomotor deficit, movement disorder, ataxia, muscle atrophy, or sensory deficit. Unexplained episodes of altered mental status, dietary aversions, vomiting, or abnormal movements should arouse strong suspicion that a child is suffering from an IEM. Conversely, children whose underlying neurologic disease is not itself progressive can nevertheless present with gradual loss of skills and emergence of new neurologic signs and symptoms for a variety of reasons, including medication side effects, intercurrent medical and psychiatric illnesses, and worsening of preexisting hydrocephalus, spasticity, dystonia, or epilepsy. Some epileptic syndromes (e.g., epileptic encephalopathies) and neurodevelopmental disorders (e.g., regressive autism) are associated with a gradual loss of function or developmental arrest during their course but are unlikely to show relentless clinical deterioration, global involvement, or evidence of CNS damage.

The critical elements of the clinical evaluation are the same as have been outlined in detail for children presenting with nonprogressive neurodevelopmental disorders (Chapter 51). To establish the progressive nature of a child's symptoms or clinical findings, however, it can be particularly helpful to review any records of the child's prior appearance and abilities to which caregivers can provide access, including photographs, videos, and examples of the child's writing and drawing. Repeated examinations over months, even years, may be necessary to uncover very subtle regression.

## Family History

A family history of developmental delay, intellectual disability, learning disability, early deaths, and seizures can be quite helpful in elucidating the etiology of a child's neurologic issues. A three-generation pedigree should be obtained. Consanguinity varies significantly from one culture to the next. Practitioners should be tactful when asking if the child is the product of a consanguineous union, one in which the parents are second cousins or more closely related.

## Maternal History

Chromosomal abnormalities account for 50% to 70% of miscarriages of less than 10 weeks gestation and are found in about 50% of couples with a history of recurrent miscarriages. Previous stillbirths, neonatal deaths, or infant deaths attributed to sudden infant death syndrome (SIDS) may be due to an IEM (Chapter 90). Exposure *in utero* to teratogens have been associated with developmental delay and intellectual disability but not with PE.

## Neonatal History

Delivery complications such as hypoxia and early postnatal complications such as hypoglycemia, CNS infection, and seizures may have profound effects on development. Patients with severe perinatal injuries, neuromuscular disorders, and epileptic encephalopathies may be difficult to distinguish from cases of early onset and severe PE given that both groups can show difficulty in reaching even the earliest developmental milestones.

## Environmental History

Lead encephalopathy and pica of other toxic substances such as mothballs (paradichlorobenzene) may cause PE. Acute and chronic hydrocarbon exposure has been associated with anxiety, mood disorders, and progressive neuropsychologic changes.

## General Medical History

The medical history can be obtained in a systematic fashion by organ systems. A history of complex congenital heart disease (CHD) may cause a progressive encephalopathy due to systemic and cerebral hypoperfusion may cause permanent cerebrovascular injury and visible hypoplasia or atrophy.

Endocrine disorders such as hypothyroidism and hyperthyroidism have been associated with developmental regression and movement disorders. Hashimoto encephalopathy has presented as a progressive myoclonic epilepsy syndrome. Both Addison disease and Cushing Syndrome are associated with a progressive encephalopathy.

Infections such as Creutzfeldt-Jakob disease (CJD) and subacute sclerosing panencephalitis (SSPE) cause progressive

neurologic deterioration that can be drawn out over many years. HIV infection may also be the cause of PE. Current criteria divide patients with HIV-encephalopathy into three groups: those who are asymptomatic, those with a mild neurocognitive disorder, and those with dementia. HIV encephalopathy was previously reported to occur in up to 30% of children with HIV. The use of highly active antiretroviral therapy (HAART) has decreased the incidence to 12%. Additional information on SSPE and HIV are provided in Chapter 115.

Nutritional disorders or vitamin deficiencies (e.g., thiamine, niacin, biotin, folate, and vitamin E) have been associated with PE. Neurologic symptoms due to these conditions are reviewed in Chapters 46 and 47.

Autoimmune encephalopathies with autoantibodies directed against proteins on the neuronal membrane (e.g., NMDA receptors) are increasingly well described and recognized in clinical practice. Symptoms may develop very acutely over the course of days, mimicking infectious meningoencephalitis, or may develop very slowly over the course of weeks to months, with early behavioral and psychiatric changes followed by seizures, dyskinesia, dysautonomia, sleep dysfunction, and an altered level of consciousness. These conditions are discussed in Chapters 118 and 119.

## EXAMINATION

The clinicians' ability to recognize clinical patterns and features suggestive of a specific etiology can significantly narrow the diagnostic evaluation of a child with PE (Chapters 1–9). Primary motor and sensory functions are readily assessed by the screening neurologic examination, even in uncooperative children, but higher cortical functions are far more difficult to evaluate. The collective observations of clinicians, parents, and teachers who suspect subtle cognitive decline should be supplemented by those of a neuropsychologist. Chapter 10 reviews the approach to neuropsychological testing in children.

Abnormalities of head size, stature, and facial morphology can suggest specific diagnoses such as Angelman syndrome. Neurocutaneous stigmata may suggest one of the phakomatoses, as with café-au-lait spots (neurofibromatosis); hypomelanotic macules and angiofibromas (tuberous sclerosis); blistering of the skin, swirling macular hyperpigmentation and linear hypopigmentation (incontinentia pigmenti); or a port wine stain on the face and glaucoma (Sturge-Weber syndrome). Hepatosplenomegaly and corneal clouding may suggest one of the mucopolysaccharidoses. Cardiomyopathy may be caused by a mitochondrial disorder. Progressive retinal degeneration has been associated with the neuronal ceroid lipofuscinoses and a cherry red spot is associated with sphingolipid storage disorders, in addition to central retinal artery occlusion, drug toxicity (quinine, dapsone), and toxic exposures (carbon monoxide, methanol).

## LABORATORY TESTING

Screening studies that might be done on a regular basis in the evaluation of a child with unexplained PE include those that look for evidence of involvement of non-CNS organ systems and narrow the differential diagnosis. These commonly include a complete blood count (CBC) and comprehensive metabolic profile (CMP). Other tests, often chosen because they can identify treatable causes of PE, include thyroid function tests, serum lead level, and tests of vitamin B<sub>12</sub> and folate levels. In patients with progressive weakness or hypotonia, a serum creatine kinase level is often done to screen for muscular dystrophies. Other tests are difficult to interpret in

cases of PE without highly suggestive and specific clinical and neuroimaging findings and so are rarely included as screening tests.

When it is difficult to decide if a patient has a static or progressive encephalopathy, the diagnostic approach may be the same as for children with global developmental delay or intellectual disability (ID), as is discussed in Chapter 51.

Increasingly microarray studies are being used for initial genetic diagnostic testing. Microarray studies can be used to screen the entire genome for copy number variants (CNVs) that are smaller (0.3 Mb) than can typically be detected by even a high-resolution karyotype (5 Mb). Array comparative genomic hybridization (aCGH) and single nucleotide polymorphism (SNP) arrays are both clinically available and, with reported yields of up to 15% to 20%, are typically used as first-line genetic tests for most children with unexplained ID. Microarrays will not detect mutations other than CNVs such as single nucleotide substitutions within an individual gene or large chromosome rearrangements. A karyotype is still recommended when the child appears dysmorphic or when there is a family history of multiple miscarriages or of similarly affected children. CNVs may be recognizably pathogenic, known to be benign, or may be variants of uncertain significance (VUS). Parental testing may be needed to guide the interpretation of a VUS. If a parent tests positive for the same CNV, it is considered more likely to be benign. However, if neither parent tests positive for the CNV and it appears to be a *de novo* mutation in the child, it is considered more likely to be pathologic.

Although less frequently ordered now, routine cytogenetic testing (G-banded karyotype) has a yield of 3.7% to 10% in patients with mild to moderate developmental delay and is helpful for diagnosing aneuploidy and rearrangements such as translocations and inversions. Fluorescent *in situ* hybridization (FISH) or multiplex ligation-dependent probe amplification (MLPA) for specific disorders such as velocardiofacial syndrome (22q11 deletion) are done on patients with suggestive clinical features. Subtelomeric FISH studies were previously recommended but such testing for copy number variants (CNV) has been supplanted by the microarray studies with broader genome-wide coverage.

Fragile X is the most commonly inherited cause of ID; however, the family history may be negative, and the dysmorphic features, usually recognizable in older children and adults, may not yet be apparent in young children. Other X-linked disorders such as Rett syndrome are found predominantly in girls. Testing for Rett syndrome (*MeCP2* gene sequencing and MLPA) has been recommended for all girls with unexplained severe ID, particularly those with developmental regression, stereotypic hand movements, deceleration of head growth, and seizures. More than one hundred other genes have been associated with X-linked ID.

Whole exome sequencing (WES), which sequences the protein encoding regions of all genes, has additional diagnostic utility and is increasingly becoming clinically available. The ability to test both parents (forming, along with the child, a trio) is crucial for WES interpretation as this technique regularly identifies hundreds or thousands of benign, inherited mutations. A 2012 study showed a diagnostic yield of 16% for WES in 100 severe ID trios. In the future, sequencing of the entire genome, including noncoding regions, is likely to become available on a clinical basis. Please refer to Chapters 34 and 35 for a more detailed discussion of genetic testing.

The yield from metabolic evaluations of children with global developmental delay and PE is 0.2% to 5%. Some of these disorders are treatable or have symptoms that can be ameliorated with no more than a change in diet. Intrauterine or early diagnosis of some of these disorders may allow affected siblings to be treated at a milder or even asymptomatic

stage of the illness. Please see Chapters 36, 50, and 51 as well as the section later in this chapter on the diagnostic approach for additional discussion.

Electroencephalography is a valuable diagnostic tool in the evaluation of children with suspected PE. Epileptic encephalopathies describe a group of disorders in which abnormal CNS electrical activity persistently disturbs neuronal networks involved in cognition. Although the value of EEG is recognized in children with a suspected epileptic encephalopathy, the diagnostic yield in children with cognitive decline without obvious clinical seizures has not been clearly determined. However, it is common practice to acquire an EEG in this subset of patients because clinical seizures may be very subtle and because it is hoped that anticonvulsant use may, in some patients with epileptic encephalopathies, improve cognitive function.

Neuroimaging studies are also an important part of the evaluation of children with PE. Magnetic resonance imaging (MRI) is the investigation of choice for structural abnormalities, neuronal migrational disorders, white matter diseases and posterior fossa structures. Computed tomography (CT) can more readily show intracranial calcifications and cranial bone abnormalities such as craniosynostosis. Specialized applications of MRI as spectroscopy, susceptibility weighted imaging, diffusion weighted imaging, and diffusion tensor imaging can provide additional information about brain structure and function. Up to 40% of patients undergoing evaluation for developmental disability show a structural or biochemical abnormality on neuroimaging. Although the abnormalities are often nonspecific, such as mild global atrophy, there are times when the findings are highly suggestive of a specific disorder (Chapter 12).

A lumbar puncture to quantify cerebrospinal fluid (CSF) amino acids, lactate, and neurotransmitter levels may be considered in patients being evaluated for PE. A recent study reported diagnostic CSF results in 25.8% of 62 patients suspected of having a pediatric neurotransmitter disease based on their clinical symptoms. See Chapter 44 for further details.

## BRAIN BIOPSY

The necessity for brain biopsy for nonneoplastic conditions has substantially diminished over the years as advances in neuroimaging, biochemical, and genetic tests have provided safer and easier means by which to make a diagnosis. However, biopsy may still play an important role in the evaluation of patients with PE that remains unexplained despite extensive noninvasive testing. In some cases, biopsy is the only method by which a particular diagnosis can be confirmed and in others, the biopsy results provide crucial information about therapeutic options and prognosis. See online chapter. 

## DIAGNOSTIC APPROACH

Professional societies and governmental agencies have produced systematic reviews and evidence-based clinical practice guidelines regarding the evaluation of children with neurodevelopmental disabilities (Miclea et al., 2015; Srouf and Shevell, 2014; Dunfield et al., 2014; Michelson et al., 2011; Miller et al., 2010; Moeschler and Shevell, 2006; Curry et al., 1997; Shevell et al., 2003; Valle website). However, these reports were focused on children with nonprogressive symptoms. Studies specifically reviewing the diagnostic workup of children with PE have a variable yield for an etiologic diagnosis depending on the inclusion criteria and which neuroimaging studies, metabolic and genetic testing is done.

Three alternative methods to approach the diagnostic evaluation of children with PE have been described. The first

approach, similar to that used to evaluate children with non-progressive developmental disorders, begins with general screening tests that are performed for all such children and then adds additional screening tests for infectious, toxic, endocrinologic, genetic, neoplastic, metabolic, autoimmune, and nutritional disorders based on the child's individual history or initial screening test results (See Table 52-8). This approach is based more on frequency of likely diseases rather than on treatability. Abnormal screening tests will often suggest the need for further neuroimaging with magnetic resonance spectroscopy or diffusion tensor imaging; further electrophysiologic testing with electroretinography or electromyography; or further metabolic or targeted genetic screening tests or tissue biopsies for microscopy or enzyme analysis.

A second approach to the evaluation of PE is to use an interactive database to generate a broad differential diagnosis. SimulConsult ([www.simulconsult.com](http://www.simulconsult.com)) is a web-based program that is freely available to clinicians and students. As clinical information is entered, the program orders its differential based on likelihood and makes suggestions regarding what additional findings and laboratory tests would most help clarify the diagnosis. A broad differential can help clinicians to avoid cognitive pitfalls that commonly contribute to diagnostic error and delay including the biases of availability and representativeness (favoring familiar diagnoses over less well-known diagnoses or disease variants) and those of framing and premature closure (favoring findings that confirm rather than question a preexisting diagnosis). DiagnosisPro ([en.diagnosispro.com](http://en.diagnosispro.com)) is another web-based database that is not specific to neurology.

A third approach, as proposed by the British Columbia Children's Hospital group, is referred to as the Treatable Intellectual Disability Endeavor (TIDE) algorithm ([www.tidebc.org](http://www.tidebc.org)) (Van Karnebeek and Stockler-Ipsiroglu, 2014). The TIDE algorithm emphasizes testing patients for treatable disorders, even when rare, before testing them for more common but untreatable disorders. This protocol is reviewed in Chapter 59. The first tier of testing, to be applied to all children presenting with PE, calls for blood and urine studies that are available at most commercial laboratories at a reasonable price and which are likely to detect up to 60% of the currently known treatable disorders (Table 52-9). Second tier tests are generally more expensive and invasive and are recommended on a more selective basis, based on clinical judgment and suggestions from textbooks, online resources, and other specialists such as metabolic geneticists. Use of the TIDE protocol has the potential to reduce the cost and diagnostic delay involved in identifying patients with treatable IEMs.

The individual disorders causing PE in childhood are too numerous to discuss in detail in this chapter, but they are presented in the online version of the book in tables based on age and symptomatology (i.e., Tables 52-10 to 52-24).

Up-to-date information about the sensitivity and availability of tests for specific genetic disorders is available through the Gene Tests website ([www.genetests.org](http://www.genetests.org)). Some genetic tests can be performed on a research basis through direct communication and cooperation between the clinician and research laboratory.

## MANAGEMENT

The specific cause of childhood PE cannot be determined in at least half of the cases (as reported in large epidemiologic surveys). However, because a small number of disorders can be at least ameliorated by medical therapies, pursuit of a diagnostic workup is warranted. Caregivers can be expected to have a great number of questions and concerns that will require a large amount of time, patience, and sensitivity on the part of

**TABLE 52-9** Treatable Intellectual Disability Endeavor (TIDE) Diagnostic Protocol

**TIER 1: NONTARGETED METABOLIC SCREENING TO IDENTIFY 54 (60%) TREATABLE IEM:**

Blood	Urine
Plasma amino acids	Organic acids
Plasma total homocysteine	Purines and pyrimidines
Acylcarnitine profile	Creatine metabolites
Copper, ceruloplasmin	Oligosaccharides
	Glycosaminoglycans
	Amino acids (when indicated)

**TIER 2: CURRENT PRACTICE ADHERING TO INTERNATIONAL GUIDELINES (1 OR MORE OF):**

Audiology	Low yhreshold for ordering tests
Ophthalmology	
Cytogenetic testing (array CGH)	
Thyroid studies	
CBC	
Lead	
Metabolic testing	
Brain MRI and 1H spectroscopy (where available)	
Fragile X	
Targeted gene sequencing/ molecular panel	
Other	

**TIER 3: TARGETED WORKUP TO IDENTIFY 35 (40%) TREATABLE IEM REQUIRING SPECIFIC TESTING:**

According to patient's asymptatology and clinician's expertise

Utilization of digital tools ([www.treatable-id.org](http://www.treatable-id.org))

Specific biochemical/gene test

Whole blood manganese

Plasma cholestanol

Plasma 7-dehydroxy-cholesterol:cholesterol ratio

Plasma pipercolic acid and urine  $\alpha$ -amino adipic semialdehyde (AASA)

Plasma very long chain fatty acids

Plasma vitamin B<sub>12</sub> and folate

Serum and CSF lactate:pyruvate ratio

Enzyme activities (leukocytes): arylsulfatase A, biotinidase, glucocerebrosidase, fatty aldehyde dehydrogenase

Urine deoxyripyridonoline

CSF amino acids

CSF neurotransmitters

CSF:plasma glucose ratio

CoQ measurement fibroblasts

Molecular analysis: CA5A, NPC1, NPC2, SC4MOL, SLC18A2, SLC19A3, SLC30A10, SLC52A2, SLC52A3, PDHA1, DLAT, PDHX, SPP, TH genes

(Adapted from Van Karnebeek, C.D., Stockler-Ipsiroglu, S., 2014. Early identification of treatable inborn errors of metabolism in children with intellectual disability: The Treatable Intellectual Disability Endeavor protocol in British Columbia. *Paediatr Child Health* 19(9), 469–471.)

the clinician. Even when disease-specific treatments are not available, the clinician can be of great assistance in maintaining the child's quality of life. Efforts should be made early in the course to direct the child to other sources of supportive care, including rehabilitation specialists, nutritionists, special education instructors, and speech, occupational, and physical therapists. When possible, the child's caregivers should be referred to a social worker who can help them obtain financial support, nursing care, and social support networks and a genetic counselor who can explain the inheritance patterns and aspects of family planning and antenatal diagnostic possibilities, provide talking points to communicate with family members, and help identify support groups and opportunities for advocacy.

## FUTURE DIRECTIONS

Earlier diagnosis of conditions causing PE, particularly before devastating neurologic symptoms develop, will improve patient treatment and family planning. Prenatal diagnosis has several advantages but is currently difficult even in families with known risks. Noninvasive prenatal testing (NIPT) can examine a pregnant mother's blood for fetal DNA abnormalities and is currently being offered to mothers at high risk for aneuploidies such as Trisomy 21. This method is likely to expand to screening for CNVs and point mutations as technical and ethical issues are worked out.

Single nucleotide polymorphisms (SNPs) are the most abundant sequence variations in the human genome, with approximately 150 million discovered thus far ([www.ncbi.nlm.nih.gov/snp](http://www.ncbi.nlm.nih.gov/snp)). Current arrays simultaneously genotype thousands of SNPs, providing information about CNVs but also about uniparental disomy and regional homozygosity (which can reflect parental consanguinity). Next generation sequencing (NGS) techniques are faster and less expensive than older sequencing methods and are already providing a greater number of patients with access to large gene panels. It is certain that the future will bring us testing methods for metabolic and genetic disorders that is increasingly personalized, sensitive and specific, cost-efficient, and better able to provide patients with a clear diagnosis with minimal delay.

## INTRODUCTION

Developmental language disorders (DLDs) include a number of conditions that adversely affect language development. The most common DLD is specific language impairment (SLI), a neurodevelopmental disorder (NDD) that affects 2% to 11% of the population, making it one of the most common NDDs. The hallmark of SLI is that a child with normal intelligence and hearing fails to develop language in an age-appropriate fashion. SLI is a clinical diagnosis, based on the presence of a normal nonverbal IQ, evidence of expressive and/or receptive language significantly below expected for age and intelligence (SLI is often defined by scoring at least 1.5 standard deviations below the mean for age on standardized, age-appropriate tests of language), and absence of other specific conditions such as autism, global intellectual disability, metabolic or genetic disorders, or severe environmental deprivation. Although this condition is commonly called “specific” language impairment, there is controversy as to how specific the condition is and whether the terminology should be changed to a more generic term, such as language impairment. Despite this controversy, however, at present the terminology remains the same. Other forms of DLD include stuttering, selective mutism, verbal apraxia, and epileptic aphasia. [Box 53-1](#) lists normal language milestones as a baseline for assessing a child’s developmental language competence.

## NEURAL SUBSTRATES OF LANGUAGE

In adults, specific brain regions, primarily in the left hemisphere, are believed to mediate language, based primarily on studies of adults with strokes and more recently on neurophysiological and functional imaging studies. The neural substrates of language during early development are not as clearly defined, and in fact may differ markedly from those that mediate language once it has developed. Children who had a left-hemisphere stroke in early life do not typically demonstrate aphasia, or even a functional language impairment. A classic study by [Bates et al. \(2001\)](#) demonstrated the differences between children with perinatal stroke and adults with late-acquired stroke in the left hemisphere, showing that children performed equally well as their typically developing counterparts on multiple aspects of language, unrelated to the hemispheric side of the lesion, whereas adults who had a later-onset left-hemisphere stroke showed significant impairments on the same tasks. Such findings suggest that language is not “hardwired” into specific brain regions, but that the process of language acquisition requires more widely distributed neural networks. Studies of very early language awareness in the first few months of life indicate that infants learn very early to attend to the linguistic traits that are relevant to the language to which they are exposed. Typically developing children attend more to speech sounds when their attention is directed to auditory rather than visual stimuli, whereas children with SLI are unable to sufficiently attend to speech sounds in the same setting, suggesting that there may be a

deficit in auditory attention or in general attentional resources at the basis of SLI. Rapid processing of sensory information, particularly in the auditory modality, may also be a contributing factor to impaired language development. Efficient processing of auditory stimuli has been shown to be impaired in many children with SLI. It is as yet unclear whether the primary deficit is in the ability to focus attention to process auditory information or whether the processing deficit is the principal causal factor. In either event, basic sensory processes are disrupted in SLI, leading to impaired language development.

## NEUROANATOMY OF SPECIFIC LANGUAGE IMPAIRMENT

Although SLI has been an important area of research and clinical focus for many years, there have been relatively few studies of brain structure in this condition, and those reported have not been consistent. Clinical neuroimaging scans (magnetic resonance imaging [MRI]) generally yield normal results, although a higher-than-expected incidence of abnormal findings, including ventriculomegaly, central volume loss, and white-matter hyperintensities, has been described, suggestive of possible disruption of normal white-matter structure. Quantitative neuroimaging techniques have focused primarily on the frontal and temporal regions thought to be important for language and have demonstrated abnormal gyrification in the inferior frontal gyrus, the absence of the normal left-right asymmetry of the planum temporale, or atypical right-greater-than-left asymmetry of both anterior and posterior temporal lobes. Arguments for atypical lateralization of the developing brain for language as a cause for SLI have been made based on the differences in brain symmetry observed in some of the imaging studies ([Badcock et al., 2012](#)). Functional neuroimaging studies have also demonstrated lack of the expected left lateralization of activation on linguistic tasks.

Diffusion-tensor imaging techniques have demonstrated white-matter structural changes in the superior longitudinal fasciculus (SLF) of adolescents with SLI. The SLF is a major white-matter tract that is thought to be crucial for language processing because it connects the anterior areas of the cortex to the posterior areas and, among other areas, the Broca’s area to the Wernicke’s area. Differences in SLF structure provide a possible structural explanation for the language-processing problems found in SLI.

Other types of imaging studies have demonstrated functional changes in the brains of children and adults with SLI. Single-photon emission-computed tomography (SPECT) studies have shown reduced cerebral blood flow in the left hemisphere of children with SLI compared with controls. With the use of transcranial ultrasound to examine blood flow to each hemisphere during a word-generation task, aberrant hemispheric blood-flow responses have been demonstrated in adults with SLI. Magnetoencephalography was used to track the spatiotemporal course of brain response to real words and pseudowords in children with SLI compared with typically developing children. Bilateral superior temporal cortex regions

**BOX 53-1** Normal Language Milestones**RECEPTIVE**

- Some words understood by 9 months
- Follows one-step commands by 12 months without being cued by a gesture

**EXPRESSIVE**

- Cooing—2 months
- Babbling—6 months
- Variable babble—8 months
- One word other than *dada* and *mama*—12 months
- 10 to 50 words used meaningfully—16–20 months
- Two-word phrases—20–24 months
- Points to at least one body part and to named objects and people on command—20 months
- Vocabulary greater than 200 words—2 years
- Two-word combinations—2 years
- Follows two-part commands—2 years
- Sentences of three to four words—3 years
- Compound and complex sentences—4 years
- Passive voice—6 years

were activated to word and pseudoword presentations, but in contrast to controls, children with SLI showed equally strong activation to both words and pseudowords. Further, children with SLI did not show the typical attenuation of activation the second time the same word was presented, indicating that the linguistic activation that underlies word recognition may be defective in SLI.

## FACTORS ASSOCIATED WITH DEVELOPMENTAL LANGUAGE DISORDERS

As with many neurodevelopmental disorders, there is a higher incidence of SLI in males (1.6:1 males:females). The cause for the gender differences is not known. Numerous biological and environmental risk factors for SLI have been identified. Low birth weight, prematurity, and prenatal exposure to drugs (e.g., cocaine) and to cigarettes have been reported to adversely affect language development, although no single perinatal complication has been definitively associated with SLI; rather, an aggregate of perinatal complications could contribute to later language impairment.

Although frequent episodes of otitis media have been suggested as causing language impairment, there is little evidence from controlled studies to indicate a causal relationship. Intermittent hearing loss may interfere with language development in at-risk children, but is not likely to cause long-term language issues in otherwise normally developing children.

Language impairment is seen in association with specific neurologic and genetic disorders. For example, perisylvian polymicrogyria (or congenital bilateral perisylvian syndrome) is a disorder of defective neuronal migration that has a spectrum of neurologic impairments that include severe epilepsy and cognitive impairment. In some children with this condition, language impairment is the most prominent feature. Language impairment is also prominent in a number of chromosomal disorders, including Down, Klinefelter, and fragile X syndromes. Epileptic encephalopathies, particularly Landau-Kleffner syndrome (LKS), may have language impairment (often receptive greater than expressive impairment) as an isolated or primary symptom. Rolandic epilepsy, often considered to be “benign,” may be complicated by language impairment and learning disabilities.

## GENETICS

Heritability rates for SLI run as high as 0.5, but they are variable and are affected by the criteria used to diagnose the disorder (SLI vs. more general DLDs that may be associated with known genetic syndromes) (Bishop and Hayiou-Thomas, 2008). The median incidence rate for language difficulties in the families of children with language impairment is up to 35%, compared with a median incidence rate of 11% in control families. Increased concordance rates in monozygotic versus dizygotic twins indicate that heredity, not just shared environment, is responsible for familial clustering.

Studies using genome-wide scanning have implicated a number of gene loci, but the same loci have not been found in a reproducible fashion (Vernes et al., 2008). Isolated families with specific mutations have been studied. In the three-generation KE family, half the members are affected with a severe speech and language disorder that is transmitted as an autosomal-dominant monogenic trait involving the *FOXP2* forkhead-domain gene. Notably, however, a screening of 270 4-year-olds with SLI was negative for the *FOXP2* mutation.

Recently HLA alleles have been associated with SLI. Maternally but not paternally inherited HLA-B B8 and HLA-DQA1 \*0501 were associated with impaired receptive language. HLA-A A2 was associated with expressive language ability. HLA-DRB1 was found with greater frequency in individuals with SLI than in controls. In other studies, the calcium-transporting ATPase 2C2 (*ATP2C2*) gene on chromosome 16 has been considered as a candidate gene for SLI.

It is unlikely that there will be one specific gene whose function would be restricted to forming the genetic basis for language acquisition. It is more likely that there are many genes that contribute to a variety of functions, and that these genes form networks that are recruited in the process of language acquisition. The issue of pleiotropy, or the influence of the same genes on multiple phenotypes, has also been discussed in the literature on SLI, given the substantive overlap in regions of linkage for a variety of developmental disorders, such as speech and sound disorders (SSD) and developmental dyslexia, and SLI and autism. Whether these are true examples of pleiotropy or outcomes of the imprecision of phenotype definitions is yet to be determined.

## DIAGNOSIS

SLI is a clinical diagnosis based on a delay in language development for expected age, in the absence of intellectual disability, autism, hearing impairment, or environmental deprivation. In children for whom formal language assessments are conducted, a score of 1.5 or more standard deviations from the normative mean on a standardized test of language is considered diagnostic for SLI.

Box 53-3 lists warning signs that suggest a DLD during the first 3 years. Language delay can be diagnosed very early. The developmental history provides strong evidence for language delay when the child does not meet expressive language milestones, does not seem to understand directions without associated gestures (e.g., “get your ball” without pointing to the ball), or does not point on command. During the examination, similar instructions can be given to the young child, and the child can be asked to point to various body parts or to point to pictures of common objects in a book. If there is a suspicion of language delay, the young child can undergo more formal language testing, such as with the MacArthur-Bates Communicative Development Inventory (normed for 8–30 months) or the Preschool Language Scale-4 (normed for birth to 6 years 11 months), both of which assess receptive and expressive language at young ages.

**BOX 53-3** Warning Signs of a Developmental Language Disorder**LIMITATIONS IN EXPRESSIVE LANGUAGE**

- Early problems with sucking, swallowing, and chewing
- Excessive drooling
- Failure to vocalize to social stimuli
- Failure to vocalize two syllables at 8 months
- Few or no creative utterances of three words or more by age 3

**LIMITATIONS IN VOCABULARY**

- Limited repertoire of words understood or used
- Slow or difficult new-word acquisition

**LIMITATIONS IN COMPREHENDING LANGUAGE**

- Excessive reliance on contextual cues to understand language

**LIMITATIONS IN SOCIAL INTERACTION**

- Reduced social interaction, except to have needs met

**LIMITATIONS IN PLAY**

- No symbolic, imaginative play by age 3
- No interactive play with peers

**LIMITATIONS IN LEARNING SPEECH**

- Numerous articulation errors in expressive speech
- Unintelligible to unfamiliar listeners

**LIMITATIONS IN USING STRATEGIES FOR LANGUAGE LEARNING**

- Use of unusual or inappropriate strategies for age level, e.g., overuses imitation (echolalia), does not imitate verbalizations of others (dyspraxia), does not use *wh*- questions for learning (*why*, *what*, *where*, etc.)

**LIMITATIONS IN ATTENTION FOR LANGUAGE ACTIVITIES**

- Little interest in book reading, talking, or communicating with peers

(Modified with permission from Nelson NW. *Childhood Language Disorders in Context: Infancy through Adolescence*. New York: Macmillan, 1993; Hall N. *Semin Pediatr Neurol* 1997;4:77–85.)

Before the age of 2 years, delay may not always equal disorder. Research on late-talking toddlers suggests that about 40% of children retained the diagnosis of SLI at ages 3 and 4 years. This is particularly true if the early language delay is primarily expressive. However, many children with early language delay who appear to “catch up” go on to have language-based learning disabilities (e.g., dyslexia). It is therefore important to recommend periodic reassessment of a child’s language and academic functioning after an early language delay has been diagnosed.

Children with receptive language impairments are more likely to have a persistent SLI. These children are more likely to have academic and social problems as a result of poor comprehension of language, and in some cases slowed processing of auditory information, which makes it difficult for them to follow a conversation or to follow a spoken lecture. Thus concern for poor language prognosis should be heightened when receptive language deficits are identified.

Speech articulation disorders may be found in isolation or in association with language disorders. Early articulation errors are common and usually mild. However, if there are other features (e.g., excessive drooling or inability to chew food properly) or if a child is not able to be understood virtually 100% of the time by age 4 years, this should raise concern about a more serious condition, such as oral-motor apraxia. A thorough oral-motor examination by the physician will

**BOX 53-4** Glossary of Terms Used in Describing Linguistic Functions

Functors	The small words of the language, such as prepositions, conjunctions, and articles; also called closed-class words because they are limited in number
Lexicon	The words in a language; the dictionary of word meanings
Mean length of utterance (MLU)	The number of morphemes per utterance
Morpheme	The smallest meaningful unit in a language, occurring either in a word or as a word. (For example, the compound word <i>compounding</i> is made up of three morphemes: <i>com-pound-ing</i> .) Prefixes, suffixes, and inflected endings such as <i>-ed</i> , <i>-s</i> , and <i>-ly</i> are also morphemes
Phoneme	A distinct sound unit in a language (In English, there are 46: 9 vowels and 37 consonants.)
Phonology	The rules a speaker follows when combining speech sounds
Pragmatics	The communicative intent of speech rather than its content (e.g., asking a question at the right time and in the right way)
Prosody	The melody of language; the tone of voice used to ask questions, for example, or to show emotion
Semantics	The meaning of words; their definition
Syntax	The grammar of a language; the acceptable relationship between words in a sentence

identify apraxia in severe cases. Milder forms may require a more extensive oral-motor assessment by a speech pathologist or pediatric occupational therapist.

**NOSOLOGY OF DEVELOPMENTAL LANGUAGE DISORDERS**

There is not uniform agreement on the proper nosology of the DLDs. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-V) of the American Psychiatric Association (2013) includes DLD under Communication Disorders, and specifies subcategories of language disorder (“language disorder” combines expressive and mixed receptive-expressive language disorders—this is synonymous with SLI in common usage), speech-sound disorder (i.e., phonological disorder), childhood-onset fluency disorder (i.e., stuttering), and social (pragmatic) communication disorder (in the absence of autistic features). These constitute general subtypes of DLDs. A more specific nosology has been proposed by Rapin (1996) based on psycholinguistic features. The subtypes are named for the linguistic areas that are most problematic (see Table 53-1 and the glossary of terms in Box 53-4).

**Articulation and Expressive Fluency Disorders****Pure Articulation Disorders**

Articulatory skills improve with age, and as with language development, the normal range is considerable. Most children speak intelligibly by age 2 years. Unintelligible speech is the

 (Modified from Nass R, Ross G. Disorders of higher cortical function in the preschooler. In: David R, ed. *Child and Adolescent Neurology*. St. Louis, MO: Mosby, 1997; Rapin I. *Preschool Children with Inadequate Communication*. London: Mackeith, 1996.)

exception at age 3 years. However, almost 50% of children at age 4 years still have mild articulation difficulties, primarily defective use of *th* or *r* sounds. At kindergarten entry, one third of children still have minor to mild articulation defects, but speech is unintelligible in less than 5%.

### Stuttering and Cluttering

Stuttering is a disorder in the rhythm of speech. The speaker knows what to say but is unable to say it because of an involuntary repetitive prolongation or cessation of a sound. Some degree of dysfluency is common as language skills evolve during the preschool years, particularly as the mean length of utterance (MLU) reaches 6 to 8 words between ages 3 and 4 years. However, stuttering, in contrast to developmental dysfluency, is probably a linguistic disorder (errors occur at grammatically important points in the sentence) and a motor planning problem. Typically, onset of stuttering is between the ages of 3 and 6 years, and reports indicate unassisted recovery rates of 75%. Thus the prevalence of stuttering as a lifetime disorder is much lower than its incidence (0.5%–1% vs. 4%–5%). However, persistence of stuttering may be associated with other aspects of language impairment, such as difficulty with processing of syntactic information.

Stuttering is often a genetic trait. Although the cause of developmental stuttering is unknown, the main theories are anomalous dominance and abnormalities of interhemispheric connections. Cluttering, by contrast, as seen in fragile X syndrome, is characterized by incomplete sentences and short outbursts of two- to three-word phrases, along with echolalia, palilalia (compulsive repetition reiterated with increasing rapidity and decreasing volume), perseveration, poor articulation, and stuttering.

### Phonological Programming Disorder

Children with the phonological programming disorder have fluent speech, and their MLU approaches normal. Despite initially poor intelligibility, serviceable speech is expected. Language comprehension is relatively preserved. Most such children show delayed rather than deviant phonology and improve during school years. It is debatable whether this disorder is a severe articulation problem or a mild form of verbal dyspraxia. The fact that patients with phonological programming disorder have more difficulty learning manual signs than do controls supports an association with dyspraxia. A prere-

mediation paired-associate learning task may help select the best remediation method for each child because some are better with symbols and some with signs.

### Verbal Dyspraxia

Children with verbal dyspraxia, also called dilapidated speech, are extremely dysfluent. These children are unable to convert an abstract phonological representation into a set of motor commands to the articulators (i.e., there is a deficit in phonology–motor conversion). Utterances are short and laboriously produced. Phonology is impaired and includes inconsistent omissions, substitutions, and distortions of speech sounds. Children with dysarthria make voicing errors that distort, whereas children with dyspraxia make place substitution errors. In conversation, they make phrasal errors. Syntactic skills are difficult to assess in the face of dysfluency. Language comprehension is relatively preserved, but many children have receptive language problems. Children with verbal dyspraxia who do not develop intelligible speech by age 6 years are unlikely to acquire it later. The frequency with which nonverbal praxis deficits—buccal-lingual dyspraxia (e.g., positioning muscles of articulation) and generalized dyspraxia—coexist with verbal dyspraxia is unknown. The presence of a more diffuse disorder of praxis has significant therapeutic implications because children with verbal dyspraxia may depend on signing and writing skills for communication. Developmental coordination disorder (DCD) is commonly comorbid with speech/language learning disabilities. Young children who are in early intervention programs for speech/language delays may have significant coordination difficulties that will become more evident at kindergarten age, when motor deficits begin to affect self-care and academic tasks.

### Disorders of Receptive and Expressive Language

#### Phonological Syntactic Syndrome

Phonological syntactic syndrome (also called mixed receptive expressive disorder, expressive disorder, and nonspecific formulation-repetition deficit) is probably the most common DLD. The phonological disturbances consist of omissions, substitutions, and distortions of consonants and consonant clusters in all word positions. The production of unpredictable

and unrecognizable sounds makes speech impossible to understand. The syntactic impairment consists of a lack of functors and an absence of appropriate inflected endings. Plurals, third-person singulars, past tense, the auxiliary verb *be*, *the* and *a*, infinitives (*to*), and case markings on pronouns are particularly vulnerable. Grammatical forms are atypical, not just delayed. Whereas a typically developing young child may say "baby cry" or "a baby crying," children with phonological syntactic syndrome produce deviant constructions, such as "the baby is cry." Telegraphic speech is common. Comprehension is relatively spared. Semantic skills tend to be intact. Repetition, pragmatics, and prosody may be normal. Autistic children with this DLD subtype produce a significant amount of jargon.

Neurologic dysfunction is especially frequent in this subtype. Sucking, swallowing, and chewing difficulties are common, and drooling is often persistent. The neurologic examination may reveal signs of oral motor apraxia, hypertension, and incoordination.

### Verbal Auditory Agnosia

Children with verbal auditory agnosia (VAA) are unable to discern meaning from spoken language, despite intact hearing. VAA may be a developmental condition, apparent from early life, or an acquired disorder, as in Landau-Kleffner syndrome. VAA is common in low-functioning children with autism. The outcome from the developmental form of VAA is generally poor. The outcome from the acquired disorder is somewhat better, with approximately one third of patients having a good outcome with specific treatment.

## Higher-Order Language Disorders

### Semantic Pragmatic Syndrome

Children with the semantic pragmatic syndrome (also called repetition strength and comprehension deficit, language without cognition, cocktail party syndrome) are fluent and often verbose speakers. Vocabulary is often large and somewhat formal. Parents are often encouraged by the child's sizeable vocabulary, only to find later that the verbosity did not indicate superior cognitive skills. Many children have trouble with meaningful conversation and informative exchange of ideas. Pragmatic skills are lacking. They often show deficits in prosody; their speech has a monotonous, mechanical, or sing-song quality. They cannot convey the additional pragmatic intentions that prosody affords, such as speaking with the proper emotion or indicating by tone of voice that they are asking a question. Comprehension may be impaired. Phonological and syntactic skills are generally intact.

### Lexical Syntactic Syndrome

Lexical syntactic syndrome (LSS) occurs in approximately 15% of children with DLD. Speech is generally dysfluent, even to the point of stuttering, because of word-finding difficulties and poor syntactic skills. Both literal and semantic paraphasias are common. Most children have delays in word acquisition and less lexical diversity than their age-matched counterparts. Verbs appear to be the most difficult lexical category for them to learn. Syntax is immature but not deviant. Phonology is spared, and speech is intelligible. Repetition is generally better than spontaneous speech. In conversation, idiom use is better than spontaneous speech. In one study, fourth graders with LSS evidenced higher disruption rates at phrase boundaries in narratives than did their age-matched peers, reflecting lexical and syntactic deficits. Pragmatics may be impaired, particularly when this syndrome occurs in

autistic children. Comprehension is generally acceptable, although complex questions and other linguistic forms taxing higher-level receptive syntactic skills are often deficient.

## OUTCOME OF DEVELOPMENTAL LANGUAGE DISORDERS

Many children with SLI, particularly those with expressive language impairment, appear to improve in their language ability by early school age. Others have persistent language impairment that remains throughout life. There is a high incidence of other problems associated with SLI, including academic, behavioral, social-emotional, and psychiatric issues, and these may occur even when language appears to have reached the normal range.

Attention deficit disorder occurs in about 40% of children with SLI and may cause additional challenges.

Dyslexia is present in approximately 65% of children with SLI. Written composition may also be a challenge for these children. These problems lead to poorer-than-expected school performance and a higher dropout rate.

Adolescents with a history of SLI have a higher likelihood of peer problems, emotional symptoms, and conduct problems (Snowling et al., 2006; Conti-Ramsden et al., 2013). Poor receptive language raises the likelihood of emotional and behavioral difficulties. Anxiety disorder, social phobia, and depression occur at a high rate in children and adolescents (20%–50%) with a history of SLI. Adolescents with SLI have a lower level of academic achievement than their typically developing peers. It is important to note that subtle language and communication problems may persist into adult life in up to 90% of cases and may cause the affected individuals to be shy in social situations and reluctant to enter into conversations with others because of their language problem.

Preschool language skills are the best single predictor of later reading ability and disability. Even children with good receptive skills who speak late may be at risk for continuing subtle language difficulties and later reading- and language-based academic difficulties. Thus both screening and follow-up studies of children with SLI are important. Follow up of 112 individuals with SLI into adult life demonstrated lower levels of functioning in the areas of communication, educational attainment, and occupational status compared with their typical peers. Such studies indicate the need for continued surveillance of individuals with SLI and adequate guidance in terms of academic and career choices (Young et al., 2002; Johnson et al., 2010).

Early intervention, not only with speech/language therapy but also with social skills training and, when indicated, psychological and career counseling, may help to reduce the long-term morbidity of SLI.

## EVALUATION OF THE CHILD WITH A SUSPECTED DEVELOPMENTAL LANGUAGE DISORDER

The workup of the child with a DLD (Box 53-6) must include an assessment of hearing and an assessment of overall level of intellectual functioning, in addition to a thorough language assessment that includes both receptive and expressive language components. Other evaluations that may be warranted include tests for auditory processing and neuropsychological assessments for associated problems such as attention deficit disorder.

Certain metabolic disorders can present with isolated language delay, so a metabolic screen is appropriate in some circumstances. Mitochondrial disorders and organic acidemias may have language impairment as their primary feature,

**BOX 53-6** Evaluation of a Child With Suspected Language Disorder

- Complete neurodevelopmental and family history and neurologic examination (including social interaction and communicative behaviors)
- Hearing test
- Office developmental screen (e.g., Denver Developmental Test, MacArthur-Bates Communicative Development Inventory, Children's Communication Checklist, Preschool Language Scale, Early Language Milestones) can be helpful
- Psychometric testing to establish general cognitive function (a nonverbal intelligence test such as the Leiter International Performance Scale–Revised or the Test of Non-Verbal Intelligence–P:4 or I:3 [TONI-P:4; TONI-I:3] is most appropriate in a language-impaired child)
- Depending on history and examination, other tests to consider:
  - Sleep electroencephalogram (EEG)
  - Overnight video EEG monitoring
  - Magnetic resonance imaging (MRI) of the brain
  - Karyotype, fragile X, microarray study, fluorescent in situ hybridization (FISH) probes
  - Metabolic screen (e.g., urine organic acids, blood amino acids)

particularly in the first few years of life. Numerous other syndromes can present predominantly with language delay.

An electroencephalogram (EEG) should be considered in a child with DLD if there is a history of a language regression or a suspicion from the history that the child might have seizures. Neuroimaging studies are not likely to be helpful unless there are abnormal findings on the neurologic examination.

## TREATMENT

Whether intensive early therapy changes the long-term outcome to an appreciable degree remains to be determined. Treatment of language-disordered preschool children varies according to the kind of language impairment and its degree of severity (Warren and Yoder, 2004). Preschool children with moderate to severe language impairment may benefit from a special education preschool for language-impaired children. Mildly impaired children may do well in a regular preschool program combined with individual speech/language therapy. Floor time–based language therapy provides a naturalistic and developmentally appropriate way of working on language skill development. Formal language work typically begins at the phonologic level, involving repetition of sounds and sound sequences to encourage fluency. Treatment of receptive disorders often necessitates the use of visual modalities, such as signs and gesture. Less severe disorders of comprehension are addressed through practiced structuring of conversations with the child. Children with severe comprehension deficits rarely progress as well in treatment as do children with primary expressive disorders.

Children with significant auditory processing disorders may benefit from a systematic computer-based approach to improving the speed of auditory processing, although benefits from this type of intervention remain controversial.

Some classroom accommodations may be necessary for the child with SLI to succeed. Children with SLI may require additional help from a resource specialist or tutor. They may require additional time for giving reports and for taking tests. Whenever possible, presentation of oral information should be accompanied by visual aids. In support of previous research,

children with SLI have problems with inferencing, linking directly observed or stated information to likely outcomes. They also have limited working memory capacity, and they are more likely to make errors related to inattention. Thus children with SLI are likely to be at a disadvantage in classroom situations, particularly for information presented orally and if the information is complex. The use of pictorial aids may help them encode the information. They may also benefit from having information broken into manageable (shorter) units.

When necessary, medications for treatment of attention deficit hyperactivity disorder (ADHD) should be considered. Because there is a high incidence of secondary emotional problems and self-esteem issues associated with SLI, referral for psychological counseling should be considered as soon as these problems become apparent. Families should be informed about their child's condition and be encouraged to provide a positive and supportive environment. A multidisciplinary approach, including physician, speech/language pathologist, teacher, psychologist, and parents, provides the most effective means of helping children with SLI.

## Nonverbal Learning Disabilities and Associated Disorders

Margaret Semrud-Clikeman and Doris A. Trauner

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

### INTRODUCTION

Nonverbal learning disabilities (NLD) are increasingly being identified by clinicians. NLD generally involve difficulties with visual-spatial reasoning, executive functioning, and mathematics difficulties (Rourke and Tsatsanis, 2000; Davis and Broitman, 2011). For many children with NLD, co-occurring attention and social perception difficulties are present (Mammarella and Cornoldi, 2014; Semrud-Clikeman et al., 2010). Although there is no diagnosis in DSM V or ICD-10, frequently these children may qualify for a diagnosis of a social communication disorder from DSM V.

There are likely two different types of NLD: one with a medical association and one without. Children with non-medical NLD generally are referred to neuropsychological and psychological clinics and only rarely are seen by medical professionals other than pediatricians and physical/occupational therapists. Neurologists and other specialists frequently see children with medically based NLD because of parent concerns about visual-spatial difficulties and social deficits (Balantyne et al., 2013; Bava et al., 2010; Beaton et al., 2010). Medical conditions frequently associated with NLD include velo-cardio-facial syndrome, some lysosomal storage diseases, and nephropathic cystinosis (Trauner et al., 2007). Neuroimaging findings have indicated differences in the corpus callosum (particularly in the splenial region), anterior cingulate gyrus, and in the parietal white matter volume and gray-matter thickness (Fine et al., 2013; Reiss et al., 1995). Further studies of structural and functional differences are needed, particularly in comparing medically related and nonmedically related cases of NLD.

### WHAT ARE NONVERBAL LEARNING DISABILITIES?

The diagnosis of NLD is a fairly new construct first developed by Myklebust and Johnson and further researched by Byron Rourke and colleagues. The incidence of NLD has been estimated to be approximately 5% of the learning disabled population (or around 1% of the general population). These children have been described as having difficulties with visual-spatial processing, mathematics, handwriting, social cognition, and in some cases attention. In contrast to these weaknesses, children with NLD have also been found to be verbally facile and to have good reading recognition skills and rote language abilities.

The definition of NLD has continued to evolve since its original conceptualization, with diagnostic descriptions varying across clinical laboratories. The original conceptualization included difficulties with spatial and temporal perception, handwriting and mathematics weakness, problems with social perception, and a higher verbal than performance IQ. Many studies utilize an approach wherein the child must meet a selection of symptoms from an array of possibilities to

qualify for a diagnosis of NLD. Although features of NLD subtypes continue to be refined, NLD is currently characterized by three broad areas of dysfunction: motoric skills, visual-spatial-organizational/memory skills, and social abilities.

Rourke was a pioneer in developing our understanding of NLD. After several decades of clinical research he conceptualized NLD as a set of assets and deficits. These strengths and weaknesses were associated with initial or primary features, which then lead to secondary and tertiary features in many areas of functioning. Using this framework, the social competence difficulties described originally by Myklebust are hypothesized to be the result of problems with visual-spatial processing.

Rourke's conceptualization was similar to that of Johnson in that both developed a neurologic hypothesis for NLD emphasizing white matter involvement. Rourke hypothesized that the myelinated fibers of the brain are related to symptoms of NLD, which subsequently included children with some genetic and medical conditions. For this reason, in addition to children without apparent congenital or acquired neurologic dysfunction, Rourke and associates began to incorporate the several additional neurologic disorders that had some or all of the features of NLD. The overlap with these diagnoses will be discussed in the next section.

### Coexistent Issues

One of the controversies in NLD is whether it is a variant or a milder form of autism. Some researchers advocate the use of the NLD phenotype as a heuristic model for understanding autism spectrum disorders (ASD) or Asperger syndrome (AS), whereas others suggest that AS is a more severe form of NLD (Brumbach et al., 1996). Still others suggest that these are two separate disorders. In the current version of DSM V, AS is no longer a diagnostic category; rather autism spectrum disorder: high functioning (HFA) is used.

Theoretical models of NLD and HFA both suggest deficits in the developing brain, likely beginning during gestation, that consequently affect the development of normal social interaction. The amygdala is particularly pinpointed as an area of system dysfunction early on that later interferes with the ability to respond to facial expressions due to faulty neural networks involving social understanding. Early experience with social referencing is crucial for the development of empathy, theory of the mind, and social reciprocity. Similarly, Rourke (1995) emphasized difficulties with the connectivity between the limbic structures and the frontal lobe rather than an impairment of specific regions.

Although there are similarities between NLD and AS/HFA in many aspects, there are also many qualitative differences between these groups. It is more common in NLD to find difficulties with mathematics and with visual-spatial processing than in AS/HFA. It is also unusual for children with NLD to show stereotyped behaviors or "bizarre" interests or an

emphasis on routine that is frequently seen in individuals with AS/HFA.

Currently there are three comprehensive reviews of NLD that have sought to evaluate the empirical evidence to determine the main characteristics of NLD and to reconcile whether this diagnosis actually exists or is a form of autism. These reviews have generally found that NLD is a complex diagnosis for which there is no consistent criteria for identification. It was also found that many children with NLD showed symptoms of attention deficit hyperactivity disorder (ADHD); predominantly inattentive type. The most robust finding was that of visual–spatial deficits, lower mathematics skills compared with reading, and problems with visual–constructive abilities. Moderate support was found for problems with visual memory and social cognition. It has also been suggested by a few authors that social comprehension ability may be evident in a subtype of NLD but not necessarily in all children with NLD. Fewer studies have systematically evaluated executive functioning and/or attentional abilities, so these areas continue to need additional study.

## Neuropsychological Findings

### Verbal-Performance IQ Split

Several studies have found a difference in the verbal and performance skills on the previous versions of the Wechsler Intelligence Scale for Children. More recent studies also have found this difference for children with NLD, but also for children with AS. In each study, children with NLD showed a larger discrepancy than those with other diagnoses. The discrepancy between verbal and performance abilities alone is not sufficient for a diagnosis of NLD but should be used as one piece of evidence.

It has been found that children with autism with a discrepantly high verbal *or* performance IQ showed significantly more apparent difficulties with social functioning. Others have found that when the nonverbal IQ was higher than the verbal IQ more social difficulties were present. Furthermore a discrepancy between verbal and performance IQ in children with AS was also found with higher verbal scores related to fewer social difficulties in another study. These findings suggest that a significant difference in verbal comprehension and perceptual reasoning on a standardized intelligence measure may be an important marker for NLD. It also is important to recognize that differences of less than 25 points happen in approximately 20% to 25% of the population and therefore are not rare. Furthermore, the discrepancy between perceptual reasoning and verbal comprehension is not in and of itself a sufficient marker for a diagnosis of NLD to be made. Unfortunately, many clinicians continue to diagnose NLD solely on this discrepancy.

### Language

Although children with NLD have been found to have relatively good vocabularies, studies evaluating pragmatic language have begun to demonstrate some difficulty in this area. Pragmatic language includes the ability to understand the meaning of what is being said (semantics) and the ability to use language appropriately in social situations (pragmatics). Children with NLD have difficulty understanding the nuances of what is being said or being able to “read between the lines.” Studies have found difficulty for children with NLD on measures of pragmatic language, particularly when it involves social referencing. Children with NLD had more difficulty interpreting humor that involved pragmatic language or plays on words (puns) compared with visually oriented slapstick humor.

## Achievement

Children with NLD show good single word reading skills with later difficulties found in reading comprehension. Simply reporting facts and information that is contained within the reading selection is generally intact, whereas questions that probe for inferential reasoning are more problematic. In addition, difficulties have been found in mathematics, particularly in mathematical computation. As math demands increase, problems occur ranging from the mechanics of lining up numbers in math problems to comprehending the higher-level abstract concepts required in division, data presentation (charts, graphs), algebra, geometry, and trigonometry. These findings suggest it might not be the academic subject that is most problematic but rather the higher order thinking required to solve a problem.

Writing is an area of particular challenge for children with NLD. For early writers, letter formation, letter spacing, and word spacing may be difficult to manage. An informal assessment of this can be accomplished by simply asking the child to write the alphabet legibly as fast as they can. A child with NLD-based problems might have difficulty physically forming letters that are legible relative to other children their age, even while they work quickly through the letters.

## Visual–Spatial and Motor Skills

Studies have found difficulties with visual–spatial skills and visual–motor ability. When children with NLD were compared with children with other disorders on measures of visual–motor organization and visual–spatial skills, the children with NLD scored worse than the other clinical groups and the control group. These findings support Rourke’s contention that visual–spatial and perceptual difficulties may underlie the social difficulties frequently found in children with NLD. Motor skills have also been evaluated in children with NLD. Studies found graphomotor difficulties present particularly in younger children. These findings suggest that children with NLD do have more difficulty on tasks which require visual–spatial reasoning as well as visual–motor control and fine motor dexterity. These difficulties are particularly present when tasks are more complex, requiring additional processing for successful completion. It is also important to note that children with disorders such as ADHD and/or AS/ASD can also show difficulties in visual–motor skills, possibly for other reasons than visual–spatial deficits (e.g., impulsivity).

## Executive Functioning

Executive functions are a relatively new area being examined in individuals suspected of having NLD. Executive functions that have been identified to be problematic for children with NLD include cause–effect reasoning, learning new material that is complex or novel, and planning and organization. Additional measures of novel problem solving have found difficulty on tasks that are of increasing complexity and that require memory and abstract reasoning skills.

Attention is a related construct to executive functioning. Children with NLD have been found to have more frequent difficulties with attention. Rourke suggested that these attentional problems may be related to visual–spatial deficits rather than to attention. Studies that have examined social perception measures found them to be highly correlated to executive functioning but not strongly related to attention. In contrast the relation between visual–spatial skills and social perception abilities was not found to be significant. A sizable minority of children with NLD show sufficient attentional symptoms for an additional diagnosis of ADHD, which also requires specific

targeted treatment. These attentional skill deficits have not been found to be as predictive of social difficulties.

### Social Perception and Psychopathology

It has been suggested children with NLD show higher rates of depression and anxiety (Pelletier et al., 2001). Others have not found significantly higher rates of internalizing behaviors when samples are studied that are community based rather than in residential treatment facilities or in psychiatric clinics. Others have found mild symptoms of social withdrawal and sadness in children with NLD, particularly those who are older and in whom peer relations become more important and valued for self-esteem. Measures that require a child with NLD to interpret a social situation that is ambiguous or does not provide verbal cues as to what is occurring have been found to be particularly difficult.

In addition, these children had difficulty perceiving humor (cartoons and nonsequiturs), suggesting that problems with humor comprehension in children with NLD may be more related to social rather than visual-spatial deficits. Further studies have found difficulties with emotional modulation and/or depressed mood to be significantly related to the child's ability to accurately recognize and interpret nonverbal cues in a social situation. If a child has difficulty with nonverbal cues and misidentifies these and acts accordingly to the mistaken perception, it is likely that the child will feel sad and may withdraw from further social interactions, particularly if there is a negative outcome.

### Neuroimaging Findings in NLD and AS/ASD

Some have hypothesized that AS/HFA and NLD may be on the same continuum. If this supposition is accurate, then neuro-

imaging studies should find similar neuroanatomical differences from typically developing children. Neuroimaging studies have generally focused on autism spectrum disorders (ASD) and/or Asperger syndrome (AS). Findings from neuroimaging studies with ASD have found a larger white matter volume in the temporal and frontal lobes, bilateral amygdala, and hippocampus. It was suggested that these larger structures may be a result of developmental adaptation of the autistic brain caused by a processing overload involving emotional learning experiences. The amygdalar-hippocampal-frontal circuit may be particularly important for mediating emotional perception and regulation and is compromised in children with social reciprocity difficulties. Evidence of enlarged amygdalar regions was not found in the one study of NLD imaging, although the anterior cingulate bilaterally was found to be smaller in the AS and NLD group compared with controls (Table 54-1).

These findings have important implications for our understanding of NLD and of ASD/AS. Previous researchers have suggested that hippocampal enlargement is related to larger amygdaloid volumes. In this theory the reciprocal connections between these structures lead to excitation of both structures through a dense interchange network. Thus a larger amygdala may result in hippocampal enlargement caused by overexcitation in both structures. Supporting this hypothesis is a previous finding that these regions interact strongly when the system is stressed. Children with ASD have a high co-occurrence of anxiety, which may be related or as a result of the enlargement of these regions. In contrast, children with NLD do not evidence the same level of anxiety and show amygdaloid and hippocampal volumes similar to neurotypical children. The smaller volume of the anterior cingulate cortex in children with NLD and ASD implicates the network that is involved in

**TABLE 54-1** Major Neuroimaging Findings in ASD and NLD

Study	Patient Groups	Main Findings
<b>STRUCTURAL MRI</b>		
Abell et al. (1999)	ASD, controls	ASD>controls in white matter volume
Groen et al. (2010); Nacewicz et al. (2006)	ASD, controls	ASD>controls in amygdalar volume
Groen et al. (2010)	ASD, controls	ASD>controls on right hippocampus volume
Semrud-Clikeman et al. (2013)	NLD, AS, and controls	ASD>controls in temporal and frontal lobes All groups equal in white and gray matter volumes AS>NLD, controls in amygdala volume; NLD<AS, controls in ACC volume
Fine, Musielak & Semrud-Clikeman (2013)	NLD, ASD, ADHD, controls	Total CC volume equal across groups; NLD<S, ADHD, controls in spenial volume
Semrud-Clikeman & Fine (2011)	NLD, AS, controls	25% of children with NLD showed benign cysts or lesions; 4% of AS and controls
Reiss et al. (1995)	Turner syndrome (TS), controls	TS<controls in gray matter volume of parietal occipital region
LePage et al. (2013)	TS, controls	TS<controls in cortical thickness in parietal occipital regions
<b>FUNCTIONAL MRI</b>		
Happe et al.	Asperger syndrome (AS), controls	AS<controls activation in anterior cingulate
Fine et al. (submitted)	ASD, NLD, controls	Controls more sensitive to emotional valence; ASD or NLD less sensitive to changes in valence of emotional stimuli ASD>activation to negative than positive stimuli
Beaton et al. (2010)	TS, controls	TS<controls in brain activation in parietal regions during visual-spatial tasks
Beaton et al. (2010)	22q11 deletion, controls	22q11>controls in lateral ventricles; brain volumes are similar
Schaer et al. (2006)	22q11 deletion, controls	22q11<controls in gyrification of frontal and parietal lobes
<b>DIFFUSION TENSOR IMAGING</b>		
Yamagata et al. (2012)	TS, controls	TS<controls in white matter integrity
Bava et al. (2010)	Cystinosis, controls	Decreased connectivity in inferior and superior parietal lobules in children with cystinosis; older children with cystinosis showed reduced connectivity and poorer visual-spatial performance

understanding the perspectives of others as well as self. A smaller volume of the anterior cingulate cortex in children with AS or NLD may be related to difficulty in the evaluation and self-monitoring of behavior. An additional study of the corpus callosum found the NLD group to have significantly smaller splenia of the corpus callosum compared with all other groups. Smaller splenia in the NLD group were associated with lower performance but not verbal scores.

## fMRI

To further investigate processing of social information in children with ASD and NLD, a functional magnetic imaging study was conducted by the author and colleagues. This study found that not only is face perception affected, but broad regions related to verbal processing were also less sensitive to valence differences. It was also found that the ASD group showed a greater activation to negative than to positive stimuli, whereas typically developing children and those with NLD demonstrated more activation to positive compared with negative stimuli.

## Neurologic Aspects of Nonverbal Learning Disabilities

Although NLDs are underrecognized by neurologists, the condition is common and the diagnosis is important in terms of directing appropriate intervention for the child. There are characteristic features both in the medical/neurodevelopmental history and on neurologic examination that may be strongly suggestive of a diagnosis of NLD. On the neurologic examination, common findings include difficulty with pencil control, drawing, and fine motor movements, and problems with staying focused on tasks without focal neurologic deficits.

**Turner syndrome** results from either a partial or complete absence of one X chromosome. It occurs in approximately 1 in 2500 girls and is associated with short stature, webbed neck, and low hairline. In the partial absence of the X chromosome, there is mosaicism, in which two distinct cell lines exist in the same girl. Many studies have merged the two subtypes of Turner syndrome and have found a consistent cognitive profile. Although most girls with Turner syndrome have normal global intellectual functioning, numerous studies have identified a pattern of neurocognitive deficits that are consistent with NLD. Verbal IQ (VIQ) is typically normal or even above average, whereas Performance IQ (PIQ) is low in comparison with VIQ. Language skills are generally preserved, with the exception of sequencing and syntactic processing. Attention problems are also common in Turner girls. Arithmetic skills are often impaired relative to controls and to other areas of academic functioning. The most consistent cognitive deficit in girls with Turner syndrome is in visual-spatial skills. These deficits are present from early life and show a widening of the gap over time on visual-spatial tasks, indicating that the deficit is not merely a delay in development of visual-spatial skills, but a true deficit.

Quantitative neuroimaging studies have revealed structural and functional differences in the brains of girls with Turner syndrome compared with controls and a difference in the trajectory of brain development. In cross-sectional studies, reductions have been found in the volume of gray matter in the parietal occipital region. Impaired white matter integrity has also been demonstrated using Diffusion Tensor Imaging (DTI). The authors suggest that genetic effects on brain development may produce very disparate pathways associated with cognitive functioning.

Within-group comparisons of brain development over time showed a different trajectory in Turner girls compared with

controls. When comparing the same brains at time 1 and time 2 (roughly ages 8 and 9 years), left parietal white matter volume and right parietal cortical thickness were both smaller in TS girls at time 2. The authors suggest that there may be a “critical period” for effective intervention in girls with Turner syndrome based on aberrant developmental trajectories.

**22q11 deletion syndrome (Velocardiofacial syndrome, DiGeorge syndrome, Shprintzen syndrome)** is common genetic disorder with an estimated prevalence of 1:2000 (Beaton et al., 2010). It is associated with a hemizygous deletion in the long arm of chromosome 22. There are a number of commonly associated features, including heart disease (supravalvular aortic stenosis being the most common type), neonatal hypocalcemia, cleft palate, short stature, facial dysmorphic features, and T-cell immunodeficiency (Robin and Shprintzen, 2005). One of the names for this syndrome is based on velocardiofacial insufficiency with subsequent hypernasal speech. Intellectual disability is common, as are ASD and attention problems. Although global intellectual functioning is often impaired in individuals with 22q11 deletion syndrome, many studies have identified a relative weakness in visual-spatial ability, mathematics, executive functioning, and attention. Neuroimaging studies have demonstrated somewhat smaller brain volume and an increase in size of the lateral ventricles in 22q11 deletion patients compared with controls, as well as reduced gyrification in the frontal and parietal lobes, indicating that these areas may have a different pattern of brain development that may in turn lead to impaired connectivity and more difficulty with visual-spatial skill formation.

**Neurofibromatosis type I (NF1)** is the most common neurocutaneous disorder with an autosomal dominant inheritance (on chromosome 17q11.2) and an estimated incidence of 1:3000. Learning disabilities constitute one of the more common problems in NF-1, being recognized in 30% to 40% of children with this disorder. The major commonality among most of the studies has been the presence of visual-spatial deficits in many children with NF-1, as well as attention problems and a lower-than-expected intelligence. Language may be as impaired as visual-spatial skills in some NF-1 patients, whereas others have more prominent nonverbal deficits. The discrepancies are not surprising, however, because neuroimaging shows white-matter lesions in this disorder, but the number, size, and location of these abnormalities may differ from one individual to another, perhaps accounting for some of the differences in cognitive function that have been identified. Despite the variability in results from different studies, it appears that the most prevalent type of cognitive deficit in NF-1 is most consistent with a modified NLD phenotype.

**Nephropathic cystinosis** is a rare autosomal recessive disorder in which the amino acid cystine accumulates in lysosomes as a result of a cystine transporter protein deficiency. The CTNS gene (on chromosome 17p13) codes for the cystine transporter protein. The incidence of cystinosis is estimated at approximately 1:100,000 individuals worldwide, with a carrier rate estimated at 1:158. This information is important because carriers may be at increased risk for subtle cognitive differences similar to those found in individuals with cystinosis. Individuals with cystinosis have been found to have neurologic and cognitive deficits consistent with NLD. Children with cystinosis have normal verbal intelligence and normal language function, but exhibit problems with visual-spatial skills, spatial memory, visual-motor coordination, mathematics, and subtle social difficulty, similar to NLD. Otherwise asymptomatic carriers of the cystinosis gene have been found to have similar but less prominent visual-motor/visual-spatial deficits. Given the relative frequency of the carrier gene for this recessive condition (1:158), this may prove to be one of the more common associations with NLD.

The studies of cognition in cystinosis have shown that this is one of the few instances in which neuroimaging differences help to explain the cognitive profile. Bava et al., using DTI, found reduced white matter integrity in the parietal regions, and the reduction correlated inversely with visual-spatial performance, suggesting a delay in white matter maturation that may have forced a different approach to neural network development for visual-spatial function.

All of these syndromes are strongly associated both with a clinical profile of NLD and, in most cases, brain structural abnormalities that include either parietal lobe or frontal-parietal developmental differences. Further studies to identify specific genes or gene interactions may help to elucidate the neural mechanisms that underlie normal development of visual-spatial skills and how better to assist in the future those individuals who are found to have NLD.

Developmental dyslexia (or specific reading disability) is defined as an unexpected difficulty in accuracy or fluency of reading for an individual's chronologic age, intelligence, level of education, or professional status. Dyslexia is, at its core, a problem with phonological processing: that is, getting to the elemental sounds of spoken language, affecting both spoken and written language. As dyslexic children progress in school, given effective instruction, reading accuracy often improves; however, lack of fluency persists and remains a lifelong problem. As a consequence, individuals who are dyslexic require accommodations for their lack of reading and/or oral fluency. Dyslexia is the most common and most comprehensively studied of the learning disabilities (LD), affecting 80% of all individuals identified as learning-disabled. Although the diagnosis and implications of dyslexia were often uncertain in the past, advances in our knowledge of the epidemiologic, neurobiologic, and cognitive influences on the disorder allow it to be approached within the framework of a traditional medical model. This chapter reviews these advances and their implications for the approach to children and adults with dyslexia.

### DYSLEXIA IS SPECIFIC—LEARNING DISABILITIES ARE NOT

Consistent in the original descriptions by the pioneers who described dyslexia, all noted that the reading problem in dyslexic children was *unexpected* in relation to their intelligence. As we review below, the unexpected nature of the reading problem was also the hallmark of what came to be known in the 1960s as LD. In recent testimony before Congress, Dr. Sally Shaywitz emphasized that “Dyslexia differs markedly from all other learning disabilities. Dyslexia is very specific and scientifically validated: we know its prevalence, cognitive and neurobiological origins, symptoms, and effective, evidence-based interventions. Learning disabilities is a general term referring to a range of difficulties which have not yet been delineated or scientifically validated. Learning disabilities are comparable to the term ‘infectious’ diseases, while dyslexia is akin to being diagnosed with a strep throat—a highly specific disorder in which the causative agent and evidence-based treatment are both known and validated.”

### Definition of Dyslexia

For over 100 years in the case of dyslexia and over 50 years in the case of LD, the most consistent and enduring core of the definition is the concept of dyslexia (and LD) as *unexpected* underachievement. The most up-to-date, scientifically supported definition of dyslexia is that in the 2015 bipartisan Cassidy-Mikulski Senate Resolution 275: “Dyslexia is defined as an unexpected difficulty in reading in an individual who has the intelligence to be a much better reader; dyslexia reflects a difficulty in getting to the individual sounds of spoken language which typically impacts speaking (word retrieval), reading (accuracy and fluency), spelling, and often, learning a second language.”

For the first time there is now empiric data confirming the unexpected nature of dyslexia.

These data come from the Connecticut Longitudinal Study, a sample survey of Connecticut schoolchildren representative of those children entering public kindergarten in Connecticut in 1983. Using the Connecticut Longitudinal Study, Ferrer et al. (2010) demonstrated that, in typical readers, reading and IQ are dynamically linked over time. Not only do reading and IQ track together over time, but they also influence one another. Such mutual interrelationships are not perceptible in dyslexic readers, suggesting that reading and cognition develop more independently in dyslexia (Figure 55-1). These findings provide the long-sought empirical evidence for the seeming paradox involving cognition and reading in dyslexia. Thus, in dyslexia, a highly intelligent person may read at a level above average but below that expected, based on his/her intelligence, age, education, or professional status.

Many confuse the impact of dyslexia with an almost total inability to read. Although that may occur, most commonly and certainly as defined legally and supported by scientific evidence, there is no reading level below which an individual, student or adult, must score to be diagnosed as dyslexic. Rather, the central point is *how* the individual reads, the effort and work that must go into the reading process for him or her to decipher the word accurately and fluently. Think of a motor disability. The question is not whether the person can cross a street, but rather what he or she must do to get to the other side, that is, use a cane or a wheelchair.

### EPIDEMIOLOGY AND ETIOLOGY

Epidemiologic data indicate that, like hypertension and obesity, dyslexia fits a dimensional model. Within the population, reading ability and reading disability occur along a continuum, with reading disability representing the lower tail of a normal distribution of reading ability (Shaywitz et al., 1992). Dyslexia is perhaps the most common neurobehavioral disorder affecting children, with prevalence rates ranging from 17.5% to 21% (Shaywitz et al., 1994).

Dyslexia is both familial and heritable. Family history is one of the most important risk factors, with 23% to 65% of children who have a parent with dyslexia reported to have the disorder. Given that dyslexia is familial and heritable, initial hopes that dyslexia would be explained by one or just a few genes have been disappointing. Thus, along with a great many common diseases, genome-wide association studies (GWAS) in dyslexia have so far identified genetic variants that account for only a very small percentage of the risk—less than 1%. Current evidence suggests “that common diseases involve thousands of genes and proteins interacting on complex pathways,” and that, similar to experience with other complex disorders (heart disease, diabetes), it is unlikely that a single gene or even a few genes will identify people with dyslexia. Rather, dyslexia is best explained by *multiple* genes, each contributing a *small* amount of the variance.

**Figure 55-1. Uncoupling of reading and IQ over time: empirical evidence for a definition of dyslexia.** Left: In typical readers, reading and IQ development are dynamically linked over time. Right: In contrast, in dyslexic readers, reading and IQ development are dissociated and one does not influence the other. (Data adapted from Ferrer E, et al. *Uncoupling of reading and IQ over time: empirical evidence for a definition of dyslexia. Psychol Sci* 2010;21:93–101.)

Recent data indicate that a large achievement gap between dyslexic and typical readers is already present early on (first grade) and persists throughout school. These data make it imperative to identify and provide effective interventions at the start of school. These data indicate that it is no longer acceptable to wait until a child is in third grade or later before undertaking efforts to identify or address dyslexia. Using data from the Connecticut longitudinal study of reading from 1st grade to 12th grade, we found that as early as 1st grade, compared with typical readers, dyslexic readers had lower reading scores and their trajectories over time never converge with those of typical readers. These data demonstrate that such differences are not so much a function of increasing disparities over time but instead reflect marked differences already present in first grade between typical and dyslexic readers. The message is that the achievement gap between typical and dyslexic readers is evident as early as first grade, and this gap persists into adolescence. These findings provide strong evidence and impetus for early identification of and intervention for young children at risk for dyslexia. Implementing effective reading programs as early as kindergarten or even preschool offers the potential to close the achievement gap (Ferrer et al. 2015) (Figure 55-2).

**PHONOLOGIC MODEL OF DYSLEXIA**

Among investigators in the field, there is a strong consensus supporting the phonologic theory. This theory recognizes that speech is natural and inherent, but that reading is acquired and must be taught. To read, the beginning reader must connect the letters and letter strings (i.e., the orthography) to something that already has inherent meaning—the sounds of spoken language. In the process, a child has to develop the insight that spoken words can be pulled apart into the elemental particles of speech (i.e., phonemes) and that the letters in a written word represent these sounds; such awareness is largely deficient in dyslexic children and adults.

**Neurobiological Evidence Supporting Dyslexia**

**Making a Hidden Disability Visible**

Using functional magnetic resonance imaging (fMRI), converging evidence from many laboratories around the world

**Figure 55-2. Reading from grades one to nine in typical and dyslexic readers.** The achievement gap between typical and dyslexic readers is evident as early as first grade and persists through adolescence. (Data adapted from Ferrer et al., *Achievement gap in reading is present as early as first grade and persists through adolescence, J Pediatr* 2015;167:1121–1125, e2.)

**Figure 55-3. Neural signature for dyslexia.** A neural signature for dyslexia is illustrated in this schematic view of left hemisphere brain systems in nonimpaired (left) and dyslexic (right) readers. In dyslexic readers, the anterior system is slightly overactivated compared with systems of typical readers; in contrast, the two posterior systems are underactivated. This pattern of underactivation in left posterior reading systems is referred to as the neural signature for dyslexia. (By W. Hill, copyright © 2003 by S. E. Shaywitz; from *Overcoming Dyslexia: a New and Complete Science-based Program for Reading Problems at any Level* by Sally Shaywitz, MD. Used by permission of Alfred A. Knopf, an imprint of the Knopf Doubleday Publishing Group, a division of Penguin Random House LLC. All rights reserved.)

has demonstrated a “neural signature for dyslexia,” that is, an inefficient functioning of posterior reading systems during reading real words and pseudowords (Figure 55-3). This evidence from fMRI has for the first time made visible what previously was a hidden disability (Shaywitz et al., 2002). These findings of significantly greater activation in posterior reading systems in typical readers than in readers with dyslexia align with the classic 19th-century reports by Dejerine of acquired alexia caused by left-hemisphere lesions in the parietotemporal areas as well as areas around the fusiform gyrus.

These data from fMRI studies in groups of children with dyslexia have been replicated in reports from many investigators and show a failure of left-hemisphere posterior brain systems to function properly during reading, particularly

the systems in the left-hemisphere occipitotemporal region (Richlan et al., 2009). Similar findings have been reported in German (18) and Italian (19) readers with dyslexia. Some studies in Chinese readers with dyslexia show brain abnormalities in left occipitotemporal and anterior frontal regions similar to those found in dyslexia in alphabetic orthographies.

Connectivity analyses of fMRI data represent the most recent evolution in characterizing brain networks in dyslexia. Measures of functional connectivity are designed to detect differences in brain regions with similar magnitudes of activation but whose activity is differentially synchronized with other brain systems across subject groups and/or types of stimuli. Most recently, Finn et al. (2013) have reported that, compared with typical readers, dyslexic readers showed reduced connectivity in the visual word-form area, a part of the left fusiform gyrus specialized for printed words.

### Implications of Brain Imaging Studies

The brain imaging studies reviewed above provide neurobiological evidence that illuminates and clarifies current understanding of the nature of dyslexia and its treatment. For example, brain imaging has taken dyslexia from what had previously been considered a hidden disability to one that is visible; the findings of inefficient functioning in posterior reading systems are often referred to as a “neural signature for dyslexia.” These findings should eliminate any thoughts of whether dyslexia is real or a “valid” diagnosis; even more so, these cutting-edge converging data from imaging laboratories worldwide should encourage the use of the word “dyslexia,” for it has meaning and relevance at levels reaching to the basic neural architecture in reading and its inefficient functioning in struggling readers. These findings too are universal, having been demonstrated in readers of English and other alphabetic scripts with very similar findings in readers of logographic languages as well.

### DIAGNOSIS

In *Overcoming Dyslexia* (Shaywitz, 2003), S. Shaywitz conceptualizes dyslexia as a weakness in phonology (getting to the sounds of spoken words) surrounded by a sea of strengths in higher-order thinking. In younger children there is an encapsulated weakness in decoding surrounded by strengths in, for example, problem solving, critical thinking, concept formation, and reasoning. In older children, adolescents, and adults, it may be thought of as an encapsulated weakness in fluent reading surrounded by these strengths in higher-order thinking.

Given that dyslexia is defined on the basis of scientific evidence as an unexpected difficulty in reading in a child or an adult in relation to intelligence, it is not surprising that a measure of intelligence, the Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V) is a critical component of a comprehensive assessment of the child (age 6 to 16 years) with dyslexia. Very often an intelligence test can reveal areas of strength, particularly in areas of abstract thinking and reasoning, which are very reassuring to parents and especially to the child him/herself. They also indicate that the reading difficulty is isolated and not reflective of a general lack of learning ability or intellectual disability.

Kindergarten and first grade teachers are now able to screen for dyslexia with a high degree of accuracy using the brief Shaywitz Dyslexia Screen available from Pearson Publishers. Currently, most children with dyslexia are not diagnosed until they are in third grade or about 9 years old, although it is possible to recognize children at-risk for dyslexia as young as 4 to 5 years of age. As shown in Box 55-1 from S. Shaywitz’s

### BOX 55-1 Clues to Dyslexia Beginning in Second Grade and Beyond

#### PROBLEMS IN SPEAKING

- Mispronunciation of long or complicated words
- Speech that is not fluent (pausing or hesitating often); lots of “ums”
- Use of imprecise language
- Inability to find the exact word
- Struggle to retrieve words: “It was on the tip of my tongue.”
- Need for time to summon an oral response, inability to come up with a verbal response quickly when questioned
- Lack of glibness, especially if put on the spot
- Spoken vocabulary smaller than listening vocabulary; hesitation to say aloud words that might be mispronounced
- Oral presentations often underestimate knowledge of the individual

#### PROBLEMS IN READING

- Very slow progress in acquiring reading skills
- Lack of a strategy to read new words
- Trouble reading unknown (new or unfamiliar) words that must be sounded out
- The inability to read small “function” words such as *that*, *an*, *in*
- Fear of reading out loud
- Oral reading that is choppy and labored
- Disproportionately poor performance on multiple-choice tests
- Inability to finish tests on time
- Disastrous spelling
- Reading that is very slow and tiring
- Messy handwriting but with excellent facility at word processing
- Extreme difficulty learning a foreign language
- Reading whose accuracy improves over time, though it continues to lack fluency and is laborious
- Lowered self-esteem, with pain that is not always visible to others
- Avoidance of reading—gains knowledge from sources other than reading, e.g., audiobooks, discussions, film
- Lack of fluency in reading increases attentional demands—vulnerable to noise, reading tiring
- Comprehension—often higher than word-reading accuracy or fluency
- Sacrifice of social life for studying
- Anxiety around test-taking or reading/speaking aloud
- Noted success, with accommodations, in a range of professions, including writing, science, medicine, architecture, law, journalism
- A history of reading, spelling, and foreign language problems in family members

(By W. Hill, copyright © 2003 by S. E. Shaywitz; from *Overcoming Dyslexia: a New and Complete Science-based Program for Reading Problems at Any Level* by Sally Shaywitz, MD. Used by permission of Alfred A. Knopf, an imprint of the Knopf Doubleday Publishing Group, a division of Penguin Random House LLC. All rights reserved.)

*Overcoming Dyslexia*, signs and symptoms of children at risk for dyslexia can be observed even before formal reading begins in school.

See Box 55-2, Clues to children at risk for Dyslexia (from © S. Shaywitz, *Overcoming Dyslexia* (2003) in the e-book )

- Delayed language
- Trouble learning common nursery rhymes such as “Jack and Jill” and “Humpty-Dumpty”
- A lack of appreciation of rhymes

- Mispronounced words; persistent baby talk
- Difficulty in learning (remembering) names of letters and numbers
- Failure to know the letters in his own name

These clues along with a positive family history represent significant risk factors for dyslexia.

The assessment approach we focus on here and elaborated in more detail in Dr. Sally Shaywitz' new edition of *Overcoming Dyslexia* (forthcoming) is an in-depth evaluation of the skills (especially phonologic) known to be related to reading success. We and other researchers have begun to recognize that one source of potentially powerful and highly accessible screening information that has thus far been ignored is the teacher's judgment about the child's reading and reading-related skills. Remarkably, we found that teachers' response to a small subset of questions (Dyslexia Screening Measure [© Sally Shaywitz, 2014] comprising 10 items from the kindergarten and 12 items from the first-grade Multigrade Inventory for Teachers [© Sally Shaywitz, M.D., 1987]) predicts children at high risk for dyslexia with a high degree of accuracy, with good sensitivity and specificity.

## Tests Helpful in the Evaluation of Children for Dyslexia

### Phonological Processing

Clinicians and researchers often use the Comprehensive Test of Phonological Processing, now in its second edition (CTOPP-2), to test for the full range of phonological skills.

### Letter Knowledge

Though not as robust as tests of phonological awareness in predicting whether the young child is at risk for dyslexia, a child's knowledge of letter names and sounds may also serve as a helpful guide to how ready she/he is to read. More formal testing can be obtained by using a reading test that contains a letter-identification section, for example, the letter-word subtest on the Wechsler Individual Achievement Test—Third Edition (WIAT-III); Kaufman Test of Educational Achievement—Third Edition (KTEA-III); or the Woodcock-Johnson IV Tests of Achievement (WJ-IV).

### Academic Achievement

Overall, in the school-aged child, reading is assessed by measuring accuracy, fluency, and comprehension. Specifically, in the school-aged child, one important element of the evaluation is how accurately the child can decode words (i.e., read single words). This is measured with standardized tests of single real word and pseudoword reading. Because pseudowords are unfamiliar and cannot be memorized, each nonsense word must be sounded out. Tests of nonsense word reading are referred to as "word attack." Reading fluency, the ability to read accurately, rapidly, and with good prosody, an often overlooked component of reading, is of critical importance because it allows for the automatic, attention-free recognition of words.

The WIAT-III, KTEA-III, and WJ-IV are each reliable, valid, and comprehensive measures of academic achievement. In addition, fluency also may be assessed by asking the child to read *aloud* using the Gray Oral Reading Test—Fifth Edition (GORT-5). In addition to reading passages aloud, single-word reading efficiency may be assessed using, for example, the Test of Word Reading Efficiency, 2nd Edition (TOWRE-2), a test of speeded oral reading of individual real words and pseudowords. Children who struggle with reading often have trouble spelling; spelling may be assessed with the WIAT-III, KTEA-III, or WJ-IV spelling test.

## Physical and Neurologic Examination and Laboratory Tests

A general physical examination has a very limited role in the evaluation of individuals with dyslexia. Primary sensory impairments should be ruled out, particularly in young children. The examination should be governed by any non-dyslexic symptoms that indicate specific areas of concern. Results of the routine neurologic examination are usually normal for children who are dyslexic. Laboratory measures, such as imaging studies, electroencephalograms, or chromosome studies, are ordered only if there are specific clinical indications not relating to dyslexia. Functional imaging is currently restricted to research studies of *groups* of typical compared with dyslexic readers, and is not sensitive enough to be used for clinical diagnosis of individual children or adults.

## OUTCOME: PHONOLOGIC DEFICIT IN ADOLESCENCE AND ADULT LIFE

### Essential Components of Diagnosis in Adolescents and Young Adults

#### Lack of Automaticity

The failure either to recognize or to measure the lack of automaticity in reading is, along with the failure to assess intelligence, perhaps one of the two most common errors in the diagnosis of dyslexia in older children and in accomplished young adults. Tests relying on the accuracy of word identification alone are inappropriate to use to diagnose dyslexia in accomplished young adults; tests of word identification reveal little to nothing of the child's *struggles* to read. It is important to recognize that, because they assess reading accuracy but not automaticity, the kinds of reading tests commonly used for school-aged children may provide misleading data on bright adolescents and young adults. The most critical tests are those that are timed; they are the most sensitive to a phonological deficit in a bright adult. However, there are very few standardized tests for young adult readers that are administered under timed and untimed conditions; the Nelson-Denny Reading Test represents an exception. Any scores obtained on testing should be considered relative to peers with the same degree of education or professional training. Clinicians and researchers have recognized that in bright young adults a history of phonologically based reading difficulties, requirements for extra time on tests and current slow and effortful reading (i.e., signs of a lack of automaticity in reading), and indications of an unexplained difficulty in reading are the sine qua non of a diagnosis of dyslexia.

#### Measure of Intelligence

The failure to include a test of intelligence such as the WISC-V represents one of the two most common and harmful errors made in the diagnosis of dyslexia. The demonstration of an unexpected difficulty in reading in relation to intelligence is a key hallmark of dyslexia. Dyslexia is an unexpected difficulty in reading that is best and most reliably and clearly demonstrated by performance on a test of intelligence, on the WISC-V, most often observed using the VCI, though the FS IQ may also be useful.

## TREATMENT

(Readers interested in a more detailed account of interventions and approaches to treating dyslexia are referred to *Overcoming Dyslexia* by Sally Shaywitz.)

The management of dyslexia demands a life-span perspective. Early on, the focus is on remediation of the reading problem. As a child matures and enters the more time-demanding setting of secondary school, the emphasis shifts to incorporate the important role of providing accommodations.

## Accommodations

An essential component of the management of dyslexia in students in secondary school, college, and graduate school incorporates the provision of accommodations. High-school and college students with a history of childhood dyslexia often present a paradoxical picture; they are similar to their unimpaired peers on measures of word recognition and comprehension, but they continue to suffer from the phonologic deficit that makes reading less automatic, more effortful, and slow. Neurobiologic data provide strong evidence for the necessity of extra time for readers with dyslexia. Whereas readers who are dyslexic improve greatly with additional time, providing additional time to nondyslexic readers results in very minimal to lack of improvement in scores. Although providing extra time for reading is by far the most common accommodation for people with dyslexia, other helpful accommodations include allowing the use of computers for writing essay answers on tests and access to recorded books (from organizations such as Learning Ally and Bookshare) and text-to-voice software from a number of vendors (including Kurzweil) and apps such as Pdf to Speech, Go Read, and many others. Dyslexic students who have difficulty accessing the sound system of their primary language will, almost invariably, have difficulties learning a foreign language. Recognizing this, many colleges and universities offer a partial waiver of the foreign language requirement for students with dyslexia. With such accommodations, many students with dyslexia are successfully completing studies in a range of disciplines, including science, law, medicine, and education.

Attention deficit–hyperactivity disorder (ADHD) has been described as the most common neurobehavioral disorder in childhood. Prevailing opinion characterizes ADHD as a disorder of executive function attributable to abnormal dopamine transmission in the frontal lobes and frontostriatal circuitry. In large part, this concept is based on the clinical efficacy of medications affecting catecholamine transmission in these regions.

The first reference to behavior now associated with ADHD was by George Still in 1902, who referred to a deficit of moral control. Within the context of this broad concept, he made the following observation: “A notable feature in many of these cases of moral deficit without general impairment of intellect is a quite abnormal incapacity for sustained attention.” Subsequent emphasis on attention and its neurologic substrate, the frontal lobe and frontostriatal circuitry, represents a refinement of the definition of the condition. This extensive history has not prevented some from questioning whether ADHD actually exists.

### DIAGNOSIS AND CONTROVERSIES IN THE DIAGNOSIS OF ATTENTION DEFICIT–HYPERACTIVITY DISORDER

ADHD is a clinical diagnosis based on criteria in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) (American Psychiatric Association [APA], 2013) (Box 56-1). Criteria are divided into two lists of symptoms, one for inattention and another for hyperactive-impulsive behavior. Based on the number of items identified, there are three classifications: ADHD/I (primarily inattentive type), ADHD/HI (primarily hyperactive-impulsive type), and ADHD/C (combined type). A study looking at the trends in the diagnosis of ADHD in the United States found that approximately 2 million more children aged 4 to 17 years were diagnosed with ADHD in 2011 compared with 2003 and that two-thirds of those with a current diagnosis of ADHD were taking medication in 2011. The DSM-5 diagnostic criteria, by reducing the number of symptoms required for a diagnosis from six to five for adolescents 17 and older and adults, will inevitably result in an increased incidence of ADHD in those age groups.

Concern has been raised about the overdiagnosis of ADHD, with the potential influence of pharmaceutical manufacturers and the misdiagnosis of normal behavior as pathologic cited as possible causes (Coon et al. 2014). The use of a stepped diagnosis, which includes five steps of care before making a definite diagnosis, has been proposed to reduce overdiagnosis without risking undertreatment (Thomas et al., 2013) (Box 56-2). One study found a higher rate of diagnoses in high-income households. The authors hypothesize that “higher rates of ADHD observed in affluent, white families likely represent an effort by these highly educated parents to seek help for their children who may not be fulfilling their expectations for schoolwork” (Getahun et al., 2013). Another study comparing the incidence of ADHD diagnoses found a higher

frequency of ADHD diagnoses in children from lower socioeconomic levels but a lower rate of medication use in that group. Adding to the problem of possible overdiagnosis, along with the easing of criteria for adolescents and adults, is that malingering ADHD among college students is not easily detected with the current measures used to diagnose ADHD.

The use of the word *often* in the list of symptoms of ADHD lends an element of subjectivity to this diagnostic schema. Symptom rating scales for parents and teachers have been developed to assist in the ascertainment of diagnostic criteria. A comprehensive review of evaluation issues in ADHD concluded that no single test can be used to make the diagnosis and that it is up to the clinician to choose a battery of tests, which, along with the history and exam, a sufficient level of diagnostic certainty. The American Academy of Pediatrics has endorsed the Vanderbilt ADHD rating scales for parents and teachers and has provided a complete “toolkit,” including a cover letter to teachers and scoring information, on the Internet (see <http://www.nichq.org/childrens-health/adhd/resources>) (Visser et al., 2013).

Developmental variability in the presentation of ADHD and the inconsistency of behavior of children with ADHD in different settings and at different times in the same setting add to the diagnostic confusion. Efforts have been made to provide a more objective basis for the diagnosis of ADHD, such as computerized continuous performance tests or tests of variables of attention. However, the correlation of these measures of attention with the behavioral disorder is not sufficient for them to be used as replacements for the behavioral criteria of the DSM.

The DSM-5 clinical criteria for diagnosing ADHD (see Box 56-1) list a number of qualifications that are too often ignored, possibly resulting in an incorrect diagnosis. The text explicitly states that for the symptoms to be diagnostically significant, “There is clear evidence that the symptoms interfere with, or reduce the quality of, social, school, or work functioning” (APA, 2013). Behavior that may not be typical but is not maladaptive does not warrant a diagnosis of ADHD. Similarly, unreasonable expectations of a child at a young age may result in a false diagnosis. The diagnostic criteria are followed by a number of statements regarding the context of the symptoms, for example, “Several symptoms are present in two or more setting, (e.g., at home, school or work; with friends or relatives; in other activities)” (APA, 2013). This qualification allows for the possibility that a child in an inadequate school environment, perhaps with excessive class size, hostile peers, or inexperienced teachers, may present with findings that are unique to that setting and do not represent a disorder of attention. Similarly, a chaotic home environment may explain the child’s presentation.

Perhaps most important is the last item, which states: “The symptoms do not happen only during the course of schizophrenia or another psychotic disorder. The symptoms are not better explained by another mental disorder (e.g. Mood Disorder, Anxiety Disorder, Dissociative Disorder, or a Personality Disorder)” (APA, 2013). If a child has symptoms that meet the diagnostic criteria for ADHD in the context of these other

**BOX 56-1** Diagnostic Criteria for Attention Deficit–Hyperactivity Disorder**DSM-5 CRITERIA FOR ADHD****Attention Deficit–Hyperactivity Disorder****Diagnostic Criteria**

A. A persistent pattern of inattention and/or hyperactivity-impulsivity that interferes with functioning or development, as characterized by (1) and/or (2):

1. **Inattention:** Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively and directly affects social and academic/occupational activities:
 

**Note:** The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.

  - a. Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (e.g., overlooks or misses details, work is inaccurate).
  - b. Often has difficulty sustaining attention in tasks or play activities (e.g., has difficulty remaining focused during lectures, conversations, or lengthy reading).
  - c. Often does not seem to listen when spoken to directly (e.g., mind seems elsewhere, even in the absence of any obvious distraction).
  - d. Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (e.g., starts tasks but quickly loses focus and is easily sidetracked).
  - e. Often has difficult organizing tasks and activities (e.g., difficulty managing sequential tasks; difficulty keeping materials and belongings in order; messy, disorganized work; has poor time management; fails to meet deadlines).
  - f. Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (e.g., schoolwork or homework; for older adolescents and adults, preparing reports, completing forms, reviewing lengthy papers).
  - g. Often loses things necessary for tasks or activities (e.g., school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, mobile telephones).
  - h. Is often easily distracted by extraneous stimuli (for older adolescents and adults, may include unrelated thoughts).
  - i. Is often forgetful in daily activities (e.g., doing chores, running errands; for older adolescents and adults, returning calls, paying bills, keeping appointments).
2. **Hyperactivity and impulsivity:** Six (or more) of the following symptoms have persisted for at least 6 months to

a degree that is inconsistent with developmental level and that negatively and directly affects social and academic/occupational activities:

**Note:** The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or a failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.

- a. Often fidgets with or taps hands or feet or squirms in seat.
  - b. Often leaves seat in situations when remaining steady is expected (e.g., leaves his or her place in the classroom, in the office or other workplace, or in other situations that require remaining in place).
  - c. Often runs about or climbs in situations where it is inappropriate. (**Note:** In adolescents or adults, may be limited to feeling restless.)
  - d. Often unable to play or engage in leisure activities quietly.
  - e. Is often “on the go,” acting as if “driven by a motor” (e.g., is unable to be or uncomfortable being still for extended time, as in restaurants, meetings; may be experienced by others as being restless or difficult to keep up with).
  - f. Often talks excessively.
  - g. Often blurts out an answer before a question has been completed (e.g., completes people’s sentences; cannot wait for turn in conversation).
  - h. Often has difficulty waiting his or her turn (e.g., while waiting in line).
  - i. Often interrupts or intrudes on others (e.g., butts into conversations, games, or activities; may start using other people’s things without asking or receiving permission; for adolescents and adults, may intrude into or take over what others are doing).
- B. Several inattentive or hyperactive-impulsive symptoms were present before age 12 years.
- C. Several inattentive or hyperactive-impulsive symptoms are present in two or more settings (e.g., at home, school, or work; with friends or relatives; in other activities).
- D. There is clear evidence that the symptoms interfere with, or reduce the quality of, social, academic, or occupational functioning.
- E. The symptoms do not occur exclusively during the course of schizophrenia or another psychotic disorder and are not better explained by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, personality disorder, substance intoxication or withdrawal).

(With permission from the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

disorders, treatment should be directed at these other conditions before concluding the child has a disorder of attention. Not addressed in the DSM-5 criteria are studies that have demonstrated that children with specific neurologic disorders can present with symptoms that meet criteria for ADHD but are attributable to the neurologic disorder rather than a primary disorder of attention. One study demonstrated symptoms of impaired attention and hyperactivity in children diagnosed with restless leg syndrome; treatment of the sleep

disturbance resolved the so-called ADHD symptoms. A subsequent double-blind study of a dopaminergic therapy in 16 children with restless leg syndrome/periodic limb movements in sleep (RLS/PLMS) and ADHD symptoms found that, compared with placebo, L-dopa significantly improved RLS/PLMS but not ADHD symptoms. The authors cautioned that the results may have been influenced by the small sample size and baseline differences in the severity of ADHD symptoms ([Subcommittee on Attention-Deficit/Hyperactivity Disorder, 2011](#)).

### BOX 56-2 Stepped Diagnostic Approach to Attention Deficit–Hyperactivity Disorder

- Step 1:** Gather baseline data from more than one source (e.g., school and home). If problems are urgent, recurring, or persistent and specific, go directly to step 6. For other cases, follow steps 2 to 5 first.
- Step 2:** Look for other explanations of behavioral problems—for example, confrontation problems and agitation may be a result of sleep deprivation, overly challenging schoolwork or workload, or tensions at home or at school.
- Step 3:** Watchful waiting—assess, monitor, and follow up with no pretense of a definitive diagnosis or active treatment.
- Step 4:** If problems remain, offer a minimal intervention, such as bibliotherapy (e.g., information brochures) or self-help training for parents of hyperactive children. Avoid the term *ADHD*, and speak in terms of concentration problems, restlessness, or behavioral difficulties.
- Step 5:** If minimal intervention is not sufficient, provide brief (five or six sessions) counseling using simple techniques to teach new attitudes and coping skills for dealing with hyperactivity and concentration problems.
- Step 6:** If concentration and behavior problems and impairment persist, more intensive therapy, usually in secondary care, is needed. Refer the patient to a developmental pediatrician or psychiatrist for definite diagnosis and treatment.

(With permission from *Attention-deficit/hyperactivity disorder: are we helping or harming?* Thomas R, Geoffrey K Mitchell GK, Laura Batstra, *BMJ* 2013;347:f6172 doi: 10.1136/bmj.f6172)

Disordered breathing during sleep has also been found to manifest with symptoms consistent with ADHD. A study of snoring in 3-year-olds found parent endorsement (“often” or “always”) of irritability and hyperactivity to be significantly higher in the habitual snoring group compared with those without habitual snoring. There are reports of children with focal epileptic discharges having symptoms suggestive of ADHD that resolved when the spike activity was suppressed with antiepileptic drugs. Many symptoms of ADHD are prevalent in neurogenetic syndromes as part of the behavioral phenotype.

The recent revision of the DSM criteria for ADHD failed to add neurologic disorders (e.g., sleep disorders, epilepsy, neurogenetic syndromes) to the list of conditions to be excluded before ADHD is diagnosed, which complicates the effort to ascertain the physiologic and genetic underpinnings of ADHD and its optimal treatment.

## COEXISTING CONDITIONS

The question of conditions coexisting with ADHD is quite complex. Should a diagnosis of ADHD be reserved for individuals with an isolated disorder of attention, hyperactivity, or impulsivity, with an alternative classification used to describe children who meet DSM-5 criteria for ADHD in the context of other neurodevelopmental problems? The term *pseudo-ADHD* has been used to describe children with comorbidities or confounding factors. In a paper describing a father and son both with orbitofrontal epilepsy and associated attention difficulties and hyperactivity, the term *attention-deficit-hyperactivity syndrome* was used to make a distinction from the specific disorder of ADHD, analogous to the distinction between Parkinson’s disease and parkinsonism. It has been proposed that ADHD be divided into subgroups based on the patterns of comorbidity.

The presumption that a response to psychostimulant medication indicates that the underlying problem is ADHD can lead to an erroneous diagnosis. Psychostimulant medications can ameliorate depression, chronic fatigue syndrome, and daytime somnolence caused by sleep disorders and enhance normal individuals’ cognitive functioning and behavior. A positive response to psychostimulants has no diagnostic significance.

## NEUROBIOLOGY OF ATTENTION DEFICIT–HYPERACTIVITY DISORDER

It has been proposed that the core deficit in ADHD is impairment of behavioral inhibition, which leads to the other symptoms of ADHD. This model of impaired behavioral inhibition is limited to ADHD/HI and ADHD/C (i.e., those with hyperactive or impulsive symptoms) and excludes children with ADHD/I (i.e., those with inattention only). Some investigators have proposed that all three ADHD subtypes can be explained as disorders of attention or executive function (other than response inhibition), with symptoms of hyperactivity and impulsivity resulting from these impairments. Others also distinguish ADHD/HI and ADHD/C from ADHD/I, but they posit that the symptoms of hyperactivity and impulsivity can result from poor inhibitory control or differences in motivational style characterized by delay aversion.

A review of the literature regarding the hypothesis that ADHD represents a primary deficit in executive control defined executive function as comprising at least four factors: 1. response inhibition and execution, 2. working memory and updating of memory, 3. set and task shifting, and 4. interference control. The most consistent effects were obtained on measures of response inhibition, vigilance and planning; children with combined and inattentive types of ADHD differed from controls and did not differ from each other, whereas children with hyperactive-impulsive type ADHD had minimal executive function impairment, suggesting that executive function weaknesses are primarily associated with inattention, rather than hyperactivity-impulsivity symptoms. The authors concluded that their findings did not support the hypothesis that executive function deficits alone were the cause of ADHD in all individuals. Rather, it is one of several important deficits comprising the neuropsychological basis for ADHD.

Inhibitory deficits and delay aversion in ADHD can be dissociated by specific types of tasks; either deficit alone is only moderately associated with ADHD, whereas combined these two deficits correctly classify nearly 90% of children with children with ADHD. Thus a formulation was proposed in which executive function (EF) is divided into cognitive aspects associated with the dorsolateral prefrontal cortex (“cool” EF) and affective aspects associated with the orbital and medial prefrontal cortex (“hot” EF). Inattention symptoms were attributed to deficits in cool EF, whereas hyperactivity-impulsivity symptoms reflected hot EF deficits.

An fMRI study found that adolescents with ADHD had difficulty accomplishing a task involving cognitive or cool aspects of executive functions such as working memory, planning, cognitive flexibility, and forethought, as manifest by a significantly greater number of activated brain regions and greater activation of those regions in adolescents with typical development than those with ADHD. The authors also found an imbalance between the high activation of the basal ganglia and cerebellum and the low activation of the prefrontal cortex for the forethought condition in ADHD.

Advances in structural and functional imaging, clinical neurophysiologic techniques, and molecular genetics have been applied to the evaluation of children with ADHD and

have provided important insights into this condition. However, inconsistency in the inclusion and exclusion criteria among studies, particularly related to comorbidity, limits comparisons between studies and their conclusions.

## Structural Imaging

A study of monozygotic twins discordant for ADHD revealed reduced caudate volume in the affected twin. In another report on twins discordant for ADHD, fathers of twins discordant for ADHD had lower ADHD scores than fathers of ADHD singletons. The rate of breech presentation was greater in affected twins than affected singletons. The data suggest that the discordant twins represented nongenetic instances of ADHD, possibly caused by injury in utero, and that the caudate abnormalities in these individuals might not be pertinent to ADHD that is genetic in nature. A study utilizing large deformation diffeomorphic mapping (LDDMM) found that boys with ADHD had significant shape differences and decreases in overall volume of the basal ganglia compared with controls, whereas girls with ADHD did not have volume or shape differences. Children with comorbidities, including other neuropsychiatric disorders, conduct disorders, mood disorder, generalized anxiety disorder, obsessive compulsive disorder, learning disabilities, or speech and language disorders, were excluded from this analysis.

A study comparing children with ADHD (combined type) who had been on chronic treatment with stimulants to untreated children with ADHD and a control group found that children with ADHD had significantly larger prefrontal regions than the controls, with no effect for medication history; the caudate volumes of the children with ADHD were smaller bilaterally, also with no medication effect. The ADHD/no-Rx group showed smaller anterior cingulate cortex volume on the right compared with the ADHD/Rx and control groups; this was the only finding for a medication difference.

A study highlighting the impact of comorbidities on imaging studies found that when the analysis of cerebral microstructure was restricted to a subgroup of those with no comorbidities (pure-ADHD subgroup), there was more microstructural complexity compared to typically developing children in the frontal and parietal lobes bilaterally, insula, corpus callosum and right external and internal capsules. The authors also found that the pure-ADHD subgroup lacked the normal age-related progression in gray- and white-matter microstructural complexity from the ages of 8 to 18 years. The authors conclude: "our results highlight the shortcomings of including diverse psychiatric comorbidities in the investigation of tissue microstructure in ADHD. Although aberrant findings have been observed with heterogeneous ADHD cohorts, these may lack clinical specificity, as potentially reflected in conflicting results from prior microstructural studies on ADHD."

## Functional Imaging

The clinical benefit from medications affecting catecholamine levels has led to a focus on frontostriatal circuitry and dopamine pathways in ADHD. Functional magnetic resonance imaging (fMRI) studies have demonstrated abnormal activation of the frontostriatal regions in children with ADHD. In normal children, maturation is associated with increased activation of the ventral frontostriatal regions and improved inhibitory control. A comparison of children with ADHD with normal control subjects demonstrated greater frontal activation and lower striatal activation during response inhibition in 10 children with ADHD (8 ADHD/C, 2 ADHD/I; children with high comorbidity scores were excluded). Administration of methylphenidate also resulted in improved performance

in a test of response inhibition, associated with increased frontal activation in ADHD children and control subjects and increased striatal activation in the children with ADHD.

Untreated adults with ADHD (with no psychiatric comorbidity) have increased striatal dopamine transporter (DAT) levels compared with normal control subjects (as measured by binding to technetium 99m TRODAT-1, the first 99mTc-labeled ligand identified by single-photon emission computed tomography [SPECT] that specifically binds DAT), which decreased after 4 weeks of methylphenidate treatment. This finding, along with increased striatal activity on positron emission tomographic (PET) scanning in adolescents with ADHD compared with normal control subjects, suggests a role for excess dopaminergic activity in striatum or nucleus accumbens in persons with ADHD.

A review and critique of functional imaging studies of ADHD notes that such studies have found multiple loci of abnormalities that are not limited to frontal-striatal circuitry, the regions thought to be most important for executive and motivational function, but also in the parietal, temporal, and motor cortices and the cerebellum. However, it is pointed out that: task specific factors influence activation patterns which may have induced variable performance levels and strategies over the course of development. In the absence of cross-sectional or longitudinal studies, "the developmental origin of differences in activation cannot be inferred." It is concluded that: "current, task-evoked functional imaging provides information about dynamic or state-dependent differences rather than fixed or trait-related differences."

## Genetic Studies

Concise reviews of advances in the genetics of ADHD, including findings that may account for the ADHD subtypes, comorbidities, and responses to specific medications, are provided in a commentary and editorial in journal issues devoted to this topic. A summary by D.V. Pauls stated that the evidence was overwhelming that ADHD is inherited and that genetic factors play an important role in the manifestation of ADHD. The fact that ADHD is an inherited condition coupled with evidence of dopaminergic involvement led to molecular genetic studies of dopamine transporter and receptor genes. Pursuit of the *DAT* gene (*SLC6A3*, formerly designated *DAT1*) was in part caused by the finding that psychostimulant medications inhibit the activity of DAT. An association between ADHD and the 480 base-pair alleles at a variable-number tandem repeat (VNTR) in *SLC6A3* has been reported. A subsequent study confirmed these findings and demonstrated a significant relation between *SLC6A3* high-risk alleles and the number of hyperactive-impulsive symptoms but not inattentive symptoms. The study involved 117 probands, all but one of whom met criteria for ADHD; the remaining child had oppositional defiant disorder (ODD). Most children with ADHD frequently had symptoms of or were diagnosed with ODD, conduct disorder (CD), and depression or dysthymia. Two subsequent studies, one with a similar rate of coexisting conditions and one with a much lower rate, failed to replicate the association between *SLC6A3* and ADHD.

Studies of DNA from ADHD probands, parents, and healthy controls found a significant association of ADHD with two *NET1* single-nucleotide polymorphisms and two *DRD1* single-nucleotide polymorphisms. There was no association with polymorphisms in 10 other genes previously reported as candidate genes. There were no significant differences in anatomic brain magnetic resonance imaging (MRI) measurements between the children with *NET1* or *DRD1* gene types, nor was there a relationship between the genetic findings and cognitive or behavioral measures. This study represented the

first replication of a previously described association between ADHD and polymorphisms in *NET1* and *DRD1* genes.

The Psychiatric Genetics Consortium has published two papers reviewing the findings on genetic relationships between five psychiatric disorders, including ADHD, based on an analysis of genome-wide single-nucleotide polymorphisms (SNPs).

### Other Potential Causes of Attention Deficit–Hyperactivity Disorder

Data reported from the National Longitudinal Survey of Youth associated hours of television watched per day at ages 1 and 3 years with parental reports of attentional problems at age 7. The children did not necessarily have clinically diagnosed ADHD; rather, they were scored as having attentional problems by the parents.

A review of the literature on the role of nutritional factors in ADHD, including food additives, sugars, food allergies or sensitivities, and essential fatty acids, concluded: that though a subset of children with behavioral problems are sensitive to one or more food components that may contribute to hyperactivity, there is not a specific food or substance that will precipitate problem behavior in all hyperactive children. There have been many reviews of the literature of food additives, noting major flaws in the methodology of those studies. However, randomized controlled trials have shown that sodium benzoate intake, a common preservative used in soft drinks and fruit juices, contributed to ADHD-like symptoms in young children.

A study looking at the effect of gestational diabetes mellitus (and) socioeconomic status (SES) on ADHD found that “the risk for ADHD increased over 14-fold ( $P = .006$ ) when children were exposed to both GDM and low SES. Neither children exposed to maternal GDM alone nor those exposed to low SES alone had a notable increased risk for ADHD. A study of a sample of 7- to 9-year-old children born extremely prematurely and/or with extremely low birth weight (ELBW) who were making normal progress at school found that biomedical variables such as birth weight and neurobiological risk are associated with aspects of executive function. Specifically, higher birth weights and lower levels of risk predicted better performance. A review of the causes of ADHD concluded that the dichotomy between genetic/biological and environmental factors in ADHD “is incorrect and unhelpful. Indeed, they are complementary rather than competing explanations” (Thapar et al., 2013).

### COEXISTING CONDITIONS

Many children who present with symptoms suggestive of ADHD have neurologic or psychiatric conditions that are the cause of those symptoms (e.g., depression, sleep disorders, epilepsy). There are other instances when multiple conditions coexist. The implications for management are significant. Just as correction of a sleep disorder may resolve the symptoms of inattention, hyperactivity, or impulsivity, addressing a child’s previously undiagnosed learning disability may resolve these symptoms. Alternatively, a child may have both problems, and remediation of the learning disability may still leave him or her with inattention, hyperactivity, or impulsivity that must be independently addressed. It has been proposed that ADHD be divided into subgroups based on the patterns of comorbidity. ADHD and CD have been posited to be distinct disorders. From a practical standpoint, most studies of children with ADHD and coexisting CD treated with psychostimulants demonstrated a reduction in physical and nonphysical

aggression and had improvement of ADHD symptoms. Anti-depressants also reduced symptoms of aggression and ADHD in these children. Anxiety disorder has been shown to be transmitted independently from ADHD in families, suggesting that these two conditions are distinct disorders. Most studies of children with ADHD and coexisting anxiety or depression found a reduced response in ADHD symptoms when treated with psychostimulants compared with children only with ADHD.

It has been proposed, inasmuch as ADHD and mood instability include impulsivity and behavioral problems in their definitions, that both ADHD and mood instability involve impairment in executive function, and given findings of overlapping neuroanatomical abnormalities and treatments, that mood instability be considered a core feature of ADHD rather than a comorbidity. A twin study found a strong genetic association between ADHD symptoms with emotional lability, supporting the idea that emotional lability may be a component of ADHD; this association was stronger in older than younger children.

A review of the overlapping symptoms associated with ADHD and sleep disorders noted that many children with primary sleep disorders have symptoms highly suggestive of ADHD. Conversely, many children with ADHD are reported to have sleep disturbances, which may be primary, attributable to the side effects of medication, or a result of comorbid conditions such as ODD, depression, and/or anxiety disorders. A comorbid sleep disorder may significantly increase the daytime impairment in a child with ADHD. It was recommended that all children presenting with ADHD symptoms be clinically assessed for the presence of sleep problems.

Reading disability and ADHD are two distinct disorders that may occur together. There is evidence of genetic linkage for ADHD and reading disability to the same region on the short arm of chromosome 6. This connection may represent a pleiotropic effect (i.e., the same gene increasing susceptibility to more than one disorder). A survey of audiologists and pediatricians found that although auditory processing disorder and ADHD/I have symptoms in common, there were features that allowed them to be distinguished from each other.

A meta-analysis of the literature reporting on tests of overall cognitive ability in ADHD analyzed data from 137 studies in which full-scale IQ (FSIQ) scores for children with ADHD were compared with those of a healthy control group. The ADHD groups had significantly lower FSIQ scores relative to the control groups, with an average decrement of 9 points in the FSIQ; the verbal and performance IQs were lower in the ADHD group. There was no difference in ADHD subtypes, although the number of children with inattentive-type ADHD was small. The authors concluded that these findings “may indicate that the disorder is characterized by mild global cognitive inefficiencies or by multiple specific deficits affecting several cognitive abilities.” They raised the possibility that the decrement could also be attributable to test-taking differences between the groups. The authors expressed surprise at the finding that for only a few of the measures was the effect size for executive functioning tasks significantly larger than effect sizes for the FSIQ. In a comparison of the mean effect size of tests of executive versus nonexecutive functions, there was greater impairment in the tests of executive function. The authors allowed for the possibility that impairment of executive function accounted for differences in overall ability, inasmuch as measures of overall ability are heavily influenced by executive function. The authors commented that achievement measures may be useful for screening for comorbid learning disabilities and characterizing deficits in motivation and behavior that result from executive dysfunction.

## DIAGNOSTIC EVALUATION

ADHD is a clinical diagnosis; there are no diagnostic laboratory nor cognitive tests. A child presenting with symptoms suggestive of ADHD should undergo screening for hearing and vision problems, potentially treatable issues that may be mistaken for ADHD. If the child's difficulties are predominantly in the school setting, an evaluation for learning disabilities should be pursued, with educational remediation if problems are identified. Social stressors may also be a significant factor, which may justify intervention by social services agencies. In general, routine diagnostic testing is not needed in the evaluation of a child for ADHD. However, specific testing may be indicated in some circumstances.

### Laboratory Studies

Features in the history or on examination may lead to specific tests for disorders manifesting as or coexisting with ADHD, such as hypothyroidism, hyperthyroidism, or phenylketonuria. Reports of an association between lead exposure and ADHD have been inconsistent. Depending on the results of such laboratory studies, therapy targeting the specific condition may be initiated. An uncontrolled study reported improvement in the parents', but not the teachers', Connors Rating Scales scores in children with ADHD treated with iron supplementation, even though they were not iron deficient. Better studies are needed before concluding that routine testing of or supplementation with iron or screening for iron deficiency is advisable.

### Electroencephalography

Studies reporting an increased frequency of epileptiform discharges in children with ADHD and reports of ADHD-type symptoms resolving when spike activity was suppressed with antiepileptic drugs have led to proposed guidelines for obtaining an electroencephalogram (EEG). These include a history of clinical events suggesting a seizure (even if only nocturnal or febrile), perinatal stress, head trauma, fluctuating behavioral manifestations, or a family history of epilepsy.

### Sleep Studies

A sleep history should be obtained. If the results suggest a diagnosis of a sleep disorder or if there is a strong family history of sleep disorders, a sleep study should be considered.

### Imaging Studies

There are few clinical indications for imaging studies in children with ADHD; if the child is clinically stable, the presence of ADHD symptoms does not call for imaging studies beyond those indicated for the primary condition.

## TREATMENT

### Nonpharmacologic Therapies

Children with ADHD need a classroom environment with minimal distractions and with seating that is somewhat isolated and close to the front of the room in front of the teacher. The setting should be fairly structured with organizational techniques such as checklists and homework assignment pads, and an uncluttered desk at home devoted exclusively to school work.

A multicenter clinical trial of various treatment strategies for ADHD concluded that stimulants were more effective

than behavioral therapies for ADHD symptoms. The combination of stimulants and behavioral therapy resulted in improved social skills but did not significantly improve ADHD symptoms over stimulants alone. A review of treatment modalities of children diagnosed with ADHD in the period from 1995 to 1999 found that among children diagnosed with ADHD, 24% also had mental illness. The most frequent treatments were stimulant medication alone (42%), stimulant medication combined with psychotherapy or mental health counseling (32%), and psychotherapy or mental health counseling alone (10.8%). Fifteen percent of children received no treatment other than office visits for initial and follow-up medical care. The percentage of children receiving psychotherapy or mental health counseling alone or in combination with stimulant medication increased with age, and males were more likely than females to receive treatment.

### Sleep

A recent study found a positive association between spindle-frequency EEG activity and motor skill learning improvement in children with ADHD (Saletin et al., 2015). This may account, at least in part, for the overlap in symptoms of ADHD and sleep disorders in children. This may also offer an opportunity for nonpharmacologic intervention in children with ADHD. Inasmuch as there is enriched sleep spindle activity in the latter part of sleep, having children with ADHD go to sleep early enough that they wake up spontaneously, rather than have the latter part of their sleep disrupted, might be beneficial to their function.

### Biofeedback Programs

Various forms of computerized training programs have been studied in treating children with ADHD. Computerized working memory training improved working memory capacity in children with ADHD and adults without ADHD. Improvement generalized to nonpracticed tasks involving prefrontal cortex, and associated with improvement in working memory was a decrease in head movements in children with ADHD. Children with ADHD trained to modify their slow cortical potentials also showed an increase in contingent negative variation (CNV) during a continuous performance task compared with those who did not receive training. Associated with this electrophysiologic phenomenon were fewer impulsivity errors on the continuous performance task, suggesting that the CNV increase represented a neurophysiologic correlate of improved self-regulatory capabilities. A meta-analysis of studies of nonpharmacologic treatments of ADHD (Hodgson et al., 2014), which was limited to studies of treatment and control groups and excluded studies using within-subjects designs to minimize placebo effects, found that behavior modification was effective in treating ADHD in children, achieving improved function across a number of domains including behavior and test performance. Neurofeedback was found to result in significant improvement in DSM-IV symptoms, test performance and behavior. There was no significant benefit established for school based treatments, parent training, working memory training, self monitoring or multimodal psychosocial treatment interventions in measurements of ADHD functional domains. Psychological treatments for ADHD were more effective among girls than boys and were least effective for children with combined-type ADHD (Martijn et al., 2009).

Use of an EEG biofeedback program was compared with the effectiveness of methylphenidate. After 3 months of the program, both groups had significant improvements in all

four subscales on the TOVA and improvement on a behavior rating scale. Changes in the EEG as a result of biofeedback were not monitored in this study. A previous study using biofeedback reported greater improvement on the test of variables of attention (TOVA) in participants with significant EEG changes than in those without changes (although there were improvements in both groups). There was no correlation between behavioral changes reported by the parents and changes in the EEG. This study did not include a control group. A study of EEG biofeedback that used a control group (i.e., association between EEG patterns and feedback to the participants was random) found no benefit from EEG biofeedback.

## Pharmacologic Therapy

The American Heart Association recommended that all children placed on stimulant medications for ADHD should have a screening electrocardiogram (ECG); the American Academy of Pediatrics concluded that this is neither necessary nor recommended and, instead, recommended cardiovascular screening based on personal, past, and family histories and the cardiovascular examination.

## Stimulant Medications

Stimulant drugs, sympathomimetic agents structurally similar to endogenous catecholamines, act centrally and peripherally by enhancing dopaminergic and noradrenergic transmission. Stimulants have been demonstrated to improve cognitive ability, school performance, and behavior.

The response to methylphenidate in a group of 28 preschoolers (3–5 years old), as measured by behavioral ratings by teachers and parents, documented improvement, with 82% rated as having normal behavior after treatment, higher than the rate generally achieved in older children. With the exception of decreased appetite, there were no adverse side effects. The investigators speculate that the higher normalization rate for preschoolers than elementary-age schoolchildren may be a function of fewer demands placed on the preschooler (e.g., shorter school day, no homework).

The most commonly reported side effects of stimulants include appetite suppression and sleep disturbance. Absorption of stimulant medications is not notably affected when taken with or after meals, which may ameliorate appetite suppression. Insomnia can be a side effect from the medication but may also be caused by a rebound effect as the medication effect subsides. This distinction is important because in the latter situation, a late afternoon or evening dose of stimulant medication may ease falling asleep. Uncommonly, there have been reports of mood disturbances and lethargy after stimulant use. Stimulants may also affect heart rate and blood pressure, but in healthy children, this change is unlikely to have clinical significance. There have been reports of psychostimulants inducing or exacerbating tic disorders, but subsequent studies have not found this to be a universal problem. Although this possibility should be discussed with children and their families, the presence of tics in a child with ADHD or a family history of tics is not an absolute contraindication to the use of psychostimulants. Concerns are often expressed regarding an increased risk of substance abuse in children treated with psychostimulants, but there is no supporting evidence. One study found that pharmacologic treatment for ADHD actually decreased the risk of subsequent substance abuse. However, although the risk of substance abuse in individuals with ADHD appears to be reduced by treatment, it is still higher than in the general population. Inasmuch as illicit substance abuse can manifest with attention difficulties,

hyperactivity, and/or impulsivity, the possibility that substance abuse is accounting for symptoms is to be considered; reevaluation after a period of abstinence may be warranted (Harstad et al., 2014).

One study evaluated the use of methylphenidate in 24 children with at least two epileptic seizures in the previous 6 months and a diagnosis of ADHD and found an improvement in ADHD symptoms for 70.8% of the children, no change in ADHD symptoms for 20.8%, and a worsening of symptoms in 8.3%. Of these 24 children, 22 (71%) showed no increase in seizure frequency; however, there was worsening in two. Santos et al. (2013) found that of 22 children with active epilepsy and ADHD treated for 3 months with methylphenidate, 4 patients reported some increase in seizure frequency, and 1 patient withdrew as a result of increased seizure frequency. There was substantial improvement in ADHD symptoms, such that 16 (73%) of the patients no longer had clinically significant ADHD symptoms. Other studies of children with ADHD and epilepsy or interictal discharges treated with methylphenidate did not find any increase in seizure frequency. Thus, although there is evidence of some risk of seizure exacerbation with stimulant use in children with ADHD and epilepsy, this does not occur in the majority of cases, and there is clear evidence of benefit; the decision to use stimulants in such cases requires an individualized consideration of the risk versus benefit.

A longitudinal study revealed that children treated with medication had a reduced height gain compared with those who were not treated. Growth suppression was still evident during the second year of treatment in the group treated continuously, indicating that this was a persistent effect. The observation that there was less growth suppression in the children who were not treated continuously suggests that interrupting treatment with stimulant medication may limit growth suppression, supporting the concept of drug holidays to address this side effect. However, there have been reports of behavioral deterioration when stimulant medications are abruptly discontinued.

The most commonly used drugs in the stimulant class include methylphenidate, dextroamphetamine, and mixed salts of L- and D-amphetamine. Although in the same class, these drugs have slightly different mechanisms of action, and patients may respond differently to each of them. Failure of one drug does not preclude success with another drug in the same class. A number of these agents are available in short- and long-acting formulations. The results of studies comparing short- and long-acting preparations have been inconsistent, making the choice of formulation an empirical one.

## Methylphenidate

Methylphenidate has fewer side effects than amphetamine. In the standard formulation, methylphenidate reaches peak concentrations between 1 and 3 hours after oral intake. It is rapidly and extensively metabolized by nonmicrosomal hydrolytic esterases in liver and other tissues, with an average half-life of 3 hours. A dose in the middle to late afternoon to facilitate completion of homework may also be warranted. Alternatives to multiple daily doses are the long-acting formulations of methylphenidate. These formulations reach peak concentration 6 to 8 hours after oral intake, obviating the need for a midday dose. When using the longer-acting formulations, the entire daily dose is given in the morning. If there is no significant improvement in symptoms at a total daily dose of 1 to 2 mg/kg, alternate medication should be considered. Another sustained-release form of methylphenidate is available as a skin patch that is placed on the skin daily for 9 hours.

## Dexmethylphenidate

Dexmethylphenidate is the D-threo-enantiomer of methylphenidate. A positron emission tomography (PET) study found specific binding of the D-enantiomer to a dopamine transporter in the basal ganglia, whereas the L-enantiomer had widespread, nonspecific binding. Studies comparing dexmethylphenidate and methylphenidate have concluded both to be effective in ADHD, but dexmethylphenidate has a longer duration. In children the starting dose of dexmethylphenidate is one-half of the methylphenidate dose (0.15 mg/kg in the morning, rounded to the nearest 2.5-mg tablet). The report of longer clinical efficacy than methylphenidate (despite the similar half-life) may eliminate the need for a midday dose, depending on the clinical response. There is no evidence that giving the D-isomer (dexmethylphenidate) at one-half of the dose of the D,L-enantiomer (methylphenidate) confers any clinical advantage.

## Dextroamphetamine

Dextroamphetamine has a time to peak concentration of 60 to 160 minutes and is metabolized in the liver. The average half-life of dextroamphetamine is 10 to 12 hours, but this varies considerably with urinary pH; at a urine pH less than 6.6, more than two-thirds of unmetabolized drug is excreted in the urine, whereas at a urine pH greater than 6.7, it is less than one-half. The initial dose of dextroamphetamine is 0.15 to 0.3 mg/kg (rounded to the nearest 5 mg). Dextroamphetamine's longer half-life compared with methylphenidate may obviate the need for a midday dose. An extended-release preparation of dextroamphetamine eliminates the need for midday dosing.

Adderall is a combination of four amphetamine salts (D-amphetamine saccharate, D-amphetamine sulfate, D,L-amphetamine sulfate, and D,L-amphetamine aspartate), with a 3:1 ratio of D-isomer to L-isomer. The time to peak concentration and half-life are similar to those for dextroamphetamine. The initial dose of Adderall is 2.5 or 5 mg, with weekly increments based on the response to a maximum dose of 1.5 mg/kg per day, up to about 40 mg. The half-life of Adderall is such that a midday dose may or may not be necessary. Adderall XR capsules, with one-half of the contents in a delayed-release formulation, eliminate the need for midday dosing; the entire daily dose is given in the morning.

## Noradrenergic Potentiation

### Atomoxetine

Atomoxetine (Strattera) is a norepinephrine-specific reuptake inhibitor that is effective in the treatment of children with ADHD. In a study comparing atomoxetine to methylphenidate and placebo, the response rate to atomoxetine and methylphenidate was essentially identical, and both were better than placebo. Appetite suppression was somewhat lower in atomoxetine compared with methylphenidate (22% versus 32%), and there was significantly less insomnia on atomoxetine (7% versus 27%). In extensive metabolizers (most patients), atomoxetine half-life is 4 to 5 hours. Substantial decreases in clearance and prolongation of the half-life are seen in poor metabolizers. The starting dose is 0.5 mg/kg per day, with gradual increase to a target dose of 1.2 mg/kg per day. In poor metabolizers (about 7% of the population), the half-life is substantially longer, and the dose requirement may be much lower. Depending on the response, midday dosing may be required for extensive metabolizers. Food does not affect absorption. Because atomoxetine is not a controlled substance

in the United States, prescriptions with multiple refills can be provided, and renewals can be done over the phone, in contrast to the procedures for stimulant medications. In December 2004 the U.S. Food and Drug Administration (FDA) asked the manufacturer to add a bolded warning about severe liver injury to the labeling, indicating that the medication should be discontinued in patients who develop jaundice or laboratory evidence of liver injury. In September 2005 the FDA directed the manufacturer to further revise the labeling to include a boxed warning regarding an increased risk of suicidal thinking in children and adolescents being treated with this drug.

## Nonstimulant Medications

It is estimated that at least 30% of children diagnosed with ADHD do not respond to or tolerate stimulant medications. Most studies have reported a reduced rate of response to psychostimulants in children with ADHD and anxiety or depression. The failure to respond to psychostimulants suggests the possibility of an incorrect diagnosis. However, genetic studies have suggested that children with ADHD respond differently to methylphenidate, depending on whether they are homozygous or heterozygous for the 10-repeat allele at dopamine transporter gene *SLC6A3*.

## Tricyclic Antidepressants

Other agents found to be effective in the treatment of ADHD include tricyclic antidepressants (TCAs). In one study, comorbidity with conduct disorder, depression, or anxiety or a family history of ADHD did not result in a differential response to desipramine. In studies comparing TCAs with stimulants, TCAs appear to more consistently improve behavioral symptoms rather than cognitive function.

There have been case reports of sudden death in children treated with desipramine. Although a subsequent epidemiologic study did not find greater risk of sudden death with desipramine, it has been suggested that a baseline ECG be obtained before initiating treatment and that serial ECGs be obtained after significant dose increments and periodically during treatment.

## Alpha-Adrenergic Agonists

The alpha-adrenergic agents clonidine and guanfacine have been widely used for treatment of ADHD, despite few clinical studies. The success of these agents for Tourette syndrome and other tic disorders has made them especially useful in children with ADHD and tic disorders, particularly if a trial of stimulant medication resulted in exacerbation of tics. Reports of three deaths of children taking a combination of methylphenidate and clonidine prompted reviews that found no evidence of an adverse methylphenidate-clonidine interaction. Nevertheless, if planning to prescribe this combination, a review of this literature and discussion of risks and benefits with the parents is advisable. Guanfacine appears to have an advantage over clonidine because it has a longer half-life and is less sedating. Guanfacine reaches a peak concentration after oral intake in 1 to 4 hours and is metabolized in the liver, with an average half-life of 17 hours. The starting dose is 0.015 mg/kg per day (to the nearest 0.5 mg), with a gradual increase to a maximum of 0.05 mg/kg or 4 mg/day, based on the clinical response. The half-life of guanfacine should allow for once-daily dosing, although in clinical studies it was administered in two to four divided doses. Guanfacine is available in 1- and 2-mg tablets (Tenex). A sustained-release form of guanfacine (Intuniv) is also available; the half-life is 16 hours, and the time to peak serum level is approximately 5 hours. This is effective as a

once-a-day dosing schedule in doses of 1 to 4 mg/day. Other agents reported to be effective in ADHD are reviewed in Table 56-1.

A review of prospective trials of medicines used for ADHD in children noted a wide heterogeneity between studies in terms of follow-up duration and the reporting criteria for adverse effects (AEs), limiting the information available on the long-term effects of ADHD treatment. The authors concluded that “drugs for ADHD are generally safe and well tolerated, with decreased appetite, insomnia, headache and abdominal pain being the most common adverse effects (AEs) observed in long-term prospective trials. Tics were reported in all long-term studies of methylphenidate. Emotional lability was reported only with mixed amphetamine salts” (Clavenna and

Bonati, 2014). It was noted that although AEs were described as mild or moderate, lack of tolerability resulted in the discontinuation of treatment in 10% to 25% of children, “with most of the AEs and discontinuation cases occurred in the first few months of drug treatment” (Clavenna and Bonati, 2014). The authors added that there was little data available regarding events that occur with a frequency of less than 1%. As a result, “many psychiatric AEs may be missed or underestimated, in particular the more severe ones (e.g., suicide attempts).” The studies available “provided scant information concerning the effect of treatments on growth and on the cardiovascular system” (Clavenna and Bonati, 2014).

A study looking at the effect of aerobic exercise on executive function in children with ADHD found that aerobic exercise

Drug	Total Daily Dose	Daily Dosage Schedule	Main Indications	Common Adverse Effects/Comments
<i>Stimulants</i>				
Dextroamphetamine	0.3–1.0 mg/kg	2 or 3 times	ADHD	Insomnia, decreased appetite Depression, psychosis (rare, with very high doses) Increased heart rate and blood pressure (mild) Possible growth reduction with long-term use Withdrawal effects and rebound phenomena
Mixed salts of l- and d-amphetamine	0.5–1.5 mg/kg	1 or 2 times	ADHD	Regular form: 6-hour duration of action Extended-release form: 10- to 12-hour duration of action
Lisdexamfetamine	30–70 mg (total)	Daily	ADHD	Less abuse potential than dextroamphetamine
Methylphenidate	12 mg/kg	1–3 times	ADHD	Regular forms: 3- to 4-hour duration of action Extended-release forms: 8- to 12-hour duration of action
Methylphenidate patch	10–30 mg/9 hours (total)	Daily	ADHD	
Dexmethylphenidate	0.5–1.0 mg/kg	2 or 3 times	ADHD	
Magnesium pemoline	1.0–2.5 mg/kg	1 or 2 times	ADHD	Associated with rare, serious hepatotoxicity; requires monitoring of liver function tests
Modafinil	200–400 mg (total)	Daily	Narcolepsy	Fewer peripheral sympathomimetic effects than amphetamines
<i>NSRIs</i>				
Atomoxetine	0.5–1.4 mg/kg	1 or 2 times	ADHD ± comorbidity Enuresis (?) Tic disorder (?) Depression/anxiety disorders (?)	Mechanism of action: noradrenergic-specific reuptake inhibitor Mild or moderate appetite depression Gastrointestinal symptoms Mild initial weight loss Mild increase in blood pressure, pulse No ECG conduction or repolarization delays Not abusable
<i>Tricyclic Antidepressants</i>				
Tertiary amines	2.0–5.0 <sup>†</sup> mg/kg	1 or 2 times	ADHD	Mixed mechanism of action (noradrenergic/serotonergic)
Imipramine	2.0–5.0 <sup>†</sup> mg/kg	1 or 2 times	Enuresis	
Amitriptyline	2.0–5.0 <sup>†</sup> mg/kg	1 or 2 times	Tic disorder	Secondary amines more noradrenergic
Clomipramine			Anxiety disorders (?) OCD (clomipramine)	Clomipramine primarily serotonergic Narrow therapeutic index Overdoses can be fatal Anticholinergic effects: dry mouth, constipation, blurred vision Weight loss Mild increase in diastolic blood pressure and ECG conduction parameters with daily doses > 3.5 mg/kg
Secondary amines				
Desipramine	2.0–5.0 <sup>†</sup> mg/kg	1 or 2 times		
Nortriptyline	1.0–3.0 <sup>†</sup> mg/kg	1 or 2 times		

Continued on following page

**TABLE 56-1** Major Drug Classes Used in the Pharmacotherapy of Attention Deficit–Hyperactivity Disorder\* (Continued)

Drug	Total Daily Dose	Daily Dosage Schedule	Main Indications	Common Adverse Effects/Comments
MAOIs Phenelzine Tranylcypromine Selegiline	0.5–1.0 mg/kg 0.5–1.0 mg/kg 0.5–1.0 mg/kg	2 or 3 times 2 or 3 times 2 or 3 times	Atypical depression Treatment-refractory depression	Difficult medicines to use in juveniles Reserved for refractory cases Severe dietary restrictions (i.e., high-tyramine foods) Drug–drug interactions Hypertensive crisis with dietetic transgression or with certain drugs Weight gain Drowsiness Changes in blood pressure Insomnia Liver toxicity (remote)
<i>Other Antidepressants</i>				
SSRIs Fluoxetine Paroxetine Citalopram Sertraline Fluvoxamine	0.3–0.9 mg/kg 0.3–0.9 mg/kg 0.3–0.9 mg/kg 1.5–3.0 mg/kg 1.5–4.5 mg/kg	1 time, in afternoon 1 time, in afternoon 1 time, in afternoon 1 time, in afternoon 1 time, in afternoon	MD, dysthymia OCD Anxiety disorders Eating disorders PTSD (?)	Serotonergic mechanism of action Large margin of safety No cardiovascular effects Irritability Insomnia Gastrointestinal symptoms Headaches Sexual dysfunction Withdrawal symptoms more common with short-acting drugs Potential drug–drug interactions (cytochrome P-450)
Bupropion (SR)	3–6 mg/kg	2 times	ADHD MD Smoking cessation Anticraving effects (?)	Mixed mechanism of action (dopaminergic/noradrenergic) Irritability Insomnia Drug-induced seizures at doses > 6 mg/kg
Venlafaxine (XR)	1–3 mg/kg	1 time	Bipolar depression (?) MD Anxiety disorders ADHD (?) OCD (?)	Contraindicated in bulimics Mixed mechanism of action (serotonergic/noradrenergic) Similar to SSRIs Irritability Insomnia Gastrointestinal symptoms Headaches Potential withdrawal symptoms Blood pressure symptoms
Nefazodone	4–8 mg/kg	1 time	MD Anxiety disorders OCD (?) Bipolar depression (?)	Mixed mechanism of action (serotonergic/noradrenergic) Dizziness Nausea Potential interactions with nonsedating antihistamines, cisapride (cytochrome P-450) Rare, serious hepatotoxicity Less manicogenic (?)
Mirtazapine	0.2–0.9 mg/kg	1 time, in the afternoon	MD Anxiety disorders Stimulant-induced insomnia (?) Bipolar depression (?)	Mixed mechanism of action (serotonergic/noradrenergic) Sedation Weight gain Dizziness Less manicogenic (?)
<i>Noradrenergic Modulators</i>				
$\alpha$ 2-Agonists Clonidine	0.003–0.010 mg/kg	2 or 3 times	Tourette disorder ADHD Aggression/self-abuse Severe agitation Withdrawal symptoms	Sedation (frequent) Hypotension (rare) Dry mouth Confusion (with high dose) Depression Rebound hypertension Localized irritation with transdermal preparation
Guanfacine (see text for information on long-acting form of Guanfacine)	0.015–0.05 mg/kg	1 or 2 times		Same as clonidine Less sedation, hypotension

**TABLE 56-1** Major Drug Classes Used in the Pharmacotherapy of Attention Deficit–Hyperactivity Disorder\* (Continued)

Drug	Total Daily Dose	Daily Dosage Schedule	Main Indications	Common Adverse Effects/Comments
Guanfacine, extended-release form β-Blockers Propranolol	1–7 mg/kg	1–4 mg/day given once a day  2 times	Aggression/self-abuse Severe agitation Akathisia	Risk for bradycardia and hypotension (dose-dependent) and rebound hypertension Bronchospasm (contraindicated in asthmatics) Rebound hypertension on abrupt withdrawal

\*Doses are general guidelines and must be individualized with appropriate monitoring. Weight-corrected doses are less appropriate for obese children, and adult doses should not be exceeded in older or larger children. When high doses are used, serum levels may be obtained to avoid toxicity.

†Dose adjusted according to serum levels (therapeutic window for nortriptyline).

ADHD, attention deficit–hyperactivity disorder; DR, delayed release; ECG, electrocardiographic; IR, immediate release; MAOIs, monoamine oxidase inhibitors; MD, mood disorder; MR, mental retardation; NSRIs, norepinephrine-specific reuptake inhibitors; OCD, obsessive-compulsive disorder; OROS, oral osmotic; PTSD, posttraumatic stress disorder; SR, sustained release; SSRIs, selective serotonin reuptake inhibitors; XR, extended release.

(Adapted from Biederman J et al. *Int J Neuropsychopharmacol* 2004;7:77.)

facilitated inhibition and set-shifting, impairments in which are thought to account for executive dysfunctions in ADHD. Another study found that aerobic exercise resulted in smaller theta/alpha ratios in the frontal and central brain regions compared with a control group.

### Complementary and Alternative Medications

A survey of parents of children referred for evaluation of ADHD reported that 54% of the parents used complementary and alternative medicine (e.g., acupuncture, nutritional supplements) for the child's ADHD symptoms in the prior year. Only 11% of the parents discussed using such interventions with their child's physician.

### OUTCOME

ADHD persists into adulthood. The symptoms of ADHD may be less obvious after the individual is older. The incidence of ADHD in adults depends on diagnostic criteria and whether historical data are obtained from the patients or their parents. As noted in the introduction, the revised criteria in the DSM-5 reduce the number of symptoms required to make a diagnosis in adults and adolescents 17 and older and from six to five, which will inevitably result in an increased incidence of ADHD in those age groups. The finding that adolescents and young adults with ADHD had more car accidents with bodily injuries indicates that this is a serious problem even in older children and adults. A pilot study of 11 adults 55 years or older diagnosed with ADHD found that these patients had the same psychiatric comorbidities as younger adults and at similar rates. Psychiatric comorbidities were pervasive in this group and tended to weaken the effect of stimulant medications on overall functioning while enhancing the effect of medication on impulsivity.

### CONCLUSIONS

Study of higher cortical function is inherently complex. Advances in neuroscience have brought new methods to this endeavor. There is still much research required for achieving an understanding of ADHD, not least of which is agreeing on a precise definition so that studies can be compared. Available evidence suggests that there may be value in distinguishing

ADHD/I from ADHD/HI and ADHD/C and in separating cases with comorbidity because these groups have different characteristics and different responses to treatment. A crucial role for the physician assessing a child for the possibility of ADHD is recognizing features in the presentation that suggest alternative diagnoses. Although much remains to be done, substantial advances in the neurobiology, diagnosis, and management of this condition have been made, and the prospect for significant enhancement of the lives of children with ADHD continues to improve.

The autistic spectrum disorders (ASD) represent a wide continuum of associated cognitive and neurobehavioral deficits, including deficits in socialization and communication, with restricted and repetitive patterns of behaviors. The terms “autism” and “autistic spectrum disorders” are used interchangeably throughout this chapter and refer to the broader umbrella of autism spectrum disorders, as defined by the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) (APA, 2013) (Box 57-1).

### CLINICAL FEATURES OF ASD

All individuals on the autistic spectrum demonstrate deficits in two core domains: social communication/interaction and restricted/repetitive behaviors. There is marked variability in the severity of symptoms across patients, and cognitive function can range from severe intellectual impairment through the superior range. The fifth edition of DSM specifies that in the context of intellectual disability, the social-communication functioning must be more impaired than would be expected on the basis of general developmental level. The symptoms must be sufficient to limit or impair everyday function to warrant a diagnosis of ASD.

### Persistent Deficits in Social Communication and Social Interaction

This refers to a *qualitative* impairment in social communication and reciprocal social interactions, which is persistent and observable across multiple contexts. There is not necessarily an absolute lack of social behaviors, but social communication and interactions are clearly atypical for the individual’s age and developmental level. Behaviors range from total lack of responsiveness to other people to an oddly stilted interaction style or inappropriate approaches and attempts to interact.

Deficits in social-emotional reciprocity often manifest as the absence of attempts to initiate social interaction and a lack of responsiveness to social overtures. Eye contact is diminished and usually is not responsive to another person’s overtures or used to get someone’s attention. For school-age children and adolescents with ASD, unfamiliar or unstructured social situations (such as recess and lunch room) are especially challenging due to their difficulty in engaging in a reciprocal interaction and the inability to understand social roles and cues.

Deficits in nonverbal communication behaviors are a hallmark of ASD. Expressive language ranges from essentially nonverbal to verbally fluent. Nonverbal communication deficits can vary from a total lack of facial expressions and nonverbal communication to a lack of integration of gestures (e.g., eye contact, smiling, nodding, shaking the head, shoulder shrugging) with verbal communication. Lack of pretend play or very repetitive “scripted” pretend play is a typical characteristic of children with ASD. The development of friendships is

challenging for children with ASD and when formed are usually around a specific shared interest; a lack of social reciprocity is still often apparent. Unfortunately, their social awkwardness often leaves children with ASD vulnerable to teasing and bullying.

### Restricted, Repetitive Patterns of Behavior, Interests, or Activities

Restricted, repetitive patterns of behavior, interest, or activities can be manifest in many ways. A common form of repetitive speech is echolalia, which may be immediate or delayed. Immediate echolalia refers to immediate noncommunicative repetition of words or phrases. Delayed echolalia (or scripted speech) refers to the use of highly ritualized phrases that have been memorized, such as from television or overheard conversations. Repetitive questioning and the persistent use of idiosyncratic phrases are other forms of repetitive speech.

Some children have stereotypical movements (e.g., floric hand-clapping or arm-flapping) whenever excited or upset. Running aimlessly, rocking, spinning, bruxism, toe-walking, or other odd postures are also common. Many children with ASD demonstrate the classic behavior of lining up objects or may be preoccupied with repetitive actions, such as opening and closing doors or repetitively flicking pieces of string. Many autistic children are so preoccupied with “sameness” that little can be changed without prompting a tantrum or other expression of distress. Restricted and repetitive behavior may take the form of excessive preoccupation with special interests. The inflexibility and idiosyncratic nature of these preoccupations interfere with the ability to carry on reciprocal conversations or sustain friendships.

Many children with ASD overreact or underreact to sensory input (such as pain or temperature) or may be interested in some sensory aspects of their environment (e.g., lights, patterns, or movement) to an unusual degree. Extreme rigidity or rituals related to the smell, texture, and look of food are common and may result in excessive food restriction.

### Onset Patterns in ASD

The onset of ASD may occur early, with abnormalities in social and communication skills becoming apparent in the first year of life, or children appear to develop normally until at least 12 months of age, followed by loss or regression of language and/or social skills. The prevalence of regression in ASD is about 30%.

Dramatic, rapid regression after a period of normal development, particularly after the age of 2 years and involving more than social communication skills, is rare and warrants a thorough medical evaluation. More typical is a “plateauing” or deceleration of development after 6 months of age. This is often accompanied by some loss of social communication skills, typically joint attention, shared affect, and the use of language. During early childhood, some children with ASD

**BOX 57-1** Diagnostic Criteria for 299.00 Autism Spectrum Disorder

- A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history (examples are illustrative, not exhaustive; see text):
1. Deficits in social-emotional reciprocity, ranging, for example, from abnormal social approach and failure of normal back-and-forth conversation; to reduced sharing of interests, emotions, or affect; to failure to initiate or respond to social interactions.
  2. Deficits in nonverbal communicative behaviors used for social interaction, ranging, for example, from poorly integrated verbal and nonverbal communication; to abnormalities in eye contact and body language or deficits in understanding and use of gestures; to a total lack of facial expressions and nonverbal communication.
  3. Deficits in developing, maintaining, and understand relationships, ranging, for example, from difficulties adjusting behavior to suit various social contexts; to difficulties in sharing imaginative play or in making friends; to absence of interest in peers.
- Specify current severity:*  
Severity is based on social communication impairments and restricted, repetitive patterns of behavior.
- B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history (examples are illustrative, not exhaustive; see text):
1. Stereotyped or repetitive motor movements, use of objects, or speech (e.g., simple motor stereotypes, lining up toys or flipping objects, echolalia, idiosyncratic phrases).
  2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior (e.g., extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take same route or eat same food every day).
  3. Highly restricted, fixated interests that are abnormal in intensity or focus (e.g., strong attachment to or preoccupation with unusual objects, excessively circumscribed or perseverative interests).
  4. Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment (e.g. apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement).
- Specify current severity:*  
Severity is based on social communication impairments and restricted, repetitive patterns of behavior.
- C. Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities, or may be masked by learned strategies in later life).
- D. Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.
- E. These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay. Intellectual disability and autism spectrum disorder frequently co-occur; to make comorbid diagnoses of autism spectrum disorder and intellectual disability, social communication should be below that expected for general developmental level.
- Note:** Individuals with a well-established DSM-IV diagnosis of autistic disorder, Asperger's disorder, or pervasive developmental disorder not otherwise specified should be given the diagnosis of autism spectrum disorder. Individuals who have marked deficits in social communication, but whose symptoms do not otherwise meet criteria for autism spectrum disorder, should be evaluated for social (pragmatic) communication disorder.
- Specify if:*  
With or without accompanying intellectual impairment  
With or without accompanying language impairment  
Associated with a known medical or genetic condition or environmental factor
- (Coding note:** Use additional code to identify the associated medical or genetic condition.)
- Associated with another neurodevelopmental, mental, or behavioral disorder
- (Coding note:** Use additional code[s] to identify the associated neurodevelopmental, mental, or behavioral disorder[s].)
- With catatonia (refer to the criteria for catatonia associated with another mental disorder)
- (Coding note:** Use additional code 293.89 catatonia associated with autism spectrum disorder to indicate the presence of the comorbid catatonia.)

(From: American Psychiatric Association. Proposed Revisions to 299.00 Autistic Disorder in DSM-V, 2013. Retrieved February 28, 2013, from <http://www.dsm5.org/ProposedRevisions/Pages/proposedrevision.aspx?rid=94#>).

continue on a worsening trajectory, others remain stable, and some improve. Currently, there is no reliable way to predict which trajectory will apply to an individual child.

Children who experience a regression with onset of symptoms of autism and an epileptiform EEG are to be differentiated from those with a diagnosis of Landau-Kleffner syndrome, an acquired aphasia associated with an epileptiform EEG, and from those with continuous spike waves during slow wave sleep (CSWS). Although in these conditions there are seizures, regression and epileptiform abnormalities, children with autistic regression have an earlier age of onset and are less likely to have bilateral, temporal EEG patterns, or electrical status during sleep (Table 57-1).

## EPIDEMIOLOGY

The prevalence of autism has dramatically increased in the United States from .4 per 1000 before 1991 to 1.2 per 1000

before 2001 and to 14 per 1000, or one in 68 children, in 2010. In the 2010 Autism and Developmental Disabilities (ADDM) cohort, ASD prevalence in children varied based on race: white (1 in 63), black (1 in 81), Hispanic (1 in 93), Asian or Pacific Islander (1 in 81), and overall (1 in 68).

Awareness of autism has been increasing in developing and developed countries, with varying but largely similar prevalence as the U.S. estimates. Several factors contribute to the apparent increase. In the past, autism prevalence was underestimated. Over time, diagnostic criteria have broadened and more recent surveys have included the broadest definitions. There is now codiagnosis with known medical disorders such as Fragile X syndrome, Tourette syndrome (TS), and Down syndrome. There also is increasing public awareness among parents and teachers as well as availability of services. Children earlier diagnosed as mentally retarded may now meet current criteria for autism. Finally, earlier age at diagnosis and population-based screening have also

**TABLE 57-1** Landau-Kleffner Syndrome-Continuous Spike Waves during Slow-Wave Sleep versus Autistic Regression with Epileptiform EEG

	<b>Landau-Kleffner Syndrome-Continuous Spike-Waves during Slow-Wave Sleep (LKS-CSWS)</b>	<b>Autistic Regression with Epileptiform EEG (AREE)</b>
Age of regression/ (symptoms)	Usually after 3 years; peak age 3–5 years. In CSWS may be as late as 12 years of age.	Usually before age 2 years with a mean age of regression of 21 months
Seizures	Usually not frequent or intractable. In approximately 25%, seizures are not present.	Seizures are not part of phenotype. In autistic spectrum disorders, when seizures occur, they are usually not frequent and respond well to antiseizure medications.
EEG	Spikes, sharp waves, or spike-and-wave discharges, usually bilateral and occurring predominantly over the temporal regions. They increase during sleep; EEG pattern of electrical status epilepticus during slow-wave sleep is common.	Infrequent spikes, usually centrotemporal. Rarely associated with CSWS. No clear correlation with interictal epileptiform discharges and improvement or worsening of underlying language and social dysfunction.
Treatment	Case reports, mostly with use of steroids, suggest improvement in language. Surgical outcomes with multiple subpial transections are variable. No controlled clinical trials.	No evidence that present medical interventions (antiseizure medications) or surgical interventions are indicated.
Outcome/Comments	Improvement occurs in late childhood/early adolescence. Approximately one third recover. Prognosis for seizure control is excellent but recovery of language is variable and not as good as for seizures.	Improvement seems related to cognitive skills. No data to determine whether interictal discharges combined with regression are markers for worse prognosis.

contributed to the reported increase. The CDC is monitoring the prevalence of autism over time in a number of U.S. sites using consistently applied ascertainment and diagnostic protocols.

The proportion of children with ASDs who had IQs less than or equal to 70 ranged from about 30% to 50% in the CDC's ADDM Network. The mean male to female ratio is about 4 to 1, but as cognitive severity increases, the male to female ratio decreases to 1.3 to 1. Children with an IQ of less than 50 are more likely than those who are high-functioning to be female and to have minor physical anomalies, neuroimaging abnormalities, microcephaly, and epilepsy. Those with specific inherited conditions, such as tuberous sclerosis or phenylketonuria, are likely to be more severely cognitively impaired. In some studies, ASD prevalence increases with increasing socioeconomic status.

### Sibling Studies

An autism diagnosis is about 20 times more likely in siblings when one child had autism—about 10.1%, compared with 0.5% prevalence in siblings of controls. The risk is 25% if there are already two siblings with ASD.

Delays in verbal and nonverbal communication have been noted in siblings of those with ASD, beginning at about 12 months of age. However, no consistent specific deficits have emerged as characteristic of Sib-ASD. Response to name at 12 months of age and response to joint attention were predictive of the degree of social impairment and eventual ASD diagnosis at 3 years of age.

### Neonatal Intensive Care and Prematurity

There is a higher rate of autism and a much higher rate of positive screening for ASD in infants with extreme prematurity. This increased risk has been associated with perinatal complications such as preeclampsia, intracranial hemorrhage, cerebral edema, low Apgar scores, and seizures. The presence of these risk factors should lead to systematic screening of toddlers and preschoolers who were born prematurely or with neonatal complications.

### Parental Age and Other Factors

Risk of ASD is higher with increasing age of mothers, and independently, with increasing age of fathers. Advanced parental age and some other risk factors may act through increasing the risk for de novo mutations. Environment mutagens such as mercury, cadmium, nickel, trichloroethylene, and vinyl chloride may play a role. Air pollution is a risk factor in most but not all studies. Vitamin D deficiency may cause mutations, as vitamin D contributes to repair of DNA damage.

### Autoimmune Factors

Autoimmune dysfunction has been associated with autism risk. The presence of maternal thyroid peroxidase antibody (TPOab) increased risk by nearly 80%. Maternal infection requiring hospitalization (but not mild common infectious diseases or febrile episodes) was associated with an increased risk of ASD. Maternal gestational or type 2 diabetes, maternal prenatal stress in the first trimester, and paternal obesity all may increase the risk of ASD. Children born within 1 year of an autistic sibling have an increased risk over those born after longer intervals. A decrease in autism risk has been associated with periconceptual folate intake and may be strongest in those with genetically inefficient folate metabolism.

### Vaccines

Resurgence of measles in the United States has focused attention on parents who have refused the measles-mumps-rubella (MMR) vaccination for fear of its causing autism. Five methodologically sound cohort studies involving 1,256,407 children and five case-control studies of 9920 children did not find an increased risk of autism with childhood vaccines or the mercury-containing preservative thimerosal, which has not been used routinely since 2001. Although thimerosal exposure from vaccines was eliminated in Sweden and Denmark by the early 1990s, the incidence of autism was accelerated. Additional data derived from passive surveillance systems also consistently failed to detect an association. There has been no evidence that the incidence of regressive autism

has increased after administration of the MMR vaccine. The MMR vaccine has been given at a constant rate since 1979 in the United States, since 1982 in Finland, and since 1998 in the United Kingdom and Denmark, but rates of autism have steadily risen. There is also no causative link with persistent GI problems or the measles virus. Even among children at high risk because of older siblings, there was no harmful association between MMR vaccine and ASD.

## Animal Models

One of the most challenging aspects of autism research is the development and validation of animal models. This is discussed in the online version of this chapter.

## Neuropathology

The underlying genetic complexity and thus corresponding mechanistic diversity has made study of ASD neuropathology challenging. Brain regions implicated in ASD pathogenesis include the superior temporal sulcus, amygdala, fusiform gyrus, dorsolateral prefrontal cortex, and the cerebellum. Post-mortem histopathological studies have shown differences between ASD and matched controls including cortical dysgenesis, such as ectopic gray and white matter and abnormal lamination. Cortical minicolumns have been demonstrated to be more numerous and narrow in ASD brains, and higher prefrontal and midtemporal spine densities in pyramidal neurons have been reported. This increase in spine density as seen in Fragile X and Down syndrome suggests that it is a common morphologic signature in many neurodevelopmental disorders.

## Neurotransmitters

Neurotransmitter abnormalities have been described in autism. A study of eight hippocampal neurotransmitter receptors demonstrated a reduction in the GABA-ergic system. Further work has implicated serotonin as central to ASD pathology, including disruption of the 5HT<sub>2a</sub> receptor binding throughout the cingulate cortex in adults, and altered platelet serotonin levels.

## Neuroimaging

Neuroimaging findings in ASD are also variable, demonstrating either decreased or increased cortical white matter volume or microstructure. However, to underscore the complexity, a recent paper demonstrated that the diffusion tensor imaging changes in ASD patients compared with healthy population controls were also seen in their apparently unaffected siblings.

Conducting MRI scans of patients with specific genetic or “syndromic” diagnoses can identify unexpected findings. For example, patients with Williams syndrome have an elevation in fractional anisotropy (FA) in areas associated with language. Other studies have shown that FA levels are altered in Fragile X patients compared with to controls but also to individuals with idiopathic ASD. Phenotypically similar ASD patients have been reported with differing FA levels, white matter and global brain volumes depending on whether a deletion or duplication at the same genetic loci is present. Elevated FA is seen in patients with a deletion at 16p11.2, whereas reduced FA is seen in those with a duplication at the same genetic locus. Because both the deletion and duplication carriers can have ASD and both can have opposing imaging findings, it is not unreasonable to see why imaging assessments of mixed idiopathic ASD groups could result in different or no significant results, depending on the type of genetics that underlie

the ASD patients in any given cohort. This suggests that future imaging for ASD should start from a cohort of patients who have similar or identical genetic or syndromic etiologies.

## Genetics of ASD

Perhaps the most significant advance in autism biology over the last decade has been in understanding the genetics of autism. Newly developed powerful genome-wide tools have shown the importance of highly penetrant single de novo genetic events, whether they are copy number variants (CNV) or single nucleotide variants (SNV). CNVs recurrent common loci include deletion or duplication of a 593 kb locus at 16p11.2, duplication at 15q11.2–q13.1 and duplication at the Williams syndrome locus at 7q11.23. Advances in the last 8 to 10 years, through testing many thousands of children with ASD or other neurodevelopmental disorders (NDD), have also proven the pathogenicity of less commonly observed CNVs (Cooper et al., 2011). Guidelines from a consensus statement from the American College of the Medical Genetics and the International Standard Cytogenomic Array (ISCA) consortium states that chromosome microarrays (or any platform that reliably detects chromosomal copy number variants) are a first-line test for determining the cause of autism in affected patients (Kearney et al., 2011).

In addition to CNV, there is now substantial evidence that SNVs play a key role in ASD. With the advent of increasingly less expensive next generation sequencing, it is possible in research and clinical settings to use whole exome sequencing in ASD patients to diagnose more than 25% of cases. This approach of deep sequencing of ASD cohorts (as well as candidate gene sequencing of larger numbers of patients) has identified dozens of new genes that are linked to ASD, using conservative genome-wide statistical thresholds. As with the discovery of CNV, the list of these genes will continue to grow. Currently, one website, <https://gene.sfari.org/autdb/Welcome.do>, houses genes, CNV, and the supporting data linking these genetic changes to ASD. The frequency of the most common CNVs in an ASD cohort is approximately 0.5% to 1%, for 16p11.2 and 15q11.2–q13.1. For SNVs, (e.g., mutations in genes CHD8, 0.3%; CHD2, 0.2%; ANK2, 0.2%; ARID1B, 0.2%) the rate of de novo mutations is lower, with the most commonly affected genes in the initial exome sequencing cohorts lower than the rate of the most recurrent CNV, such as 16p11.2 deletion/duplication. The Simons Foundation Autism Research Initiative (SFARI) website lists 706 genes associated with ASD, with varying levels of evidence supporting this link.

Both the aforementioned CNV and SNV are principally implicated in ASD because the genetic mutation is de novo, not present in either parent, and likely occurs in the paternal or maternal zygotes. However, there has been substantial evidence linking ASD to a pattern of familial inheritance, with heritability ranging from 55% to 90%. Additionally, ongoing studies confirm that inheritance of common, less penetrant mutations play a key role in ASD biology (Krumm et al., 2015) and that combining findings from both inherited and de novo mutations will better allow development of a model of ASD etiology and pathogenesis.

## SCREENING AND DIAGNOSTIC EVALUATION FOR ASD

ASDs can be reliably diagnosed in children in the second year of life, and early intervention has proven to be beneficial to social and communicative function. However, the average age at diagnosis in the United States continues to be high (53 months). Parents often voice concerns months to years before

a formal diagnosis is achieved and appropriate intervention initiated.

Age at diagnosis varies as a function of ethnicity and socioeconomic status (SES) (Daniels and Mandell, 2013). The mean age at diagnosis in Medicaid-eligible children is 64.9 months, considerably higher than the U.S. average. In addition, Medicaid-eligible African American children were 2.6 times less likely than white children to receive an autism diagnosis on their first specialty care visit, with ADHD being the most common diagnosis.

The 1 in 93 prevalence rate for Hispanic children actually represents a considerable narrowing in the gap relative to white children over the past decade. Although a majority of primary care practitioners (PCPs) offered some form of developmental screening, only 29% offered Spanish ASD screening, and only 10% offered both Spanish general developmental and Spanish ASD screening. Many children, particularly non-English-speaking families with low SES, still are not receiving appropriate early screening and treatment.

The CDC has a website to increase public and professional awareness of autism and other neurodevelopmental disorders, called "Learn the Signs. Act Early," at <http://www.cdc.gov/ncbddd/actearly/>. The CDC website offers downloadable educational information and screening instruments at <http://www.cdc.gov/ncbddd/actearly/hcp/index.html>. There also is a developmental pediatric curriculum to improve recognition of ASD that would be appropriate for child neurologists at <http://www.cdc.gov/ncbddd/actearly/act/class.html>.

The Child Neurology Society and American Academy of Neurology (AAN/CNS) published the initial *Practice Parameter for the Screening and Diagnosis of Autism*. The American Academy of Pediatrics Council of Children with Disabilities subsequently published a set of guidelines on the identification and management of children with ASD; both were reaffirmed in 2010. Risk factors include having a sibling with ASD or whenever there is parental, other caregiver, or pediatrician concern.

## Screening Instruments for ASD

"Red flags" for critical delays in social communication development can be recognized or queried and should initiate prompt evaluation for an ASD (Box 57-2). ASD screening tools should be used whenever a concern is raised about an infant's or child's social communication development. ASD screening and diagnostic instruments were reviewed by Charman and Gotham (2013) and Johnson and Myers (2007) (Fig. 57-1).

## Diagnostic Instruments for ASD

The combined administration of the semistructured Autism Diagnostic Observation Schedule™—second edition (ADOS-2) and the Autism Diagnostic Interview™—revised (ADI-R) a structured parent interview, are considered the gold standard for the diagnosis of autism in research settings. Many clinical settings use the ADOS-2 independently of the ADI-R. Both instruments are available for purchase (in many languages), and training/ workshop information are available at <http://www.wpspublish.com/app/>.

## Speaking with Parents about a New Diagnosis of ASD

Many parents have known that "something is wrong" for a considerable amount of time and may even come into the evaluation with a chief complaint that "I think my child has autism." However, many parents, although hoping to be vindicated in the diagnosis, also may be hoping that they have been wrong.

### BOX 57-2 Red Flags for Social Communication Development

Prompt evaluation should occur for any of the following:

#### No vocalizations by 6 months

*A parent should be able to have a reciprocal "conversation" by this age, consisting of at least several volleys back and forth.*

#### No polysyllabic consonant babbling by 12 months

*At least some of these vocalizations should be directed at someone with communicative intent.*

#### No gestures by 12 months

*The earliest gesture an infant learns is to raise his/her arms to request to be picked up, usually once sitting independently.*

*Pointing should be with an isolated index finger, not the whole hand, and should be used "to request" or "to show," not just pointing at pictures in a book or pointing to have an adult label items.*

*Any use of hand-over-hand by the child, e.g., putting a parent's hand on the cabinet door where the cookies are kept or using the parent's hand to point at pictures in a book, is a hallmark of ASD.*

#### No spontaneous (not echoed) single words by 16 months other than *mama* or *dada*

*Spontaneous words must be beyond those used to simply label items and must be used by the child to communicate, to request, to show, or to share.*

#### No spontaneous (not echoed) phrases by 24 months or sentences by 36 months

*Spontaneous phrases and sentences must be used by the child to communicate, to request, to show, or to share.*

#### Any loss of social communication abilities, including babbling, single words, phrases, response to name, social engagement, or gestures

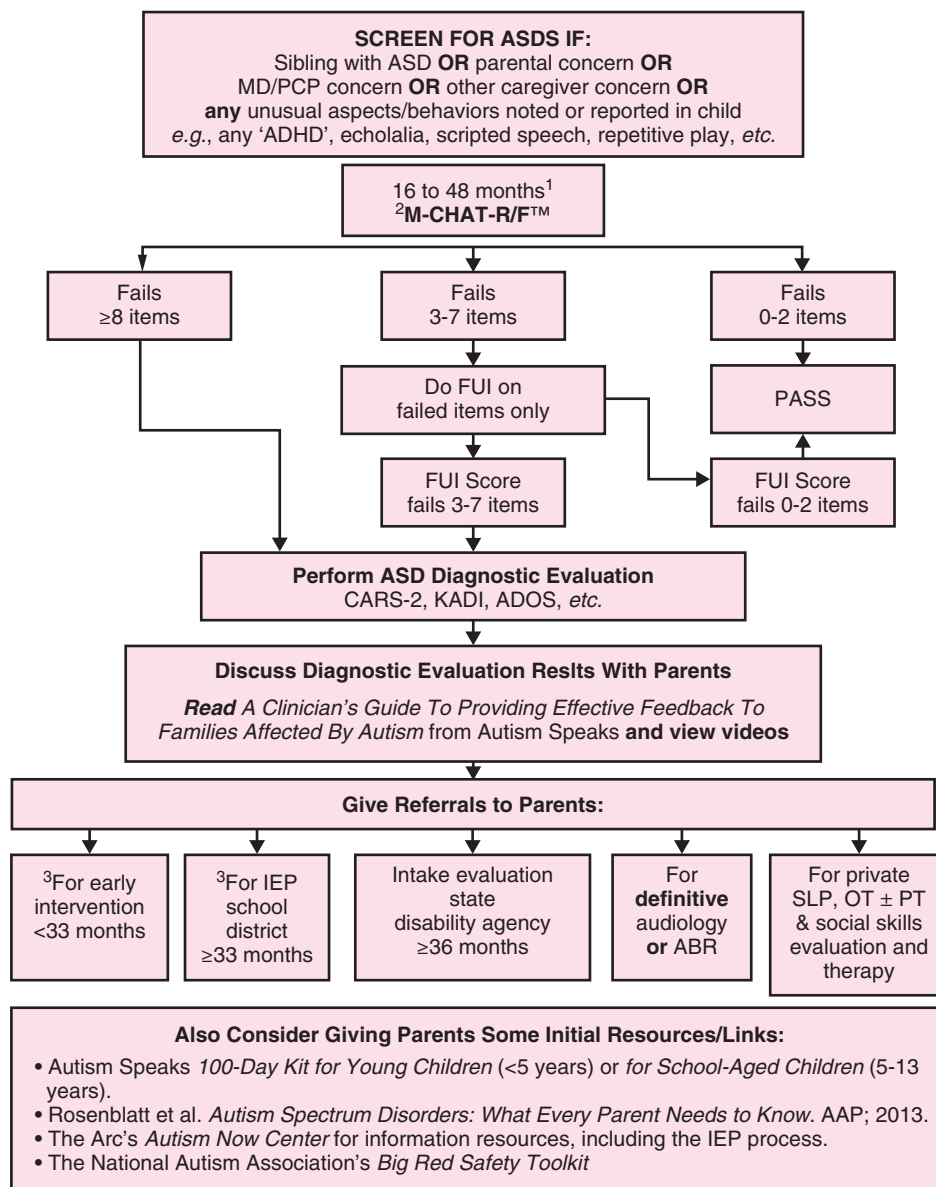

*If a parent reports their infant has decreased or stopped any social communication milestones, this is usually the hallmark of the onset of regression.*

Clinicians should consider incorporating the following points during the evaluation and subsequent counseling. Families should be encouraged to ask questions, offer observations, and provide information. Clinicians should ascertain behaviors seen during the evaluation are typical for this child. Clinicians need to be aware of and address safety issues. The results of the evaluation process should be reviewed, particularly detailing the child's strengths and areas of difficulties. The diagnosis of ASD should be clearly stated, and details of the symptoms of ASD should be described, especially the core deficits of social communication and restricted, repetitive behaviors. The clinician should prioritize the next steps to further evaluate and treat the child and provide the family with contact information to accomplish these steps. It is also important to discuss incorporating ongoing family support as well as providing contact information for external support groups. It is helpful to conclude on a positive note, reminding the parents about the child's and family's strengths.

## Recommendations for a Child with Newly Diagnosed ASD

All initial diagnostic evaluations resulting in a diagnosis of ASD should provide the following referrals at a minimum:

1. Evaluation for Individuals with Disabilities Education Act (IDEA) services:
  - Children older than 33 months of age: by the local provider of Early Intervention (EI) services. Many states have

<sup>1</sup>For 9-15 months, consider the *CSBS DP Infant-Toddler Checklist*<sup>™</sup>; for ages ≥4 years, the *Social Communication Questionnaire*<sup>™</sup>

<sup>2</sup>Free download in multiple languages at: <http://www.mchatscreen.com/>

<sup>3</sup>If child does not qualify for EI or an IEP, refer to Head Start/Early Head Start, and re-refer to ECI or ISD in 4-6 months

**Figure 57-1.** Child Neurology “Road Map” for ASD Screening and Diagnosis. (Courtesy of Pauline A. Filipek MD.)

a centralized website that provides contact information by zip code or city.

- Children 33 months of age and younger: by the local school district to perform a Full Individual Evaluation (FIE) in order to prepare an Individualized Education Plan (IEP). Parents must make the request for an FIE in writing.
- 2. Definitive hearing evaluation, either audiology or auditory brainstem responses.
- 3. Private speech, OT and/or PT evaluations, as indicated.
- 4. For a child 36 months of age and older, refer the child for an intake evaluation at the state’s agency for developmental disabilities.

Safety issues also should be addressed during the initial evaluation. Wandering away from home or school is a

significant safety problem in half of all children with ASD, with a substantial number at risk for bodily harm, primarily from traffic injuries (65%) or drowning (24%). Nonverbal or minimally verbal children who wander should wear identification bracelets.

## THE NEUROLOGIC EVALUATION IN AUTISM

The neurologic examination in ASD is usually relatively straightforward, with the exception of several possible findings: large head circumference (HC) or frank macrocephaly, somatic overgrowth, motor abnormalities including hypotonia, dyspraxia, stereotypies, and gait disturbances, and/or self-injurious behaviors (SIB).

## Large Head Size and Somatic Overgrowth

Many reports have noted that head circumferences in children with ASD are shifted upward, with the mean approximately at the 75th percentile, with correspondingly increased whole brain volume. This is presumed due to an accelerated brain growth rate in infancy, as HC is normal by adolescence and adulthood as is postmortem brain weight. However, many reports are finding either HC within the normal range and comparable to typical controls or large but proportional to somatic overgrowth. Children with ASD, particularly boys, are often taller and heavier than typically developing children of the same age.

## Motor Disturbances in Tone, Gait, Praxis, and Stereotypies

Hypotonia is common in children with ASD but not uniquely so. Gait disturbances also have been reported in ASD, localized to abnormal cadence, and hip and ankle kinematics and kinetics; such disturbances may be more pronounced in children with severe rather than with mild ASD symptoms.

Motor dyspraxia, defined as impaired ability to perform skilled gestures, was identified in almost 30% of children with ASD and normal cognitive function, in 75% of children with ASD and intellectual disability (ID), and in 56% of a nonautistic, intellectually delayed control group. Dyspraxia in ASD strongly correlates with the core social, communicative, and behavioral impairments, as measured by the ADOS. Both motor function and visual-motor integration contribute to the dyspraxia.

Motor stereotypies are very common in ASD and have an earlier onset (younger than 3 years) than tics (5 to 7 years) and tend to be consistent and fixed, frequently involving hands, arms, or the entire body. These include hand or finger mannerisms, body rocking, and unusual posturing. Self-injurious behavior (SIB) is reported to occur in varying proportions of individuals with ASD (i.e., 35 to 50%).

## Clinical Testing

### Definitive Evaluation of Hearing

Many children with ASD are first described by parents as acting "as if deaf." However, most children with autism have normal hearing. Pronounced to profound bilateral hearing loss or deafness was present in 3.5% of all children with ASD, a prevalence greater than that for the general population but similar to the rate for individuals with ID. In contrast, hyperacusis was commonly found, affecting almost 20% of an ASD sample. Definitive audiological evaluation or brainstem auditory-evoked potential testing should be performed in all children with autism so that, if indicated, appropriate referrals can be made.

### Lead Level

Children with developmental delay who spend an extended period in the oral-motor stage of play are at increased risk for lead toxicity, which may still be present in certain environments. The prevalence of pica in this group can result in high rates of substantial and often recurrent exposure to lead and other metals. All children with developmental delay or autism should have a periodic lead screen until the pica disappears.

### Electroencephalography

There is insufficient evidence to recommend for or against the use of routine screening EEGs in autistic children.

Epileptiform EEG abnormalities and interictal discharges (IEDs) have been reported in children with ASD (up to 30%) but do not typically correlate with clinical seizure activity.

## Neuroimaging Studies

Routine MRI studies to evaluate a child with autism to determine the etiology is not warranted unless there is neurologic evidence of lateralizing signs or other critical symptomatology. There is a very low prevalence of focal lesions or other abnormalities in ASD, most of which are deemed coincidental. PET and single-photon emission computed tomography (SPECT) are not indicated in the diagnostic evaluation of ASD.

## Metabolic Testing

Metabolic screening is indicated only in the presence of suggestive clinical and physical findings (e.g., lethargy, cyclic vomiting, early seizures, dysmorphic or coarse features), ID, questionable newborn screening, or birth outside of the United States.

## Tests of Unproven Value

Unsupported claims have led a number of parents to seek various tests in the hope of finding a treatable cause of autism. There is no evidence to support routine clinical testing of undocumented value (e.g., trace elements in the hair, celiac antibodies, immunologic or neurochemical abnormalities, micronutrients such as vitamin levels, intestinal permeability, stool analysis, urinary peptides, and so forth).

## COEXISTENT MEDICAL CONDITIONS

### Gastrointestinal Problems

Feeding habits and food preferences of children with autism typically are unconventional; however, the majority of children have intakes that meet or exceed dietary standards.

Children with ASD have more GI symptoms than comparison groups, with an overall odds ratio of 4.42, (1.90 to 10.28) (McElhanon et al., 2014). Individuals with ASD should receive the same standard of care in the diagnostic workup and treatment of gastrointestinal concerns as patients without ASD. Available data do not support the use of a casein-free diet, a gluten-free diet, or a combined gluten/casein-free diet as a primary treatment for individuals with ASD, despite anecdotal reports of some benefit.

### Sleep Disturbances

The majority of children with autism have sleep problems, often severe, and usually involving extreme sleep latencies, lengthy nighttime awakenings, shortened night sleep, and early morning awakenings. Children with autism also have more unusual and obligatory bedtime routines. These behaviors may lead to memory and learning issues, maladaptive daytime behaviors, and parental stress.

### Epilepsy

Epilepsy of all seizure types occur frequently in children with autism. The overall rate, even in idiopathic cases of autism with normal IQ, is higher (13% to 17%) than the risk in the general population (1% to 2%). There is a bimodal distribution of age of onset, with peaks occurring at younger than 5 years and during adolescence and with the rate increased in those with intellectual disability or underlying medical

conditions. The prevalence of epilepsy was 21.5% in subjects with ASD and ID compared with 8% in those with ASD and no ID. The presence of cerebral palsy or focal motor findings also increases risk.

The focus of an NIH workshop on autism and epilepsy (Tuchman et al., 2013) was the commonality of possible mechanisms and how we can learn about the pathophysiology of both conditions when they occur together, for example, in disorders such as Fragile X syndrome and Tuberous Sclerosis Complex (TSC). Both abnormal synaptic plasticity and excitatory/inhibitory imbalance can be contributing factors. Changes associated with seizures and epileptogenesis may disrupt normal activity-dependent developmental processes. Changes in functional connectivity determined by EEG are being explored as a biomarker for early identification of ASD. By 12 months of age, high risk infants later diagnosed with ASD showed reduced functional connectivity compared with those who were not later diagnosed.

Seizures in children with autism should be treated as they would be in children without autism, with even more attention than usual paid to the possible behavioral and cognitive side effects of antiseizure drugs. Repetitive and stereotypic behaviors could mimic temporal lobe seizures, and inattention from absence seizures may be construed as autistic behavior.

## PHARMACOLOGIC THERAPY

Drug treatment should be one facet of a comprehensive, multidisciplinary approach that includes structured special educational techniques, language or communication interventions, behavior modification, and parent training (Table 57-2). The goal of pharmacologic treatment is to improve specific behaviors such as anxiety, repetitive motor behaviors, obsessive-compulsive symptoms, impulsivity, depression, mood swings, agitation, hyperactivity, aggression, and self-injurious behavior. Although no medication directly influences cognitive impairment, controlling symptoms may allow the child to maximize benefits from educational and behavioral treatments that are directed toward the core impairments. Dosing should start with low amounts and slowly be escalated with careful attention to possible side effects, the most common of which is activation, defined as overactivity, agitation, or emotional lability.

Of the 2853 children enrolled in the Autism Treatment Network, 27% were on psychotropic medication. Use was less common in children age 5 and under and was associated with gastrointestinal symptoms and sleep problems. In children with comorbid diagnoses of ADHD, bipolar disorder, obsessive-compulsive disorder, depression or anxiety, use was 82%, compared with 16% in children without psychiatric comorbidity.

## Neuroleptic Agents

Neuroleptics that block dopamine receptors, such as haloperidol, thioridazine, and trifluoperazine, were used until the development of drugs that were more effective in blocking serotonin receptors. Haloperidol decreased motor stereotypies, hyperactivity, withdrawal, and negativism in children with autism, but use is limited by the risk of extrapyramidal symptoms. Weight gain and metabolic changes are common side effects of neuroleptics.

Risperidone and aripiprazole are the only two medications approved by the Federal Drug Administration (FDA) for the treatment of irritability (including aggression, self-injurious behavior, temper tantrums, and mood swings) in school-age children and adolescents with autistic disorder.

These agents have been associated with weight gain, prolactin increases, hyperglycemia, and sedation in some patients. In an 8-week, randomized trial in 101 children with ASD, low dose risperidone (0.5 to 3.5 mg/d) improved irritability, hyperactivity, and stereotypies. Treatment effects were maintained over 16 weeks, and medication discontinuation resulted in return of behavioral symptoms. An 8-week, double-blind, randomized, placebo-controlled trial with aripiprazole in 218 children and adolescents with autistic disorder compared three doses of the drug (5, 10, or 15 mg/d) to placebo. All doses improved irritability, although only the 5 mg/day group reached statistical significance, possibly due to a high placebo response (35%). Improvement was reported within 2 weeks.

## Opiate Antagonists

Naltrexone was evaluated in clinical trials with the hypothesis that autism is associated with hypersecretion of brain opioids, including beta-endorphins, and that many symptoms are similar to those induced by opiate administration. In several small studies, 1mg/kg/day decreased hyperactivity and modestly improved behavior, with mild GI side effects and drowsiness.

## Serotonin Reuptake Inhibitors (SRIs)

Because of the efficacy of serotonin reuptake inhibitors (e.g., clomipramine, fluoxetine, sertraline, fluvoxamine, and paroxetine) on anxiety and obsessive-compulsive symptoms, and the finding of serotonin abnormalities in individuals with autism, there has been interest in treating disruptive behaviors with these agents. Results of open-label and observational studies as well as double-blind, placebo-controlled, randomized trials have been mixed and suggest that efficacy of SRIs may be moderated by age, with better responsiveness in adults than in children. Studies of fluvoxamine and fluoxetine have shown some benefit in autistic adults but not in children.

A large, double-blind, randomized, placebo-controlled trial of 149 children and adolescents with ASD (ages 5 to 17 years) failed to find any effects of citalopram on repetitive behaviors. The most frequently reported side effects were activation, stereotypy, diarrhea, insomnia, dry skin, and pruritus. Two subjects treated with citalopram had seizures. There was a high placebo response rate (34%), which underscores the need for placebo-controlled trials.

The 5HT<sub>1A</sub> serotonin agonist buspirone was evaluated in a randomized, blinded trial of 166 children ages 2 to 6 years, in doses of 2.5 mg or 5 mg/bid compared with placebo. The primary outcome was the ADOS composite score, which was not affected in either treatment group. Those given the lower dose improved on the repetitive behavior score. This study evaluated pretreatment blood serotonin and regional patterns of metabolism on PET scan. Children with pretreatment elevated blood serotonin and regional patterns of tryptophan on PET scan suggesting brain inflammation were less likely to improve. A Cochrane review of SSRIs did not find overall evidence of benefit in children with ASD, although reduction in anxiety or depressive symptoms in older children may be beneficial (Williams et al., 2013).

In summary, the neuroleptics risperidone and aripiprazole can be used for irritability, aggression, SIBs, and mood swings. SRIs, selective SRIs, and other medications affecting serotonin and dopamine levels can reduce certain symptoms, such as ritualized behaviors, stereotypies, and aggression. Although SRIs appear to be safe, children may be sensitive to the behavioral activation of these drugs. Seizures have

**TABLE 57-2** Medications Used to Decrease Specific Symptoms Associated with Autism Spectrum Disorder\*

Drug	Dose	Age <sup>i</sup>	N	Efficacy	Side Effects
<b>Neuroleptic Agents</b>					
Risperidone	0.25–2.5 mg/d <20 kg 0.5–2.5 mg/d 20–45 kg 0.5–3.5 mg/d >45 kg Mean = 2.4 mg/d	5–17	101	Decreased tantrums, aggression, self-injury, hyperactivity	Weight gain; increased appetite; transient sedation
Risperidone	1.2–2.9 mg/d child Mean = 2.0 mg/d 2.4–5.3 mg/d adult Mean = 3.6 mg/d	8–56	36	Decreased irritability, hyperactivity	Increased appetite; weight gain; sedation
Risperidone	.125–.175 vs. 1.25–1.75 vs. placebo	5–17	96	Higher dose improves global function and irritability	Somnolence sedation increased appetite
Risperidone	0.01–0.06 mg/kg/d Mean = 1.17 mg/d	5–12	79	Decreased irritability, hyperactivity, noncompliance, conduct problems	Weight gain; transient somnolence; mildly increased heart rate and blood pressure
Risperidone	0.5–1.5 mg/d Mean = 1.14 mg/d	2.5–6	24	Minimal improvement in global autism severity scores	Weight gain; increased prolactin levels
Risperidone	1.0–10.0 mg/d	18–43	n = ?	Reduced repetitive behavior, aggression, self-injury, property destruction	Transient sedation
Aripiprazole	5 mg/d, 10 mg/d, or 15 mg/d	6–17	218	Reduced irritability, hyperactivity, stereotypy at all doses	Sedation, EPS, weight gain
Aripiprazole	2–15 mg/d	6–17	98	Reduced irritability, hyperactivity, stereotypy, inappropriate speech; global improvement	Decreased prolactin level, weight gain, EPS
Aripiprazole	2–15 mg/d Continuation active tx vs. placebo	6–17	85	No difference in time to relapse	
<b>Opiate Antagonists</b>					
Naltrexone	1.0 mg/kg/d	3–8	41	No improvement over placebo in behavior and learning; improved hyperactivity	None greater than placebo
Naltrexone	1.0 mg/kg/d 2 weeks only	3–8	24	No improvement in communication skills	Transient sedation
Naltrexone	40 mg/d Single dose	3–7	23	Decreased hyperactivity, improved attention	Not reported
Naltrexone	1 mg/kg /dose	3–7	23	Decreased hyperactivity and improved attention by teacher, but not parent, report	No side effects
<b>Serotonin Reuptake Inhibitors</b>					
Fluvoxamine	Mean dose = 276.7 mg/d	18–53	n = 30	Reduced repetitive thoughts and behavior, and aggression; improved social communication	Transient nausea and sedation
Buspirone	2.5 mg or 5 mg /d	2–6	166	Improvement in repetitive behaviors not total ADOS	
Clomipramine	5–10 mg/d	8–17	34	No improvement executive fcn	Diarrhea, headache, fatigue
Fluoxetine	4.8–20 mg/d Mean = 10.6 mg/d; 0.38 mg/kg/d	5–17	39	Modest reduction in repetitive behaviors, but no improvement in global functioning	Agitation requiring dose reduction
Citalopram	2.5–20 mg/d Mean = 16.5 mg/d	5–17	149	No improvement in repetitive behavior or global functioning	Increased energy, inattention, impulsivity, hyperactivity, stereotypy, diarrhea, insomnia, dry skin
<b>Stimulants</b>					
Methylphenidate	0.125, 0.25, or 0.5 t.i.d. mg/kg /day	5–14	72	Reduced inattention, distractibility, hyperactivity, and impulsivity	Irritability, decreased appetite, difficulty falling asleep, emotional outbursts
Methylphenidate	.25, .5 mg/kg/dose	5–13	33	Positive efforts on social behavior	None discussed
Methylphenidate	10–40 LA AM, 2.5–10 mg afternoon	7–13	24	Decreased hyperactive and impulsive behavior	Loss of appetite, insomnia
Atomoxetine	20–100 mg/d Mean = 44.2 mg/d	5–15	16	Reduced hyperactivity, impulsivity, social withdrawal	Transient nausea and fatigue

Continued on following page

**TABLE 57-2** Medications Used to Decrease Specific Symptoms Associated with Autism Spectrum Disorder\* (Continued)

Drug	Dose	Age <sup>†</sup>	N	Efficacy	Side Effects
<b>Antiseizure Drugs</b>					
Lamotrigine	Mean = 5.0 mg/kg/d	3–11	28	No improvement greater than placebo in disruptive behavior and autism symptoms	Aggression, insomnia, echolalia
Levetiracetam	20–30 mg/kg/d	5–17	20	No improvement in disruptive behavior or irritability	aggression, agitation
Divalproex sodium	500–1500 mg/d	5–17	13	Reduction in compulsive-type repetitive behavior	Irritability, weight gain, aggression
Divalproex sodium	125 mg QD titrated up to 500 bid	5–17	27	Reduction in irritability	Irritability
Bumetanide	.5mg bid	3–11	60	Improved autistic behaviors and global function	Diarrhea, increased irritability

\*Includes only double-blind, randomized, placebo-controlled trials.

<sup>†</sup>Age in years.

EPS, Extrapyramidal symptoms.

emerged in a few instances, although this is a seizure-prone population, and it is not clear whether the medications were causal. Concern has been raised about possible association of fluoxetine and other selective SRIs with suicidal ideation in depressed children, and the FDA has recommended that children taking these medications be carefully monitored. Evidence for developmentally sensitive altered regulation of serotonin synthesis in autistic children provides a rationale for giving serotonergic drugs to very young autistic children to improve synaptic plasticity during periods of brain development.

## Medications to Treat Hyperactivity

Hyperactivity is an important target symptom that can be improved with psychostimulant medication. The Research Units on Pediatric Psychopharmacology (RUPP) Autism Network conducted a randomized, double-blind, placebo-controlled trial of methylphenidate in children with ASDs and high levels of hyperactivity and/or impulsiveness. Doses at the 0.25 and 0.5 mg/kg/day level were effective in reducing hyperactivity and impulsivity but less effective in reducing inattention, at 4 weeks and after 8 weeks. A randomized, crossover study of 24 children ages 7 to 12 showed that extended release MPH improves hyperactivity and impulsivity.

Atomoxetine is a nonstimulant medication for ADHD that inhibits the presynaptic norepinephrine transporter. In a placebo-controlled, double-blind crossover study with 16 children with ASD and ADHD symptoms, atomoxetine was more effective than placebo in reducing hyperactivity. The response rate was similar to that reported for methylphenidate, (mean highest dose was 44.2 [SD = 21.9] mg/d). Side effects, including gastrointestinal symptoms, fatigue, and tachycardia were common but transient. Other trials also demonstrated a beneficial effect of atomoxetine on hyperactivity in children with ASD. Two small placebo-controlled trials found that clonidine, an adrenergic receptor agonist, had some effect in decreasing irritability and hyperactivity in children and adults with autism.

## Antiseizure Drugs

Antiseizure drugs have been used for behavioral manifestations of autism, particularly for treating intense rapid mood shifts. Small, randomized trials of lamotrigine and levetiracetam showed no benefits, but sodium divalproex showed some promise for irritability and repetitive behaviors. Bumetanide,

which is currently being evaluated for the treatment of neonatal seizures, was compared with placebo in 60 children (0.5mg bid) and improved both global functioning and some autistic behaviors. Larger placebo controlled trials are needed.

It has been hypothesized that the mechanism of benefit from these medications might be their effect on subclinical seizures. However, there is no evidence or controlled trial investigating whether treatment with anticonvulsants in children with autism, who have epileptiform discharges but no clinical seizures, might improve behavioral or developmental outcomes.

## Cholinesterase Inhibitors

Acetylcholine (ACh) plays a significant role in attention and memory performance. Acetylcholinesterase inhibitors (AChE) slow the hydrolysis of ACh. Animal studies have suggested that administration of these agents early in development may enhance learning. A randomized, controlled 6-week trial, conducted in 43 children with autism showed that donepezil (2.5 mg/d), used for the treatment of memory decline, attention, and learning in Alzheimer disease, improved language and reduced overall autistic features. However, the analyses pooled blinded and nonblinded data, leaving the results susceptible to confounders such as placebo effects.

## Glutamatergic and Gamma-Aminobutyric Acidergic Agents

On the theory that there is a disturbance of excitatory and inhibitory transmission in ASD, NMDA and GABA receptor modulators have been tried. Memantine and amantadine were not effective, but arbaclofen and oxytocin showed some benefit.

In summary, a number of medications, particularly atypical neuroleptics, psychostimulants, and SRIs, may help decrease specific symptoms associated with autism, such as behavioral outbursts, stereotypic or compulsive behaviors, aggression, anxiety, inattention, and oppositional behavior. Reduction in these behaviors can improve quality of life and promote better opportunities for learning. However, there must be careful attention to matching the medication with the targeted behavior and to possible developmental differences in treatment response. Side effects are common, must be monitored closely and weighed carefully against the drug's benefits.

## Complementary and Alternative Medicine

A significant number of families seek complementary or alternative medicine (CAM) treatments, few of which have been studied in well-designed trials. Surveys have estimated that about one third of children were using complementary and alternative medicine. It is reasonable to respect the parents' belief if the complementary medicine is not toxic, but if the treatment is potentially harmful, negotiating a safer replacement practice should be attempted.

Children with autism often have sleep difficulties. Melatonin therapy has been used to treat the sleep disturbances in ASD, based on low plasma levels or urinary excretion of melatonin. Four double-blind, placebo-controlled crossover studies were performed in a total of 70 children with ASD using 3 to 10 mg of regular or controlled-release melatonin. Up to 94% of children derived significant benefits in sleep including sleep duration and latency but not awakenings, without evidence of significant side effects. An open-label melatonin study in 24 ASD children that involved titrating the dose to a maximum of 9 mg showed sleep latency improved at 1 or 3 mg doses. Larger long-term, double-blind, placebo-controlled crossover studies will be needed to document the efficacy of melatonin across the behavioral subtypes of ASD.

Immunoglobulin has been administered intravenously in open trials and not found to be useful. Reported dramatic improvement after the administration of secretin as part of endoscopy in three autistic children led to widespread use by parents. Subsequent blinded, randomized trials did not substantiate its efficacy.

Proponents of chelation therapy suggest that mercury and other heavy metals may be poorly eliminated by children with autism and that this interferes with neurodevelopment through modulation of immune function and other biochemical systems. Despite the lack of scientific evidence of a link between exposure to mercury or other heavy metals and autism, chelation is still used. No placebo-controlled studies have examined the safety or efficacy of chelation for treating autism, and deaths resulting from hypocalcemia have been reported from the inappropriate use of the chelator, edetate disodium (EDTA), including one boy with autism.

Hyperbaric oxygen therapy (HBOT) has been tried on the theory that autism is associated with oxidative stress and neuroinflammation. Although one randomized, controlled trial showed a few differences in outcome between control and HBOT treated groups, there were no differences when replicated, and HBOT carries a risk of barotrauma and exacerbation of pulmonary disease.

In summary, studies are negative or inadequate to recommend nutritional supplements, melatonin, hormones, gluten-free and casein-free diets, immunoglobulins, secretin, vitamin B6, magnesium, dimethylglycine, omega 3 fatty acids, HBOT, and chelation therapy. It is challenging to perform clinical trials enrolling children with autism, but without well-designed, blinded studies, safe and effective therapies cannot be determined. Problems include standardization of diagnoses, heterogeneity of target behaviors, and lack of cooperation of subjects. Whenever feasible, parents should be encouraged to participate in clinical trials to make progress in assessing new therapies. Information about ongoing trials and their locations can be found at [www.clinicaltrials.gov](http://www.clinicaltrials.gov).

## EDUCATIONAL AND BEHAVIORAL INTERVENTIONS

The core deficits associated with autism affect all aspects of the individual's life, necessitating a comprehensive and multidisciplinary approach. The primary source of intervention

for most children with ASD, from birth to age 21, is through the educational system. The Treatment and Education of Autistic and Related Communication Handicapped Children (TEACCH) Program is a structured teaching program founded at the University of North Carolina in the early 1970s. Originally developed as a classroom-based program for school-age children and adults, TEACCH has subsequently been adapted for home-based intervention for young children.

Intervention should be initiated as early as possible. Comprehensive early intervention programs based on basic learning principles for teaching skills and facilitating more appropriate and adaptive behaviors have been tested for their effectiveness in children and adults with autism and other developmental disabilities. Among the most extensively tested programs are Applied Behavioral Analysis (ABA) and Discrete Trial Training (DTT). Improvements in cognitive functioning and language level have been demonstrated at the group level. Improvements in adaptive behavior and autism symptoms have been more variable. Overall, baseline IQ and language skills predict better response to treatment. However, prediction at the individual level is not yet established.

Other comprehensive early education programs also have shown evidence of improving outcomes for children with ASD. Learning Experiences: Alternative Programs for Preschoolers and Parents (LEAP) was developed for implementation in early education classrooms. LEAP integrates behavioral techniques into naturalistic teaching situations, with a focus on integrating children with disabilities into the activities of typically developing children, and has a strong parent education component. Pivotal Response Treatment (PRT) is a naturalistic behavioral program that has been shown in single-subject design studies to be effective for young children with ASD, but has not undergone a randomized, controlled trial. The Denver Model and its adaptation for toddlers, the Early Start Denver Model (ESDM), emphasize the need to establish interpersonal relationships as a foundation to achieving other developmental milestones.

Core deficits in social understanding and social relationships are concerns throughout the life span, and social skills training (SST) is often a component of a treatment plan. Group-based SST programs show promise, but with a few exceptions, they have not been rigorously evaluated. The Joint Attention, Symbolic Play, and Regulation (JASPER) program is a parent-delivered, in-home, manualized treatment program for preschool children that has been shown to improve responsiveness to joint attention and initiation of joint attention, as well as symbolic play. The Children's Friendship Training (CFT) program for school-aged children integrates parents into a group-based social skills program focusing on behaviors critical to initiating and maintaining friendships. It was shown to improve social skills, friendship behaviors, and self-reported loneliness. The Program for the Education and Enrichment of Relational Skills (PEERS) is a group-based intervention for adolescents with ASD that integrates parents into the program to help with generalization of skills into the home and community. Studies demonstrated benefits in social skills and increased frequency of peer socialization.

The PEERS and CFT programs were originally developed for children with ADHD, and adapted for use in autism. Similarly, cognitive behavior therapy (CBT) for children with anxiety disorder has been effectively adapted to treat anxiety in high-functioning ASD. Adapting evidence-based interventions for specific symptom domains and comorbid symptoms in ASD is a reasonable strategy, but there remains a great need for rigorously designed research to demonstrate efficacy.

Although the needs of individuals with ASDs change over time, there is need for lifelong support. In particular, transitions (e.g., to high school, to higher education or vocational training, or to independent or assisted living) are critical periods during which supports already in place may be lost because of changes in eligibility or funding sources.

## RESOURCES FOR FAMILIES AND PRACTITIONERS

- Autism Speaks ([www.autismspeaks.org](http://www.autismspeaks.org)) offers numerous services and resources for families on its website. Of particular interest are the 100-Day Kits for parents of newly diagnosed young ([https://www.autismspeaks.org/docs/family\\_services\\_docs/100day2/100\\_Day\\_Kit\\_Version\\_2\\_0.pdf](https://www.autismspeaks.org/docs/family_services_docs/100day2/100_Day_Kit_Version_2_0.pdf)) and for school-aged children 5 years and older ([https://www.autismspeaks.org/sites/default/files/docs/100\\_day\\_kit\\_for\\_school\\_age\\_children\\_final\\_small.pdf](https://www.autismspeaks.org/sites/default/files/docs/100_day_kit_for_school_age_children_final_small.pdf)) that are specifically developed to assist parents during the stressful period after diagnosis. There are additional Autism Speaks Tool Kits available addressing other topics, such as advocacy, behavioral health treatments, psychopharmacology and deciding whether to begin medication, toilet training, and sleep tools ([https://www.autismspeaks.org/family\\_services/tool-kits](https://www.autismspeaks.org/family_services/tool-kits)).
- The American Academy of Pediatrics has a useful website ([www.healthychildren.org](http://www.healthychildren.org)) on which one can search on the topic “autism.” The AAP has recently published a book specifically addressing pertinent behavioral and medical advice topics facing parents of children with ASD ranging in age from very young toddlers through adolescence (<http://shop.aap.org/Autism-Spectrum-Disorders-What-Every-Parent-Needs-to-Know-Paperback/>).
- The Department of Education’s Center for Parent Information and Resources ([www.parentcenterhub.org](http://www.parentcenterhub.org)) has autism-specific information on special education laws and on educational practices.
- The Arc maintains a website (<http://www.thearc.org/page.aspx?pid=2530>) for people with intellectual and developmental disabilities and their families that provides a wealth of information on the special education. The Arc’s Autism Now Center provides information resources, including the IEP process (<http://autismnow.org/>).
- The Organization for Autism Research has several useful brochures and educational publications geared toward families, educators, and other professionals, many of which are in Spanish and English ([www.researchautism.org](http://www.researchautism.org)).
- The National Autism Association’s Big Red Safety Toolkit (<http://nationalautismassociation.org/docs/BigRedSafetyToolkit.pdf>) provides information and resources for families on wandering and water safety.
- The National Research Council produced a monograph that evaluated evidence-based interventions for children with ASD aged 8 years and under (<http://www.nap.edu/openbook.php?isbn=0309072697>).
- For clinicians, the AAN/CNS Practice Parameter: Screening and Diagnosis of Autism (<http://www.childneurology.org/resources/resources-detail-view/practice-parameter-screening-and-diagnosis-of-autism>) and the detailed background paper ([http://www.childrenslearninginstitute.org/duncan-programs/autism-center/documents/AU2906\\_241reprint.pdf](http://www.childrenslearninginstitute.org/duncan-programs/autism-center/documents/AU2906_241reprint.pdf)) continue to be a valuable resource.
- The First Signs program provides resources, including a video glossary of signs of ASD and referral guidelines. The First Signs website (<http://firstsigns.org>) includes recommendations and information about obtaining autism screening instruments. There are also summaries of evidence-based interventions available to parents and practitioners.
- The Agency for Healthcare Research and Quality provides a summary of the evidence for effectiveness of interventions for children, youth, and adults with ASD (<http://effectivehealthcare.ahrq.gov>).
- The National Autism Center ([www.nationalautismcenter.org](http://www.nationalautismcenter.org)) provides resources for parents and professionals including a National Standards Report, which synthesizes research related to the effectiveness of interventions for ASD based on age, diagnostic groups, and intervention targets.
- The National Institutes of Health website ([www.nih.gov](http://www.nih.gov)) can be searched for current research, as can those of specific institutes, including the National Institute of Neurologic Disorders and Stroke ([www.ninds.nih.gov](http://www.ninds.nih.gov)), National Institute of Child Health and Human Development ([www.nichd.nih.gov](http://www.nichd.nih.gov)), and the National Institute of Mental Health ([www.nimh.nih.gov](http://www.nimh.nih.gov)). The CDC’s National Center for Birth Defects and Developmental Disabilities has a website ([www.cdc.gov/ncbddd/autism/index.html](http://www.cdc.gov/ncbddd/autism/index.html)) devoted to providing evidence-based information on ASD and its treatment, including links to resources.
- The National Dissemination Center for Children with Disabilities is now affiliated with the Center for Parent Information and Resources (<http://www.parentcenterhub.org/>) has information on special education laws and on educational practices, among other timely topics.
- The federal Interagency Autism Coordinating Committee (IACC) website has compiled information about research and Federal activities related to research and service provision for ASD (<http://iacc.hhs.gov/index.shtml>).

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Neurodevelopmental disorders are associated with health comorbidities and behavioral challenges. Comorbidities discussed in this chapter include hypertonia, musculoskeletal deformities, feeding and gastrointestinal issues, seizures, osteoporosis, sleep disorders, and behavior.

## HYPERTONIA

Hypertonia is a resistance to passive stretch of a muscle across a joint and is divided into three subtypes: (i) spasticity, (ii) dystonia, and (iii) rigidity (Sanger et al., 2003). Spasticity is the presence of increasing tone with increasing speed of muscle stretch and the presence of a spastic catch. Dystonia is “a movement disorder in which involuntary sustained or intermittent muscle contractions cause twisting and repetitive movements, abnormal postures or both” (Sanger et al., 2003). Hypertonia is present in cerebral palsy (CP), acquired brain injury, and neurodegenerative or neurometabolic conditions. Spasticity and dystonia are common, and rigidity is rarely seen. Hypertonia contributes to impaired motor control, the development of contractures, pain, and challenges with caregiving.

## Assessment

The Hypertonia Assessment Tool (HAT) has been developed to aid in identifying the hypertonia subtypes. Spasticity can be assessed by doing a slow and fast stretch of a muscle, with spasticity diagnosed if a spastic catch and increased tone are elicited with the fast stretch. Dystonia is characterized by fluctuations in tone, in which both tone and involuntary postures can be triggered by a tactile stimulus or a voluntary movement in another body part. Clinicians use the Modified Ashworth Scale and the Modified Tardieu Scale to measure the severity of spasticity. The Modified Ashworth Scale grades the severity of the hypertonia on a 5-point ordinal scale (Table 58-1).

The Modified Tardieu Scale consists of performing a muscle stretch at two velocities, slow and fast, with measurement of the angle of the spastic catch in the fast stretch (defined as R1) and passive range during the slow stretch (defined as R2). The angular difference between R1 and R2 is defined as the dynamic window and represents the therapeutic opportunity for spasticity reduction treatments such as botulinum toxin injections. For dystonia, the Burke-Fahn-Marsden Dystonia Rating Scale and the Barry-Albright Dystonia Scale are used to grade severity.

## Interventions

Hypertonia reduction goals include the following:

1. enhanced motor performance,
2. as an adjunct to casting/splinting to increase or maintain range,
3. pain relief, and
4. enhanced caregiver ease of care.

The determination of goals is done with the child’s physical abilities in mind. For example, in children with CP, motor abilities are graded using the Gross Motor Function Classification Scale (GMFCS) (Palisano et al., 1997) (Table 58-2).

For children who are ambulatory (GMFCS level of I-III), hypertonia intervention goals focus on enhanced motor performance and maintaining range. For a severe physical disability, goals focus on ease of care and pain relief. Intervention approaches are also based on whether a child has generalized or focal hypertonia. For generalized hypertonia, oral medications or intrathecal baclofen may be good options; for focal hypertonia, botulinum toxin A injections may be a consideration.

## Spasticity Interventions

A systematic review of pharmacologic treatment of spasticity in CP identified that for focal spasticity that warrants treatment, botulinum toxin type A should be offered as an effective and generally safe treatment (level A) (Quality Standards Subcommittee of the American Academy of Neurology et al., 2010). For generalized spasticity that warrants treatment, diazepam should be considered for short-term treatment (level B), and tizanidine may be considered (level C). There was insufficient evidence to support or refute the use of dantrolene, oral baclofen, or continuous intrathecal baclofen (level U).

### 1. Nonpharmacologic Rehabilitation Strategies

All children with hypertonia benefit from rehabilitation consult to consider the following:

- stretching and positioning,
- splinting,
- casting a muscle to provide a prolonged stretch, and
- assessment of specialized equipment needs.

### 2. Oral Medications for Spasticity

Oral medications are used for generalized hypertonia when the hypertonia significantly affects care or comfort. A conservative approach is undertaken, given the potential for cognitive side effects.

Baclofen is a muscle relaxant that is an agonist for gamma-aminobutyric acid (GABA) B receptors on both presynaptic and postsynaptic neurons in the spinal cord and the brain. Baclofen is the drug of first choice for many clinicians; however, studies show inconsistent evidence. It has a short half-life (4.5 hours) and is given orally 3 to 4 times per day. Dosing recommendations are up to 2 mg/kg/day (80 mg maximal dosage), starting at a lower dosage (e.g., 2.5 mg 3 times a day) and titrating upward. Side effects include drowsiness, which can be minimized by increasing the dosage slowly. The long-term effects on cognitive function are unknown. If baclofen is discontinued, the child should be weaned to avoid withdrawal.

**TABLE 58-1** Modified Ashworth Scale

Modified Ashworth Scale Grade	Descriptor
0	No increase in muscle tone
1	Slight increase in muscle tone, manifested by a catch and release or by minimal resistance at the end of the range of motion when the affected part(s) is(are) moved in flexion or extension
1 +	Slight increase in muscle tone, manifested by a catch followed by minimal resistance through the remainder of the range of motion, but the affected part(s) is(are) easily moved
2	More marked increase in muscle tone through most of the range of movement, but the affected part(s) is(are) easily moved
3	Considerable increases in muscle tone; passive movement difficult
4	Affected part(s) is(are) rigid in flexion or extension

(Adapted from Mutlu A, Livanelioglu A, Gunel MK. *BMC Musculoskelet Disord* 2008; 9:44.)

**TABLE 58-2** Gross Motor Function Classification System (Children Aged 6–12 Years)

Level I	Walks without restrictions; limitations in more advanced motor skills
Level II	Walks without assistive devices; limitations walking outdoors and in the community
Level III	Walks with assistive mobility devices; limitations walking outdoors and in the community
Level IV	Self-mobility with limitations; children are transported or use power mobility outdoors and in the community
Level V	Self-mobility is extremely limited even with the use of assistive technology

(Adapted from Palisano R, Rosenbaum P, Walter S, et al. *Dev Med Child Neurol* 1997; 39:214–223.)

Diazepam binds the benzodiazepine-GABA receptor complex presynaptically and postsynaptically and augments GABA-mediated inhibition at the spinal cord. Diazepam is the drug of first choice for muscle spasms following orthopedic surgery. It is given three to four times per day as required, with dosage ranges of 1 to 5 mg per dose for children greater than 5 years of age. Side effects include drowsiness, memory impairment, and respiratory depression.

Tizanidine binds alpha1 adrenergic receptors presynaptically and inhibits the release of excitatory neurotransmitters in the spine. It has been used in adolescents as a second-line medication. Dosing has not been established in pediatrics, with adult dosing being a 2- to 8-mg/dose given 2 to 4 times per day. Side effects include liver dysfunction and sedation.

### 3. Neurosurgical Procedures

Intrathecal baclofen treatment consists of a pump with a reservoir for liquid baclofen that is inserted into the abdominal wall; the pump is connected to a catheter that is inserted into the intrathecal space, with the tip in the cervical or thoracic region. Baclofen is delivered as an infusion and binds to GABA

B receptors in the dorsal cord, with the dose typically ranging from 300 to 800 micrograms per day. This treatment is often reserved for severe generalized spasticity. Side effects include infections, respiratory depression, and withdrawal, including severe muscle spasms if there is a problem with the drug delivery system.

Selective dorsal rhizotomy involves a partial transection of the dorsal nerve root in the lumbar and sacral nerve roots (L1 to S2), producing a permanent reduction of spasticity in the legs. The evidence for its effectiveness to improve long-term motor outcomes is inconclusive. A critique of the evidence includes small sample sizes with limited power to explore subgroups of children who may respond better than others. Rhizotomies continue to be offered in select clinics, typically to children with bilateral spastic CP–spastic diplegic subtype who are functioning at a GMFCS level of II to III. Current surgical techniques have good safety records with minimal side effects.

### 4. Botulinum Toxin Injections

Botulinum toxin injections are used for focal management. The toxin creates a reversible neuromuscular blockade, with tone reduction that lasts approximately 2 to 3 months. There is level A evidence for its use to improve short-term motor function in children when paired with therapy as compared with therapy alone (Quality Standards Subcommittee of the American Academy of Neurology et al., 2010). Potential indications are enhanced motor function, improved range in hypertonic muscles when paired with splinting/casting, ease of caregiving, salivary management, and relief of spasms. Side effects include localized weakness and the potential for systemic spread.

### Treatment of Dystonia

Dystonia can be treated with many of the options outlined previously, including rehabilitation, oral medications such as baclofen and benzodiazepines (diazepam, lorazepam), intrathecal baclofen, and botulinum toxin injections. In addition, trihexyphenidyl and deep-brain stimulation can be considered.

Trihexyphenidyl inhibits excess cholinergic activity. Many clinicians use this as their drug of first choice, although there is minimal evidence for its effectiveness. Starting dosages are between 0.1 and 0.2 mg/kg/day in 3 to 4 divided doses. The dosage is gradually increased to 0.5 to 0.75 mg/kg/day. Side effects include dry mouth, blurred vision, confusion or sedation, urinary retention, nausea, and chorea.

Deep-brain stimulation involves the stimulation/modulation of the globus pallidus to reduce dystonia. Research has demonstrated some effectiveness for individuals with dystonic CP. This procedure is considered in severe generalized dystonia associated with pain. Potential side effects include complications from insertion of the electrodes, including hemorrhages and infection.

### MUSCULOSKELETAL DEFORMITIES

Individuals with spasticity can develop contractures and bony deformities. Musculoskeletal (MSK) deformities in nonhypertonic neurodevelopmental disorders include atlanto-axial instability and scoliosis.

Muscles that are spastic contract as the child grows, putting the child at risk for development of contractures. Strategies to promote flexibility include stretching, positioning, splints, and serial casting. Tendon releases/lengthening can be undertaken.

Children with physical disabilities are at risk for hip subluxation and dislocation (Shore, Spence, and Graham, 2012). For children with hypertonia, hip dislocation can be painful. Hip surveillance is critical and consists of a clinical assessment (e.g., GMFCS level, hip pain, difficulty opening the legs for caregiving) and an anterior-posterior (AP) x-ray with measurement of Reimer's migration percentage. Management includes positioning and bracing to stretch the adductor muscles. Surgical approaches include soft tissue releases and bony reconstruction, including femoral varus derotation osteotomies plus or minus a pelvic osteotomy.

Children with neurologic disorders (e.g., CP, Rett syndrome, Duchenne muscular dystrophy) can develop progressive scoliosis. If present, an AP spine x-ray determines the curvature (defined as the Cobb angle). An orthopedic consult is recommended. Smaller curvatures are managed with customized seating or bracing; however, if the curvature is large and progressive, spinal instrumentation is recommended.

Atlanto-axial instability (AAI) occurs when there is excessive movement between the atlas (C1) and axis (C2), and spinal compression can ensue. It is seen in Down syndrome, osteogenesis imperfecta, and skeletal dysplasias. Clinical symptoms include neck pain, spasticity, and torticollis. If warranted, a lateral cervical x-ray should be performed. AAI is defined as a distance of greater than 5 mm between the odontoid process and the posterior border of the anterior arch of the atlas.

## FEEDING AND GASTROINTESTINAL ISSUES

Children with neurodevelopmental disorders are at higher risk for feeding and nutritional problems as compared with their typically developing peers. Over half of children with CP experience difficulties with feeding or nutrition, with a higher risk of these issues in those more severely affected by the disorder. Children with neurodevelopmental disorders may have either increased or decreased resting energy expenditure compared with their typically developing peers (Marchand et al., 2006). Children with autism spectrum disorders (ASD) may have restricted diets because of their insistence on sameness in meals or sensory aversions to certain tastes or textures. Nutritional issues can result in growth failure, overweight, micronutrient deficiencies, and osteopenia, putting the child at risk of further impairment. Successful management of feeding and nutrition issues can result in fewer hospitalizations and a better overall health status for this population.

### Assessment of Feeding and Nutrition

Parents commonly experience anxiety about their child's eating habits, and it is best to first elicit the parents' concerns as well as the influence of the family's social and cultural expectations for eating. A thorough medical history should follow and must include a respiratory history to assess for any indication of aspiration leading to respiratory disease, and a gastrointestinal history eliciting symptoms of gastroesophageal reflux (GER), vomiting, or constipation. Medications such as atypical antipsychotics may result in increased appetite, whereas others, such as stimulants used in the treatment of attention-deficit/hyperactivity disorder (ADHD), may lead to decreased appetite. An essential element of the history is a description of the child's developmental skills; this will provide the lens through which to determine expectations for feeding skills. The clinician then obtains a detailed feeding history (Table 58-3).

When possible, age-referenced growth percentiles for height, weight, and body mass index should be monitored using the World Health Organization growth charts (or CDC

**TABLE 58-3** Feeding History

<b>MODE OF FEEDING</b>	By mouth, nasogastric tube, gastrostomy tube, gastrojejunal tube
<b>TIMING OF FEEDING</b>	Time of meals and snacks Length of meals Length of feeds for those with feeding tubes (including continuous/overnight feeding)
<b>LOCATION OF FEEDING</b>	Positioning (upright versus supine—may be relevant for gastroesophageal reflux) Seating support (consider gross motor developmental level) Behavioral elements (e.g., at the table versus in front of television)
<b>NUTRITIONAL COMPOSITION AND VARIETY OF FOOD</b>	Food offered at each meal Same or different from what the rest of the family is eating Considerations of food groups, caloric intake, and vitamins/minerals/fiber
<b>CONSISTENCY OF FOOD</b>	The prepared texture of the food Which consistencies cause problems (solids versus thin liquids) Concurrent difficulty managing oral secretions
<b>DESCRIPTION OF THE CHILD DURING FEEDING</b>	Delayed or multiple swallows (indicative of oral-motor coordination difficulties) Gaspings/choking (indicative of aspiration) Arching (indicative of gastroesophageal reflux)

(Adapted from Marchand V, Motil KJ, NASPGHAN Nutrition Committee. *J Pediatr Gastroenterol Nutr* 2006; 43:123–135.)

charts after 2 years of age). For a child whose height is limited by the disorder, it may be necessary to plot weight according to the age at which the child's height represents the 50th percentile. In children with musculoskeletal issues preventing accurate measurement of height, measurements of the upper arm and lower leg can be obtained and compared against reference standards. Other measurements, such as triceps skinfold thickness, can provide information about the child's nutritional status.

A systematic physical examination should follow. The respiratory examination should include auscultation for any signs of chronic lung disease resulting from aspiration. The gastrointestinal examination should include examination of dentition (including signs of enamel erosion from GER) and a full abdominal examination. A fecal mass felt in the abdomen indicates constipation.

### Investigations

The most definitive investigation for dysphagia is the video fluoroscopic swallowing study, in which the child is given various textures of food mixed with barium. The progression of the barium from the mouth to the stomach is captured on video to assess for aspiration, dysmotility, and GER.

## Management of Common Feeding and Nutritional Issues

### Gastroesophageal Reflux

GER is a common comorbidity and can be an important cause of pain. Medical management begins with a proton-pump inhibitor. Medications such as domperidone can be used

to promote gastric motility, although there are potentially significant adverse effects associated with these agents, including cardiac conduction abnormalities. If conservative measures fail, a gastrostomy/gastrojejunal feeding tube or surgical fundoplication may be warranted.

### Constipation

Constipation is a common condition in children with neurodevelopmental disorders. Polyethylene glycol is a well-tolerated and effective oral agent. Management usually begins with a dose to achieve a “cleanout,” with the goal being to completely empty the bowel. After this, polyethylene glycol can be titrated to a dose that results in a daily soft bowel movement.

### Need for Gastrostomy Feeding Tubes

Because of difficulties in oral-motor coordination, prolonged feeding time, and the potential for nutritional deficiencies, some children with neurodevelopmental disorders require a feeding tube. Although this is often a difficult decision for parents, gastrostomy tubes are associated with improved weight gain, decreased feeding time, and increased quality of life for caregivers.

## SEIZURES IN NEURODEVELOPMENTAL DISORDERS

Seizures and epilepsy, the condition of recurrent unprovoked seizures, affect up to 50% of children with neurodevelopmental disorders (Depositario-Cabacar and Zelleke, 2010). Seizures are more likely in children with more complex neurodevelopmental disabilities (Faulkner and Singh, 2013). Children with CP and intellectual disability or ASD and intellectual disability are more at risk of seizures than those with intellectual disability alone. In contrast to typically developing children, those with neurodevelopmental disorders are also more likely to have both earlier-onset epilepsy and lifelong drug-resistant seizures.

### Diagnosis

Diagnosis of seizures in children with neurodevelopmental disorders may be difficult because of the presence of stereotypes and motor and cognitive impairments that mimic seizures. Children with neurodevelopmental disorders often present with nonepileptic events that resemble clinical seizures without an electrographic correlate. When clinical seizures are suspected, a careful history should include an account of clinical events that details semiology, duration, and frequency. If the history is suggestive of seizures, an electroencephalogram (EEG) should be performed.

EEGs may demonstrate both nonepileptiform and epileptiform abnormalities. Nonepileptiform abnormalities, such as focal and/or generalized slowing, are more likely to be identified in children with neurodevelopmental abnormalities and are not necessarily associated with an increased risk of seizures. Epileptiform abnormalities, such as spike and slow-wave discharges, are associated with an increased risk of seizures. With a strong clinical history for seizures and an EEG finding of epileptiform discharges, a presumptive diagnosis of seizures can be made. When clinical events are difficult to characterize, a prolonged video EEG may capture events to clarify diagnosis.

Children with neurodevelopmental disorders may have abnormalities on EEGs, even in the absence of clinical seizures. The contribution of epileptiform discharges to cognitive

impairment in children with neurodevelopmental disorders remains controversial. In the syndromes of continuous spike-wave in sleep (CSWS) and Landau-Kleffner syndrome (LKS), typically developing children present with electrical status epilepticus of sleep (ESES) and cognitive regression. Successful treatment and resolution of the ESES is associated with an improvement in cognition, suggesting that the epileptiform discharges, rather than seizures, are responsible for the cognitive regression. However, whether this phenomenon can be generalized to children with cognitive impairment in the context of other neurodevelopmental disorders is not clear.

### Treatment

The goal of seizure treatment is the same in all children: freedom from seizures without treatment side effects and optimized quality of life. There are some special considerations when treating seizures in children with neurodevelopmental disorders.

### Antiepileptic Drug Adverse Effects

Children with neurodevelopmental disabilities may not be able to clearly communicate the presence of treatment-related adverse effects. It is important to inform caregivers of the potential for specific adverse effects to allow for careful monitoring at home. Children with an intellectual disability may be more sensitive to the sedation associated with some antiepileptic drugs (AEDs). Nonverbal children may demonstrate agitation or aggression in response to certain AEDs. When caregivers report adverse effects, a dose reduction may be sufficient to reduce the effect. When dose adjustments do not result in remission of adverse effects, a change in AED should be undertaken.

### Polypharmacy

Children with neurodevelopmental disorders often have multiple seizure types and drug-resistant seizures requiring multiple AEDs. Because polypharmacy is associated with an increased incidence of adverse effects, efforts should be made to minimize polytherapy. This may include reducing the number of AEDs or reducing the dose of each AED when multiple drugs are used in combination. When a single drug fails to control seizures and a second is added with good effect, an effort should be made to reduce the first drug to avoid polypharmacy. When required, the adverse effects of polypharmacy can be limited by selecting drugs that utilize varied mechanisms of action and by considering drug interactions.

### Withdrawal of Antiepileptic Drugs

Although many children with seizures and neurodevelopmental disabilities will require lifelong AED therapy, withdrawal of the AED should be *considered* in children who have been seizure-free for 2 years or more. Caregivers should be instructed in the use of a rescue medication, such as rectal, nasal, or buccal benzodiazepines.

### Drug-Resistant Epilepsy

Children with neurodevelopmental disorders often present with drug-resistant seizures, defined as failure to achieve seizure freedom with an adequate trial of two appropriate AEDs. These children should be referred to a comprehensive epilepsy program for surgical assessment. For children not deemed to be resection surgery candidates, vagal nerve stimulation and ketogenic diet treatment should be considered.

## Treating Seizures in Children with Attention-Deficit/Hyperactivity Disorder

There has been concern that medications used to treat ADHD may lower the seizure threshold in children with and without epilepsy. This is not well supported by evidence, but is frequently listed in information leaflets. An evidence-based review determined that methylphenidate is associated with a low risk of seizures in children with well-controlled epilepsy. There is also emerging evidence that methylphenidate can be used safely in children with difficult-to-treat epilepsy. In clinical practice, ADHD treatments are frequently combined with AEDs. When seizure frequency increases with the addition of an ADHD treatment, an adjustment to AED treatment may be needed.

## Treating Seizures in Children with Cerebral Palsy

The sedating effects of some AEDs may particularly affect children with low axial tone, resulting in impaired swallowing and risk of aspiration. Caregivers should be advised to monitor for sedation and changes in airway protection in vulnerable children. Excess sedation may also have an adverse effect on quality of life in children with CP.

## FRAGILITY FRACTURES (OSTEOPOROSIS)

Children with physical disabilities can sustain fragility fractures. Decreased weight bearing, poor nutritional status, and medications (e.g., steroids and AEDs) increase risk. An evidence-informed practice guideline recommends preventative strategies of optimizing nutrition and dietary calcium, supplementing vitamin D, and promoting weight-bearing activity (Fehlings et al., 2012). For individuals with a fragility fracture, a bone mineral density test should be undertaken and bisphosphonates considered.

## SLEEP DISORDERS

Up to 80% of children with neurodevelopmental disorders experience sleep disorders, including difficulty initiating or maintaining sleep and sleep-disordered breathing, such as obstructive sleep apnea (Simard-Tremblay et al., 2011). Sleep difficulties influence behavior and learning, and create chronic stress for caregivers.

It is important to consider underlying triggers for night awakenings. Children with hypertonia can experience muscle pain, leading to awakenings. Children with severe physical disabilities are not able to reposition themselves and require repositioning. Pain from esophagitis is worsened when the child lies down. Seizures can lead to disrupted sleep.

Behavioral approaches can be considered for difficulty initiating and maintaining sleep, with a focus on establishing a bedtime routine, teaching the child to fall asleep alone, and minimizing positive interactions that happen during the night (e.g., parental contact). Behavioral approaches should be tried before medications (e.g., melatonin or clonazepam). A systematic review of melatonin found it to be “probably effective” at assisting with bedtime settling, but not effective for night awakenings.

## BEHAVIOR

Behavioral problems are among the most frequent concerns in children with neurodevelopmental disorders. Many neurodevelopmental disorders have a high co-occurrence with other behavior-based disorders; for instance, the reported frequency

of ADHD symptoms in children with ASD ranges from 20% to 78%.

Although there is a biological basis underpinning behavior problems in neurodevelopmental disorders, it is important to remember that behavior is shaped by interactions with the environment. Because of this, it is important not to simply attribute the problem behavior to the diagnosis, as a more in-depth exploration can lead to effective management strategies. It is also essential to base one’s behavioral expectations on the child’s developmental age, instead of chronologic age.

## Assessment of Behavior

The list of medical conditions that can present with a change in behavior covers every bodily system. Individuals with difficulty communicating may have trouble expressing pain, and any change in behavior needs to be met with a thorough review of systems to ensure that no treatable source of pain is missed. Investigations should be based on a differential diagnosis and should be undertaken systematically.

Many behavior experts suggest an ABC approach to evaluating behavior (Antecedent conditions, Behavior, and Consequences). Antecedent conditions are those that directly precede the behavior. One useful question to ask parents and caregivers is, “If I were to offer you a large sum of money to get the child to perform the behavior, what strategy would you try?” This can often help to identify the most successful strategy. Next, the clinician should get a thorough description of the target behavior by asking whether the behavior is directed toward others, property, or the child himself or herself. This can provide clues to the underlying function of the behavior (is there something the child is trying to gain/avoid?), and help to identify significant safety concerns that warrant more intensive intervention. The consequences for behavior powerfully shape the likelihood of using the same behavior in the future. If the child is inadvertently rewarded for the behavior, this may further reinforce it.

Consideration must also be given to the child’s social situation. Changes in behavior are a common presenting symptom of nonaccidental injury or neglect, and the clinician must always be attuned to and ready to report any indication of maltreatment. The social situation may also inform the management strategy, because the insight and willingness of families needed to implement behavioral strategies will differ.

## General Principles of Management of Behavior Problems

In general, behavioral interventions should be attempted before prescribing psychoactive medications. Behavioral strategies are developed after assessing the function of the behavior using the ABC method and can focus on both antecedent conditions and consequences. Some common strategies to improve antecedent conditions include providing ample warning for transitions, avoiding moving from preferred to nonpreferred activities, and allowing choices between acceptable activities. Basic consequence-based strategies can include a token economy or reward system and redirection to an alternative activity. If simple measures are not effective, consultation with an expert in behavioral management is appropriate.

## Psychopharmacology

A full discussion of the use of psychoactive medications is beyond the scope of this chapter. For some neurodevelopmental disorders, such as ADHD, there are various medications with good evidence of effectiveness. For other disorders, such

as ASD, there are currently no medications that treat the core symptoms, and instead medications are often prescribed based on co-occurring symptoms, such as ADHD-like symptoms, anxiety, or aggression. When considering prescribing a medication for a child with a neurodevelopmental disorder, it is important to clearly define the target behavior(s) and to determine how any improvement will be demonstrated. Further, psychoactive medications have varying adverse-effect profiles, and it is important to routinely monitor for these. An excellent resource for monitoring for adverse effects of atypical antipsychotics is the 2015 [Canadian Alliance for Monitoring Effectiveness and Safety of Antipsychotics in Children \(CAMESA\)](#) guideline.

## INTRODUCTION

This chapter aims to provide an overview of the exciting advances made over the past decades in the development and implementation of “targeted” or “causal” treatments for neurodevelopmental disorders (NDDs), defined as interventions targeting the underlying pathophysiology at a cellular or molecular level. NDDs can be regarded as phenotypes of many genetic conditions with manifestations that include intellectual developmental disability (IDD; defined as intellectual disability with an IQ < 70 at age 5+ years or global developmental delay with deficits in two or more developmental domains at < 5 years), learning disabilities, or autism spectrum disorder (ASD), with or without comorbidities such as epilepsy, cerebral palsy/motor dysfunction, and behavioral disturbances/psychiatric diseases. In this chapter we briefly discuss causal therapies for the following sets of conditions: (1) genetic NDD syndromes, including fragile X syndrome (FXS), Rett syndrome (RS), tuberous sclerosis complex (TSC), and Down syndrome (DS); and (2) inborn errors of metabolism (IEMs) and congenital hypothyroidism (CH). Although NDDs are heterogeneous in etiology, phenotypic presentation, and treatment types, early identification is a prerequisite for initiation of specific intervention to improve outcomes and reduce family burden. Diagnosis is a challenge given the rarity of these conditions, so general awareness and tools (genome-wide sequencing, digital apps) to facilitate diagnosis by clinicians are essential. A systematic approach to the identification of genetic conditions amenable to treatment in children with NDDs shows that collectively these rare diseases account for a significant proportion of cases. The effects, types, and accessibility of treatments vary widely between disorders and patients. Low patient numbers combined with a large heterogeneity in genotypes, phenotypes, and response size and type pose significant challenges to meeting evidence-based standards for treatments. We outline approaches to these challenges and progress in treatment of NDDs.

## RETT SYNDROME, DOWN SYNDROME, TUBEROUS SCLEROSIS, AND FRAGILE X SYNDROME

### General Concepts Surrounding Treatment for Neurodevelopmental Disorders

Given the impossibility of doing controlled trials for every treatment used in a rare NDD, current medical treatments utilized for NDDs are often employed off-label based on a generalization from other disorders and/or based on symptoms for which there are approved treatments. For only a handful of cases are there specific disease-related treatments approved by the U.S. Food and Drug Administration (FDA) that have demonstrated efficacy in controlled trials. Historically, treatment for NDDs has been almost entirely supportive, designed to support the person to achieve the highest level of adaptive development and function possible and treat co-occurring medical, neurologic, and behavioral symptoms

that may be interfering with function. This could include medical support for control of seizures, sleep management, behavioral modification and/or psychopharmacology for maladaptive behaviors, and special education programs, in addition to cognitive behavioral, occupational, speech/language, and physical therapy. These interventions do not fully treat the disorder and are not directed at the underlying mechanism of disease. Thus there is clearly an unmet need in NDDs, and treatments that modify the underlying disorders would be a tremendous advance.

NDDs have a highly heterogeneous etiology with many very-low-incidence but high-impact single-gene or contiguous-gene causes, and even more combinations of common low-impact genetic risk factors operating in concert. Because targeting such a broad array of potential etiologies with specific therapies is virtually incomprehensible, single-gene NDDs, such as TSC, FXS, and RS, have emerged as neurobiological models in which extensive study of the neurobiology and synaptic mechanisms of disease in cellular and animal models has identified compounds that target the underlying disorder. These conditions also serve as clinical models for translation of such targeted treatments to humans. DS, with abnormal gene dose for many genes, is a model for identifying the final common effects of multiple gene defects at a systems level in the brain and then directing treatment to correction of the systems defect. [Table 59-1](#) shows targeted treatments now being explored for genetic NDDs.

## Rett Syndrome

RS is primarily caused by loss-of-function mutations in the X-linked *MeCP2* (*methyl-CpG-binding protein 2*) gene ([Pozzo-Miller, Pati, and Percy, 2015](#)). Girls are predominantly affected, with variation in the phenotype related to both genotype and X-inactivation. Girls with classical RS have normal early growth and development up to 6 to 18 months, followed by regression with acquired microcephaly, a loss of purposeful hand use, stereotyped movements including hand wringing, gait apraxia and ataxia, tremor, seizures, apnea, hyperventilation, severe IDD, and features of ASD.

*MeCP2* codes for a protein that binds to methylated DNA and regulates gene transcription. Genetic correction and restoration of *MeCP2* gene expression in neurons or glia has proven to be sufficient to rescue abnormal behavioral and synaptic phenotypes of the *MeCP2* knockout mouse. *MeCP2* appears to regulate insulin-like growth factor-1 (IGF-1) and Akt signaling activity in the *MeCP2* knockout mouse, and IGF-1 or its terminal tripeptide restores dendritic spine dynamics and reverses many Rett-like features, including locomotor impairment, breathing abnormalities, and heart-rate irregularities, in *MeCP2* knockout mice.

A phase 1 proof-of-concept trial of recombinant human IGF-1 in girls with RS showed good safety and improved apnea, anxiety, and mood scores, along with reversal of right frontal alpha-band asymmetry on electroencephalogram (EEG). A phase 2a double-blind placebo-controlled trial of NNZ-2566 (Neuren Pharmaceuticals), a peptidase-resistant

**TABLE 59-1** Targeted Treatments in Clinical Development (2015) for Genetically Defined Neurodevelopmental Disorders\*

NDD	Treatment	Target From Animal/Cellular Models	Development Phase
Fragile X syndrome	Lithium	Inhibits excessive GSK3B signaling and PI turnover	1
	AFQ056	mGluR5 NAM—reduces mGluR5-regulated activation of dendritic translation	2b
	RO4917523	mGluR5 NAM—reduces mGluR5-regulated activation of dendritic translation	2b
	Arbaclofen	GABA-B agonist—reduces presynaptic glutamate release	3
	Minocycline	Reduces excessive activity of MMP-9 resulting from dysregulation in absence of FMRP	2
	Ganaxolone	GABA-A agonist—increases deficient GABA signaling	2
	Acamprosate	GABA-A/B agonist	2
	NNZ-2566	Inhibits excessive ERK/Akt signaling	2
	Metadoxine	Inhibits excessive ERK/Akt signaling	2
Lovastatin	Inhibits ERK pathway	1	
Down syndrome	RG1662	GABA-A $\alpha 5$ receptor subunit inverse agonist—reduces excessive GABA signaling	2b
Rett syndrome	Mecasermin (rhIGF-1)	Activation of Akt pathway	1
	NNZ-2566	Akt pathway effects, reversal of LTP/dendritic spine deficits	2
	Fingolimod	Increases BDNF through binding of S1P receptors	1
	Glatiramer Acetate	Increases BDNF	2
Tuberous sclerosis complex	Everolimus	Inhibits excessive mTOR activity	2
Neurofibromatosis	Everolimus	Inhibits excessive mTOR activity	2
	Lovastatin	Inhibits ERK pathway	2
Phelan–McDermid syndrome	IGF-1 (Increlex)	Activation of Akt pathway	2
Angelman syndrome	Minocycline	Increase LTP	2
Prader–Willi syndrome	Oxytocin	Deficit in oxytocin neurons	2

\*BDNF, brain-derived neurotrophic factor; GABA, gamma-aminobutyric acid; IGF-1, insulin-like growth factor-1; LTP, long-term potentiation; mTOR, mammalian target of rapamycin; NAM, negative allosteric modulator; NDD, neurodevelopmental disorder.

analog of the IGF-1 terminal tripeptide, in 53 girls with *MeCP2* mutation-confirmed RS showed good safety, improvement in three different efficacy domains, and improvement in a subject-specific efficacy score summing the direction of change in all efficacy outcome measures when compared for NNZ-2566 and placebo. This analysis itself represents a novel solution to the problem of measuring efficacy across multiple domains for a targeted treatment in an NDD.

## Down Syndrome

DS (trisomy 21), is the most common genetic cause of IDD (Martinez-Cue et al., 2013). There is high unmet need to develop effective therapies to improve learning, memory, and speech in those with DS, to improve functioning and increase independence. Ts65Dn mice have an extra chromosome 16 in an area analogous to human chromosome 21 and have neuronal morphology similar to that of humans with DS; these mice show deficits in learning and memory, which appear to result from a selective decrease in the number of excitatory synapses and excessive gamma-aminobutyric acid (GABA)-mediated inhibition. Use of GABA-A receptor antagonists, particularly nonconvulsant, nonanxiogenic GABA-A receptor inverse agonists selective for the  $\alpha 5$ -subtype ( $\alpha 5$ IA, RO4938581), successfully improved memory and learning deficits, normalized excessive GABAergic synaptic markers, and reversed hippocampal long-term potentiation (LTP) deficits in the Ts65Dn mouse (Martinez-Cue et al., 2013). Based on the preclinical work, RG1662, a selective orally active GABA-A  $\alpha 5$  receptor subunit inverse agonist with high selectivity for the GABA-A  $\alpha 5$  subunit-containing receptor RG1662, was studied in a phase 2a placebo-controlled safety/pharmacokinetics (PK) trial in DS. RG1662 had a good safety profile and is currently in a placebo-controlled phase 2b efficacy trial targeting

memory, language, and cognition in adults with DS, and a safety/PK trial in adolescents and children with DS.

## Tuberous Sclerosis

Tuberous sclerosis complex (TSC) is a genetic multisystem disorder associated with dermatologic findings; growth of benign tumors in the brain, skin, kidneys, heart, liver, and lungs, and less frequently in the retina, gingiva, bones, and gastrointestinal tract; epilepsy; ASD; IDD; and other behavioral problems (Ebrahimi-Fakhari and Sahin, 2015). Magnetic resonance imaging (MRI) of the brain frequently shows cortical tubers (focal malformations of cortical development characterized by disorganized lamination and giant cells expressing markers of neuronal and glial differentiation) and subependymal nodules (SENs), which can evolve into subependymal giant-cell astrocytomas (SEGAs).

TSC is caused by a mutation of either *TSC1* or *TSC2*. *TSC1* and *TSC2* proteins function as a heterodimeric complex to inhibit mammalian target of rapamycin (mTOR) signaling. mTOR is a kinase that integrates multiple signals to regulate cellular growth, axon growth and specification, synapse development, and synaptic plasticity by modulating translation initiation. Mutations of either *TSC1* or *TSC2* release inhibition of mTOR, resulting in constitutive activation of the mTOR pathway. Rapamycin (sirolimus) inhibits mTOR activity and was shown to improve myelination and cytopathologic architecture, restore normal synaptic function, eliminate epilepsy, prolong survival, and reverse learning and social deficits in TSC mice. Sirolimus (rapamycin) and everolimus (rapamycin analog) were shown to reduce the size of renal angiomyolipomas and SEGAs in patients with TSC. Everolimus is FDA approved for treatment of SEGAs at any age and renal angiomyolipomas in adults with TSC. An open-label trial of

everolimus in 20 TSC patients with refractory epilepsy showed reduction of seizure frequency/duration and improved behavior and quality of life. A current randomized placebo-controlled phase 2 study aims to assess the effect of everolimus on neurocognition, seizures, sleep, ASD, behavior, and academic skills.

## Fragile X Syndrome

FXS, the most common known inherited cause of IDD and ASD, is caused by a trinucleotide repeat (CGG) expansion mutation of more than 200 CGG repeats (termed the “full mutation”) in the promoter region of *FMR1* (*fragile X mental retardation 1*), which results in methylation and transcriptional silencing of *FMR1* with consequent loss or significant reduction in expression of FMRP (fragile X mental retardation protein) (Gross, Hoffmann, Bassell, and Berry-Kravis et al., 2015). Females with FXS are more mildly affected than males as a result of production of FMRP from the normal *FMR1* allele in cells expressing the nonmutated X chromosome.

FMRP is an mRNA binding protein that regulates (inhibits) dendritic translation of proteins involved in synaptic plasticity in response to synaptic activation by multiple Gq-linked receptors, including group 1 metabotropic glutamate receptors (mGluR1/mGluR5). Activation of these receptors results in signaling through ERK- and mTOR-dependent pathways, resulting in loss of FMRP repressor function at the ribosome and a pulse of new protein synthesis. FMRP also regulates the activity of some presynaptic and postsynaptic ion channels, such as BK and SLACK channels, through direct protein-protein interactions. These regulatory functions of FMRP are critical for synaptic maturation and plasticity. In the *Fmr1* knockout mouse, there is a constitutive elevation of synaptic proteins usually controlled by FMRP and immature elongated morphology of dendritic spines, abnormal spine density, and abnormal synaptic plasticity, including excessive internalization of AMPA receptors; enhanced mGluR-activated hippocampal and cerebellar long-term depression (LTD); impaired LTP in the hippocampus, cortex, and amygdala; impaired circuit physiology; and audiogenic seizures. The morphologic abnormalities and synaptic plasticity deficits found in the *Fmr1* knockout mouse are associated with numerous learning, social, and behavioral phenotypes. The *Drosophila* model of FXS shows defects in circadian rhythms, synaptic branching, courtship behavior, and learning.

The abnormalities observed in the *Fmr1* knockout mouse have led to treatment targets directed at (1) reduction of excess signaling from group 1 mGluRs or other Gq-linked receptors to the dendritic translational machinery, (2) reduction of excessive activity of individual proteins normally regulated by FMRP, (3) increased activation of surface AMPA receptors, (4) modification of activity of GABA and other systems that regulate glutamate signaling, (5) blocking of excessive translation of FMRP-regulated mRNAs, and (6) correction of abnormal channel activities normally directly regulated by FMRP (Table 59-2). Treatments aimed at all of these types of targets, in particular mGluR5 negative allosteric modulator (NAMs), have resulted in pharmacologic and genetic reversal of a remarkable number of phenotypes in the *Fmr1* knockout mouse and *dfxr* fly models.

The successful preclinical testing in FXS models has led to early proof-of-concept clinical trials and some subsequent larger trials for proposed targeted treatments. Several agents have shown benefits in early-phase or open-label trials in FXS: lithium (mechanism 1 in previous list, reduces phosphatidylinositol [PI] turnover and GSK3B activity) resulted in improvement in behavior, verbal memory, and abnormal ERK phosphorylation rates in lymphocytes; minocycline

(mechanism 2, inhibits MMP9) resulted in mild improvement over placebo in global behavior and reduction of blood MMP-9 levels in responders; arbaclofen (mechanism 4, GABA-B agonist, lowers presynaptic glutamate release) showed improvement over placebo for social withdrawal and parent-nominated problem behaviors; acamprosate (mechanism 4, GABA-A/GABA-B agonist) showed improvement in hyperactivity and social functioning; fenobam (mechanism 1, mGluR5 NAM) showed improvement in abnormal prepulse inhibition (PPI); and AFQ056 (mechanism 1, mGluR5 NAM) suggested improvement in maladaptive behavior over placebo in a posthoc analysis in the subgroup with full methylation of *FMR1*. Larger placebo-controlled trials of arbaclofen, AFQ056, and RO4917523 (mGluR5 NAM) over 3 months in adults and adolescents with FXS have not shown behavioral benefit but have addressed cognitive or learning outcomes. A phase 3 arbaclofen trial in children with FXS showed improved behavior and parenting stress in the highest-dose group relative to placebo, but full analyses are pending. FXS has been an important model to illustrate hurdles in the translation of targeted treatments to NDDs, given problems demonstrating efficacy for behavior in larger trials and ongoing uncertainties about how to optimally demonstrate changes in the disease course in a clinical trial setting. It is clear that issues related to outcome measures, placebo effects, length and timing (age) of treatment, and how to study learning need to be solved to be able to demonstrate the potential benefits of these drugs for synaptic plasticity, as seen in animal models.

## Generalization of Treatment From Single-Gene Disorders to NDDs and ASD

RS, TSC, and FXS all show significant clinical and molecular pathway overlaps with ASD and NDDs (Ebrahimi-Fakhari and Sahin, 2015; see Table 59-1). Dysregulated mTOR signaling in TSC results in abnormal dendritic regulation of translation, and other proteins in the mTOR pathway are products of genes associated with ASD and NDDs, including mutations of neurofibromin 1 in neurofibromatosis type 1 (NF-1) and phosphatase and tensin homolog in PTEN-deficiency syndromes. This suggests that dysregulation of the TSC/mTOR pathway predisposes to ASD and that mTOR inhibitors that treat TSC may be effective for a subgroup other NDDs, such as efficacy of sirolimus for growth of plexiform neurofibromas in NF-1.

There is also significant molecular and cellular pathway overlap between FMRP and gene products associated with ASD and NDDs (Figs. 59-1 and 59-2). Like TSC1/TSC2, FMRP is a regulator of mTOR-dependent dendritic translational activation pathways. The Akt pathway is dysregulated in both RS and FXS; this discovery led to a phase 2 clinical trial of NNZ-2566 in FXS that illustrated potential targeted treatment overlap between NDDs sharing dysregulated molecular pathways. Molecular overlap between FXS and other ASD/NDDs is focused on signaling of dendritic translational regulation, which is one of the key pathways onto which gene products associated with autism cluster, and falls roughly into three categories: (1) defects in proteins in the signaling cascade modulating FMRP-regulated translation, (2) defects in proteins regulated directly by FMRP, and (3) defects in proteins involved in the balance of glutamate and GABA systems. Indeed, the FMRP/ASD/NDD pathway overlap has been recently supported by the findings that: (1) FMRP binds about a third of the genes associated with ASD in exome screening studies, (2) genes that code for FMRP target mRNAs are more likely than other genes with similar expression patterns to contribute to ASD, and (3) common variants in genes involved in postsynaptic regulation of FMRP are risk factors for ASD. If

targeted treatments directed at molecular pathways, as in TSC, RS, FXS, or other single-gene NDDs, and treatments for circuit dysfunction and glutamate/GABA balance as in DS are ultimately successful (Table 59-1), it is possible that these can be extended to reverse neural defects and clinical manifestations in subgroups of ASD and NDDs with shared pathway deficits.

## INBORN ERRORS OF METABOLISM

IEMs constitute a large group of monogenic conditions characterized by impaired chemical intracellular transformations that typically affect the synthesis or breakdown of molecules, leading to the accumulation of toxic molecules, or lack of cell energy or necessary substrates for many important biochemical processes. The majority of these affect the central nervous system (CNS) in the child and thus present as neurodevelopmental disabilities, specifically IDD, epilepsy, cerebral palsy, autism, and behavioral and psychiatric disturbances.

## Intellectual Developmental Disabilities

An overview of the 89 IEMs presenting with IDD as the predominant phenotypic feature for which causal therapy was available in 2015 (van Karnebeek and Stockler, 2012; van Karnebeek, Shevell, Zschocke, Moeschler, and Stockler, 2014) is provided in Table 59-3. Nearly all of these conditions are associated with additional phenotypic features. Neurologic features include ataxia, behavioral disturbance, dementia, dystonia, encephalopathic crisis, epilepsy, hearing loss, hypotonia/myopathy, neuroimaging abnormalities (basal ganglia, cerebellum, cerebrum, cysts/dysgenesis, white matter, mixed), neuropathy, ocular movement abnormality, psychiatric disturbance, sensorineural hearing loss, spasticity, stroke, vision loss, and various types and degrees of movement disorders (e.g., spasticity, dyskinesia, and ataxia). However, it is important to note that a significant number of these conditions can present with unspecific IDD as the sole feature (e.g., creatine transporter deficiency). Other presentations vary from neurodegenerative +/- multiorgan involvement to "stable IDD" (i.e., without a history of regression or plateauing); some are characterized by acute decompensations—often in the neonatal or early childhood period—or present with a late-onset form of unspecific or chronic nature. Of note, nonneurologic or systemic features is a prominent phenotype in 57 (64%) of the 89 treatable IDs listed in Table 59-3.

## Diagnostic Approach to Treatable Inborn Errors of Metabolism

To enhance early diagnosis of treatable IEMs in children presenting with IDD, the two-tiered TIDE protocol was designed (Box 59-1). The first tier involves biochemical group tests in blood and urine, which potentially indicate 60% of the currently known treatable conditions. The next step is to apply the 2014 diagnostic practice parameters for IDD, which include chromosome microarray as a first-line test and, in selected cases, fragile X testing, neuroimaging, and other tests, in combination with the second tier of the TIDE algorithm for the identification of the remaining 35 treatable IDs. The latter conditions require a more targeted approach, including single-metabolite or primary molecular analysis, based on a clinical differential diagnosis; these tests often require more invasive sampling procedures and/or extensive funding. A free digital application is available (via [www.treatable-ID.org](http://www.treatable-ID.org) and the Apple App store as the TIDE-BC App) that supports the diagnostic algorithm and provides information on the symptoms, tests, and treatments for these rare diseases.

### BOX 59-1 Two-Tiered Algorithm for Diagnosis of Treatable IEMs in IDD\*

#### FIRST TIER: IN ALL PATIENTS WITH UNEXPLAINED ID, NONTARGETED SCREENING TO IDENTIFY 54 (60%) TREATABLE IEMs

##### Blood:

- Ammonia, lactate
- Plasma amino acids
- Total homocysteine
- Acylcarnitine profile
- Copper, ceruloplasmin

##### Urine:

- Organic acids
- Purines and pyrimidines
- Creatine metabolites
- Oligosaccharides
- Glycosaminoglycans

#### SECOND TIER: TARGETED METABOLIC WORKUP TO IDENTIFY 35 (40%) TREATABLE IEMs REQUIRING SPECIFIC TESTING

According to patient's symptomatology and clinician's expertise. Utilization of textbooks and digital resources (e.g., app available at [www.treatable-ID.org](http://www.treatable-ID.org))

Consider the following biochemical/gene tests:

- Whole-blood manganese
- Plasma cholestanol
- Plasma 7-dehydroxy-cholesterol:cholesterol ratio
- Plasma pipercolic acid and urine alpha-AASA
- Plasma very-long-chain fatty acids
- Plasma vitamin B<sub>12</sub> and folate
- Serum and CSF lactate:pyruvate ratio
- Enzyme activities (leukocytes): arylsulphatase A, biotinidase, glucocerebrosidase, fatty aldehyde dehydrogenase
- Urine deoxypridonoline
- CSF amino acids
- CSF neurotransmitters
- CSF:plasma glucose ratio
- CoQ measurement fibroblasts
- Molecular analyses: *CA5A*, *NPC1*, *NPC2*, *SC4MOL*, *SLC18A2*, *SLC19A3*, *ALC30A10*, *SLC52A2*, *SLC52A3*, *PDHA1*, *PDHX*, *SPR*, *TH* genes

Note: The first-tier testing comprises group metabolic tests in urine and blood that should be performed in every patient with IDD of unknown cause. Based on the differential diagnosis generated by the patient's signs and symptoms, the second-tier test is ordered individually at a low threshold.

\*alpha-AASA, alpha-aminoadipic semialdehyde; CSF, cerebrospinal fluid; IDD, intellectual developmental disability; NDD, neurodevelopmental disability.

## Treatments, Outcomes, and Evidence

Treatments include dietary restriction/supplementation, cofactors/coenzymes, vitamins, substrate inhibition, (small molecule) substrate reduction, enzyme replacement, bone marrow and hematopoietic stem cell transplant, and gene therapy (Fig. 59-3) (van Karnebeek and Stockler, 2012). The majority of treatments are affordable, accessible, and safe. Therapeutic effects include improvement in and/or stabilization of psychomotor and cognitive development, behavioral and psychiatric disturbances, seizures, and neurologic and systemic manifestations. As shown in Table 59-3, improvement of cognitive and psychomotor development is only achieved for 20% of IEMs, whereas for the majority of treatable IDs, related outcomes are positively influenced by therapy. Inherent to small patient numbers in diseases such as these, evidence levels are often limited (most rank at level 4). This is

**TABLE 59-3** Overview of Treatable Inborn Errors of Metabolism Presenting With Intellectual Developmental Disability (*n* = 89 in 2015)

Biochemical Category	Disease Name	MIM #	Major Phenotype	Therapeutic Modality(-ies)	Treatment Effect	Level(s) of Evidence	Clinical Practice
Amino acids	Hyperornithinemia-hyperammonemia-homocitrullinemia (HHH) syndrome	238970	IDD, epilepsy, psych, CP	Dietary protein restriction, ornithine supplement, sodium benzoate, phenylacetate	B, C, D, E, F, G	4	Standard of care
	late-onset (l.o.) Non-ketotic hyperglycinemia	605899	IDD, epilepsy, psych, CP	Glycine restriction; +/-sodium benzoate, NMDA receptor antagonists, other neuromodulating agents	B, D, E, F	4-5	Standard of care
	Phenylketonuria	261600	IDD, epilepsy, psych, CP	Dietary phenylalanine restriction +/- amino-acid supplements [BH4 supplement]	B, D, E [C]	2a (4)	Standard of care [individual basis]
	3-Phosphoglycerate dehydrogenase (3-PHGDH) deficiency	601815	IDD, epilepsy, CP	L-serine and +/- glycine supplements	D, E, F	4	Standard of care
	Phosphoserine aminotransferase (PSAT) deficiency	610992	IDD, epilepsy, CP	L-serine and +/- glycine supplements	D, E, F	4	Standard of care
	Phosphoserine phosphatase (PSPH) deficiency	614023	IDD, epilepsy, CP	L-serine and +/- glycine supplements	D, E, F	4	Standard of care
	Tyrosinemia type II	276600	IDD	Dietary phenylalanine and tyrosine restriction	D, G	4-5	Standard of care
Cholesterol	Sterol-C4-methyl oxidase-like (SC4MOL) deficiency	607545*	IDD	SC4MOL deficiency	B, G	4-5	Standard of care
	Smith-Lemli-Opitz syndrome	270400	IDD	Cholesterol and simvastatin	B, D	4-5	Individual basis
	Cerebrotendinous Xanthomatosis	213700	IDD, psych, CP	Chenodesoxycholic acid, HMG reductase inhibitor	B, D, E, G	4	Standard of care
Creatine	Arginine:glycine amidinotransferase (AGAT) deficiency	612718	IDD, epilepsy, CP	Creatine supplements	A, D, E	4	Standard of care
	Creatine Transporter defect	300352	IDD, epilepsy, psych, CP	Creatine, glycine, arginine supplements	F	4-5	Individual basis
	Guanidinoacetate Methyltransferase (GAMT) deficiency	612736	IDD, epilepsy, psych, CP	Arginine restriction, creatine and ornithine supplements	B, D, E, F	4	Standard of care
Fatty aldehydes	Sjögren-Larsson syndrome	270200	IDD	Diet (low fat, medium chain and essential fatty acid supplements) and zileuton	D, G	5	Individual basis
Glucose transport	GLUT1 deficiency syndrome	606777	IDD, epilepsy, CP	Ketogenic diet	E, F	4	Standard of care
	Hyperinsulinism-Hyperammonemia syndrome	606762	IDD, epilepsy	Diazoxide	D	4-5	Standard of care
Hyperhomocysteinemia	Cobalamin C deficiency	277400	IDD, psych, CP	Hydroxocobalamin	C, D, E, G	4	Standard of care
	Cobalamin D deficiency	277410	IDD, psych, CP	Hydroxocobalamin/cyanocobalamin	C, D, E, G	4	Standard of care
	Cobalamin E deficiency	236270	IDD, psych, CP	Hydroxocobalamin/methylcobalamin, betaine	C, D, G	4	Standard of care

**TABLE 59-3** Overview of Treatable Inborn Errors of Metabolism Presenting With Intellectual Developmental Disability (*n* = 89 in 2015) (Continued)

Biochemical Category	Disease Name	MIM #	Major Phenotype	Therapeutic Modality(-ies)	Treatment Effect	Level(s) of Evidence	Clinical Practice
	Cobalamin F deficiency	277380	IDD, psych, CP	Hydroxocobalamin	C, D, G	4	Standard of care
	Cobalamin G deficiency	250940	IDD, Psych, CP	Hydroxocobalamin/ methylcobalamin, betaine	C, D, G	4	Standard of care
	Homocystinuria	236200	IDD, psych, CP	Methionine restriction, +/-pyridoxine, +/- betaine	C, D, E, G	2c	Standard of care
	I.o. Methylenetetrahydrofolate reductase (MTHFR) deficiency	236250	IDD, psych, CP	Betaine supplements, +/-folate, carnitine, methionine supplements	C, D, E, G	4	Standard of care
Lysosomes	Aspartylglucosaminuria	208400	IDD	Haematopoietic stem cell transplantation	D	4–5	Individual basis
	Gaucher disease type III	231000	IDD, epilepsy	Haematopoietic stem cell transplantation	D, G	4–5	Individual basis
	Hunter syndrome (MPS II)	309900	IDD	Haematopoietic stem cell transplantation	D, G	4–5	Individual basis
	Hurler syndrome (MPS I)	607014	IDD	Haematopoietic stem cell transplantation	D, G	1c	Standard of care
	I.o. Metachromatic leukodystrophy	250100	IDD, psych, CP	Haematopoietic stem cell transplantation	D, E	4–5	Individual basis
	Niemann–Pick disease type C	257220	IDD, psych, CP	Migalastat	D, E	1b	Standard of care
	Sanfilippo Syndrome A (MPS IIIa)	252900	IDD, psych	Haematopoietic stem cell transplantation	D	4–5	Individual basis
	Sanfilippo syndrome B (MPS IIIb)	252920	IDD, psych	Haematopoietic stem cell transplantation	D	4–5	Individual basis
	Sanfilippo syndrome C (MPS IIIc)	252930	IDD, psych	Haematopoietic stem cell transplantation	D	4–5	Individual basis
	Sanfilippo syndrome D (MPS IIIc)	252940	IDD, psych	Haematopoietic stem cell transplantation	D	4–5	Individual basis
	Sly Syndrome (MPS VII)	253220	IDD	Haematopoietic stem cell transplantation	D	4–5	Individual basis
	$\alpha$ -Mannosidosis	248500	IDD	Haematopoietic stem cell transplantation	D	4–5	Individual basis
Metals	Hypermanganesemia with dystonia, polycythemia, and cirrhosis (HMPDC) syndrome	613280	IDD, CP	Iron chelation therapy	D, E, G	4	Individual basis
	Mental retardation, enteropathy, deafness, peripheral neuropathy, ichthyosis, and keratoderma (MEDNIK) syndrome	609313		Zinc acetate	D, E, G	4–5	Standard of care
	Menkes disease / occipital horn syndrome	304150	IDD, epilepsy, CP	Copper histidine	D, E	4	Individual basis
	Wilson disease	277900	IDD, psych, CP	Zinc and tetrathiomolybdate	E, G	1b	Standard of care
	Aceruloplasminemia	604290	IDD, CP	Iron chelation	D, E	4	Standard of care
Mitochondria	Coenzyme Q10 deficiency	607426	IDD, epilepsy, CP	Coenzyme Q10 supplements	E, F	4	Standard of care
	Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS)	540000	IDD, epilepsy, psych, CP	Arginine supplements	C, D, E, F	4–5	Standard of care
	Pyruvate dehydrogenase deficiency	312170; 245348; 245349	IDD, epilepsy, CP	Ketogenic diet and thiamine	A, C, D, E	4	Standard of care

**TABLE 59-3** Overview of Treatable Inborn Errors of Metabolism Presenting With Intellectual Developmental Disability (*n* = 89 in 2015) (Continued)

Biochemical Category	Disease Name	MIM #	Major Phenotype	Therapeutic Modality(-ies)	Treatment Effect	Level(s) of Evidence	Clinical Practice
Neurotransmission	Aromatic L-amino acid decarboxylase deficiency	608643	IDD, CP	MAO inhibitors, B <sub>6</sub> , anticholinergics, dopa agonists	A, D, E, F	4	Standard of care
	Dihydropteridine reductase (DHPR) deficiency	261630	IDD, CP	BH4, diet, amine replacement, folinic acid	A, E	4	Standard of care
	Guanosine triphosphate cyclohydrolase I (GTPCH1) deficiency	261630	IDD, CP	BH4, amine replacement	A, E	4	Standard of care
	Pterin carbinolamine dehydratase (PCD) deficiency	264070	IDD	BH4	A, E	4	Standard of care
	6-pyruvoyl-tetrahydropterin synthase (PTPS) deficiency	261640	IDD, epilepsy, CP	BH4, diet, amine replacement	A, E	4	Standard of care
	Sepiapterin reductase deficiency	612716	IDD, CP	Amine replacement	A, E	4	Standard of care
	Succinic semialdehyde dehydrogenase (SSADH) deficiency	271980	IDD, epilepsy, psych, CP	Vigabatrin	B, E, F	4	Individual basis
	Tyrosine hydroxylase deficiency	605407	IDD, CP	L-dopa substitution	A, E	4	Standard of care
	Vesicular monoamine transporter 2 deficiency	193001*	IDD, CP	Dopamine agonists	A, D, E	4	Standard of care
Organic acids	3-Methylcrotonyl glycinuria type I/II	210200/ 210210	IDD, CP	Dietary protein restriction; carnitine, glycine, biotin supplements; avoid fasting; sick-day management	C, E	5	Standard of care
	3-Methylglutaconic aciduria type I	250950	IDD, CP	Carnitine supplements, avoid fasting, sick-day management	C	5	Standard of care
	Cobalamin A deficiency	251100	IDD, psych, CP	Hydroxocobalamin, protein restriction	C, G	4	Standard of care
	Cobalamin B deficiency	251110	IDD, psych, CP	Hydroxocobalamin, protein restriction	C, G	4	Standard of care
	Ethylmalonic encephalopathy	602473	IDD, CP	N-acetylcysteine, oral metronidazole	E, G	4	Standard of care
	Glutaric acidemia II	231680	IDD, CP	carnitine, riboflavin, $\beta$ -hydroxybutyrate supplements; sick-day management	C, E, G	5	Standard of care
	HMG-CoA lyase deficiency	246450	IDD, CP	Protein restriction, avoid fasting, sick-day management	C, E	5	Standard of care
	l.o. Glutaric acidemia I	231670	IDD, CP	Lysine restriction, carnitine supplements	C, D, E, G	2c	Standard of care
	l.o. Isoleucic acidemia	243500	IDD, CP	Dietary protein restriction, carnitine supplements, avoid fasting, sick-day management	C, E, G	2c	Standard of care
	l.o. Methylmalonic acidemia	251000	IDD, psych, CP	Dietary protein restriction, carnitine supplements, avoid fasting, sick-day management	C, E, G	2c	Standard of care
	l.o. Propionic acidemia	6065054	IDD, CP	Dietary protein restriction, carnitine supplements, avoid fasting, sick-day management	C, E, G	2c	Standard of care
	Maple syrup urine disease (variant)	248600	IDD, psych, CP	Dietary restriction of branched amino acids, avoid fasting, [liver transplantation]	B, C, D, E [A, C, E]	4 & 4	Standard of care [individual basis]

**TABLE 59-3** Overview of Treatable Inborn Errors of Metabolism Presenting With Intellectual Developmental Disability (*n* = 89 in 2015) (Continued)

Biochemical Category	Disease Name	MIM #	Major Phenotype	Therapeutic Modality(-ies)	Treatment Effect	Level(s) of Evidence	Clinical Practice
	2-Methyl-3-hydroxybutyryl-CoA dehydrogenase (MHBD) deficiency	300438	IDD, CP	Avoid fasting, sick-day management, isoleucine-restricted diet	C, E	5	Standard of care
	mitochondrial 3-hydroxy3-methylglutaryl-coenzyme A (mHMG-CoA) synthase deficiency	605911	IDD, CP	Avoid fasting, sick day management, +/- dietary precursor restriction	C, E	5	Standard of care
	Succinyl-CoA:3-ketoacid CoA transferase (SCOT) deficiency	245050	IDD, CP	Avoid fasting, protein restriction, sick-day management	C, E	5	Standard of care
	$\beta$ -Ketothiolase deficiency	203750	IDD, CP	Avoid fasting, sick-day management, protein restriction	C, E	5	Standard of care
Peroxisomes	X-linked adrenoleukodystrophy	300100	IDD, epilepsy, psych	Stem cell transplantation [gene therapy]	D, E [D, E]	1c [5]	Individual basis
	Pyrimidine 5-nucleotidase superactivity	GENE OMIM# 606224	IDD, CP	Uridine supplements	A, B, E, F, G	1b	Standard of care
Urea cycle defect	Carbonic anhydrase VA deficiency	615751	IDD	Carglumic acid, sick-day protocol	C	4–5	Standard of care
	Citrullinemia type II	605814	IDD, CP	Dietary protein restriction, arginine supplement, sodium benzoate, phenylbutyrate [liver transplantation]	B, C, D, E, F, G [C]	2b [4]	Standard of care [individual basis]
	l.o. Argininemia	207800	IDD, psych, CP	Dietary protein restriction, arginine supplement, sodium benzoate, phenylbutyrate [liver transplantation]	B, C, D, E, F, G [C]	2b [4]	Standard of care [individual basis]
	l.o. Argininosuccinic aciduria	207900	IDD, psych, CP	Dietary protein restriction, arginine supplement, sodium benzoate, phenylbutyrate [liver transplantation]	B, C, D, E, F, G [C]	2b [4]	Standard of care [individual basis]
	l.o. Carbamoyl phosphate synthetase (CPS) deficiency	237300	IDD, CP	Dietary protein restriction, arginine supplement, sodium benzoate, phenylbutyrate [liver transplantation]	B, C, D, E, F, G [C]	2b [4]	Standard of care [individual basis]
	l.o. Citrullinemia Type I	215700	IDD, psych, CP	Dietary protein restriction, arginine supplement, sodium benzoate, phenylbutyrate [liver transplantation]	B, C, D, E, F, G [C]	2b [4]	Standard of care [individual basis]
	l.o. N-acetylglutamate synthase (NAGS) deficiency	237310	IDD, psych	Dietary protein restriction, arginine supplement, sodium benzoate, phenylbutyrate, carginic acid [liver transplantation]	B, C, D, E, F, G [C]	2b [4]	Standard of care [individual basis]
	l.o. Ornithine transcarbamylase (OTC) deficiency	311250	IDD, psych, CP	Dietary protein restriction, citrulline and arginine supplement, sodium benzoate, phenylbutyrate [liver transplantation]	B, C, D, E, F, G [C]	2b [4]	Standard of care [individual basis]

	Molybdenum cofactor deficiency type A	252150	IDD, epilepsy, CP	Precursor Z (CPMP)	A, E, F	4	Individual basis
	Pyridoxine-dependent epilepsy	266100	IDD, epilepsy	Pyridoxine	A, F	4	Standard of Care
	Thiamine-responsive encephalopathy	606152	IDD	Thiamin supplement	E	4–5	Standard of care

This table provides an overview of all treatable inborn errors of metabolism (IEMs; with phenotype Mendelian Inheritance in Man number [MIM#]; \*indicates the gene) presenting with intellectual developmental disability (IDD) along with the disease's other prominent phenotypic features, the specific therapy(ies) available with relevant level(s) of evidence, therapeutic effect(s) on primary and/or secondary outcomes, and use in clinical practice. For 10 IEMs, two therapies are available; these are listed separately (*in brackets*) with corresponding level of evidence, therapeutic effect(s), and use in clinical practice (*also in brackets*).

**Individual basis:** The decision to initiate a specific treatment depends on a careful evaluation of the specific patient characteristics, physician's opinion, availability of treatment, and potential side effects.

**Levels of evidence** (source: <http://www.cebm.net>): Level 1a = systematic review of randomized controlled trials (RCTs), 1b = individual RCT, 1c = all or none (= [prolongation of] survival with therapy); level 2a = systematic review of cohort studies, 2b = individual cohort study, 2c = outcomes research (focused on end results of therapy for chronic conditions, including functioning and quality of life (source: [www.ahrq.gov/clinic/outfact.htm](http://www.ahrq.gov/clinic/outfact.htm)); level 3 = systematic review of case-control studies; level 4 = individual case-control study or case series/report; level 4 to 5 = single case report; level 5 = expert opinion without critical appraisal.

**Major phenotypes:** Neurodevelopmental disabilities (NDDs) include the following major phenotypes: CP, cerebral palsy; epilepsy; IDD, intellectual developmental disability; psych, psychiatric/behavioral disturbances (including autism).

**Sick-day management:** Intervention(s) to guarantee sufficient fluid and caloric intake to maintain anabolic state, plus continuation/modification of disease-specific therapy.

**Standard of care:** Initiation of the specific treatment upon diagnostic confirmation is generally accepted by experts worldwide as "best clinical practice."

**Therapeutic effect(s):** A, improves psychomotor/cognitive development/IQ; B, improves behavioral/psychiatric disturbance(s); C, prevents acute metabolic decompensation; D, prevents, halts, or slows clinical deterioration; E, improves neurologic manifestations (including neuroimaging); F, improves seizure/epilepsy control; G, improves systemic manifestations.

because of methodological shortcomings other than effect size per se. A prominent example of this is AGAT deficiency, for which treatment comprises oral creatine, which can normalize neurodevelopmental functioning with timely initiation but only has an evidence level of 4. Finally, many treatments with limited evidence levels are considered the standard of care.

## Treatable Inborn Errors of Metabolism Presenting With Other Neurodevelopmental Disorder Phenotypes

### Epilepsy

Seizures may be the first and the major presenting feature of an IEM or be preceded by other major symptoms (e.g., reduced level of consciousness or loss of skills, progressive weakness, ataxia, and upper motor signs) (Rahman, Footitt, Varadkar, and Clayton, 2013). The common metabolic causes of seizures

vary according to the age at presentation and/or involvement of specific cortical areas of the brain; specific seizure types characteristic of individual IEMs are rare. Features from the history examination, imaging, and first-line biochemical investigations can all provide clues as to which IEM may be involved.

The IEMs with epileptic symptoms that are amenable to metabolic therapy are listed in Table 59-3. The response to targeted metabolic therapy differs among IEMs, and outcomes depend on the manifestation of the disease. In some cases, seizures are a consequence of acute metabolic stress on the CNS (e.g., in the case of hyperammonemia or hypoglycemia), and treatment of the underlying neurometabolic condition stabilizes seizures. In other treatable IEMs, seizures are the main manifestation, and disease progression can lead to drug-resistant epilepsy (e.g., GAMT deficiency). In a few metabolic disorders, such as phenylketonuria (PKU) and biotinidase deficiency, seizures can be prevented completely if caught early (via newborn screening) and treated (biotin 10–100 mg/

day). However, conventional antiepileptic medications may be needed in addition to metabolic therapy for some IEMs (e.g., glutaric aciduria type 1).

### Atypical Cerebral Palsy

A significant number of IEMs ( $n = 67$ ) present as cerebral palsy mimics (i.e., with movement disorders); [Table 59-3](#) lists those amenable to causal therapy ([Leach, Shevell, Bowden, Stockler-Ipsiroglu, and van Karnebeek, 2014](#)). An example is Segawa disease, also called GTPCH1-deficient dopa-responsive dystonia (GTPCH1-DRD), characterized by dystonia in childhood that is often misdiagnosed as cerebral palsy (CP). This neurotransmitter disorder can be diagnosed by standard analysis of neurotransmitter metabolites in the cerebrospinal fluid (CSF). Individuals with GTPCH1-DRD benefit from treatment with levodopa/carbidopamine and in some cases 5-hydroxytryptophan and BH4. The majority of treated individuals show rapid clinical improvement in CP-related symptoms (spasticity, dystonia, general tone) and are able to lead “an entirely normal life.” Similarly, for 26 (39%) of all IEMs presenting with atypical CP, a treatment is available that targets the primary underlying pathophysiology; for the remaining 41 (61%) IEMs, treatment is available that stabilizes disease or prevents further damage (e.g., fatty acid oxidation disorders; [Leach et al., 2014](#)).

The symptoms that should prompt the clinician to search for an underlying IEM or other neurogenetic defect include, but are not limited to, the following “red flags”: normal MRI findings on imaging; abnormalities isolated to the globus pallidus; severe symptoms in the absence of a history of perinatal injury; a pattern of familial disease inheritance, or consanguinity; neurodevelopmental regression, or progressively worsening symptomatology; isolated muscular hypotonia; rigidity (as opposed to spasticity) on physician examination; and unexplained paraplegia. Metabolic and molecular testing are required for diagnosis; importantly, lumbar puncture, although invasive, should not be avoided because it allows for CSF neurotransmitter, glucose, and amino acid analysis, which is highly sensitive and often guides the clinician in further diagnostic and therapeutic decisions.

### Psychiatric Disease

Psychiatric disease is another frequent phenotype of IEMs and can be divided into three categories: acute, treatable IEMs (urea cycle abnormalities, remethylation disorders, acute intermittent porphyria); chronic, treatable IEMs (Wilson’s disease, Niemann–Pick disease type C, homocystinuria resulting from cystathionine beta-synthase deficiency, cerebrotendinous xanthomatosis); and chronic IEMs that are more difficult to treat (lysosomal storage diseases, X-linked adrenoleukodystrophy, creatine deficiency syndromes; [Bonnot et al., 2014](#)). Treatments are listed in [Table 59-3](#) for all IEMs with significant psychiatric or behavioral disturbances except acute intermittent porphyria (preventive measures and hemin IV in the acute phase).

The following atypical psychiatric features should trigger a search for IEMs in patients with schizophrenia: first-level features, defined as atypical on their own (confusion, visual hallucinations more prominent than auditory hallucinations, catatonia, progressive cognitive decline, treatment resistance, fluctuating schizophrenia core symptoms), and second-level features, defined as atypical when associated with first-level features (acute onset, early onset, IDD, unusual or severe side effects; [Bonnot et al., 2014](#)). Accurate diagnosis is crucial because early symptoms often respond well to treatment.

## CONGENITAL HYPOTHYROIDISM

Congenital hypothyroidism (CH), affecting 1 in 2000 to 1 in 4000, is the most common treatable cause of IDD worldwide. Untreated, common symptoms include decreased activity and increased sleep, feeding difficulty, constipation, and prolonged jaundice. On examination, common signs include myxedematous facies, large fontanels, macroglossia, a distended abdomen with umbilical hernia, and hypotonia.

Known genetic conditions etiologic of CH include TSHB mutations, TSH receptor inactivating mutations, thyroid dysgenesis (TTF-2, NKX2.1, or PAX-8 mutations), thyroid dyshomogenogenesis (sodium-iodide symporter, hydrogen peroxide, or DUOX2[A] mutations), thyroid peroxidase mutations (Pendred syndrome: Pendred gene, thyroglobulin or deiodinase mutations) or defects in thyroid hormone transport (MCT8 mutation; [Rastogi and LaFranchi, 2010](#)). Therapy with levothyroxine is recommended, with the goal of ensuring that these patients are able to have growth and mental development that is as close as possible to their genetic potential. This is achieved by rapidly restoring free thyroxine (T4) and thyroid-stimulating hormone (TSH) to the normal range and then maintaining clinical and biochemical euthyroidism ([Rastogi and LaFranchi, 2010](#)). Studies have shown that the timing of therapy (early diagnosis via newborn screening with optimization of treatment within the first 2–3 years) is crucial to neurologic outcome.

## CONCLUSIONS AND FUTURE DIRECTIONS

Novel genetic etiologies of NDDs are increasingly identified based on rapid-sequencing methods. It will be important to map disorders onto shared cellular pathways and circuit dysfunctions targetable for novel treatments approaches, including genetic manipulations such as adenoviral-mediated gene therapy, small-molecule therapies targeted to key pathways, receptor or channel ligands that alter signaling in specific neurons or circuits, or microRNAs that can inhibit production of specific key pathway proteins. These could be combined with cellular targeting of therapeutic molecules through linkage to receptor or transporter ligands to encourage transport into the CNS and individuals neurons.

Such novel disease-modifying therapies to reverse the underlying dysfunctional neural mechanisms, combined with the awareness and early diagnosis of the large expanding group of IEMs, makes this an exciting time in the treatment of NDDs, providing hope and relief for families dealing with these challenging conditions.

## INTRODUCTION

With a growing evidence base of tolerable and effective psychotropic medications and more refined targets for treatment, psychopharmacology has become standard practice for many neuropsychiatric disorders, resulting in increased use of medications in children and broadening of the practitioner base for prescribing (see [Table 60-1](#)) ([AACAP, 2009](#)). There are excellent efficacy and safety data for the short-term treatment of attention deficit hyperactivity disorder (ADHD) with stimulants; of anxiety disorders with selective serotonin reuptake inhibitors (SSRIs); of obsessive-compulsive disorder (OCD) with clomipramine and SSRIs; of depression with SSRIs; and of schizophrenia, bipolar disorder, and irritability and behavioral dysregulation in different pediatric disorders with atypical antipsychotics. In contrast, there remain very little data from placebo-controlled efficacy studies on the short-term benefit of so-called mood stabilizers (e.g., lithium, anticonvulsants) for neuropsychiatric disorders. However, little is known regarding the long-term usefulness of any psychotropic medication, and there is increasing concern about the long-term effects of psychotropic drugs on growth and development. Although medication combinations are commonly used in children, studies of these combinations are also uncommon.

## STIMULANTS FOR ADHD

Stimulants for behavioral issues in children have been in clinical use since 1937. Since then, stimulant medications have been consistently found efficacious, leading to comprehensive guidelines for treatment ([Pliszka, 2007](#)). Although behavioral treatment may be considered, in head-to-head studies, medication alone has been shown to be more beneficial than behavioral therapy alone in children 5 years of age and older. The combination of medication and behavioral therapy is specifically helpful for oppositional behavior and anxiety in children with ADHD.

The stimulant medications are now used in those with autism spectrum disorders and in preschoolers, although the response rate is less robust than in typically developing older children, and rates of adverse events are higher. These children may experience a worsening of ADHD (e.g., hyperactivity and irritability) or other symptoms (e.g., tics or stereotypies). Parent training and behavioral treatments remain the primary interventions with autistic patients and preschoolers with ADHD.

Despite substantial data supporting the efficacy of stimulants, their use in children remains controversial to the public at large. Concerns have been expressed about the potential for overdiagnosis of ADHD and overuse of stimulant medications in children. Although there is documentation of increases in stimulant use, there is little evidence to support the notion that more children are treated with stimulants than there are cases of ADHD in the population at large. Stimulant medications have also come under public scrutiny because of concerns about safety and side effects. In the context of

parental concerns, prudent practice therefore necessitates an evaluation that leads to confidence in the diagnosis, fully informed consent, and use of appropriate doses with close monitoring, combined with effective and available psychosocial treatments.

Identification of co-occurring conditions and risk factors for adverse effects is essential because some medications may be contraindicated, or medication management may require dosing modification or closer monitoring. For stimulant medications, baseline height, weight, family or personal history of a tic disorder, and family or personal history of cardiac disease, including nonvasovagal syncope and sudden death, are also important. The treating clinician, based on physical examination and history, should consider the need for an electrocardiogram (ECG). During the dose-adjustment phase, children often are monitored for side effects, including blood pressure, pulse, height, and weight.

The most common side effects of stimulants are decreased appetite, insomnia, and nervousness. A baseline of sleep and eating patterns, tic symptoms in the patient and family, and anxiety and mood symptoms should be obtained before starting stimulants, to avoid misattribution of such problems to the stimulant treatment. Short-term reductions in weight gain and height have been reported in many studies. The possibility of long-term growth suppression with long-term use of stimulants remains a controversial topic. Tic increases observed after starting stimulants appear to reflect the natural waxing and waning of tic severity. Sudden death may be a very rare side effect of stimulant use in children; however, the risk is quite limited and poorly defined. There is no evidence for increased risk of addiction from appropriate treatment with stimulants for ADHD. Despite their impact on a broad range of ADHD-related symptoms, including irritability, stimulant medications can be associated with undesirable changes in mood and behavior.

After a maintenance dose is achieved, visit intervals can vary from 1 to 3 months or more. Ongoing monitoring of medication efficacy involves assessment of the patient's level of functioning in school, family, community, and peer groups. Data are collected from behavioral observations during office visits and parent and teacher reports and rating scales.

## NONSTIMULANT MEDICATIONS FOR ADHD

Atomoxetine is a nonstimulant medication, potentially offering several advantages over stimulant medications: longer duration of action, lower misuse or abuse potential, lower risk of rebound effects, lower risk of precipitating tics or psychosis, and ease of prescribing.

Children should undergo standard psychiatric and medical assessment for ADHD as is done with stimulants. No laboratory screening is required, although obtaining baseline and follow-up liver function studies should be considered in view of reports of rare but severe acute liver dysfunction. Baseline values for weight, heart rate, and blood pressure should be obtained. The effectiveness and tolerability of combining

**TABLE 60-1** Labeled and Off-Label Use of Neuropsychopharmacologic Agents in Children and Adolescents

Drug	Labeled Use in Children and Adolescents	Off-Label Use/Clinical Practice in Children and Adolescents
<b>STIMULANTS</b>		
Amphetamine, mixed salts	ADHD (≥3 yrs—IR, ≥ 6 yr—ER, narcolepsy (≥6 yrs, IR only)	
Dextroamphetamine	ADHD (≥6 yrs), narcolepsy (≥6 yrs)	
Lisdexamfetamine	ADHD (≥6 yrs)	
Methylphenidate	ADHD (≥6 yrs), narcolepsy (≥6 yrs)	
Dexmethylphenidate	ADHD (≥6 yrs)	
<b>NON-STIMULANTS</b>		
Atomoxetine	ADHD (≥6 yrs)	
Clonidine	ADHD (≥6 yrs—ER)	Aggression, tic disorders
Guanfacine	ADHD (6-17 yrs—ER)	Aggression, tic disorders
<b>BENZODIAZEPINES</b>		
Clonazepam	None	As a group—agitation, catatonia, short-term anxiety
Lorazepam	Anxiety (≥12 yrs), insomnia (≥12 yrs)	
<b>TRICYCLIC ANTIDEPRESSANTS</b>		
Amitriptyline	Depression (≥12 yrs)	As a group—depression, anxiety disorders, ADHD and pain syndromes
Clomipramine	OCD (>10 yrs)	
Desipramine	None	
Imipramine	Enuresis (≥6 yrs), depression (≥12 yrs)	
Nortriptyline	Depression	
<b>SEROTONIN REUPTAKE INHIBITORS</b>		
Citalopram	None	As a group—depression, anxiety disorders
Escitalopram	Depression (≥12 yrs)	
Fluoxetine	OCD (≥7 yrs), depression (≥8 yrs)	
Fluvoxamine	OCD (≥8 yrs)	
Paroxetine	None	
Sertraline	OCD (≥6 yrs)	
<b>OTHER ANTIDEPRESSANTS</b>		
Bupropion	None	Depression, ADHD
Desvenlafaxine	None	Depression, anxiety disorders
Duloxetine	None	Depression, chronic pain
Venlafaxine	None	Depression, anxiety disorders, ADHD
Mirtazapine	None	Depression, Anxiety disorders
<b>MOOD STABILIZERS</b>		
Lithium	Bipolar Disorder (≥12 yrs)	Aggression
Carbamazepine	Seizure disorders	As a group—bipolar disorder, aggression, mood instability
Gabapentin	Seizure disorders	
Lamotrigine	Seizure disorders	
Topiramate	Seizure disorders	
Valproate	Seizure disorders	
<b>TYPICAL NEUROLEPTICS</b>		
Chlorpromazine	Severe behavioral disturbances	As a group—psychotic disorders
Haloperidol	Psychosis, tics, severe behavioral disturbance	
Pimozide	Tics	
<b>ATYPICAL NEUROLEPTICS</b>		
Aripiprazole	Irritability in autistic disorder (6-17 yrs) Bipolar I disorder (≥10 yrs), schizophrenia (≥13 yrs)	As a group—psychotic disorders, Tourette syndrome, aggression
Clozapine	None	
Olanzapine	Bipolar I disorder (≥13 yrs), schizophrenia (≥13 yrs)	
Quetiapine	Bipolar I disorder (≥10 yrs), schizophrenia (≥13 yrs)	
Risperidone	Irritability in autistic disorder (6-17 yrs), bipolar I disorder (≥10 yrs), schizophrenia (≥13 yrs)	
Ziprasidone	None	

ADHD, attention deficit hyperactivity disorder; IR, immediate release; OCD, obsessive-compulsive disorder; ER, extended release

atomoxetine with methylphenidate in children who have not responded to monotherapy have been reported in a few patients.

Two  $\alpha_2$  agonists, clonidine and guanfacine, are prescribed in the treatment of ADHD, Tourette syndrome, aggressive or self-injurious behavior, and the physiologic symptoms of anxiety. Extended-release (ER) guanfacine and ER clonidine have been found effective and are most studied. Before the

initiation of clonidine or guanfacine, baseline ECG, heart rate, and blood pressure should be obtained. A history of syncope or cardiovascular disease is a relative contraindication. Heart rate and blood pressure should be monitored regularly during therapy for hypotension and bradycardia.

The most common side effects of clonidine and guanfacine include sedation, dizziness, fatigue, dry mouth and eyes, nausea, hypotension, and constipation. Syncope has been

reported in a few children on guanfacine ER. Abrupt discontinuation can lead to rebound hypertension on these agents.

## ANTIDEPRESSANTS

### Tricyclic Antidepressants

Tricyclic antidepressants are approved for the treatment of depression in adults and adolescents. The use of tricyclic antidepressants for the treatment of depression in children and adolescents has declined because of their equivocal efficacy and safety in this population and the availability of serotonin reuptake inhibitors with a more favorable side-effect profile.

The tricyclic clomipramine has been approved for use in children 10 years of age or older for OCD, but it is also considered second-line treatment in clinical practice, again in part because of a less favorable side-effect profile compared with the SSRIs. Although amitriptyline is still commonly used in neurologic settings for adults, its side-effect profile in doses effective for the treatment of anxiety and depression is often prohibitive—particularly sedation and weight gain. Nortriptyline, the primary metabolite of amitriptyline, is often better tolerated in treatment. Tricyclic antidepressants have been prescribed as third-line treatments for patients with ADHD who have failed adequate trials of other agents. Imipramine appears to be effective in treating enuresis in children who have failed nonmedication interventions and desmopressin.

As with ADHD, assessment for anxiety disorders and depression requires the gathering of information through clinical interview, other informants, and medical evaluation, including laboratory screening (AACAP, 2007). The diagnostic evaluation of children with depression and anxiety should also determine whether other coexisting conditions are present. Risk factors for adverse effects with tricyclic antidepressants should be identified.

A medical evaluation is required before initiating tricyclic antidepressants. A baseline ECG, orthostatic blood pressure and heart rate, complete blood cell count (CBC), electrolyte determination, renal and hepatic function tests, thyroid function tests, and urinalysis should be performed. Other laboratory screening measures may be indicated, based on findings in the history or physical examination. Because of the risk of adverse cardiac effects, serial ECGs are recommended with the use of all tricyclic antidepressants. They should be obtained at baseline, during titration, and at the final dose.

Side effects of tricyclic antidepressants include sedation, weight gain, orthostatic hypotension, and anticholinergic side effects (i.e., dry mouth, constipation, blurred vision, urinary retention, and exacerbation of narrow-angle glaucoma). Although the role of the tricyclic antidepressants is unclear, it has been speculated that the cause of rare reported sudden death on these medications is likely a result of malignant arrhythmias. It is not clear whether the vulnerability to such medication effects can be determined from routine monitoring of cardiac function through regular ECGs.

Behavioral side effects include early and acute increases in anxiety or depression, or manic episodes or rapid cycling in patients. A family history of bipolar disorder may be a risk factor for this effect, but such a history is not an absolute contraindication for the use of antidepressants. A discontinuation syndrome may result from abrupt cessation of antidepressants. The U.S. Food and Drug Administration (FDA) mandated a black-box warning regarding increases in suicidal ideation for all antidepressants.

### Selective Serotonin Reuptake Inhibitors

The SSRIs, including citalopram, escitalopram, fluvoxamine, fluoxetine, paroxetine, and sertraline, have FDA approval for

a number of mood, anxiety, and eating disorders in adults. In children and adolescents, fluoxetine, fluvoxamine, and sertraline have FDA approval for OCD, fluoxetine also has FDA approval for major depression, and escitalopram has FDA approval for major depression in adolescents (12 years and older). The use of the SSRIs for depression increased significantly through the 1990s. In 2004 the FDA issued a black-box warning for increased risk of suicidal ideation and behavior in children and adolescents using all antidepressants. Since this time, prescriptions of antidepressants in the pediatric population have decreased.

Although some individuals may do better on one SSRI than another, comparative treatment trials suggest similarity in efficacy across all agents in this class. The SSRIs may demonstrate benefit in as little as 1 week, with substantial benefit occurring in 8 to 12 weeks. Improvement may continue at a more gradual rate for up to 6 to 12 months.

The assessment of mood and anxiety disorders before initiation of an SSRI is similar to that described earlier for the tricyclic antidepressants. Risk factors for adverse effects of SSRIs should be identified, and should include a family and personal history of bipolar disorder, history of suicidal ideation or behavior, sensitivity to other SSRIs, concurrent medications that could inhibit or could be inhibited by the SSRI, pregnancy, and hepatic or renal disease. No medical evaluation is required before initiating SSRI treatment, but it may be prudent to clear a child medically by means of a medical history and physical examination.

For all of the SSRIs, treatment usually is initiated with a low dose that is adjusted upward slowly at weekly intervals. Because the time–response pattern for the SSRIs occurs over a minimum of weeks, too aggressive titration often leads to early side effects and may result in early discontinuation of the medication and the need to start again with another medication. Starting low and slowly titrating upward may allow the patient time to develop some tolerance to some of the side effects. However, going too slowly may put the patient at risk for being undertreated.

The adverse-event profiles of SSRIs are similar. In placebo-controlled trials of the SSRIs, a few adverse effects occurred significantly more often on active medication than on placebo. These include gastrointestinal symptoms, insomnia, and anxiety or agitation. Other adverse effects that occur more often on active medication but are less common overall include somnolence, tremor, sweating, sexual dysfunction, epistaxis, and allergic reactions, including rash. The most common causes of medication discontinuation, other than lack of efficacy, are the behavioral or psychiatric side effects, such as anxiety or agitation.

Activation occurs in about 10% to 20% of patients. This activation syndrome (distinct from the mood improvement effects of the antidepressants) can result in a number of complaints, including anxiety, mental restlessness, increased activity level or akathisia, increased impulsivity, and disinhibition. This activation is very similar to but milder than what some children experience when they take diphenhydramine. Activation effects usually appear very early in treatment or after a dose change. Patients do not appear to develop tolerance to these symptoms, but they resolve with dose reduction or discontinuation. Much less common but also serious are manic and hypomanic reactions. In brief clinical trials, manic reactions are much less common (1% to 2%) than activation, occur later in treatment after a period of improvement, do not always go away with dose reduction or discontinuation, and may require medical intervention to control.

Children with anxiety and mood disorders who benefit from SSRI treatment do not always have uniform outcomes. For most, symptom relief is associated with return to normal

and appropriate function. However, some children, especially those with behavioral problems or those at risk for other behavioral problems (i.e., poor parental discipline and monitoring), may present with increasing behavior problems after successful treatment of anxiety and depression. Children with anxiety and mood disorders also experience an evolution of symptoms over time. Children first presenting with separation anxiety at age 8 years may evolve into a generalized anxiety disorder or have periods of recurrent depression in their middle to late teens, for example. Half of adequately treated depressed adolescents have a recurring episode within a few years.

The SSRIs have also been reported to induce an apathy syndrome. Although it may manifest early in treatment, those with anxiety and depression may not be sensitive to this subtle medication effect until after a period of recovery.

In general, cardiac side effects from SSRIs are rare. However, citalopram can cause prolongation of the QT interval, and the FDA has issued a safety alert indicating that doses over 40 mg are no longer recommended because this dose potentiates risk for torsades de pointes.

Some individuals do appear to have a discontinuation syndrome with abrupt cessation of therapy that includes flu-like symptoms, such as malaise and gastrointestinal symptoms. Antidepressants with shorter half-lives appear to be more commonly associated with discontinuation syndromes than SSRIs with longer half-lives.

As noted earlier, antidepressants carry warnings in their product labeling regarding the increased risk for suicidal ideation and behavior (i.e., suicidality) in the course of treatment. The mechanism of this effect has never been clear, but it may be attributed to the positive energizing effects of antidepressants outpacing the improvement in baseline low mood and suicidality.

### Other Antidepressants

The serotonin–norepinephrine reuptake inhibitors, which include duloxetine, venlafaxine, and desvenlafaxine, have FDA approval for treatment of depression and anxiety disorders in adults, but data are limited for children and adolescents, and the use of serotonin–norepinephrine reuptake inhibitors in children and adolescents is off-label.

Bupropion is approved by the FDA for the treatment of depression, nicotine dependence, and smoking cessation in adults only. Off-label uses of bupropion include monotherapy in the treatment of depression in children and adolescents and as a second-line agent in the treatment of ADHD. Bupropion may improve symptoms of ADHD in prepubertal children, although a study demonstrated that effect sizes of bupropion and placebo differences were smaller than those for standard stimulant medications. Adolescents with ADHD and co-occurring depression may demonstrate improvement with bupropion.

### ANXIOLYTICS

Anxiety disorders are one of the most prevalent categories of childhood and adolescent psychopathology. Co-occurring conditions, such as other anxiety disorders, depression, and ADHD, are common. Treatment of anxiety disorders in children and adolescents is multimodal, including psychoeducational and cognitive behavioral therapy, family therapy, school interventions, and pharmacotherapy (Connolly and Bernstein, 2007). Medication choices are multiple, but serotonin reuptake inhibitors are the pharmacologic treatment of choice.

The role of benzodiazepines is limited to the short-term management of anxiety symptoms because data supporting

their use in children is sparse. In cases of severe anxiety, they may be added to tricyclic antidepressants or SSRIs for acute management of anxiety symptoms until the therapeutic effects of the antidepressants emerge. Benzodiazepines can be useful for the short-term management of specific anxiety-provoking situations, such as medical procedures, or as short-term adjunctive treatment with SSRIs in the initial treatment of severe anxiety disorders, or in treatment of catatonia.

In considering benzodiazepine therapy for a patient, the clinician should inquire about any possible history of substance abuse. The patient and family should be informed about the risks of tolerance, dependence, and withdrawal effects, in addition to possible effects on cognitive and motor functioning. After the treatment trial is complete, the medication should be tapered slowly because of the potential for withdrawal and rebound anxiety. The most frequent adverse effects in children and adolescents are sedation, drowsiness, and decreased mental acuity. Benzodiazepines may also cause paradoxical agitation, aggression, and hyperactivity. Anterograde amnesia also has been associated with benzodiazepines, particularly high-potency benzodiazepines.

Buspiron is approved for use in the treatment of anxiety disorders in adults, but unpublished, industry-sponsored, randomized controlled trials in children do not demonstrate benefit. The most common adverse effects of bupiron are dizziness, headache, drowsiness, and lightheadedness.

### MOOD STABILIZERS

The term *mood stabilizers* refers to medications used to treat severe fluctuating moods, including depression and mania in bipolar disorder. Mood stabilizers have antimanic and antidepressant properties and treat specific mood states without negatively affecting other mood states (e.g., worsening depression when mania is treated, or vice versa). Attempts to mark boundaries between chronic and cyclic irritable mood in children have led to more stringent bipolar diagnostic criteria and the development of the diagnosis of Disruptive Mood Dysregulation Disorder in the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (APA, 2013).

Mood stabilizers used in clinical practice can be grouped into three categories: lithium, anticonvulsants, and antipsychotics. As with childhood depression, children with bipolar affective disorder are thought to be less responsive to medication compared with adults. Combination of mood stabilizers, or a mood stabilizer with an antipsychotic, is sometimes required to stabilize acute manic symptoms. It appears that second-generation antipsychotics may be more effective for bipolar disorder in children than anticonvulsants or lithium.

Given the complexity of making an accurate diagnosis, the treatment-resistant nature of pediatric bipolar illness, and the complicated regimens of medication sometimes required, the average pediatric neurologist is encouraged to request consultation from a child psychiatrist if faced with a child patient with possible bipolar disorder (McClellan, Kowatch, and Findling, 2007).

### Lithium

Lithium is approved by the FDA for use in the treatment of bipolar affective disorder for children 12 years of age and older. It is effective in managing acute manic and depressive episodes, preventing or diminishing the intensity of subsequent episodes in maintenance treatment, and decreasing mood instability between episodes. Data in children and adolescents with bipolar disorder are limited and offer mixed results, but there

is concern that lithium is underused compared with other newer mood stabilizers of questionable efficacy.

Before starting lithium therapy, the patient should be screened for pregnancy, renal disease, or diabetes mellitus. A medical evaluation should be completed, including an ECG, laboratory screen for electrolytes, kidney and thyroid function tests, complete blood count (CBC), urinalysis, and urine pregnancy screen. Lithium levels between 0.8 and 1.0 mEq/L may offer the best prophylaxis against mania, whereas lower levels may be adequate for prophylaxis against depression. After mood symptoms are stabilized, lithium levels should be routinely checked every 3 to 6 months.

Side effects of lithium are polydipsia, polyuria or enuresis, gastric distress (i.e., nausea, vomiting, and diarrhea), weight gain, tremor, fatigue, leukocytosis, acne, and mild cognitive impairment. Serious renal side effects are rare but occur. Lithium therapy can induce alterations in thyroid function tests and produce hypothyroidism. Lithium can have rare but serious cardiac side effects. Intrauterine exposure to lithium during the first trimester has been associated with teratogenic effects, most commonly Ebstein's anomaly.

### Valproic Acid

The initial support for use of valproic acid in child psychiatric practice came from the adult literature. The evidence for its use in the treatment of juvenile bipolar disorder, however, is limited. Divalproex sodium has also been shown in small studies to benefit children and adolescents with explosive temper and mood lability and for treatment of core symptoms of autism and associated symptoms of affective instability, aggression, and impulsivity.

In addition to the routine psychiatric or neurologic history, patients should be asked about risk factors affecting treatment with valproate, including pregnancy, disorders of metabolism, hepatic or renal disease, concomitant medications, and coagulation disorders. Laboratory screening should include liver function tests and a CBC, and a pregnancy test in females. Families should be educated about potential signs of hepatic or pancreatic toxicity and polycystic ovary disease.

Although therapeutic levels for treating mania have not been established, achieving a plasma concentration of 85 to 110 mg/L is needed to declare a trial adequate for determining outcome in an individual patient. Divalproex ER allows for once-daily dosing. Maintenance involves monitoring of the therapeutic response and side effects and requires laboratory screening. Liver enzymes, CBC, and serum valproic acid levels should be periodically monitored.

Adverse effects include sedation, nausea, vomiting, gastrointestinal upset, increased appetite, weight gain, and hair loss. Rare side effects include thrombocytopenia, platelet dysfunction, prolonged bleeding time, and elevation in liver enzymes, which can occur without clinical symptoms. Children younger than 2 years appear to have an increased risk of hepatotoxicity, and extreme caution should be used in this population.

### Carbamazepine

Limited data are available on the efficacy of carbamazepine for the treatment of bipolar disorder children and adolescents. Justification for its use in clinical practice has rested on the adult literature, which is difficult to interpret. Patients should be evaluated for medical conditions that may contraindicate use of carbamazepine, including liver disease, hematologic disorders, immune disorders, cardiac disease, and pregnancy. Laboratory screening should include a urine pregnancy screen, liver function tests, and a CBC. Recommended levels are the same as those for seizure disorder, 4 to 12 mg/ml.

The most common adverse effects are nausea, vomiting, sedation, and ataxia. Carbamazepine can cause mild elevations in liver transaminases; hepatitis, indicated by elevated liver transaminase levels greater than three times normal; and cholestasis, indicated by elevations in bilirubin and alkaline phosphatase. Carbamazepine therapy has been associated with leukopenia in 1% to 2% of patients and agranulocytosis or aplastic anemia in 1 of 250,000 patients. Other adverse effects observed with carbamazepine include cognitive or behavioral disturbance, CNS toxicity, altered cardiac conduction, and life-threatening dermatologic conditions (i.e., exfoliative dermatitis, toxic epidermal necrolysis, and Stevens-Johnson syndrome).

### Other Mood Stabilizers

Although lithium and valproate are first-line pharmacologic treatments for bipolar disorder in adults, many children and adolescents do not respond adequately to these medications and cannot tolerate the side effects. In clinical practice, newer anticonvulsants are beginning to be used for the treatment of bipolar disorder. Many of these newer anticonvulsants have a more favorable adverse-effect profile, but use of these medications is more appropriate for patients with bipolar disorder who are unresponsive to traditional therapies or cannot tolerate traditional agents.

Data on lamotrigine in pediatric bipolar disorder are limited to case series and open-label trials but suggest that, in adolescents, lamotrigine may be effective for the treatment of bipolar depression, treatment of mania, and maintenance treatment of bipolar disorder.

Because supporting data are limited in pediatric populations, the use of lamotrigine in children and adolescents for the treatment of bipolar disorder should be reserved for those who have failed alternative treatments and demonstrate persistent disabling symptoms.

A painstaking approach to slow dose adjustment of lamotrigine decreases the risk for rash, including Stevens-Johnson syndrome. Dosing must be adjusted upward for children taking concomitant carbamazepine, phenytoin, phenobarbital, or primidone, which increases lamotrigine clearance, and dosing must be reduced for children taking concomitant valproate, which decreases lamotrigine clearance.

Common adverse effects observed in clinical studies include dizziness, ataxia, somnolence, headache, diplopia, blurred vision, nausea, vomiting, and rash. Lamotrigine has been associated with serious rashes requiring hospitalization and discontinuation of treatment.

Other newer anticonvulsants include topiramate, gabapentin, and oxcarbazepine, all with little empirical data to support their use in young people with mood disorders.

### DOPAMINE RECEPTOR ANTAGONISTS: TYPICAL ANTIPSYCHOTICS

*Dopamine receptor antagonist* is a term used to refer to a medication that is a high-affinity antagonist of dopamine receptors. Other terms used to refer to these drugs include *typical antipsychotics*, *neuroleptics*, and *major tranquilizers*. The antipsychotic effects of these medications are thought to be mediated through the inhibition of dopamine binding at dopamine D<sub>2</sub> receptors, resulting in the reduction of dopaminergic neurotransmission in the central nervous system (CNS). The neurologic side effects appear to be mediated by dopamine antagonism in the nigrostriatal pathway. Other side effects associated with these antipsychotics result from activity at adrenergic, cholinergic, and histaminic receptors.

Dopamine receptor antagonists are distinguished from serotonin–dopamine antagonists, also called novel or atypical antipsychotics or second-generation antipsychotics. In contrast to typical antipsychotics, the serotonin–dopamine antagonists have a higher ratio of serotonin type 2 to dopamine D<sub>2</sub> receptor blockade. Additionally, they appear to have reduced risk of short- and long-term neurologic side effects and to be superior in treating negative symptoms of schizophrenia and acute mania. Unfortunately, as patients and clinicians gained experience with serotonin–dopamine antagonists, other adverse effects, such as weight gain, hyperglycemia, and hyperlipidemia, were recognized. Head-to-head comparisons of first- and second-generation antipsychotics in the treatment of schizophrenia in adult and pediatric populations have revealed no significant difference in efficacy and reinforce the continued role of these earlier medications. Typical antipsychotics continue to be used in certain neuropsychiatric diagnoses, such as Tourette syndrome (Murphy et al., 2013), and when excessive weight gain and metabolic abnormalities result from atypical antipsychotics.

Typical antipsychotics can be classified by their dopamine receptor binding potency. High-potency antipsychotics (e.g., haloperidol, fluphenazine, pimozide) are more likely to cause extrapyramidal symptoms, whereas low-potency antipsychotics (e.g., chlorpromazine, thioridazine) are more likely to cause side effects mediated by cholinergic,  $\alpha_1$ -adrenergic, and histaminic receptor activity.

Side effects of dopamine receptor antagonists include orthostatic hypotension, peripheral anticholinergic effects (i.e., dry mouth, blurred vision, constipation, urinary retention), central anticholinergic effects (i.e., agitation, delirium, hallucinations, seizures, and coma), hyperprolactinemia, leukopenia, agranulocytosis, jaundice, photosensitivity, decreased seizure threshold, and weight gain. Thioridazine has been associated with irreversible retinal pigmentation. Chlorpromazine has been associated with skin pigmentation and deposits in the lens and cornea, which usually do not affect vision. Rarely, cardiotoxicity and sudden death have been associated with some typical antipsychotics, especially low-potency antipsychotics and pimozide.

Neurologic side effects of dopamine receptor antagonists include parkinsonism, dystonias, akathisia, and dyskinesias (collectively called extrapyramidal symptoms). Children and adolescents appear to be more sensitive than adults to these side effects. Neuroleptic malignant syndrome is a severe life threatening complication.

## ATYPICAL ANTIPSYCHOTICS

Serotonin–dopamine antagonists (also called atypical or second-generation antipsychotics) differ from typical antipsychotics in that they have a higher ratio of serotonin type 2 to dopamine type 2 receptor blockade. Risperidone, olanzapine, quetiapine, ziprasidone, and clozapine are serotonin–dopamine antagonists. Aripiprazole is commonly grouped with the second-generation antipsychotics, but it has a unique mechanism of action as a partial dopamine agonist.

Direct comparisons of serotonin–dopamine antagonists and dopamine receptor antagonists using rigorous methodology in children and adolescents have been limited. When studied, the extrapyramidal symptoms reported by patients on serotonin–dopamine antagonists do not differ substantially from those reported by patients on dopamine receptor antagonists, except for severity. With the exception of clozapine, dyskinesias have been reported with all of the serotonin–dopamine antagonists.

Weight gain has emerged as one of the most common and troubling side effects for children and adolescents on the

serotonin–dopamine antagonists. Emerging evidence reveals that serotonin–dopamine antagonists can cause development of metabolic syndrome and diabetes even with short-term treatment. As with typical antipsychotics, elevated prolactin levels can develop with the serotonin–dopamine antagonists. Cardiovascular effects have been noted with the serotonin–dopamine antagonists. Quetiapine and clozapine can cause dizziness and orthostatic hypotension, thought to be mediated by adrenergic blockade. QT prolongation has been observed with ziprasidone and clozapine.

Given the possible adverse effects of all antipsychotics and our limited knowledge of their long-term safety, careful monitoring of pediatric patients is a necessity (Correll, 2008). Recommended baseline measurements include laboratory screening (e.g., CBC, electrolytes, liver and renal function tests, thyroid function test, and fasting glucose and lipid levels), height, weight, and baseline assessment of extrapyramidal symptoms using clinician ratings (e.g., Abnormal Involuntary Movement Scale). A baseline ECG is recommended before initiating ziprasidone or clozapine.

## Risperidone

Risperidone is labeled for use in the treatment of schizophrenia and the manic phase of bipolar disorder, either alone or in conjunction with lithium or valproate in adults. In pediatric populations, risperidone is labeled for use in the treatment of schizophrenia ( $\geq 13$  years), the acute manic phase of bipolar disorder ( $\geq 10$  years), and irritability associated with autism (5 to 16 years). Risperidone has also been found to be effective in conduct disorder, aggression in children with subaverage IQ, and Tourette syndrome. Risperidone can cause sedation, dizziness, orthostatic hypotension, increased appetite, weight gain, and extrapyramidal symptoms.

## Olanzapine

In pediatric populations, olanzapine is labeled for the short-term treatment of schizophrenia and bipolar manic or mixed episodes in adolescents of 13 years of age or older. Additionally, olanzapine has been found useful in the treatment of autism and Tourette syndrome. Compared with the other atypical antipsychotics, olanzapine has consistently had the highest risk for weight gain.

## Quetiapine

In pediatric populations, quetiapine is approved for the acute treatment of schizophrenia in adolescents of 13 years or older and treatment of mania associated with bipolar disorder in children and adolescents of 10 years or older. Quetiapine was originally thought to have less risk of weight gain, but quetiapine use in typical clinical practice can increase weight in children and adolescents.

## Ziprasidone

In pediatric populations, use of ziprasidone is off-label. Before ziprasidone therapy is initiated, a careful history must be obtained to identify possible cardiac contraindications. Baseline ECG and follow up after reaching final dosage are recommended.

## Aripiprazole

Experience with aripiprazole in pediatric populations is growing, and aripiprazole has FDA approval for the acute treatment of schizophrenia in adolescents of 13 years or older,

for manic or mixed episodes of acute mania in children and adolescents of 10 years or older, and for irritability associated with autistic disorder in children and adolescents of 6 years or older. As with other mania treatments, combination treatment may be more efficacious than treatment with aripiprazole alone.

## Clozapine

Clozapine is off-label for use in pediatric populations, but it has been found effective in the management of treatment-refractory childhood-onset schizophrenia in randomized, double-blind comparison trials. Its use is limited by increased risk of adverse events. Additionally, clozapine is the only antipsychotic for which the risk of tardive dyskinesia is considered minimal. Seizures are reported in 4% of patients, with increasing risk at higher doses. Other adverse events include cardiomyopathy, hepatitis, cerebrovascular accidents, and severe anticholinergic toxicity. Agranulocytosis (absolute neutrophil count [ANC] < 500 mm<sup>3</sup>) is a serious and potentially fatal adverse effect of clozapine. The FDA requires painstaking monitoring of the white blood count (WBC) and ANC throughout the course of treatment. Experience with clozapine in the treatment of treatment-refractory childhood-onset schizophrenia has shown that neutropenia is more common in children than in adults and is estimated to occur at a rate of 10% to 13%.

## CONCLUSION

Children do benefit from psychiatric medication when treatment is provided in the context of (1) a thorough diagnostic assessment that integrates information from multiple sources, (2) knowledge of the available data for adults and children in the literature, (3) knowledge of standards when prescribing medications off-label, (4) an analysis of the risks and benefits of treatment options, (5) appropriate involvement of the child and parent or guardian in the informed consent process, and (6) close monitoring for adverse effects during therapy. Pediatric neurologists should be prepared to consult child psychiatrists regularly when questions of appropriate diagnosis, of treatment choice of medication versus psychosocial therapies, and of safety and efficacy of medication are outside their scope of practice.

## Overview of Seizures and Epilepsy in Children

Phillip L. Pearl

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

**INTRODUCTION**

An estimated 65 million people worldwide live with epilepsy. In the United States, there are approximately 3 million people diagnosed with epilepsy, and 150,000 new cases diagnosed are each year. The annual direct medical cost of epilepsy in the United States is \$12.5 billion. Epilepsy is the fourth most common neurologic disease, following migraine, stroke, and Alzheimer-related dementia. There are many gaps in care, including in the areas of access, prevention, education, and stigma. The comorbidities are vast, and include neurologic (e.g., autism), psychiatric (e.g., mood disorders, suicidality), and somatic (e.g., fractures) conditions. The range of outcomes is wide, from age-restricted conditions and long-term resolution to unemployment or underemployment, poorer overall health status, and increased mortality. Among the population with newly diagnosed epilepsy, children and older adults are the most rapidly growing segments (Hesdorffer et al., 2013). This chapter provides an overview of the changing conceptualization, categorization, and terminology of seizures and epilepsy and introduces the multiple-chapter section that follows.

**An Ancient Disease in Modern Times**

The term *seizure* derives from a Latin word meaning “attack” or “to take over,” and some of its earliest documented usage was as a military term by Thucydides in his description of the Peloponnesian wars, which took place from 431 to 404 BCE. *Epilepsy* derives etymologically from the Greek word *epilambanein*, meaning “repeated attacks,” and was used as a descriptor of events from wars to diseases. It was known as a sacred disease or the “falling sickness” in ancient times, and physicians of the Hippocratic school, circa 400 BCE, recognized that this was not a supernatural affliction but a physical malady. In particular, they emphasized an important role of heredity in its origin. The more modern understanding of epilepsy as a paroxysmal disorder of brain function, and the notion that a convulsion was but a symptom of epilepsy, began with the writings of John Hughlings Jackson (1835–1911) (Temkin, 1971). Today we conceptualize a seizure as a transient event emanating from abnormal excessive neuronal activity in the brain, and epilepsy as an enduring condition whereby an imbalance between excessive neuronal excitation and deficient inhibition leads to a predisposition to recurring seizures (Fisher et al., 2005). The protean manifestations of seizures, recognition of the heterogeneity of epilepsy along with its comorbidities, and new concepts in the definition, categorization, pathophysiology, management, and outcomes derive from these early concepts, but with dramatic recent advancements.

Thus a seizure may be provoked (i.e., situational) or, in contrast, a manifestation of an enduring predisposition to recurrent seizures and thus representative of epilepsy, the preferred term for the anachronistic term *seizure disorder*. A provoked or situational seizure implies that the seizure occurred as an isolated event related to the acute situation (e.g., fever, acute head impact, hypoglycemia, or postsyncopal). In general, after a first unprovoked seizure in childhood, the risk of a recurrence is about 50%, and after the second the risk is about 80%. Seizures are still viewed as unprovoked if they occur with stressors related to personal activity, such as sleep deprivation or severe emotional distress, unless these stressors are extreme. Traditionally, epilepsy had been diagnosed only after a child had at least two unprovoked seizures at least 24 hours apart. The definition of epilepsy, however, has been broadened.

**New Conceptual and Practical Definitions**

The International League Against Epilepsy (ILAE) has been addressing the core concepts and definitions applicable to seizures and epilepsy, along with changes in classification, since the first publication on classification and terminology in 1960, updated in 1981 for seizures and in 1989 for the epilepsies. Based on advances in basic and clinical neurosciences, and the mandate to incorporate these into clinical practice, the definitions and terminology for both seizures and epilepsy were revised in a special report published in 2010 (Berg et al., 2010), although this revision remains in debate. Generalized seizures are defined as seizures occurring in and rapidly engaging bilaterally distributed networks, and are classified as tonic-clonic, absence, myoclonic, clonic, tonic, and atonic (Table 61-1). Focal seizures are no longer dichotomized as simple versus complex, which was previously based upon whether an alteration of consciousness was present, and furthermore are also no longer called “partial,” recognizing that they are no less complete than are generalized seizures. Instead, focal seizures are described according to their manifestations (e.g., focal motor, autonomic, dyscognitive) if there is impairment of consciousness or awareness. Of relevance to child neurologists, neonatal seizures are no longer regarded as unclassified or a separate seizure type, and instead are classified within the proposed scheme. In addition, there is an “unknown category” that includes epileptic spasms, which subsumes infantile spasms and recognizes that these may continue past infancy or even begin after the age of 1 year.

The earlier concepts of idiopathic, symptomatic, and cryptogenic epilepsy have been replaced by genetic, structural-metabolic, and unknown. The three new terms should not be conflated with the three prior terms, despite the rough resemblance. The concept that idiopathic likely represented

a pharmacoresponsive disorder with a predictable age-related remission, along with absence of comorbidities, had to be discarded with the realities of the natural history and variety of cognitive and behavioral disorders documented in many patients heretofore diagnosed with idiopathic epilepsy. Only about half of patients with childhood absence epilepsy are seizure-free after treatment with the initial medicine (Glaser et al., 2010). Patients with juvenile myoclonic epilepsy have now been demonstrated to have abnormal structural imaging findings and impaired cognitive development in the first 2 years after diagnosis compared with controls in a prospective trial. In addition, only half of subjects were seizure-free for 1 or more years after 2 years of treatment. The term *structural-metabolic* is intended to distinguish this admittedly heterogeneous group from that of genetic, that is, genetic versus everything else. The “unknown” group is a moving target, especially as new genes are identified, whether coding for channels, receptors, or other structures, or possessing other modifying or regulatory functions.

More recently, a practical clinical definition of epilepsy has been proposed by the ILAE that takes into account the propensity for recurrent seizures even after a single seizure in selected patients, as well the criteria for when epilepsy may be considered to be resolved. The diagnosis of epilepsy may now be applied after a single unprovoked seizure if there is a likelihood of further seizures similar to the general recurrence risk (which is 60%+) after having had two unprovoked seizures over the subsequent 10 years (Table 61-2). Additionally, if the clinical criteria are met to establish the presence of a recognizable epilepsy syndrome even after a single seizure (e.g., juvenile myoclonic epilepsy in the appropriate setting), the diagnosis of epilepsy may be established. Reflex seizures (e.g., following visual patterns or flashes of light) are essentially included in the category of unprovoked seizures in terms of the definition of epilepsy. Epilepsy is considered resolved in the case of an age-dependent epilepsy syndrome in individuals past the applicable age, or in patients who have remained seizure-free for the last 10 years, with no seizure medicines used for the last 5 years (Fisher et al., 2014).

Of particular relevance to pediatric practitioners are the time-honored electroclinical syndromes that identify clusters of characteristics that help to group patients into recognizable cohorts. These designations are meaningful in terms of diagnostic and therapeutic implications and prediction of

**TABLE 61-2** Operational (Practical) Clinical Definition of Epilepsy

Epilepsy is a disease of the brain defined by any of the following:

1. At least two unprovoked (or reflex) seizures occurring > 24 h apart
2. One unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years
3. Diagnosis of an epilepsy syndrome

Epilepsy is considered to be *resolved* for the following individuals:

1. Those who had an age-dependent epilepsy syndrome but are now past the applicable age
2. Those who have remained seizure-free for the last 10 years, with no seizure medicines for the last 5 years

(Adapted from Fisher RS, Acevedo C, Arzimanoglou A, et al. *Epilepsia* 2014; 55: 475–482.)

outcomes. Clinicians rely on recognizing these patterns to manage and counsel patients and families. Whereas common syndromes such as childhood absence epilepsy and benign rolandic epilepsy previously were classified using the dichotomy of focal versus generalized seizures, this scheme has been abandoned because new gene discoveries have revealed that many of the syndromes overlap these somewhat artificial boundaries. Thus the syndromes have been reorganized based on presentation by age, which is clinically friendly, especially for the developmental approach to disease adapted by pediatric practitioners (Berg et al., 2010) (Table 61-3). Still, the diversity and heterogeneity of etiologies in epilepsy have led to a renaming of this group of disorders as the “epilepsies,” and the majority of patients will not fit easily into a defined electroclinical syndrome. The syndromes are in a state of flux because the conditions underlying them have been further elucidated with advances in neuroimaging and gene discovery.

## Conceptual Evolution and a New Lexicon for the Epilepsies

The Institute of Medicine (IOM) released a landmark report, “Epilepsy across the Spectrum: Promoting Health and Understanding,” that highlighted gaps in the knowledge and management of epilepsy and recommended actions for improving the lives of patients and families (Hesdorffer et al., 2013). The focus on epilepsy has thus enlarged from that of a “seizure disorder” to a wide spectrum including a diversity of seizure types, underlying syndromes, etiologies, comorbidities, and outcomes. The committee responsible for the report was also focused on the longstanding stigma associated with the condition, and suggested that use of the term *epileptic* be discontinued because of its negative connotation. Thus the preferred term is *person with epilepsy*, and the term *antiseizure medications* is preferred over *antiepileptic drugs*. This updated terminology will be employed throughout this text.

## EPIDEMIOLOGY

Epidemiologic studies have addressed the incidence and prevalence of epilepsy in children, although differing case ascertainment methods, definitions of epilepsy, age range of subjects, and inclusion of children with febrile seizures make comparison between studies challenging. The newborn period is an additional complicating factor because newborns will have seizures as the result of an acute encephalopathy but without possessing an enduring predisposition to develop ongoing epilepsy. Many incidence/prevalence studies have excluded babies younger than 1 month of age. The issue of whether to include febrile or “illness-related” seizures can also

**LESS SPECIFIC AGE RELATIONSHIP**

Familial focal epilepsy with variable foci (childhood to adult)  
 Reflex epilepsies (e.g., photosensitive, audiogenic, or reading-induced seizures; may or may not coexist with spontaneous seizures)

\*Not listed as a syndrome by the International League Against Epilepsy (ILAE) but instead recognized under absence seizures with special features.

be confusing, especially when documentation of fever is not always available, children may have a mixture of febrile and afebrile seizures, and seizures associated with acute illness may be difficult to interpret if there is no fever. The age range for febrile seizures is typically given as 6 months to 5 years (basically, to the sixth birthday), although some children older than 5 years will have a seizure with fever but not go on to develop epilepsy.

The average incidence of epilepsy in children across studies is approximately 0.1%. The reported incidence has a wide range, from 41 in 100,000 in all children in Nova Scotia to 187 in 100,000 in children 6 to 9 years of age in Kenya. In developed countries, the incidence has ranged from 33.3 to 82 children less than age 16 years per 100,000 persons per year. The incidence is highest in the first year of life, with a range of 81 in 100,000 in Rochester, Minnesota, in 1945; to 54 to 118 in 100,000 in Nova Scotia, from 1977 to 1985; to 130 in 100,000 in Iceland, from 1995 to 1999. A more recent assessment in Rochester, Minnesota, for 1980 to 2004 showed an incidence of 102 in 100,000 in children up to 12 months of age (Wirrell et al., 2011). The incidence during childhood is about 50 in 100,000, and in adolescence is about 20 in 100,000, similar to

most published rates in adults in developed countries (Wirrell et al., 2011). The incidence is essentially the same in boys and girls.

Despite the previous discussion regarding the new classification of epilepsy syndromes, only about a third of children with epilepsy can be assigned to a specific syndrome, and many of these syndromes are quite rare. Thus incidence data for specific syndromes are inconsistent and overly sensitive to small shifts in the number of reported cases. Yet for a more historically common breakdown of seizure types, studies have shown that focal-onset seizures are more common, occurring in 55% to 60% of children with epilepsy, than are generalized seizures (reported in approximately 40%) (Wirrell et al., 2011), whereas spasms comprise 2% to 5% of pediatric epilepsy.

The prevalence of epilepsy in children is approximately 5 in 1000 in developed countries. As expected, prevalence is higher than incidence because epilepsy is a chronic disorder, although some children will have a flurry of seizures at one time without recurrence. Comparisons between countries can be difficult to interpret, because the proportion of children in the population varies from country to country, with the highest found in developing countries. In underdeveloped countries, the prevalence rates are higher and have a wide range, from 7.5 to 44.3 in 1000 children.

**DIAGNOSIS**

In clinical practice, the diagnosis of epilepsy rests not only on the traditional definition of two unprovoked seizures and the new definition based on recurrence risk as discussed earlier, but in particular on the differential diagnosis of a seizure versus mimicking events. Misinterpretation and misdiagnosis are not uncommon occurrences. The now widespread use of cellular video and abundant use of video electroencephalogram (EEG) monitoring, whether with inpatient or ambulatory EEG systems, certainly add to the traditional history taking when exploring the underpinnings of paroxysmal clinical events. Still, the details of provoking factors; underlying acute, subacute, and chronic illnesses; and the patient's clinical situation, medical and family history, and environment are mandatory aspects of history taking that go far in constructing the essential differential diagnosis. Parents and observers vary in their capacity to describe these frightening events, and history taking remains an art. Even among neurologists, discordant diagnoses have been reported in 35% of cases of possible first seizures. Additional events may be necessary to establish a diagnosis of epilepsy. Disorders that are frequently confused with epilepsy commonly include syncopal seizures associated with vasodepressor syncope or breath-holding spells. Differential diagnosis of paroxysmal events is described in more detail in the subsequent chapter on seizure management and outcome. The problem of psychogenic nonepileptic seizures is a significant challenge, although there are specific features that incriminate this diagnosis, as is covered in detail in a separate chapter.

The EEG can establish a diagnosis of epilepsy if a seizure is recorded, but interictal EEGs can be problematic because false positives and false negatives occur. Up to 5% of children have epileptiform activity on EEG without having clinical seizures, and up to 40% of children with chronic epilepsy do not demonstrate interictal epileptiform discharges on EEG. EEG findings may confirm syndrome diagnosis but may also change significantly over time, may reveal conflicting findings, and are subject to high interreader variability.

Likewise, the diagnosis of epilepsy cannot be based on brain-imaging studies. The presence of an anomaly on magnetic resonance imaging (MRI) increases the possibility of epilepsy and, depending on the nature of the abnormality,

increases the likelihood of a specific seizure type or epilepsy syndrome. For example, lesions typical of tuberous sclerosis in the first year of life increase the risk that a child will have infantile spasms.

## OVERVIEW AND SUMMARY

There are many unanswered questions in identifying an accurate description of the incidence, prevalence, comorbidities, and spectrum of the epilepsies, especially given the shifting sands in definitions and classification systems. Overall, it is estimated that the lifetime risk of having a seizure of any kind is 8%, and the lifetime risk for epilepsy is about 1%. About 3% to 4% of all children will have a febrile seizure, although the overall risk of later epilepsy following a febrile seizure is only 2% to 3%. With the exception of febrile seizures, provoked seizures appear to have little risk of recurrence once the provoking factor has resolved, unless there are specific associated risk factors (e.g., the presence of cerebral hemorrhage or penetrating head injury in traumatic brain injury) (Lowenstein, 2009). The advent of modern neurogenetics and increasingly common use of testing for gene microdeletions and microduplications and mutations in nucleotide sequencing in child neurology practice have virtually transformed the practice of pediatric epilepsy, with increasing identification of causes of severe epilepsies and epileptic encephalopathies heretofore poorly understood.

This section begins with a set of chapters covering the fundamentals of the clinical and basic science of epilepsy: principles of management and outcome, neurophysiology, and genetics. Then the broad categories of seizure types, generalized and focal seizures, are covered in addition to the common provoked seizures of childhood, febrile seizures, for which new data and concepts have shed new light on this usually benign but also heterogeneous seizure type. Specific attention is paid to the problems of epileptic spasms and status epilepticus. Then the age-related syndromes, tabulated in this chapter, are expanded as individual chapters, followed by discussions of the acquired and inherited metabolic epilepsies. Each of these topics has important applications to pediatrics. Treatment approaches are then presented in chapters on antiseizure medication therapy, epilepsy surgery, neuromodulation, and dietary therapy. The topics of psychogenic nonepileptic seizures and comorbidities complete the section, with emphases on behavioral and cognitive aspects and a newly added chapter on the problem of mortality. Children with epilepsy are at increased risk for earlier mortality than expected based on age, although this risk is very small, estimated as 1 in 10,000, for patients presenting with a new diagnosis of epilepsy with no neurologic deficit or complicating factors (Callenbach et al., 2001; Camfield, Camfield, and Veugelers, 2002). Early mortality is multifactorial and related to accidents, comorbidities, and complications of seizures and status epilepticus, but sudden unexpected death in epilepsy patients

(SUDEP) has emerged as the leading cause. Risk of the latter climbs to approximately 1 in 1000 in patients with medically refractory epilepsy evaluated for surgical candidacy. Thus the spectrum of epilepsy, from its causes to manifestations, comorbidities, and outcomes, is wide in all respects.

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

The goals of this chapter are to outline when to start antiseizure treatment for children with epilepsy, factors that influence routines of care, when to stop medicines, and how to predict the seizure and social outcomes as children with epilepsy become adults.

### STARTING ANTISEIZURE TREATMENT

Antiseizure treatment is usually started when epilepsy is diagnosed but there are exceptions. After a first unprovoked seizure in childhood, the risk of a recurrence is about 50%, and after the second seizure the risk is about 70% to 80%. By convention, epilepsy is diagnosed only after a child has had two or more unprovoked seizures. A recent official report from the International League Against Epilepsy (ILAE) suggests that epilepsy is a disease of the brain defined by any of the following conditions: 1) at least two unprovoked (or reflex) seizures occurring more than 24 hours apart; 2) one unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years; 3) diagnosis of an epilepsy syndrome. We doubt that many children should start treatment after a first seizure even if the risk of recurrence is very high, because the direct consequences of a second seizure are typically small. In addition, based on a large randomized Italian study, the chance of a long-term remission is unchanged if antiseizure medicines are started after the first or the second seizure.

The diagnosis of an epilepsy syndrome may also not lead to antiseizure treatment, especially in children with rolandic epilepsy in whom seizures are usually infrequent and mainly nocturnal. Many children with this diagnosis can be managed without treatment. The term “unprovoked” implies that there has been no closely associated concurrent illness, fever, or acute brain injury. Recurrent seizures immediately after a head injury or associated with drug intoxication do not qualify for the diagnosis of epilepsy. Specific provoking factors leading to reflex seizures are permitted, such as seizures provoked by patterns and flashes from video terminals in children with photosensitive epilepsy. Seizures are still viewed as unprovoked if they occur with stresses related to personal activity, such as sleep deprivation or severe emotional distress, unless these stresses are extreme.

Before starting treatment it is imperative that the diagnosis of epilepsy be definite. **Box 62-1** lists a number of conditions that may mimic epilepsy. If there is doubt, we are of the opinion that it is better to wait for further similar episodes. Home video may be very valuable. The diagnosis of epilepsy cannot be made from an EEG unless an actual seizure is recorded. Interictal “epileptic” discharges are seen in 3% to 5% of children without seizures. It is also critical that the proposed benefits of treatment are greater than the potential consequences of treatment. For example, a child with infrequent, brief, focal seizures without loss of awareness or motor control may not benefit from treatment, given that all medications have some side effects and that the process of taking daily medicines is intrusive.

The value of treatment is a reduction in recurrent seizures with the hope that associated psychosocial problems, stigma, and injuries will be reduced. There is no evidence that treatment has any effect on the chance of long-term remission, and there is no convincing human evidence that one seizure makes the occurrence of another more likely. Although there is a risk of sudden unexpected death in epilepsy (SUDEP) for anyone with seizures, the risk is tiny in childhood-onset epilepsy. Fear of SUDEP should not be a significant motivation to start treatment. Another reason for starting treatment is to attempt to reduce EEG interictal spike discharges in patients with “epileptic encephalopathy.” Here it is postulated that these spike discharges interfere with cognition. Most of these patients have multiple clinical seizures and the decision to start medication is not difficult. Others with epilepsy syndromes such as Landau-Kleffner syndrome or continuous spike-wave in slow wave sleep often have few overt seizures—the potential role of treatment is improved cognition. This issue is dealt with in Chapters 70 to 72. Unfortunately, few conventional antiseizure medicines suppress interictal spikes.

### Which Medicine to Start With?

There are very few randomized clinical trials in children with new-onset epilepsy that compare different medicines in “head-to-head” studies. For the most part, clinicians must rely on experience and expert consensus (low forms of evidence). The SANAD study randomized 3158 patients with newly diagnosed epilepsy (mainly adults) to a series of antiseizure medicines and found that, as a first antiseizure medicine, lamotrigine was most effective for focal epilepsy and valproate was best for generalized epilepsy. However, many pediatric epilepsy syndromes were not included in this study. Chapters that follow on individual syndromes outline the “best” first choices for particular syndromes. Factors that should enter the decision of which medication to start first include the specific syndrome, the age of the child, cost, availability of the medication, and ease of administration. There is an unproven but sensible assumption that the best medication should improve rather than exacerbate comorbid problems. For example, lamotrigine or valproate might improve comorbid depression, whereas levetiracetam or clobazam might exacerbate oppositional defiant disorder.

### Routines of Care

The “correct” dose of an antiseizure medicine suppresses seizures completely but causes no or minor side effects. This simple concept is not easily applied in clinical practice. Some children have long intervals between seizures, and so it may take many months to be confident that seizures are suppressed. The “rule of threes” may be useful—if there have been no seizures for three times the usual seizure-free interval, then it is likely that the medication is effective. At the beginning of treatment, many children have had too few seizures to estimate the “usual” interval.

**BOX 62-1** Disorders That May Mimic Childhood Epilepsy**CONFUSED WITH GENERALIZED TONIC-CLONIC SEIZURES**

Pallid syncope (reflex anoxic seizure)  
 Vasodepressor syncope (reflex anoxic seizure)  
 Cyanotic breath-holding attacks  
 Collapsing attacks with cardiac dysrhythmias  
 Cataplexy

**CONFUSED WITH GENERALIZED ABSENCE SEIZURES**

Behavioral staring attacks  
 Complex partial (dyscognitive) seizures  
 Tic disorder

**CONFUSED WITH COMPLEX PARTIAL (DYSCOGNITIVE) SEIZURES**

Self-stimulatory behavior, especially in children with autistic spectrum disorders  
 Sleep walking  
 Night terrors  
 Temper tantrums with amnesia for the rage event  
 Benign paroxysmal vertigo  
 Migraine-related disorders

**CONFUSED WITH EPILEPTIC MYOCLONUS**

Physiologic hypnagogic myoclonus  
 Benign infantile sleep myoclonus  
 Startle disease

It is often postulated that antiseizure medicines are most likely to be effective if the serum level is in the “therapeutic range.” This appealing concept is without scientific proof. Three randomized trials comparing regular blood level monitoring with no monitoring have failed to show any benefit in seizure control. One of the trials showed more clinical toxicity with monitoring than without. The “therapeutic range” for most antiseizure medicines is not based on randomized trials and typically has been developed in a non-evidence-based mode (Camfield and Camfield, 2003).

It is also important to realize that only about 20% of children with epilepsy will have *smooth sailing* epilepsy, which means that they will have no further seizures once the first medicine is introduced (Camfield et al., 1993). Therefore the clinician, patient, and family need to start treatment with the expectation that it may be difficult to find the optimal dose of the optimal drug. The process continues to be characterized by a great deal of trial and error.

Once a drug has been started, monitoring for side effects is important. Based on personal experience, we recommend that patients be seen in person about a month after starting an antiseizure medicine and that the visit focuses on side effects, restrictions, and social aspects. It is surprisingly easy for families and others to lose track of what the child was really like before medications were started. The child may not be able to report a change, and if seizures are controlled, parents may choose to ignore some important behavioral or cognitive effects. Again, there is scant evidence that serum levels “in the therapeutic range” predict a lack of side effects. Side effects may only be recognized when a medicine is changed or discontinued.

There is no evidence that regular monitoring of blood and urine reduces the chance of serious biological reactions to any antiseizure medicine. Minor alterations in these “routine” investigations mean that the tests need to be repeated and may lead to an unnecessary discontinuation of an effective

medicine. For example, a child receiving carbamazepine may develop a viral illness that suppresses the blood neutrophil count, which could lead to the false conclusion of impending bone marrow failure.

There are many ways of enhancing adherence with therapy. Simple measures are to avoid more than twice-daily dosing with medication at breakfast and bedtime. Families need to know what to do if they miss a dose, information that will depend on the specific medication. A 7-day pill dispenser may help some patients. Prescription quantities for many months at a time makes it less likely that families will run out of medication. Most of all, adherence is improved by providing a clear understanding of the rationale for treatment. Issues of adherence should be addressed at every visit. We are of the strong impression that simply asking patients about adherence in a nonaccusative fashion is a more effective technique than multiple blood level determinations.

Injuries resulting from seizures are not uncommon. About 10% of children with epilepsy will eventually have an injury as the result of a seizure that is sufficient to require medical or dental consultation. These injuries usually occur months or years after starting medication, usually occur during normal activities, and cannot be prevented except by complete seizure control. Restrictions to the child’s normal activities are usually not warranted, particularly if the seizures appear to be controlled. Drowning in the bathtub is a concern—a shower is a safer alternative.

**PREDICATION OF SEIZURE OUTCOME**

For many children, epilepsy is transient, and with maturation, the problem seems to vanish. At the time of diagnosis, it is possible to predict that at least 50% to 70% of children will outgrow their disorder and be able to discontinue medication (Berg et al., 2014). The longer the follow-up, the higher the proportion with remission of symptoms. In Rochester, MN, 115 children with epilepsy beginning before age 10 years were followed through the Mayo Clinic record linkage system. Ten years later, 75% had been seizure-free for at least 5 years, and 51% no longer received medication. At the end of a remarkable 30-year follow-up study of children with epilepsy from a population-based sample in Turku, Finland, Sillanpää et al. (1998) found that 76% of survivors had been seizure-free for at least 3 years, although a number of these patients continued with treatment.

Across most studies, factors that predict which children will outgrow their epilepsy have included normal intelligence, normal neurologic examination findings, relatively small numbers of seizures at diagnosis (which means that complex partial or dyscognitive seizures are unlikely to remit), age of seizure onset younger than 1 year of age (unfavorable), age of seizure onset older than 1 year and younger than 12 years (favorable), and absence of a remote symptomatic cause (an identified brain problem that preceded the onset of epilepsy).

A causative lesion on magnetic resonance imaging (MRI) makes remission unlikely; however, two population-based studies have shown that, even with such a lesion, approximately 30% will go on to a seemingly permanent remission (Dhamija et al., 2011). In addition, failure of the first medicine to control seizures in adults is ominous with possibly only a 10% chance of success with subsequent medicines. In children the failure of the first medicine is not as ominous. In the Nova Scotia study, 42% of those who failed their first antiseizure eventually entered remission versus 61% of those who did not fail the first drug. Failure of a second medicine to control seizures is now used as a definition of pharmacoresistant epilepsy and should lead to a careful reevaluation of the

**TABLE 62-1** Scoring System for Remission of Childhood Epilepsy at the Time of Diagnosis

Variable	Score*
Age of first seizure (months)	
<12	99
12–144	142
>144	0
Intelligence	
Normal	111
Retardation	0
Previous neonatal seizures	
No	218
Yes	0
Number of seizures before starting medication	
1 or 2	72
3–20	123
>20	0

\*Add the scores from this column. If the total score is greater than 495, the child is predicted to have remission of epilepsy. (Adapted from Sillanpaa M, Camfield PR, Camfield CS. Predicting long term outcome of childhood epilepsy in Nova Scotia, Canada, and Turku: Validation of a simple scoring system. *Arch Neurol* 1995;52:589.)

diagnosis and consideration of other types of treatments such as surgery or the ketogenic diet.

Based on clinical features present at the time of diagnosis, it is possible to predict the long-term outcome with moderate accuracy. In an 8-year follow-up study of a population-based study of 504 children with epilepsy from Nova Scotia, a predictive scoring system was developed; it is outlined in [Table 62-1](#) (Camfield et al., 1993). Those with a good prognosis had an 80% chance of remission (i.e., seizure-free and no longer receiving medication). For those with one or more of the adverse factors scored, the chance of remission was less but still about 40%. The Dutch Study of Epilepsy in Childhood found comparable predictive variables and supplemented these with the clinical course in the first 6 months of treatment (Wirrall et al., 2011). Rates of correct prediction were similar.

The Dutch and Nova Scotia studies were combined to allow study of 1055 newly diagnosed patients with 5 or more years of follow-up. Multivariate analysis that included clinical factors, syndrome diagnosis, and response to treatment in the first 6 months revealed that, at the time of diagnosis, a prognostic scoring scheme could correctly predict remission or no remission in about 70%. This means that at the time of diagnosis if parents ask, “Will the seizures be outgrown?” the physician will give the wrong answer in about one-third of cases.

Surprisingly, most epilepsy syndromes do not have a definite outcome; however, a few specific syndromes allow an accurate prognosis. Epilepsy is virtually always outgrown in cases of rolandic epilepsy, benign myoclonic epilepsy of infancy, and benign occipital epilepsy, early onset type. Epilepsy is virtually never outgrown in children with Rasmussen syndrome, Lennox-Gastaut syndrome, or Dravet syndrome. Other syndromes have a variable prognosis with some having a permanent remission and others with the same syndrome continuing to require treatment for ongoing seizures. For example, about 65% of children with childhood absence epilepsy will enter a long-term remission, whereas 35% will not.

## Intractability

Defining intractable epilepsy is difficult, and many definitions have been suggested (Wirrell, 2013). For a study of 613

children with epilepsy from Connecticut, Berg and Shinnar (1994) defined intractability as a “failure, for lack of seizure control, of more than two first-line antiseizure medications with an average of more than 1 seizure per month for 18 months and no more than three consecutive months seizure free during that interval.” There were 60 (10%) intractable cases in the first 24 months after diagnosis. Using the ILAE classification from 1989, the proportions of intractable patients in each major syndrome grouping were as follows: cryptogenic/symptomatic generalized, 34.6%; idiopathic generalized, 2.7%; other localization related, 10.7%; and unclassified, 8.2%. Sillanpää’s follow-up study from Turku, Finland, defined intractability as one or more seizures per year in the past 10 years of follow-up. After 20 years of follow-up, 22% of patients met this criterion. Predictors of intractability included poor initial response to medication, remote symptomatic cause, and status epilepticus. The Dutch Study of Childhood Epilepsy (using Berg and Shinnar’s definition of intractability), with 453 children followed for 5 years, found that 6% were intractable. For the Nova Scotia study, intractability was defined as “at least one seizure each 3 months for the last year of follow-up, with failure of at least three antiseizure drugs.” For those with epilepsies characterized by partial and generalized tonic-clonic seizures, 8% of 511 children became intractable during an average of 8 years of follow-up. After 20 years of follow-up, 51% of 75 patients with childhood-onset symptomatic generalized epilepsy had intractable seizures. In this study, the major predictor of intractability was severe neurologic deficit at the time of diagnosis.

The ILAE’s current definition of intractability is failure of two appropriate medications. The definition is most applicable to adults, because some children who meet this definition will still have a permanent remission.

An important issue in the definition of intractability is the length of follow-up, because a number of children with intractable epilepsy eventually become well controlled. For example, in a series of 145 children with intractable seizures (>1 seizure per month for  $\geq 2$  years) followed over 18 years, Huttenlocher and Hapke observed that 75% of normally intelligent children and 30% with mental handicap eventually had complete or nearly complete seizure remission (i.e., <1 seizure per year). In contrast, another study retrospectively reviewed the history for adults undergoing a workup for intractable epilepsy. It was common to find long periods of remission during childhood. Apparently, intractable epilepsy in childhood may seem to resolve spontaneously but on rare occasions re-emerges as intractable epilepsy in adulthood.

In summary, intractability for an individual child is difficult to predict before several years of treatment. Intractability appears to decrease with prolonged follow-up, although the burden of this wait-and-see approach may be substantial. Failure of a second medication is an important, but not absolute, risk factor for intractability. As a general rule, consideration for epilepsy surgery should await failure of three appropriate drug treatments. Other factors influence this decision, including seizure etiology, severity, frequency, MRI findings, and the duration of epilepsy.

## When to Stop Antiseizure Medicines

About 60% to 70% of children with epilepsy who have become seizure-free for 1 to 2 years can successfully stop medication treatment (Berg and Shinnar, 1994); however, the rate of success is higher if the seizure-free period has been 2 years compared with 1 year. The rate of success is no greater if medication is continued for up to 5 years seizure-free. Factors that predict successful discontinuation of medication include generalized seizures, age of onset before 10 to 12 years, normal

neurologic examination, and, in some studies, resolution of interictal EEG spike discharges. Children with no adverse factors have an 80% to 90% success rate. Each factor has an additive effect and those with all of the adverse factors may have only a 10% to 20% success rate.

If an initial discontinuation trial is unsuccessful, medication is usually restarted with a return to seizure freedom. The risk that seizures will not come under control again and become intractable is only about 1%. When medications are restarted, about 50% of children again become seizure-free for sufficient time to try to discontinue medication a second time, with a 70% success rate.

This approach is not applicable to all epilepsy syndromes. For example, the remission rate for juvenile myoclonic epilepsy (JME) is low, although several studies suggest that eventually 40% will no longer require daily medication. Still many experts suggest that medication for juvenile myoclonic epilepsy should be lifelong and that further attempts to discontinue medication after an initial failure are probably not warranted.

The optimal length of treatment has been addressed in several randomized trials. A Scandinavian study randomized 207 children at the time of diagnosis of epilepsy to receive 1 or 3 years of treatment. If the child was seizure-free for the last 6 months of study, medication was discontinued. This practice meant that some of the children in the 1-year treatment group had been seizure-free for only 6 months before medication was stopped. The success rate for those in the short-treatment group was significantly less than for the 3-year group (53% vs. 71%). A Dutch study randomized 161 children with epilepsy that was controlled within 2 months of starting treatment to 6 months or 1 year of treatment. The 6-month group had a higher relapse rate when medication was stopped; however, by 2 years later, the rates of remission were identical. Nonetheless, for a substantial number of children, epilepsy was a short-lived disorder requiring only short-term medication use. Medication treatment for benign rolandic epilepsy often is not needed, and further studies will likely identify other children who do not require drug treatment.

The optimal rate of taper of medication has been subject to a randomized trial—6 weeks versus 9 months. Although the success rate was slightly higher with the slower taper (not statistically significant), we suspect that most clinicians choose a 1- to 3-month schedule. If seizures are to recur after medicine discontinuation, it is nearly always within the first 6 months. Recurrences after 2 years are extremely unlikely.

## SOCIAL OUTCOME

Follow-up studies into adulthood have increasingly shown that many adults with childhood-onset epilepsy have unsatisfactory social outcomes. The reasons for this lack of success are unproven but are likely related to four themes. First, varying degrees of cognitive problems are very common in children with epilepsy. These problems are present at the onset of the epilepsy, although they may be exacerbated by medication side effects and frequent seizures. They are very likely to influence academic success, eventual employment, and self-esteem. Second, attention-deficit/hyperactivity disorder, depression, other psychiatric disorders, and behavior disorders are more common in children with epilepsy than controls and are known to have a negative effect on social outcome, especially on personal relationships. Austin and colleagues reported that, at the time of diagnosis, 40% of children were at significant risk of behavior problems, as judged by scores on the Child Behavior Checklist (Austin et al., 2002). Those with multiple recurrent seizures were at even higher risk. Ostrom and colleagues demonstrated greater cognitive and behavioral problems and the need for special educational

assistance among 51 outpatient children with idiopathic or cryptogenic epilepsy compared with their classmate controls (Ostrom et al., 2005). Some of these issues are reviewed in more detail in Chapter 82. Third, the diagnosis of epilepsy is associated with considerable stigma in most cultures, which undoubtedly affects social outcome by limiting friendships, activities, and eventual choice of employment. For example, Trostle reported that parents indicate a reluctance to have their normal children play with a child with epilepsy (Trostle, 1988). Less than one third of 20,000 U.S. high school students indicated that they would date a person with epilepsy. Finally, poorly controlled seizures limit many important activities such as driving. Most countries require a year without seizures in order for a person to drive; however, there is considerable variation between locations.

The Nova Scotia epilepsy cohort showed that when children with childhood absence epilepsy became young adults they were much more likely to have a multitude of social difficulties than a chronic disease control group (children with juvenile rheumatoid arthritis). These difficulties included poor education, alcohol abuse, unemployment, and inadvertent pregnancy. Other studies have compared children with epilepsy to those with asthma with similar findings. Therefore social difficulties related to epilepsy are not simply the non-specific effect of a chronic disease.

In Finland, children with “epilepsy only” were followed into young adulthood and compared with age- and sex-matched controls. “Epilepsy only” meant having normal intelligence and no other neurologic handicaps. About 30% of patients had significant social adjustment problems with decreased rates of stable relationships, marriage, social contacts, job satisfaction, and work achievement. Rates of unemployment or underemployment were high. Social outcome was not clearly related to epilepsy remission. In the Nova Scotia study, seizure-related factors did not predict social outcome. The strongest predictor of poor social outcome in young adulthood was the presence of a learning disorder, although predictive models were inaccurate; the main reasons for the unsatisfactory outcomes were unclear.

Wakamoto and colleagues studied 148 normally intelligent young adults (>20 years old) living in a rural district of Japan who had childhood-onset epilepsy. This population-based study found that 72% attended regular classes (vs. 99% of those without epilepsy), 66% (vs. 97%) entered high school, 67% (vs. 95%) had employment, and 23% (vs. 33%) married.

Few studies have addressed the social outcome of children with specific epilepsy syndromes. Several studies have indicated a favorable outcome for adults with previous benign rolandic epilepsy. The Nova Scotia study has provided population-based data about social outcome 20 to 35 years after diagnosis for a variety of epilepsy types in patients with normal intelligence. Information was gathered by semistructured interviews, and adverse outcomes were defined as failure to complete high school, pregnancy outside of a stable relationship (<6 months), depression or another psychiatric diagnosis, unemployment, living alone, never in a romantic relationship for more than 3 months, and poverty. Table 62-2 shows the percentage of patients with each of these adverse events. We note that, except for rolandic epilepsy, about 75% of each syndrome group had a major indicator of poor social outcome (Camfield and Camfield, 2014).

The social outcome for those with intellectual disability (ID) is perhaps more difficult to study, because of difficulties in assessing social outcome, especially in those with moderate to severe ID. About 20% of children with new-onset epilepsy have ID with more than expected having moderate to severe ID (75%). In the Nova Scotia study after 20 years of

**TABLE 62-2** Adult Social Outcome for Epilepsies in Patients with Normal Intelligence: The Nova Scotia Population-Based Study

 \*Adverse social outcomes: failure to complete high school, pregnancy outside of a stable relationship (<6 months), depression or another psychiatric diagnosis, unemployment, living alone, never in a romantic relationship >3 months, and poverty.

follow-up, almost none of these patients were able to live independently.

If the long-term social outcome of childhood epilepsy is to be improved, physicians must address these issues with equal enthusiasm to medical treatment. Learning problems, sexuality, and socialization should be assessed regularly and appropriate interventions considered. Early referral to both local and Internet sites for an epilepsy support group may also be of benefit.

This chapter reviews the cellular basis of seizures and the factors that enhance susceptibility of the immature brain to seizures and epilepsy. We emphasize how dysfunction of ion channels and synaptic transmission can lead to cellular hyperexcitability and hypersynchronous neuronal firing, the hallmark features of seizures. The mechanisms of actions of antiseizure drugs (ASDs) are also summarized.

A seizure is defined as abnormal neuronal firing leading to a clinical alteration of neurologic function (motor, sensory, autonomic, or psychological). A seizure reflects aberrant activity at the level of both single neurons and the neuronal network. Epilepsy is the condition of spontaneous recurrent seizures arising from heightened electrical activity within the brain. Epilepsy is not a singular disease—it is heterogeneous in terms of etiology, clinical features, and pathophysiology. An epilepsy syndrome refers to a constellation of signs and symptoms that often occur together, such as seizure type, age of seizure onset, responsiveness to certain ASDs, and characteristic electroencephalogram (EEG) findings, underlying genetics, and natural history. Epileptogenesis is the process by which neural circuits undergo structural and/or physiologic changes, resulting in an enduring epileptic state.

## CLASSIFICATION OF SEIZURES

Seizures are divided into two groups, according to their site of origin and pattern of spread. Focal seizures arise from a localized brain region; the associated clinical manifestations are related to the function ordinarily subserved by that area. Focal discharges can spread locally through synaptic and nonsynaptic mechanisms, distally to subcortical structures, and through commissural pathways that may eventually involve the entire cortex.

Primary generalized seizures begin with abnormal electrical discharges in both hemispheres simultaneously and involve reciprocal thalamocortical connections, manifesting on EEG as bilateral synchronous spike-waves. The manifestations of generalized seizures range from brief impairment of consciousness (e.g., absence seizure) to whole-body convulsion (generalized seizure).

## CELLULAR ELECTROPHYSIOLOGY

### Excitation–Inhibition Balance

Seizure activity can be conceptualized as a perturbation in the normal balance between neuronal inhibition and excitation, involving a localized region or widespread brain areas (Stafstrom, 2014). This concept is admittedly oversimplified. For example, factors once thought to be solely inhibitory (e.g.,  $\gamma$ -aminobutyric acid [GABA]-ergic synaptic transmission) can be excitatory in some instances. Furthermore, synaptic inhibition is critical for certain normal brain rhythms and probably also plays a role in abnormal rhythmic activity, such as spike-wave discharges. The discovery of novel genetic mutations has required expansion of the excitation–inhibition imbalance concept. For example, mutations in genes encoding several

proteins involved in both excitatory and inhibitory synapse development and stabilization can lead to epilepsy.

## Overview of Ion Channels

Two major types of ion channels—voltage-gated and ligand-gated—are responsible for inhibitory and excitatory activity (Fig. 63-3). Voltage-gated channels include sodium and calcium channels that depolarize the cell membrane toward action potential threshold; potassium channels largely dampen neuronal excitation. Voltage-gated channels are activated by membrane potential changes that alter the conformational state of the channel and allow selective passage of charged ions through a pore. Ligand-gated channels are activated when a neurotransmitter is released from a presynaptic terminal into the synaptic cleft and binds selectively to a recognition site on the receptor localized on the postsynaptic membrane. This binding activates a cascade of events, including a conformational shift to open an ion-permeant pore. Passage of ions across these channels results in depolarization (i.e., inward flux of cations) or hyperpolarization (i.e., inward flux of anions or outward flux of cations). Ion channel mutations underlie several epilepsy syndromes, giving rise to the concept of “epilepsy channelopathies” (Child and Bennarroch, 2014; Steinlein, 2014).

## Voltage-Dependent Membrane Conductances

### Depolarizing Conductances

A rapidly inactivating inward sodium conductance underlies the depolarizing phase of the action potential. Each sodium channel is composed of a complex of three polypeptide subunits: a major  $\alpha$  subunit and two smaller  $\beta$  subunits that influence the kinetic properties of the  $\alpha$  subunit. Sodium channel dysfunction can lead to epilepsy and several ASDs work by blocking sodium channels.

Neuronal voltage-dependent calcium channels contribute to the depolarizing phase of the action potential and affect neurotransmitter release, gene expression, and neuronal firing patterns. Calcium currents underlie neuronal burst discharges. Several subtypes of calcium channels are distinguished on the basis of electrophysiological properties, pharmacologic profile, molecular structure, and cellular localization. The molecular structure of voltage-gated calcium channels is similar to that of sodium channels, with a principal pore-forming  $\alpha_1$  subunit and one or more smaller subunits that modulate the channel's kinetics.

### Hyperpolarizing Conductances

Depolarizing sodium and calcium currents are counterbalanced by an array of voltage-dependent hyperpolarizing (inhibitory) currents, primarily mediated by potassium channels that act by decreasing neuronal excitation. The prototypic voltage-gated potassium channel is composed of four membrane-spanning  $\alpha$  subunits and four regulatory  $\beta$  subunits assembled in an octameric complex to form an

**Figure 63-3. Normal neuronal firing.** Schematic shows a neuron with one excitatory (E) and one inhibitory (I) input. Right trace shows membrane potential (in millivolts [mV]), beginning at a typical resting potential ( $-70$  mV). Activation of E leads to graded excitatory postsynaptic potentials (EPSPs), the larger of which reaches threshold (approximately  $-40$  mV) for an action potential. The action potential is followed by an after-hyperpolarization (AHP), the magnitude and duration of which determine when the next action potential can occur. Activation of I causes an inhibitory postsynaptic potential (IPSP). The inset shows a magnified portion of the neuronal membrane as a lipid bilayer with interposed voltage-gated  $\text{Na}^+$  and  $\text{K}^+$  channels; the direction of ion fluxes during excitatory activation is indicated. After firing, the membrane-bound  $\text{Na}^+\text{-K}^+$  pump and star-shaped astroglial cells restore ionic balance. (With permission from Stafstrom, C.E., 2004. *An introduction to seizures and epilepsy: cellular mechanisms underlying classification and treatment*. In: Stafstrom, C.E., Rho, J.M. (Eds.), *Epilepsy and the Ketogenic Diet*. Humana Press, Totowa, NJ, pp. 3–29. Reprinted with permission of Springer Science+Business Media.)

ion-selective pore. Potassium conductances include delayed rectifiers (involved in action potential termination); an A-current (which in part determines the interspike interval and cell firing rate); an M-current (activated by cholinergic muscarinic agonists and which affects resting potential and cell firing rate); and calcium-activated potassium conductances (which are sensitive to intracellular calcium concentration and modulate cell firing rate and interburst interval).

Hyperpolarizing conductances induce antiseizure effects. Some newer ASDs (topiramate, levetiracetam) act in part by modulating potassium channels. Retigabine opens potassium channels and enhances activation of KCNQ2 and KCNQ3 potassium channels. Mutations in KCNQ2 and KCNQ3 have been linked to benign familial neonatal seizures and, in the case of KCNQ2, early onset epileptic encephalopathies.

## Synaptic Physiology

### Inhibitory Synaptic Transmission

Synaptic inhibition is mediated by two basic circuit configurations—feedback and feedforward. Feedback inhibition occurs when excitatory principal neurons synapse onto inhibitory interneurons, which project back to the principal neurons and inhibit them (negative-feedback loop). Feedforward inhibition occurs when axons synapse directly onto inhibitory interneurons, inhibiting downstream principal neurons.

GABA, the main inhibitory neurotransmitter in the brain, is synthesized from glutamate by the rate-limiting enzyme

glutamic acid decarboxylase. GABA released from axon terminals binds to two classes of receptors,  $\text{GABA}_A$  and  $\text{GABA}_B$ . Dysfunction in either GABA receptor or their subunits can result in epilepsy (Hirose, 2014).

The  $\text{GABA}_A$  receptor consists of an ion pore and binding sites for agonists and a variety of modulators, such as benzodiazepines and barbiturates, each of which affects the kinetic properties of the receptor. The  $\text{GABA}_A$  receptor is a heteropentameric complex composed of combinations of polypeptide subunits arranged in topographic fashion to form an ion channel that is selectively permeable to chloride ions. Several types of subunits ( $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ ,  $\epsilon$ ,  $\pi$ ,  $\rho$ ) have been described. Most functional  $\text{GABA}_A$  receptors follow the general motif of containing either  $\alpha$  and  $\beta$  or  $\alpha$ ,  $\beta$ , and  $\gamma$  subunits with variable stoichiometry. Subunits may be differentially sensitive to pharmacologic agents, making  $\text{GABA}_A$  receptors useful targets for new ASDs.

Activation of  $\text{GABA}_A$  receptors on mature neurons results in influx of chloride ions, generating fast inhibitory postsynaptic potentials, hyperpolarizing the membrane, and inhibiting cell firing. In the immature brain, however,  $\text{GABA}_A$  receptor activation depolarizes the postsynaptic membrane, because of a reversed chloride electrochemical gradient that is a consequence of the evolving expression of cation chloride cotransporters during development.

Metabotropic  $\text{GABA}_B$  receptors are located both postsynaptically and presynaptically.  $\text{GABA}_B$  receptors act through guanosine triphosphate (GTP)-binding proteins to control calcium or potassium conductances. Postsynaptic  $\text{GABA}_B$  receptors mediate slow, long-lasting inhibitory postsynaptic

potentials, primarily in dendrites. Activation of GABA<sub>B</sub> receptors on axon terminals reduces the amount of GABA released, resulting in disinhibition. Abnormalities of GABAergic function, including synthesis, synaptic release, receptor composition, trafficking or binding, and metabolism, can each contribute to a hyperexcitable state.

### Excitatory Synaptic Transmission

Glutamate is the principal excitatory neurotransmitter of the brain. Glutamatergic activity is critical for normal brain development and activity-dependent synaptic plasticity. There are two broad classes of glutamate receptors—ionotropic and metabotropic. Ionotropic glutamate receptors are divided into *N*-methyl-*D*-aspartate (NMDA) and non-NMDA receptors, based on biophysical properties and pharmacologic profiles. Each ionotropic glutamate receptor subtype consists of a heterotetramer that determines its functional properties. An NMDA receptor consists of an obligate GluN1 subunit plus GluN2A, GluN2B, GluN2C, GluN2D, and/or GluN3A and GluN3B subunits.

NMDA receptors contain a binding site for glutamate (or NMDA) and recognition sites for a variety of modulators (glycine, polyamines, MK-801, zinc). NMDA receptors also demonstrate voltage-dependent block by magnesium ions—when the membrane is depolarized and the magnesium block of the NMDA receptor is alleviated, NMDA receptor activation results in influx of calcium and sodium ions. Calcium entry initiates a number of second messenger pathways, such as stimulation of a variety of kinases that subsequently activate signal transduction cascades, leading to changes in transcriptional regulation. NMDA receptor activation leads to generation of relatively slow and long-lasting excitatory postsynaptic potentials. These synaptic events contribute to epileptiform burst discharges.

Non-NMDA ionotropic receptors are divided into  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and kainate (KA) receptors. AMPA receptors are heterotetramers composed of combinations of GluA1, GluA2, GluA3, and/or GluA4 subunits. Kainate receptors are composed of combinations of GluK1, GluK2, GluK3, GluK4, and/or GluK5 subunits. AMPA receptors are responsible for the fast-rising, initial part of the excitatory postsynaptic potential. The depolarization generated by AMPA receptors is necessary to activate NMDA receptors. Non-NMDA receptors typically pass sodium current, but certain subunit combinations endow the receptor with increased calcium permeability, a finding with implications during development as well as for epilepsy.

Metabotropic glutamate receptors (mGlu, through mGlu<sub>8</sub>) represent a large, heterogeneous family of G-protein-coupled receptors that subsequently activate various transduction pathways—i.e., phosphoinositide hydrolysis and activation of adenylate cyclase and phospholipases C and D. Metabotropic receptors modulate voltage-dependent potassium and calcium channels, nonselective cation currents, and ligand-gated receptors (i.e., GABA and glutamate receptors), and they can regulate glutamate release. Metabotropic glutamate receptors have been implicated in a wide variety of normal neurologic processes (e.g., long-term potentiation underlying learning and memory) and disease states (e.g., epilepsy).

### Abnormal Neuronal Firing

Specific pathophysiological mechanisms mediate each seizure stage, including transition from normal neuronal firing to interictal epileptiform bursts, to ictal activity, and to the post-ictal state. Intracellular and EEG changes are seen in normal, interictal, and ictal states (Fig. 63-4). When extrapolated to

thousands of synaptic contacts, it can be envisioned how inhibition can “sculpt” cellular responses. For epileptic firing to spread to noninvolved cortical areas, powerful inhibitory influences (inhibitory surround) that normally keep aberrant excitability in check must be overcome. The intracellular correlate of the focal interictal epileptiform discharge on the EEG is the paroxysmal depolarization shift (PDS) (see Fig. 63-4). If PDSs occur in several adjacent neurons, synchronous firing is facilitated.

### Synchronizing Mechanisms

The hippocampus normally exhibits several forms of neuronal synchronization, including sharp waves, dentate spikes, theta activity, 40 Hz oscillations, and 200 Hz oscillations. Synchronized neuronal activity is essential for normal hippocampal function, but exaggerated synchrony may generate seizures. Synchronized activity that does not normally trigger seizures may do so in a hippocampus that has undergone selective neuronal loss, synaptic reorganization, or changes in receptor expression.

Recurrent excitatory circuits are another substrate for neuronal synchronization. Recurrent excitatory collaterals are a normal feature of the hippocampal CA3 region. CA3 pyramidal cells form direct, monosynaptic connections with other CA3 pyramidal cells, contributing to the synchronized bursts that characterize this region. In the epileptic temporal lobe, synaptic reorganization and axonal sprouting (termed “mossy fiber sprouting”) lead to aberrant recurrent excitation, providing a mechanism to synchronize other regions of the hippocampus and beyond. In the normal hippocampus, for example, dentate granule cells form few or no monosynaptic contacts with neighboring granule cells. However, in the epileptic hippocampus, mossy fiber sprouting results in direct excitatory interactions among granule cells.

Nonsynaptic mechanisms, including gap junctions, electrical field (ephaptic) effects, and changes in extracellular ion concentrations, can also synchronize neuronal firing.

### Glial Mechanisms for Modulating Epileptogenicity

Glia play a major role in epilepsy (Hubbard et al., 2013). The ionic balance between the intracellular and extracellular compartments is altered after seizure activity. Astrocytes help to restore ionic homeostasis by regulating (buffering) extracellular potassium levels. A variety of potassium channels mediate potassium uptake into glia; glial end-feet contacting the brain microvasculature provides a convenient “sink” for released potassium. Glia also transport synaptically released glutamate out of the extracellular space through glutamate transporters. Finally, glia modulate excitability by regulating extracellular pH using a proton exchanger and bicarbonate transporter.

### Physiology of Absence Epilepsy

Generalized spike-wave discharges accompanying absence seizures reflect a widespread, phase-locked oscillation between excitation (spike) and inhibition (slow-wave) in thalamocortical networks. Pyramidal neurons from neocortical layer VI send excitatory projections to thalamic relay neurons and inhibitory GABAergic neurons of the nucleus reticularis thalami (Fig. 63-7). Excitatory outputs of thalamic relay neurons impinge on apical dendrites of layer VI pyramidal neurons. This reciprocal circuitry is responsible in large part for normal EEG oscillations during wake and sleep states but can become pathologically active and generate the generalized spike-wave discharges that underlie absence seizures.

**Figure 63-4. Abnormal neuronal firing.** Abnormal neuronal firing is shown at the levels of the brain (**A**) and a simplified neuronal network (**B**), consisting of two excitatory neurons (1 and 2) and an inhibitory interneuron (solid circle, 3). Electroencephalogram (EEG; top set of traces) and intracellular recordings (bottom set of traces) are shown for normal (left column), interictal (middle column), and ictal (right column) conditions. Numbered traces refer to like-numbered recording sites. Note the time scale differences in different traces. **A**, Three EEG electrodes record activity from superficial neocortical neurons. In the normal case, activity is low-voltage and desynchronized (i.e., neurons are not firing together in synchrony). In the interictal condition, large spikes are seen focally at electrode 2 (and to a lesser extent at electrode 1, where they may be called sharp waves), representing synchronized firing of a large population of hyperexcitable neurons (expanded in time below). The ictal state is characterized by a long run of spikes. **B**, At the neuronal network level, the intracellular correlate of the interictal EEG spike is called the paroxysmal depolarization shift (PDS). The PDS is initiated by a non-NMDA-mediated, fast excitatory postsynaptic potential (EPSP) (shaded area), but it is maintained by a longer, larger, NMDA-mediated EPSP. The post-PDS hyperpolarization (asterisk) temporarily stabilizes the neuron. If this post-PDS hyperpolarization fails (right column, arrow), ictal discharge can occur. The lowest traces, recordings from neuron 2, show activity similar to that recorded in neuron 1, with some delay (double-headed arrow). Activation of inhibitory neuron 3 by firing of neuron 1 prevents neuron 2 from generating an action potential (i.e., the inhibitory postsynaptic potential [IPSP] counters the depolarization caused by the EPSP). If neuron 2 does reach firing threshold, additional neurons will be recruited, leading to an entire network firing synchronously (i.e., a seizure). NMDA, *N*-methyl-D-aspartate. (With permission from Stafstrom, C.E., 2004. *An introduction to seizures and epilepsy: cellular mechanisms underlying classification and treatment*. In: Stafstrom, C.E., Rho, J.M. (Eds.), *Epilepsy and the Ketogenic Diet*. Humana Press, Totowa, NJ, pp. 3–29. Reprinted with kind permission of Springer Science+Business Media.)

Two ion channels in thalamic relay neurons regulate thalamocortical activity. The low-threshold (T-type) calcium channel is activated by small membrane depolarizations. Calcium influx through these channels triggers low-threshold spikes and activates bursts of action potentials. This burst underlies the spike portion of a generalized spike-wave oscillation. ASDs known to be clinically effective against absence seizures (ethosuximide, valproic acid) block T-type calcium currents.

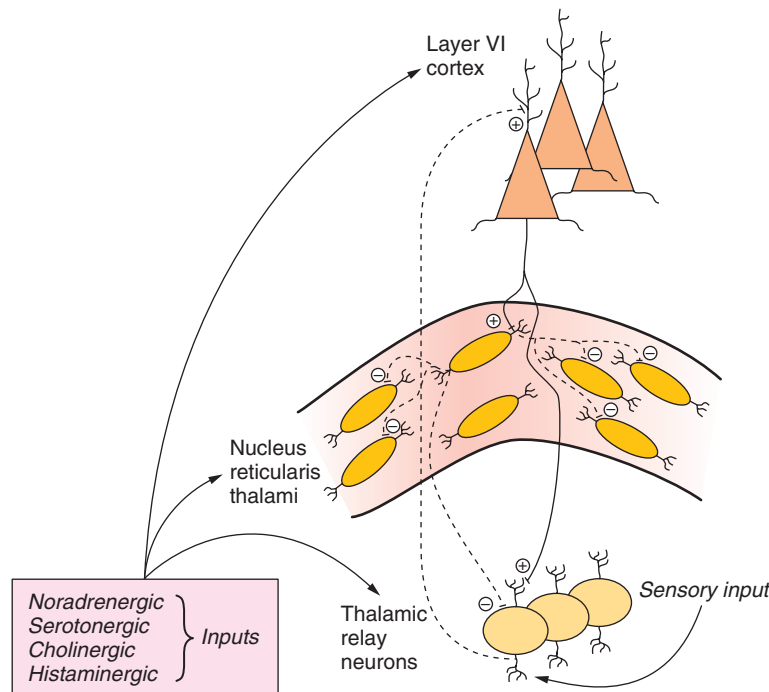

The second important ion channel involved in regulating thalamocortical rhythmicity is the hyperpolarization-activated cation (HCN) channel. HCN channels are activated by hyperpolarization and produce a depolarizing h-current carried by inward flux of sodium and potassium ions. This depolarization brings the membrane potential toward threshold for activation of T-type calcium channels, producing a calcium spike and action potential burst. Unlike other voltage-gated conductances that are either inhibitory or excitatory, h-currents are both inhibitory and excitatory, possessing an inherent negative-feedback property—hyperpolarization activates HCN channels and leads to depolarization that then deactivates these channels. H-currents tend to stabilize membrane potential around the resting potential, countering hyperpolarizing and depolarizing inputs.

## INCREASED SEIZURE SUSCEPTIBILITY OF THE DEVELOPING BRAIN

Seizure incidence is highest during the first decade and especially during the first year of life. Multiple physiologic and developmental factors contribute to the increased susceptibility of the immature brain to seizures (Dulac et al., 2013). The net effect is alteration of excitatory–inhibitory balance in favor of enhanced excitation; developmental changes involve ion channels, neurotransmitters and their receptors, structural changes, and ionic gradients. Seizure propensity in the very young involves a complex interplay between the timing of these cellular and molecular changes, which at times can be opposing, complementary, or synergistic.

## Development of Ionic Channels and Membrane Properties

The relative timing of ion channel development plays a major role in the enhanced excitability of the immature brain. Sodium and calcium ion channels develop relatively early. Action potentials are longer in early development and mediate greater calcium current, increasing excitability by enhancing

**Figure 63-7. Thalamocortical circuitry.** Normal oscillatory rhythms, when perturbed, can produce generalized spike-wave discharges seen with absence seizures. This circuitry involves excitatory projections from layer VI neocortical pyramidal neurons onto thalamic relay (TR) neurons and inhibitory neurons comprising the nucleus reticularis thalami (NRT). TR neurons send excitatory axons back to the neocortex. Activation of NRT neurons results in recurrent inhibition of adjacent neurons and TR neurons. The neurotransmitters at the excitatory (+) and inhibitory (–) synapses are thought to be glutamate and gamma-aminobutyric acid (GABA), respectively. Low-threshold (T-type) calcium channels and hyperpolarization-activated cation (HCN) channels in TR and NRT neurons help to regulate intrinsic rhythmicity. Extrinsic modulatory influences on this circuitry include inputs from the forebrain and brainstem nuclei and the sensory inputs from other thalamic nuclei.

neurotransmitter release. However, the brain must achieve a critical balance; activity-driven calcium channel activation is necessary for normal developmental processes such as cellular differentiation, migration, and synaptogenesis, but excessive intracellular calcium can cause neuronal damage and seizures. Mutations of the  $\alpha 1$  subunit of the sodium channel are responsible for a spectrum of developmental epilepsies, including genetic epilepsy with febrile seizures plus and Dravet syndrome (severe myoclonic epilepsy of infancy).

A large variety of potassium channels mediate outward currents that counter depolarizing influences and stabilize membrane excitability. Potassium channels develop slightly later than sodium and calcium channels. During a window of early development, the net balance of ion fluxes tilts toward excitation, explaining the increased susceptibility of the immature brain to seizures.

### Development of Neurotransmitters, Receptors, and Transporters

Excitatory synapses form before inhibitory synapses. Each glutamate receptor subunit has a distinct ontogenetic profile. For example, NMDA receptors are transiently overexpressed early in postnatal development, when they are needed for critical developmental processes. The early developmental stoichiometry of NMDA receptor subunits favors prolonged depolarizing responses. Early in development, NMDA receptor subunits GluN2A, GluN2B, and GluN3A are elevated and there is decreased sensitivity to blockade by magnesium ions and enhanced calcium influx. All of these physiologic adaptations favor depolarization, seizures, and excitotoxicity. Similarly, the

developmental profile of AMPA receptors consists of subunit stoichiometries that enhance calcium influx. Developmental expression of metabotropic glutamate receptors also favors overall hyperexcitability.

Fast-acting electrical synapses are more prevalent in the developing neocortex and hippocampus than in the mature brain. Electrical transmission facilitates rapid synchrony of the neuronal network and promotes seizure spread.

GABA<sub>A</sub> receptor subunits also exhibit a developmental profile and GABA's physiologic action varies during brain maturation (Ben-Ari et al., 2012). Early in development, GABA exerts an excitatory action, rather than an inhibitory action, because of the specific distribution of chloride ions across the cell membrane. Up to about a few months of age in humans, the intracellular chloride concentration is much higher than that in mature neurons. This chloride ion distribution is caused by the presence of a membrane pump, NKCC1, which actively imports chloride ions. Thus, when GABA<sub>A</sub> receptors are activated, postsynaptic chloride-permeable channels open and chloride ions exit the neuron down their electrochemical gradient, resulting in decreased intracellular negativity and a depolarizing current that can generate action potentials and activate NMDA receptors.

As development proceeds, the expression and activity of NKCC1 declines and that of another transporter, KCC2, increases. KCC2 has the opposite action—it actively extrudes chloride from the neuron, leaving the extracellular compartment with a higher chloride concentration. Binding of GABA to the GABA<sub>A</sub> receptor on a mature neuron results in chloride influx, hyperpolarizing the neuron.

The transition from GABAergic excitation to inhibition is an important physiologic milestone. As glutamatergic

synapses develop and begin to mediate their characteristic excitatory action, GABA switches to its mature inhibitory action (via a change in expression of the chloride transporters described above). This time-point also corresponds to other developmental milestones, namely, the appearance of GABA<sub>B</sub> inhibitory responses and disappearance of large oscillatory currents known as giant depolarizing potentials (GDPs). GDPs are seen only at early ages, are dependent on both NMDA and depolarizing GABA action, and facilitate the formation of synapses and neuronal circuits. Seizure susceptibility peaks during this time window, when GABA is still excitatory, excitatory glutamate receptors have not yet matured, and GABA<sub>B</sub> inhibition is not yet complete. This window of heightened excitability corresponds to approximately term gestation in humans, when neonatal seizures are common.

Phenobarbital, which enhances GABA<sub>A</sub> receptor opening, is the most common ASD used to suppress neonatal seizures, but its efficacy is imperfect. Over development, GABA<sub>A</sub> receptor sensitivity to benzodiazepines varies. Novel approaches to the management of neonatal seizures are needed. In this regard, bumetanide, a diuretic that blocks NKCC1 and suppresses epileptic activity in brain slices and animal models, might afford clinical utility but this remains to be demonstrated.

## Structural Maturation of the Brain and Seizure Susceptibility

In the developing brain, synaptic connections are formed, stabilized, or pruned as a function of neuronal activity. Such changes are referred to as plasticity, a general phenomenon that influences the brain's capacity to learn and respond to the environment. The same properties that govern plasticity may also contribute to increased susceptibility of the epileptic network to synchronize as a result of brain injury. These excessive excitatory connections are later pruned, stabilizing neuronal excitability.

## Regulation of the Ionic Environment

The development of several ion transport mechanisms favors excitability early in life. In addition to the developmental profiles of NKCC1 and KCC2, expression of the sodium-potassium pump (Na<sup>+</sup>,K<sup>+</sup>-ATPase) also follows a developmental pattern. Extracellular accumulation of potassium after a seizure can further depolarize the neuronal membrane, exacerbating ictal activity. The ability of glial cells to clear extracellular potassium improves with age.

## Epileptogenesis in the Developing Brain

The preceding paragraphs emphasize the mechanisms by which the immature brain is susceptible to seizures. The developing brain is also prone to the development of epilepsy, a process called epileptogenesis (Rakhade and Jensen, 2009). Factors playing a role in epileptogenesis are best understood according to a temporal sequence. In the first hours to days after a precipitating brain injury or severe seizure, immediate early genes are activated, leading to transcription of proteins that alter subsequent excitability. After a seizure, many receptors and other proteins involved in excitability are phosphorylated, including potassium channels and GABA<sub>A</sub>, AMPA, and NMDA receptors. Later, over days to weeks, inflammation occurs. Chronic epileptogenic changes are expressed weeks to months later, including altered neurogenesis and gliosis. Therefore the epileptogenic cascade progresses from changes

at the gene level to changes at the structural level. These multifactorial processes provide potential biomarkers to identify which individuals are at risk for the development of epilepsy and optimal ways to circumvent the process.

## ANTISEIZURE DRUG MECHANISMS

Most ASDs exert their principal effects on the following molecular targets: GABA<sub>A</sub> receptors, glutamate receptors, and voltage-dependent sodium and calcium channels. Several ASDs are thought to possess multiple relevant mechanisms of action (Rogawski and Loscher, 2004; White et al., 2007).

Until recently, the primary drugs for treating focal epilepsy were phenytoin and carbamazepine, both of which block sodium channels in a voltage-, frequency-, and use-dependent manner. Repetitive neuronal firing is limited by both of these agents. Oxcarbazepine, a structural analog of carbamazepine, also blocks sustained repetitive firing and is especially effective against focal seizures. Lamotrigine also blocks sodium channels but has a broader spectrum of activity, with efficacy against both generalized and focal seizures. Lacosamide enhances slow inactivation of sodium channels (whereas older sodium channel-blocking ASDs enhance fast inactivation). Like most sodium channel blockers, rufinamide stabilizes fast sodium channel inactivation.

Binding of benzodiazepines or barbiturates to their respective recognition sites on postsynaptic GABA<sub>A</sub> receptors results in enhanced inhibitory current. Vigabatrin is an irreversible inhibitor of the major GABA degradative enzyme, GABA transaminase, and elevates synaptic GABA levels.

Valproic acid is a broad-spectrum ASD that induces a wide variety of biochemical and neurophysiologic changes in multiple neurotransmitter systems. Its precise mechanism of action remains unclear, but recent studies have indicated that valproic acid inhibits histone deacetylases. Valproic acid also elevates brain GABA levels and diminishes repetitive firing, implying an action on voltage-gated sodium channels.

Felbamate is the first pharmacologic agent to potentiate GABA<sub>A</sub> receptor-mediated responses and inhibit NMDA receptor-mediated responses within the same drug concentration range. These dual actions may result in synergism with respect to seizure protection. Similarly, topiramate inhibits the AMPA or kainate subtypes of glutamate receptor and augments GABA<sub>A</sub>-mediated chloride currents.

Zonisamide is a broad-spectrum agent that has a unique mechanistic profile. It reduces repetitive neuronal firing, consistent with actions on sodium channels; it also blocks low-threshold T-type calcium currents, predicting efficacy against generalized spike-wave epilepsies.

Levetiracetam has proven efficacy against partial and generalized seizures. Levetiracetam binds to a specific synaptic vesicle protein, SV2A, which is involved in neurotransmitter release. The exact mechanism by which SV2A binding leads to an antiepileptic action is unknown.

Pregabalin, like gabapentin, binds to the  $\alpha 2\delta$  subunit of voltage-activated calcium channels, reducing presynaptic glutamate release. Retigabine (ezogabine) selectively targets potassium channels and not only can reduce repetitive neuronal firing but also can block action potential propagation at the critical axon hillock. Perampanel suppresses seizure activity by competitively blocking AMPA-type glutamate receptors.

Current ASDs suppress seizures and their spread, but there is no clear evidence that they are antiepileptogenic (i.e., disease-modifying). As underlying mechanisms are better understood, it may be possible to design more specific, rational, age-specific, and epilepsy-specific treatments.

## SUMMARY

An epileptic seizure can arise from numerous factors that increase neuronal excitability and synchrony. Unique differences in the ontogeny of ion channels, synapses, and transporters render the immature brain more susceptible to seizures than the adult brain. The concept of excitation–inhibition imbalance is key to understanding the genesis of seizures and epilepsy, yet this concept needs to be expanded to include other cellular mechanisms, particularly in light of recently discovered mutations that underlie rarer forms of epilepsies, such as the epileptic encephalopathies. Ultimately, seizures reflect perturbations of a complex array of cellular and network changes at multiple hierarchical levels of brain structure and function. The major goals of pediatric epilepsy research are to develop pathophysiology- and age-specific treatments, encompassing a more personalized or precision approach to patient care, to reduce seizures and their adverse consequences.

## INTRODUCTION

The concept of genetic epilepsy is that the condition is the direct result of a known or presumed genetic defect, and seizures are the core symptom of the disorder. The knowledge regarding the genetic contribution may derive from specific molecular genetic studies that have been well replicated and even become the basis of diagnostic tests. Alternatively, the central role of a genetic component may rely on evidence from appropriately designed family studies. Although the term *genetic* designates the fundamental nature of the disorder, it does not exclude the contribution of environmental factors to the expression of the disease. Genetics has seen a dramatic evolution of information in the past decade, including the definition of rare mendelian epilepsies, which has given insight into broader disease mechanisms and identification of the substrates involved in the more complex inheritance patterns that underlie most genetic epilepsy syndromes. This chapter is intended to provide the most updated information on the genetics of the epilepsies and to introduce newer concepts underlying genotype–phenotype correlation and functional consequences of gene mutations. Some of the most important genetic discoveries in the field have been made possible by a careful definition of the phenotype by epileptologists. On the other hand, epileptogenic gene mutations discovered by molecular biologists have led to recognition of previously unidentified clinical forms of epilepsy (Noebels, 2015). The identification of the genetic basis of epilepsies has improved understanding of the pathophysiology and resulted in targeted therapeutic approaches. Epilepsy syndromes are organized by age at onset: neonatal (<44 weeks' gestational age), infant (<2 years), child (2–12 years), and adolescent (12–18 years).

## EPILEPSIES WITH ONSET IN NEONATAL PERIOD

### Benign Familial Neonatal Epilepsy

Benign familial neonatal epilepsy (BFNE) is a rare benign autosomal-dominant epilepsy characterized by recurrent seizures from the first few days of life and generally limited to the first months of life. Seizures, lasting 1 to 2 minutes but recurring up to 20 to 30 times daily, are characterized by tonic posturing with shifting laterality, accompanied by autonomic symptoms and progressing to clonic jerks.

The responsible genes, *KCNQ2* (20q13.3) and *KCNQ3* (8q24), encode Kv7.2 and Kv7.3, subunits that coassemble as heteromeric tetramers to form voltage-gated potassium channels (Maljevic and Lerche, 2014). Genetic alteration of *KCNQ2* is 10 times more common as a cause of BFNE compared with *KCNQ3*. Over 50 mutations have been described in *KCNQ2*, and 6 have been identified in *KCNQ3*. Deletions and duplications of *KCNQ2* have also been described.

Pathologic mutations in *KCNQ2/3* cause a loss of function through effects on the channel pore, voltage sensor, and domains important for regulation, assembly, and trafficking, which are induced by a haploinsufficiency mechanism. The

functional consequence is a reduction (<20%–30%) in the M-current, a muscarine-regulated, slow, noninactivating sub-threshold potassium current that plays a key role in controlling neuronal excitation. *KCNQ2/3* expression increases over the first postnatal weeks in rodents, during which time the M-current may play a predominant role in regulating neuronal excitability. A critical window may determine the age dependence of BFNE. Retigabine is a drug that specifically augments the M-current and suggests the possibility for a targeted therapeutic approach.

### *KCNQ2* Encephalopathy

De novo *KCNQ2* mutations have been found in patients with severe neonatal-onset epilepsy with intractable seizures and profound psychomotor impairment. The timing of onset and the seizure semiology are similar to those in BFNE, but the interictal electroencephalogram (EEG) is characterized by a burst-suppression pattern or multifocal epileptiform activity. Genetic studies indicate that *KCNQ2* mutation accounts for more than 10% of cases of neonatal epileptic encephalopathy. Although response to retigabine has been described, the best success in treating the seizures appears to be with sodium channel blockers, carbamazepine in particular (Pisano et al., 2015). Sodium channels are bound together with the potassium channels encoded by *KCNQ2/3* in critical locations for action potential generation and maintenance. Modulation of one channel affects the functioning of the entire complex, offering insight into why sodium channel blockers may be particularly effective for a disease caused by potassium channel mutations.

Outcomes remain poor despite seizure control, arguing for additional developmental roles for *KCNQ2*. Compared with mutation associated with BFNE, mutations that cause *KCNQ2* encephalopathy may lead to quantitatively more substantial loss of channel function or to gain of function. Together with reports of occasional poor outcomes in some families with BFNE, it is likely that BFNE and *KCNQ2* encephalopathy likely lie along a phenotypic spectrum determined largely by genotype, but with a significant role for the modifying influences of genetic background.

### Ohtahara Syndrome (Early Infantile Epileptic Encephalopathy)

Ohtahara, West, and Lennox–Gastaut syndromes are three age-dependent epileptic encephalopathies, presenting in the neonatal, infantile, and toddler periods, respectively. Each is characterized by frequent seizures of a particular type, a unique and severely abnormal interictal EEG, and poor neurodevelopmental outcomes. The same etiologies may give rise to multiple age-dependent epileptic encephalopathies, and an affected individual may evolve from one syndrome to another with age, suggesting that each condition represents a common final reaction to brain insult determined by developmental period.

Ohtahara syndrome (OS) presents within the first 3 months, with tonic spasms as the main seizure, a burst-suppression pattern on EEG, high mortality, and severe neurodevelopmental impairment. OS is most often associated with gross structural lesions, but nonlesional genetic causes account for up to one-third of cases. The genes mutated in OS tend to be regulators of cortical development and/or synaptic function (Nabbout and Dulac, 2012).

Mutations in the *Aristaless*-related homeobox (*ARX*) gene, a transcriptional regulator during cortical development, represent an important cause of X-linked cause of OS. However, de novo heterozygous mutation of the gene encoding syntaxin binding protein 1 (*STXBP1*) has been shown to be the most common genetic cause of OS, accounting for approximately one-third of nonstructural causes. *STXBP1* mutation has also been implicated in West syndrome and in cases of mental retardation and nonsyndromic epilepsy. *STXBP1* is a member of the Sec1p/Munc18 family of SNARE (soluble NSF attachment protein receptor) regulators, required for exocytosis. *STXBP1* promotes the formation of fusion complexes via interaction with two N-terminal domains of syntaxin 1a. Causative mutations commonly lead to premature termination, nonexpression, or impaired binding of *STXBP1* to syntaxin 1a, leading to dysfunctional neurotransmission through haploinsufficiency.

Loss-of-function mutations in *CASK* (Xp11.4), encoding calcium/calmodulin-dependent serine protein kinase, have been described in males with OS. *CASK* appears to be required for synapse formation and cortical development. De novo missense mutations of *GNAO1* (16q13) encoding the alpha subunit of a heterotrimeric guanine-binding protein (G-protein), a signaling molecule with a role in calcium current inhibition, have been reported to result in a neonatal epileptic encephalopathy and a hyperkinetic movement disorder. Frameshift and missense mutations have been reported in *SLC35A2* (Xp11.23), which encodes a transporter important for galactosylation. Homozygous mutations in *SLC25A22* (11p15.5), which encodes a mitochondrial glutamate transporter, have been described in consanguineous families with OS. Finally, the OS phenotype has been associated with *KCNQ2* and *SCN2A* mutation, although there is increasing evidence that these two genes are associated with unique phenotypes.

### Benign Familial Neonatal-Infantile Epilepsy

Benign familial neonatal-infantile epilepsy (BFNIE) is an autosomal-dominant benign epilepsy with a high penetrance. Age of onset ranges from 2 days to 6 months in different family members. Seizures are focal, with eye deviation, apnea, and cyanosis, and they may occur in clusters. Seizures abate by 1 year of life, with a low risk of recurrence.

BFNIE has been shown to be linked to missense mutation causing gain or loss of function in *Nav1.2*, a sodium channel, encoded by *SCN2A* (2q24.3). *Nav1.2* resides at the axon hillock of excitatory neurons, where it is critically poised to influence the firing of these cells. *Nav1.2* is supplanted over time by *Nav1.6*, which may account for the limited temporal expression of benign epilepsy caused by *SCN2A* mutation.

### Epileptic Encephalopathy Associated With *SCN2A*

Analogous to the situation with *KCNQ2*, de novo missense or nonsense mutation in the *SCN2A* gene is associated with severe developmental phenotypes in the setting of refractory epilepsy presenting in the neonatal and infantile periods. A hyperkinetic movement disorder may be seen. Mutations

associated with the epileptic encephalopathy result in less conservative amino acid substitutions, suggesting more profound effects on channel structure and function.

## EPILEPSIES WITH ONSET IN INFANCY

### Benign Familial Infantile Epilepsy

Benign familial infantile epilepsy (BFIE) has an autosomal-dominant inheritance pattern and presents with clusters of brief focal seizures with shifting laterality at 4 to 20 months (median 6 months). The disorder has been found mainly associated with mutations in the *PRRT2* gene (16p11.2), which encodes proline-rich transmembrane protein 2, found in presynaptic terminals and implicated in the regulation of neurotransmitter release. Although approximately 80% of BFIE is related to *PRRT2*, mutations in *KCNQ2*, *KCNQ3*, and *SCN2A* have been reported as well (Zara et al., 2013).

Mutation of *PRRT2* is also a cause of a familial form of paroxysmal kinesigenic dyskinesia (PKD), a movement disorder of late childhood through early adulthood characterized by brief attacks of dystonia or choreoathetosis usually triggered by sudden movement, although unprovoked attacks (nonkinesigenic) can also occur (Heron and Dibbens, 2013). BFIE and PKD resulting from *PRRT2* mutation can occur in the same family or even the same patient, and the term *infantile convulsions with choreoathetosis* (ICCA) has been used to refer to this scenario. Seizures tend to be readily responsive to carbamazepine.

The vast majority of the mutations of *PRRT2* leading to BFIE and/or PKD are predicted to cause to protein truncation, leading to haploinsufficiency. Over 80% of cases are the result of a particular frameshift resulting from an insertion of an additional cytosine at c.649 to 650, likely as a result of polymerase slippage at the site, which lies in a poly C tract, predicted to be prone to hairpin secondary structure. De novo mutation of *PRRT2* causes approximately half of sporadic cases of benign infantile epilepsy with the same phenotypic spectrum as the familial form. Homozygous mutation of *PRRT2* is associated with a much more severe phenotype that includes significant cognitive disability.

### Epileptic Encephalopathy Associated With Cyclin-Dependent Kinase-Like 5 (*CDKL5*)

Mutation or deletion of *CDKL5*, encoding cyclin-dependent kinase-like 5, causes a unique epileptic encephalopathy presenting with seizures in the first 3 months of life, very often near the end of the neonatal period. The condition is X-linked (Xp22) and is principally seen in girls (12:1 female-to-male ratio). Initially there is hypotonia and poor eye contact. Subsequently, epileptic spasms occur with or without hypsarrhythmia, and a distinctive "hypermotor-tonic-spasms" sequence has been described. Ultimately, children suffer from refractory epilepsy with multiple seizure types, including tonic, myoclonic, and spasms; interictal EEG deteriorates with high-amplitude slowing and bursts of spikes and polyspikes. Developmentally, only about a third of females with the condition learn to walk, and males acquire minimal motor skills. A significant proportion of girls will have a deceleration of head growth and hand stereotypies of some form.

*CDKL5* is a serine-threonine kinase capable of signaling to nuclear targets, including the product of *MECP2*, the gene responsible for Rett syndrome. Loss-of-function mutations may cause more severe phenotypes when they affect the catalytic domain of the kinase, but severity is also likely influenced in females by the extent to which the normal gene copy escapes X-inactivation. Predictably, males, who lack a second

X chromosome with a wild-type *CDKL5*, are more severely affected.

A *CDKL5* knockout mouse model replicates behavioral aspects of the human condition, including limb claspings, abnormal eye tracking, and hypoactivity, although not seizures. Pathophysiological correlates include reduced dendritic arborization and altered activity of the mammalian target of rapamycin (mTOR) pathway. Other studies have implicated *CDKL5* in neuronal morphogenesis via *RAC1*-mediated control over the actin cytoskeleton.

## Epilepsy of Infancy With Migrating Focal Seizures

Epilepsy of infancy with migrating focal seizures (EIMFS) is a severe electroclinical syndrome, presenting within the first 6 months of life with intractable multifocal seizures that grow increasingly frequent until they are nearly continuous, migrating from one focus to another. Multiple independent seizures can evolve simultaneously. Interictal EEG progresses from normal to disorganized with multifocal epileptiform abnormalities. Neurodevelopmental outcome is typically severe, and there is often acquired microcephaly. Mortality of 28% was reported in the original series.

The most common known cause, accounting for 50% of cases, is de novo mutation in *KCNT1* (9q34.3), a sodium-activated potassium channel. The channel, known as SLACK (sequence like a calcium activated potassium channel), mediates the slow hyperpolarization that accompanies repetitive neuronal firing. Pathologic mutations increase the current amplitude through increased cooperativity between individual channels. Mutation of the same gene account for some cases of autosomal-dominant nocturnal frontal lobe epilepsy, a familial condition that presents in later childhood. The mutations of *KCNT1* resulting in EIMFS have been shown to lead to lower-magnitude increases in conductance, indicating a bimodal genotype–phenotype correlation.

Quinidine has been shown to reverse the increased conductance imparted by the pathologic gain of function mutations in vitro, and a case report has demonstrated efficacy in clinical practice (Bearden et al., 2014). Seizure control has been suggested to improve neurodevelopmental outcomes. However, the C-terminus of SLACK interacts with the fragile X mental retardation protein, raising the possibility that mutation of *KCNT1* could deleteriously affect signaling through important developmental pathways, apart from its effects on cortical excitability. *SCN1A* mutation and *SLC25A22* homozygous mutation represent less frequent causes.

## West Syndrome

West syndrome (WS) is an age-dependent epileptic encephalopathy with onset typically around 6 months of age, characterized by epileptic spasms, hypsarrhythmia, and developmental regression. Although the predominant causes are congenital or acquired structural lesions, such as the cortical tubers of tuberous sclerosis complex, associated with *TSC1* and *TSC2* gene mutation, which alone account for more than 7% of cases of WS, there are nonmalformation related genetic etiologies as well. Whereas West syndrome on the one hand represents a common final pathway of many inborn and acquired insults, the underlying etiology creates the context in which the spasms occur, informs their electroclinical manifestation, and determines the treatment approach and outcome (Dulac et al., 2010). As with Ohtahara syndrome, many of the implicated genes are associated with forebrain development and synaptic function.

Mutation of Aristaless-related homeobox (*ARX*) gene (Xp22), encoding a transcription regulator, causes X-linked infantile spasms syndrome (ISSX). *ARX* mutation leads to a wide phenotypic spectrum of X-linked cognitive impairment, including nonsyndromic intellectual disability with or without epilepsy, OS, ISSX, and overt brain malformation. Spasticity and dystonia are additional clinical features. Most of the pathologic mutations in *ARX*, including those giving rise to the ISSX phenotype, cause an expansion in two polyalanine tracts in the *ARX* gene product. Missense mutations or truncations that affect the homeodomain or regions important for transcriptional activation or repression can also cause phenotypes, including ISSX. There is a great deal of pleiotropy within families sharing the same mutation, with some males developing OS, for instance, and others with an ISSX phenotype. Nevertheless, clinical severity has been associated with the length of polyalanine tract expansion, which is thought to interfere with proper localization of *ARX* to the nucleus. A genotype–phenotype correlation also holds in the sense that full loss of function of *ARX* results in the most severe presentation.

In rodents, *ARX* encodes a transcription factor that acts downstream from *Dlx1* and *Dlx2*, transcriptional regulators important in specifying interneuronal fate. *ARX* is required for the migration of populations of interneurons into the cerebral cortex. A mouse knockin of a polyalanine-expanded *ARX* gene causes loss of subpopulations of GABAergic interneurons in the cerebral cortex and deep gray nuclei and causes epileptic spasms in mice during their second and third weeks of life.

A myocyte enhancer factor 2c (*MEF2C*) gene (5q14.3) mutation has been associated with a clinical phenotype that includes intellectual disability with autistic features and a hyperkinetic movement disorder. More than two-thirds of patients develop epilepsy, and the majority have onset in infancy; 20% of patients with *MEF2C* mutation develop infantile spasms. Infants with *MEF2C* mutation are hypotonic, and one-third of patients have myoclonic seizures that may precede epileptic spasms. Complete loss of function mutation is associated with epilepsy. *MEF2C* encodes a transcription factor critically positioned within regulatory networks underlying forebrain development.

Duplication of the region containing the Forkhead box G1 (*FOXG1*) gene, 14q13, or gene mutation results in phenotypes that include epilepsy. Haploinsufficiency of *FOXG1* causes severe intellectual disability with acquired microcephaly, dyskinesia, and epilepsy in two-thirds of patients with onset after infancy. In contrast, 14q13 duplication causes variable developmental delay, prominently affecting language, and more than half of patients develop infantile spasms. The epilepsy usually resolves after the toddler years. *FOXG1* is a transcriptional repressor specific to the brain that is implicated in neurogenesis.

De novo mutation of *SPTAN1* (9q34.11), encoding alpha-2 spectrin, causes infantile spasms and hypsarrhythmia in association with cerebral hypomyelination, in addition to atrophy of the cerebellum and brainstem. Children suffer from spastic quadriplegia, acquired microcephaly, and severe intellectual disability. There is a high rate of mortality in the first few years of life. Infantile spasms evolve in the majority of patients, with an onset at 3 to 4 months. Responsible mutations in the last two spectrin repeats lead to dominant negative interference with heterodimerization with a beta spectrin. Spectrins are part of the membrane cytoskeleton. Alpha-2 spectrin is necessary for proper myelination in zebrafish.

WS can be caused by de novo mutation of *DNM1* (9q34), encoding dynamin-1 and a GTPase specific to the brain that is responsible for synaptic vesicle endocytosis at the presynaptic terminal in response to neuronal activity.

## Dravet Syndrome and Genetic Epilepsy With Febrile Seizures Plus

Dravet syndrome (DS) is characterized by seizure onset between 4 and 8 months, with a peak at 6 months of prolonged hemiclonic or generalized seizures, most often triggered by elevated temperature. Later, other seizure types appear, including myoclonic. An early photosensitivity is present in approximately 40%. Children develop neuropsychiatric impairment and ataxia and are at elevated risk of sudden unexplained death in epilepsy (SUDEP). Recent evidence suggests that the severe neurodevelopmental outcome in DS is not related only to seizures, but may be the direct result of the genetic alteration.

The major gene for DS, *SCN1A* (2q24.3), was originally identified in families with genetic epilepsy with febrile seizures plus (GEFS+), an autosomal-dominant epilepsy with incomplete penetrance, in which at least two family members are affected. The most common phenotype is characterized by the association of febrile seizures, at times extending beyond 6 years of age, with afebrile generalized tonic-clonic seizures. GEFS+ is associated with *SCN1A* mutations, generally missense, in roughly 10% of cases. Clinical heterogeneity within families sharing the same mutation is the rule. The discovery of GEFS+ families with family members with DS was followed by discovery of de novo mutations in sporadic cases. De novo *SCN1A* mutation accounts for 70% to 80% of DS and usually arises in the paternal allele.

*SCN1A* encodes a neuronal sodium channel Nav1.1 alpha subunit, which has four homologous regions, each encoding six transmembrane domains, and a region controlling interactions with the permeable ion (Oliva, Berkovic, and Petrou, 2012). There are over 300 mutations described. More than half of mutations are truncating, with the remainder being largely missense mutations, although deletion and duplication have been reported as well. Truncating mutations seem to contribute to a more severe phenotype. The issue is confounded by genetic and/or environmental modifying factors, as is clear from the variability of phenotypic expression observed in GEFS+ families carrying *SCN1A* mutations. One potential modifying gene is *SCN9A*, encoding a different sodium channel. Mutations of *SCN1B*, *GABRG2*, *GABRA1*, and *STXBPI* have also been reported as associated with DS.

Mice heterozygous for *SCN1A* develop ataxia and age-dependent, temperature-sensitive epilepsy with myoclonic and generalized seizures. These mice have been demonstrated to have reduced sodium currents in cerebellar Purkinje cells, explaining the ataxia. Sodium currents are also reduced in cortical inhibitory interneurons but not in excitatory pyramidal neurons, explaining how loss of function in a sodium channel gene could result in a hyperexcitable cerebral cortex. Additional work has suggested that parvalbumin-positive interneurons, including chandelier and basket cells, with fast-spiking physiology are specifically affected. This explains the observation that sodium channel blockers typically aggravate the condition. The reduced GABAergic tone may explain the therapeutic response to clobazam and stiripentol, which enhance inhibitory GABAergic transmission.

### Epileptic Encephalopathy Associated With *SCN8A*

De novo mutation of *SCN8A* (2q24.3), encoding sodium channel Nav1.6, causes 1% of early-onset epileptic encephalopathies, presenting with multiple seizure types during infancy, with a mean age at onset of 4 to 5 months. A strikingly high rate of SUDEP has been observed in patients reported to

date (12.5%). Nav1.6 is the most abundant sodium channel in the brain and plays a critical role in regulating neuronal excitability. Pathogenic missense mutations in *SCN8A* are thought to cause a gain-of-function effect, including impaired channel inactivation or shifted voltage dependence of channel activation leading to hyperexcitability. Correspondingly, in contrast to the *SCN1A*-related epilepsies, sodium channel blockers have been found to be among the most useful agents in treating seizures in *SCN8A* epilepsy.

### Epilepsy Associated With Protocadherin 19 (*PCDH19*)

*PCDH19* mutation causes a “girls-only epilepsy” presenting between 6 and 36 months (median of 10 months), with seizures triggered by elevations in body temperature. There is a characteristic “stormy” ictal pattern with clusters of brief (1- to 5-minute) seizures for several days, with variable periods of quiescence, lasting weeks to months to years. Seizures are most commonly focal tonic, associated with apnea. Interictal EEG may be normal or show slowing and/or focal or multifocal epileptiform discharges. Cognitive outcome—one-third each normal intellect, mild intellectual disability, and moderate-severe intellectual disability—does not seem to be associated with epilepsy severity. *PCDH19* mutations are often de novo, but they can be transmitted with an unusual X-linked inheritance pattern that spares males in the carrier state (Depienne and LeGuern, 2012). Responsible mutations are largely loss of function, with half leading to premature termination. *PCDH19* (Xq22.1) encodes a protocadherin involved in cell-cell adhesion and signaling, and it has been proposed that protocadherin related cell-cell interaction is perturbed by tissue mosaicism present in the disomy X condition (i.e., some cells will express *PCDH19*, whereas some neighboring cells will not. That tissue mosaicism is necessary for the disease is supported by the report of a male patient with a somatic mutation. There is no clear genotype-phenotype correlation, and the phenotypic range in females has been speculated to be caused by the relative skew of X-inactivation.

### Other Early-Onset Epilepsies

Novel de novo mutations are being reported at an accelerating pace. *CHD2* (15q26) encodes chromodomain helicase DNA-binding protein 2. De novo mutations have been reported in association with a phenotype manifesting between 1 and 3 years of life, characterized by myoclonic and absence seizures, photosensitivity, and intellectual disability ranging from mild to severe. *SYNGAP1* (6p21.3) encodes synaptic Ras GTPase-activating protein 1. De novo mutations have been reported in association with intellectual disability, autism, and epilepsy characterized by a variety of generalized seizure types with onset between 1 and 3 years of life.

## SYNDROMES WITH ONSET IN CHILDHOOD AND ADOLESCENCE

### Epilepsy-Aphasia Syndromes

Epilepsy-aphasia syndromes are epileptic encephalopathies that manifest in early childhood with language regression associated with the EEG pattern of continuous spike and wave during slow-wave sleep (CSWS). Landau-Kleffner syndrome affects previously normal children who develop acquired epileptic aphasia, whereas the epileptic encephalopathy associated with CSWS is a condition of more global regression, and in half of cases there is premorbid delay. Mutations in *GRIN2A* (16p13.2), encoding the NMDA receptor alpha-2

subunit, are found in 10% to 20% of children with the epilepsy-aphasia syndromes, opening up the potential for novel therapeutic approaches.

### Idiopathic Generalized Epilepsies

Childhood absence epilepsy (CAE), juvenile absence epilepsy (JAE), and juvenile myoclonic epilepsy (JME), are generalized epilepsies with genetic underpinnings. Positive family history is common, but inheritance is not straightforward, and a complex polygenetic etiology has been suggested. When the syndromes occur within GEFS+ families, mutation in *SCN1A*, *SCN1B*, or *GABRG2* may be identified. Mutation of *CACNA1H* at 16p13.3 has been identified as an important cause of primary generalized epilepsies in the Han Chinese population. *CACNA1H* encodes a subunit of the neuronal voltage-gated T-type calcium channel subunit, responsible for the signature 3-Hz spike-and-wave pattern seen in CAE.

An autosomal-dominant form of JME has been described that results from a loss-of-function mutation of the *GABRA1* gene at 5q34. *GABRA1* encodes the alpha-1 subunit of the GABA<sub>A</sub> receptor, mutation of which has been associated with CAE as well. Loss-of-function mutations in *EFHC1* are associated with JME in a variety of affected families of differing origin. *EFHC1* at 6p12.3 encodes a protein of unknown function with calcium-binding EF-hand motif, a helix-loop-helix structural domain found in a large family of calcium-binding proteins. There is evidence that the protein modulates apoptotic activity and R-type voltage-dependent calcium channel properties. The complex polygenic inheritance patterns involved in the primary generalized epilepsy syndromes reveal that a single epilepsy phenotype can be generated by combinations of varied mutations, and that, conversely, a given mutation can be associated with more than one phenotype.

### Autosomal-Dominant Nocturnal Frontal Lobe Epilepsy

Autosomal-dominant nocturnal frontal lobe epilepsy (ADNFLE) is inherited with near complete penetrance and presents during the first or second decade of life with brief clusters of nocturnal tonic postural or hypermotor seizures. The ictal EEG may show frontally predominant sharp- and slow-wave activity, or it may fail to reveal a definite ictal pattern. *KCNT1*, described previously as the major cause of EIMFS, also causes ADNFLE. Mutations in genes encoding the alpha-4 (*CHRNA4*), beta-2 (*CHRN2*), and alpha-2 (*CHRNA2*) subunits of the nicotinic acetylcholine receptor have been reported associated with this phenotype in about 10% of patients. The acetylcholine receptor is a pentameric ion channel. The second transmembrane domain of each subunit lines the ion channel pore and is the site for the majority of the mutations that have been described for *CHRNA4* and *CHRN2*. Functionally, the mutations appear to alter the desensitization kinetics of the receptor, leading to hyperexcitability.

Outcomes for ADNFLE associated with nicotinic receptor subunit mutations are generally good. However, the disease does not typically remit, and the majority of patients require antiepileptic medication, with one-third well controlled on carbamazepine and another third requiring more than one agent. In contrast, *KCNT1* mutation gives a more severe phenotype, in which the seizures may be refractory; half also suffer from behavioral or psychiatric disturbances, and up to a quarter have intellectual disability.

### Autosomal-Dominant Focal Epilepsy With Auditory Features

Autosomal-dominant focal epilepsy with auditory features (ADFEAF) has a penetrance of greater than 50% and presents during the second to fourth decades. Seizures are focal at onset, occurring with a frequency from several per month to twice a year. Auditory auras are reported in roughly 50%.

Roughly half of cases of ADFEAF are associated with mutation in *LGII1*, encoding leucine-rich glioma inactivated 1 protein at 10q24. Over 20y mutations have been described, resulting in truncations, deletions, or single amino acid substitutions. Rarely, mutations are associated with idiopathic generalized epilepsy syndromes in some family members as well.

In vitro studies show that mutant LGI1 fails to be secreted, thereby blocking its access to postsynaptic scaffolding proteins, where it plays a role in AMPA receptor-mediated synaptic transmission. Additional studies have found a role for the protein in presynaptic potassium channel assembly, with mutant forms of the protein resulting in changes in the inactivation kinetics of the channel, potentially providing a mechanism for hyperexcitability.

### Familial Focal Epilepsy With Variable Foci and DEPDC5-Related Epilepsies

Familial focal epilepsy with variable foci (FFEVF) is an autosomal-dominant syndrome with a variable penetrance of 50% to 80%, characterized by focal epilepsy, with age of onset ranging widely from the first weeks of life to fifth or sixth decade (mean of 12 to 13 years). In affected family members, seizure semiology varies according to seizure focus, most often (70%) in the frontal or temporal lobe, which tends to remain consistent throughout life. Seizure frequency and severity are likewise variable. Interictal abnormalities are found in roughly half of recordings and most often reveal epileptiform activity arising from the frontal or temporal regions. The responsible gene, encoding disheveled, Egl-10, and pleckstrin domain-containing protein 5, *DEPDC5* (22q11.3), represents an important genetic cause of both autosomal-dominant familial (including some families with familial temporal lobe epilepsy and ADNFLE) and sporadic focal epilepsies. Mutations are loss of function, often premature truncations or deletions, and are thought to result in disease through a haploinsufficiency mechanism. The *DEPDC5* gene product is a member of the GATOR1 complex, an inhibitory regulator of the mTOR pathway, which plays a critical role in cellular growth and proliferation and in aspects of neuronal development. Components of the mTOR signaling cascade are associated with tuberous sclerosis complex and malformations of cortical development. Indeed, like *TSC1/TSC2*, the GATOR1 complex regulates GTPases that directly influence mTOR activity. Intriguingly, focal dysplasias—in particular, bottom-of-the-sulcus dysplasias—have been identified in some FFEVF family members but not others.

## Febrile Seizures

Syndi Seinfeld and Shlomo Shinnar

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Febrile seizures are a form of acute symptomatic seizures. They occur in 2% to 5% of children and are the most common form of childhood seizures. In the past, it was believed that febrile seizures were associated with a poor prognosis. It is now accepted that the majority of children with febrile seizures do well, but a subgroup of children do experience consequences. Epilepsy will eventually develop in a small minority of children who have had febrile seizures (Nelson and Ellenberg, 1976; Annegers et al., 1979; Berg et al., 1992). This understanding is based on large epidemiologic studies (Nelson and Ellenberg, 1976; Annegers et al., 1979; Berg et al., 1992), as well as on prospective studies from emergency departments not selected for tertiary referral bias. This chapter reviews the current understanding of the prognosis and management of febrile seizures.

### DEFINITIONS

A febrile seizure is defined by the International League Against Epilepsy as a seizure occurring in association with a febrile illness, in the absence of a central nervous system infection or acute electrolyte imbalance in children older than 1 month of age without prior afebrile seizures. This definition is similar to the one adopted by the National Institutes of Health (NIH) Consensus Conference, except that the NIH definition described a febrile seizure as an event usually occurring between 3 months and 5 years of age. The febrile illness must include a body temperature of more than 38.3° C, although the increased temperature may not occur until after the seizure.

Febrile seizures are further classified as simple or complex. A febrile seizure is complex if it is focal, prolonged (lasting for more than either 10 minutes (Annegers et al., 1979) or 15 minutes (Nelson and Ellenberg, 1976)), or multiple (occurrence of more than one seizure during the febrile illness). Conversely, it is simple if it is an isolated, brief, generalized seizure. Although neurologically abnormal children are more likely to experience complex febrile seizures and have a higher risk for subsequent afebrile seizures, the child's prior neurologic condition is not used to classify the seizure as simple or complex. When a careful history is obtained, approximately 30% of patients with febrile seizures presenting to the emergency department are found to have complex features.

### EPIDEMIOLOGY

Febrile seizures are the most common form of childhood seizures. The peak incidence is at the age of approximately 18 months. In the United States and Western Europe, they occur in 2% to 4% of all children. In Japan, however, 9% to 10% of all children experience at least one febrile seizure, and rates as high as 14% have been reported from the Mariana Islands in Guam. Ninety percent of seizures occur within the first 3 years of life, 4% before 6 months, and 6% after age 3 years. Approximately 50% appear during the second year of life, with a peak incidence between age 18 and 24 months. Children with longer febrile seizures have a younger median age at first febrile seizure (Hesdorffer et al., 2011).

Traditionally, it was thought that febrile seizures most commonly occur as the first sign of a febrile illness. More recent studies, however, found that only 21% of the children experienced their seizure either before or within 1 hour of the onset of the fever, whereas 57% had a seizure after 1 to 24 hours of fever, and 22% experienced their febrile seizure more than 24 hours after the onset of the fever.

Some children are at increased risk of experiencing a febrile seizure. A case-control population-based study (Bethune et al., 1993) examined the risk factors for a first febrile seizure and found that the following four factors were associated with an increased risk of febrile seizures: a history of febrile seizures in a first- or second-degree relative, a neonatal nursery stay of more than 30 days, developmental delay, and attendance at day care. Children with two of these factors had a 28% chance of experiencing at least one febrile seizure.

Another case-control study, using febrile controls matched for age, site of routine pediatric care, and date of visit, examined the issue of which children with a febrile illness were most likely to experience a febrile seizure (Berg et al., 1995). On multivariate analysis, significant independent risk factors were the height of the peak temperature and a history of febrile seizures in an immediate relative. Gastroenteritis as the underlying illness had a significant inverse (i.e., protective) association with febrile seizures. Similar results on the importance of the peak temperature were reported from a hospital-based study.

The majority of febrile seizures are simple seizures. In a study of 428 children with a first febrile seizure, 35% had at least one complex feature, including focality in 16%, multiple seizures in 14%, and prolonged duration (longer than 10 minutes) in 13%. Approximately 6% of children had at least two complex features, and 1% had all three complex features. Of most concern have been prolonged febrile seizures. In that study, 14% of the children had seizures lasting longer than 10 minutes; 9%, longer than 15 minutes; and 5%, longer than 30 minutes, or febrile status epilepticus. Although febrile status epilepticus accounts for only 5% of febrile seizures, it accounts for approximately 25% of all cases of childhood status epilepticus, and for more than two thirds of cases of status epilepticus in the second year of life. The distribution of first febrile seizure duration can be described using a two-population model, one with short seizure duration and the other with long seizure duration, with the cutoff at approximately 10 minutes (Hesdorffer et al., 2011). This suggests that a 10-minute criterion, rather than 15 minutes, is more appropriate for the definition of a complex febrile seizure.

### INITIAL EVALUATION

The American Academy of Pediatrics has guidelines for evaluation of a first simple febrile seizure, and states that clinicians should work to identify the source of the fever when a child presents within 12 hours of a simple febrile seizure. In the absence of suspicious findings in the history or on physical examination, routine serum studies are of limited value in the evaluation of a child older than 6 months with a febrile

seizure. The labs that are performed should be based on the clinical presentation of the febrile illness.

As reported in several studies, the incidence of meningitis in children with an apparent febrile seizure is between 2% and 5%. In all of the reported series, however, a majority of the children with meningitis had identifiable risk factors. One series reported that the children with meningitis had one of the following four features: a visit for medical care within the previous 48 hours, seizures on arrival to the emergency room, focal seizures, or suspicious findings on physical or neurologic examination. It is well accepted that there is a low yield on routine lumbar puncture in the absence of risk factors. A lumbar puncture is still recommended in children with a prolonged febrile seizure, as well as in any child with persistent lethargy. A lumbar puncture should be strongly considered in a child who has already received prior antibiotic therapy.

The study, Consequences of Prolonged Febrile Seizures (FEBSTAT), recruited 199 children aged 1 month through 5 years who had a febrile seizure that lasted more than 30 minutes. Children recruited most often had focal seizures that were usually their first febrile seizure. Seizure duration in this group was very prolonged, suggesting that the longer the seizure continued, the less likely it was to spontaneously cease. As part of the FEBSTAT study, 136 children had cerebrospinal fluid (CSF) samples from a nontraumatic lumbar puncture done on initial presentation, and it was confirmed that febrile status epilepticus rarely causes CSF pleocytosis (Frank et al., 2012).

Electroencephalograms (EEGs) are of limited value in the evaluation of the child with febrile seizures. EEGs are more likely to be abnormal in the older child with febrile seizures and in children with a family history of febrile seizures, with a complex febrile seizure, or with preexisting neurodevelopmental abnormalities. There is no evidence at this time that an EEG will predict either recurrence of febrile seizures or the development of subsequent epilepsy. EEGs are indicated in the diagnostic evaluation of status epilepticus of all types, including febrile. They may be of particular interest in the child with febrile status epilepticus, as they may have predictive value for the development of subsequent epilepsy. The FEBSTAT study performed baseline EEGs within 72 hours of the episode of febrile status epilepticus. Review of their baseline EEGs showed that there was focal slowing or attenuation in a substantial proportion of children, and the slowing and attenuation were highly associated with MRI evidence of acute hippocampal injury.

## PATHOPHYSIOLOGY

The pathophysiology of febrile seizures remains unclear. An age-specific increased susceptibility to seizures induced by fever is likely. Although it was thought that the rate of rise of the temperature was the key factor, more recent data suggest that it is the actual peak temperature (Berg et al., 1995). Gastroenteritis is associated with a lower incidence of febrile seizures. Herpesvirus-6 and herpesvirus-7 infections have had a high reported rate of association with febrile seizures. The FEBSTAT study evaluated children for the presence of human herpes virus (HHV) via HHV-6A, HHV-6B, or HHV-7 DNA and RNA in serum. The study concluded that HHV-6B infection is commonly associated with febrile status epilepticus, and HHV-7 infection is less frequently associated with it. Together, HHV accounted for the infection in one third of the febrile status epilepticus subjects in the study.

## RELATED MORBIDITY AND MORTALITY

The mortality associated with febrile seizures is extremely low. No deaths were reported from the National Collaborative

Perinatal Project (Nelson and Ellenberg, 1976) or the British Cohort Study. Even in cases of febrile status epilepticus, which represents the extreme end of complex febrile seizures, the mortality rates in recent series are extremely low. Neither the National Perinatal Project nor the British studies found any evidence of permanent motor deficits after febrile seizures. This finding coincides with a recent series of febrile status epilepticus studies.

The cognitive abilities of children with febrile seizures have been extensively studied. No reports describe acute deterioration of cognitive abilities after febrile seizures, even when the studies limited to febrile status epilepticus are included. Cognitive abilities and school performance of children with febrile seizures were found to be similar to those of controls in three large studies. The Collaborative Perinatal Project found no difference in IQ scores or performance on the Wide Range Achievement Test at the age of 7 years between children with febrile seizures and their siblings. The British National Child Development Study reported that children with febrile seizures performed as well in school at 7 and 11 years of age as their peers without a history of febrile seizures. The more recent British Cohort Study also found no difference between 5-year-olds with febrile seizures and 5-year-olds without a history of febrile seizures on a variety of performance tasks.

Even prolonged febrile seizures do not appear to be associated with adverse cognitive outcomes. In the British Cohort Study, no differences were found between 5-year-olds with and those without febrile seizures, even when the analysis was limited to complex febrile seizures. A study of 27 children with febrile convulsions lasting more than 30 minutes found no differences in cognitive function at 7 years of age between them and their siblings.

## RECURRENT FEBRILE SEIZURES

Approximately one third of the children with a first febrile seizure will experience a recurrence, and 10% will have three or more febrile seizures (Nelson and Ellenberg, 1976). Factors associated with a differential risk of recurrent febrile seizures are summarized in Table 65-1. The most consistent risk factors reported are a family history of febrile seizures and age at first febrile seizure (before age 18 months) (Nelson and Ellenberg, 1976). This relationship appears to be attributable to the longer period during which a child with a younger age at onset will be in the age group at risk for febrile seizures, rather than to a greater tendency to have seizures with each specific illness.

**TABLE 65-1** Risk Factors for Recurrent Febrile Seizures and for Epilepsy After a Febrile Seizure

Recurrent Febrile Seizures	Epilepsy
<b>DEFINITE RISK FACTOR</b>	
Family history of febrile seizures	Neurodevelopmental abnormality
Age less than 18 months	Complex febrile seizure
Height of peak temperature	Family history of epilepsy
Duration of fever	Duration of fever
<b>POSSIBLE RISK FACTOR</b>	
Family history of epilepsy	More than 1 complex feature
<b>NOT A RISK FACTOR</b>	
Neurodevelopmental abnormality	Family history of febrile seizures
Complex febrile seizure	Age at first febrile seizure
More than 1 complex feature	Height of peak temperature
Gender	Gender
Ethnicity	Ethnicity

(Data from multiple sources [see online].)

In studies that examined features of the acute illness, the peak temperature and also the duration of the fever before the seizure were associated with a differential risk of recurrent febrile seizures. Studies by Berg et al. found that patients with a peak temperature of 101° F had a 42% recurrence risk at 1 year, compared with 29% for those with a peak temperature of 103° F and only 12% for those with a peak temperature of 105° F or greater. For those with a febrile seizure within 1 hour of recognized onset of fever, the recurrence risk at 1 year was 46%, compared with 25% for those with prior fever lasting 1 to 24 hours and 15% for those with more than 24 hours of recognized fever before the febrile seizure.

The data regarding a family history of unprovoked seizures or epilepsy are conflicting. A large study in Rochester, MN, found no difference in recurrence risk between children with a family history of epilepsy (25%) and those with no such family history (23%). Other studies have found more equivocal results. However, even those studies that report an increased risk of recurrence in children with a family history of unprovoked seizures found only a modest increase in risk. A complex febrile seizure is not associated with an increased risk of recurrence in most studies. If the initial febrile seizure is prolonged, however, a recurrent febrile seizure also is more likely to be prolonged. The presence of a neurodevelopmental abnormality in the child also has not been demonstrated to be significantly associated with an increased risk of subsequent febrile seizures.

Children with multiple risk factors are at highest risk for recurrence. A child with two or more risk factors has a greater than 30% recurrence risk at 2 years, and the child with three or more risk factors has a greater than 60% recurrence risk. By contrast, the child older than 18 months with no family history of febrile seizures who experiences a first febrile seizure associated with a peak temperature higher than 40° C after a recognized fever longer than 1 hour in duration (i.e., no risk factors) has a 2-year recurrence risk of greater than 15%. No correlation has been identified between duration of the first febrile seizure and duration of the second febrile seizure (Hesdorffer et al., 2011).

## FEBRILE SEIZURES AND SUBSEQUENT EPILEPSY

Data from five large cohorts of children with febrile seizures indicate that epilepsy subsequently develops in 2% to 10% of children who experience febrile seizures (Annegers et al., 1979). The higher number comes from the study by Annegers et al., which had the longest follow-up period. In addition, in population- and community-based studies, 15% to 20% of children and adults with epilepsy have a history of prior febrile seizures. In most studies, the risk of developing epilepsy after a single simple febrile seizure is not substantially different from the risk for this disorder in the general population (Annegers et al., 1979).

The risk factors for the development of epilepsy after febrile seizures are summarized in Table 65-1. The presence of a neurodevelopmental abnormality, the occurrence of a family history of epilepsy, and the occurrence of complex febrile seizures are associated with an increased risk of subsequent epilepsy (Annegers et al., 1979). Two studies also have found that the occurrence of multiple febrile seizures was associated with a slightly but statistically significant increased risk of subsequent epilepsy. In addition, in the one study that examined this issue, febrile seizures that occurred within 1 hour of a recognized fever (i.e., at onset) were associated with a higher risk of subsequent epilepsy.

Some controversy exists regarding whether the number of complex features affects the risk of recurrence. Two studies have examined this issue in detail. Both found that prolonged

febrile seizures (i.e., febrile status epilepticus) were associated with an increased risk of subsequent epilepsy above that for a complex febrile seizure that was less prolonged. The study by Annegers et al., however, found that the presence of two complex features (e.g., prolonged and focal) further increased the risk of subsequent epilepsy, whereas this association was not found in the study by Berg et al. Note that these two factors are not independent because prolonged febrile seizures are more likely to be focal (Berg et al., 1992, 1997).

Age at first febrile seizure, the height of peak temperature at first seizure, and a family history of febrile seizures, all of which are associated with a differential risk of recurrence for febrile seizures, are not associated with a differential risk of developing epilepsy (see Table 65-1) (Annegers et al., 1979). Duration of fever before the febrile seizure appears to be the only common risk factor for both recurrent febrile seizures and subsequent epilepsy. It may well be a marker for overall seizure susceptibility.

The type of epilepsy that develops after febrile seizures is variable. It has been reported that, in persons with generalized febrile seizures, generalized epilepsies usually develop, whereas focal epilepsies develop in those with focal seizures. This finding suggests that the febrile seizures may be an age-specific expression of seizure susceptibility in patients with an underlying seizure diathesis. Febrile seizures also can be the initial manifestation of specific epilepsy syndromes, such as severe myoclonic epilepsy of infancy. In general, the types of epilepsy that occur in children with prior febrile seizures are varied and not very different from those that occur in children without such a history. The association between prolonged febrile seizures and subsequent epilepsy is being evaluated by the FEBSTAT study that is currently ongoing.

## FEBRILE SEIZURES, MESIAL TEMPORAL SCLEROSIS, AND TEMPORAL LOBE EPILEPSY

One of the most controversial issues in epilepsy is whether prolonged febrile seizures cause mesial temporal sclerosis and mesial temporal lobe epilepsy. Prolonged febrile seizures also are usually focal (Hesdorffer et al., 2011). In many cases febrile seizures may be an age-specific marker for future seizure susceptibility.

FEBSTAT and two affiliated studies prospectively recruited 226 children aged 1 month to 6 years with febrile status epilepticus and controls with simple febrile seizures to evaluate hippocampal sclerosis (Lewis et al., 2014). They found that hippocampal T2 hyperintensity after febrile status epilepticus represents acute injury often evolving to a radiologic appearance of hippocampal sclerosis after 1 year. Furthermore, impaired growth of normal-appearing hippocampi after febrile status epilepticus suggests subtle injury even in the absence of T2 hyperintensity. The presence and severity of these acute changes are predictive of subsequent anatomic mesial temporal sclerosis that may occur before the development of clinical seizures. A long-term goal of the prospective FEBSTAT study is to better define the relationship between prolonged febrile seizures, hippocampal sclerosis, and mesial temporal lobe epilepsy. The FEBSTAT study has performed a baseline MRI, with special attention to the hippocampus on 191 of the recruited children. A statistically significant abnormal or equivocally increased hippocampal T2 signal following febrile status epilepticus was observed in 22 children compared with none in the control group. Findings from this study indicate that prolonged febrile seizures are likely to be focal, and are much longer than previously thought. The median duration is an hour, and they usually do not stop on their own but require the administration of a benzodiazepine (Seinfeld et al., 2014).

Developmental abnormalities of the hippocampus were more common in the febrile status epilepticus group, with hippocampal malrotation being the most common finding.

## GENETICS

Genetic influences clearly play a major role in febrile seizures. Children with a positive family history of febrile seizures are more likely both to experience a febrile seizure (Bethune et al., 1993; Berg et al., 1995) and to experience recurrent febrile seizures, than children without such a family history. A study of 32 twin pairs and 673 sibling relationship cases reported a concordance rate of 56% in monozygotic twins and 14% in dizygotic twins. Concordance for clinical symptoms, including age at onset and degree of fever, was higher in the twin pairs than in the sibling relationship patients. The results were consistent with a multifactorial mode of inheritance for febrile convulsions in an analysis of the Rochester, MN, dataset. In population-based studies, a majority of children with febrile seizures do not have a first- or second-degree relative with a history of febrile seizures (Bethune et al., 1993).

An autosomal-dominant mode of inheritance has been postulated for a subset of children with febrile seizures, but such cases are relatively rare. Candidate genes in these autosomal-dominant families include both sodium and gamma-aminobutyric acid (GABA) channel mutations. A related syndrome of generalized epilepsy with febrile seizures plus (GEFS+) also has been mapped to several different loci in different families and has been associated with mutations in sodium, potassium, and GABA channels. The phenotype of febrile seizures plus may account for children without a specific epilepsy syndrome who have febrile seizures and then developed generalized epilepsy, with the most severe phenotype of myoclonic-astatic epilepsy. Febrile seizures represent an example of the interplay between genetic susceptibility and environmental factors.

## TREATMENT

It is accepted that antipyretic agents do not reduce the risk of a febrile seizure or a seizure recurrence. Prophylactic antiepileptic drug therapy for febrile seizures should be withheld, as the benefits of treatment do not outweigh the risks. There is a concern regarding prolonged febrile seizures. In contrast, brief febrile seizures are not thought to have any long-term consequences. This leads to a therapeutic approach that does not treat brief febrile seizures but focuses on preventing prolonged ones (Subcommittee on Febrile Seizures, 2011).

Febrile seizures often cease by the time a child is examined, but prolonged episodes should be treated similar to seizures of any other etiology. If seizure activity is ongoing when the child arrives at the emergency department, treatment to terminate the seizure is mandatory. All seizures, regardless of etiology, should be treated after 5 minutes. Intravenous (IV) diazepam or lorazepam is known to be an effective treatment option, but treatment should not be delayed because of lack of IV access. In cases in which IV access is difficult, rectal diazepam or diazepam gel, and intramuscular midazolam are appropriate for use. If the seizure activity continues after an adequate dose of a benzodiazepine, then a full status epilepticus treatment protocol should be used.

For either prehospital or in the emergency department management, terminating a prolonged febrile seizure is important to prevent the potential long-term consequences, including mesial temporal sclerosis (Seinfeld et al., 2014). The FEBSTAT study showed that these seizures rarely stop spontaneously and that the time to first drug is highly

correlated with the total duration as they are difficult to stop even with medications (Seinfeld et al., 2014). More aggressive early treatment in the ambulance may result in shorter seizure duration.

A majority of febrile seizures are brief, lasting less than 10 minutes, and no intervention is necessary. Rectal diazepam has been demonstrated to be effective in terminating febrile seizures. Rectal diazepam gel is U.S. Food and Drug Administration-approved and readily available in the United States and is an option for treatment of febrile seizures at home. Candidates for this treatment include children at high risk for prolonged or multiple febrile seizures and those who live far from medical care.

Febrile seizures, by definition, occur in the context of a febrile illness. Recommendations for antipyretic therapy should recognize its limitations and avoid creating undue anxiety and feelings of guilt in the parents.

Diazepam, given orally or rectally, at the time of onset of a febrile illness will reduce the probability of a febrile seizure. Although the effect is statistically significant, it is clinically modest. In one large randomized trial comparing placebo with oral diazepam (in a dose of 0.33 mg/kg every 8 hours with fever), seizure recurrence by 36 months was noted in 22% of the diazepam treatment group, compared with 31% of the placebo treatment group. This modest reduction in seizure recurrence must be weighed against the side effects of sedating children every time they have a febrile illness. Intermittent therapy with phenobarbital at the onset of fever is ineffective in reducing the risk of recurrent febrile seizures.

Long-term antiepileptic drug therapy is rarely indicated in the treatment of febrile seizures (Subcommittee on Febrile Seizures, 2011). It will not reduce the risk of subsequent epilepsy. The goal of therapy is to prevent prolonged febrile seizures. Children at risk for prolonged or multiple febrile seizures, or those who live far from medical care, should be prescribed an abortive agent.

## COUNSELING AND EDUCATION

In a majority of cases, counseling and education will be the sole treatment. Education is the key to empowering the parents who have just experienced a frightening and traumatic event. The parents' perception of their child's disorder will be an important factor in their later coping and will ultimately affect their perception of quality of life.

Febrile seizures are a common and mostly benign form of childhood seizures. An understanding of the natural history and prognosis will enable the physician to reassure the families of affected children and to provide appropriate counseling and management while avoiding unnecessary diagnostic and therapeutic interventions. Advances in basic science, genetics, and imaging are providing new insights into this common pediatric disorder that continues to be the subject of active research. The next phase will potentially lead to interventional trials that aim at preventing the consequences of very prolonged febrile seizures. But, while focusing on these, it is important to remember that the vast majority of febrile seizures, although very frightening, do not appear to have any long-term sequelae.

## Generalized Seizures

Gregory L. Holmes

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

As reviewed in Chapter 61, seizures are classified into two basic groups: focal (previously called partial) and generalized. Generalized seizures are those defined as occurring in bilaterally distributed networks, whereas focal seizures involve networks limited to one hemisphere, with either discretely localized or more widely distributed disturbances. Focal seizures involve only a portion of the brain at the onset but can propagate and become secondarily generalized, evolving to bilateral, convulsive seizures involving tonic, clonic, or tonic and clonic components. Primarily generalized seizures are those in which the first clinical changes indicate initial synchronous involvement of both hemispheres without clinical, electroencephalographic (EEG), or other evidence of focal onset. Impairment of consciousness is usual during generalized seizures, although some seizures, such as myoclonic, may be so brief that the level of consciousness cannot be assessed. The generalized seizures span a wide range of clinical presentations, ranging from the rather benign-appearing absence seizure to the dramatic and frightening generalized tonic-clonic seizure.

In most epidemiologic studies, primarily generalized seizures are reported to be less common than focal seizures. Of the primarily generalized seizures, generalized tonic-clonic are the most common, followed by absence and myoclonic seizures.

These epidemiologic studies may be somewhat misleading. With improvement of diagnostic techniques in recent decades, especially with long-term EEG/video monitoring, it has become clear that the prevalence of primarily generalized tonic-clonic epilepsy has been overestimated. In fact, most generalized tonic-clonic seizures begin as focal seizures and then generalize.

This chapter discusses generalized tonic-clonic seizures and absence, myoclonic, tonic, and atonic seizures. Syndromes in which generalized seizures are prominent are discussed in Chapters 70 to 73.

### GENERALIZED TONIC-CLONIC SEIZURES

Some children with generalized tonic-clonic seizures, or their parents, are aware of the impending seizure, hours or days before it occurs. The child may have a headache, insomnia, irritability, or a change in appetite. This prodrome is to be distinguished from an aura, which occurs before generalization of the seizure. Unlike the aura, the prodrome is not associated with any EEG epileptiform activity. Although auras were previously believed to occur only with focal seizures, it is now clear that auras also commonly occur in generalized tonic-clonic seizures. The auras in generalized tonic-clonic seizures may be similar to those occurring with focal seizures, such as déjà vu and epigastric rising, or may be more vague and difficult for the child to describe.

As indicated by the name, generalized tonic-clonic seizures have two distinct phases: tonic and clonic. Loss of consciousness usually occurs simultaneously or shortly after the onset of a generalized stiffening of flexor or extensor muscles—the tonic phase. The loss of consciousness usually is complete, and it is unusual for patients to have awareness of what happened

during the seizure. During the tonic phase, prolonged extension of the back, neck, and all limbs often occurs. The eyes remain open, and a cry or yell is common. The tonic phase typically lasts 10 to 30 seconds and is followed by the clonic phase, which usually starts with a rapid tremor and then slows to massive jerks of the extremities and trunk. A decrescendo pattern to the frequency (although not necessarily the strength) of the jerks is seen as the seizure ceases. The clonic phase typically lasts 30 to 60 seconds.

Cyanosis is common and results from the arrest of ventilation during the tonic phase and insufficient short breaths during the following clonic phase. Pupillary dilation, salivation, sweating, hyperthermia, and incontinence are common.

A postictal state always follows the clonic phase. During the postictal phase the child may have a stertorous respiratory pattern, which is a strong indication that the event was an epileptic seizure rather than nonepileptic event. The duration is quite variable. Some patients, even after a severe and prolonged seizure, respond within a minute or so, whereas other patients may be difficult to arouse for 20 to 30 minutes. Although the postictal phase initially consists of stupor, it may be followed by confusion or agitation.

Some patients have seizures provoked by flickering lights and have a photoparoxysmal response to strobe light on EEG. The photoparoxysmal response is characterized by spike-and-wave and polyspike-and-wave complexes that are bilaterally synchronous, symmetric, and widespread (Fig. 61-1). The photoparoxysmal response may be self-limited and cease during stimulation or continue beyond the stimulation. The most effective frequency of the flash is 10 to 20 Hz.

The seizures evoked by photic stimulation usually are primarily generalized in type: generalized tonic-clonic, absence, or myoclonic seizures. Although patients with focal seizures may have photoparoxysmal responses during an EEG study, it is unusual for a focal seizure to be precipitated by photic stimulation.

Photosensitive epilepsy can be classified into two major groups: (1) pure photosensitive epilepsy, in which clinical seizures occur only when the patient is exposed to the photic stimulus, and (2) photosensitive epilepsy, in which spontaneous seizures occur in addition to those induced by light stimulation. Precipitating stimuli that can produce a seizure include sunlight reflected from water, sunlight viewed through leaves of trees in a breeze or while driving along tree-lined streets, discotheque lighting, faulty fluorescent lamps, television, and video games.

Photoparoxysmal responses in children under the age of 5 years are uncommon, and unlike in older children are more likely to occur at slower frequency trains (1-5 Hz). In young children photoparoxysmal responses are seen in neurogenetic disorders such as Dravet syndrome and the epileptic encephalopathies.

### Electroencephalographic Findings

In patients with focal seizures with secondarily generalization, the interictal EEG features are similar to those described for

focal seizures. Patients with primarily generalized tonic-clonic seizures typically have either normal interictal EEG activity or bursts of generalized spike-and-wave discharges. As with absence seizures, spike-and-wave or polyspike-and-wave activity can occur with photic stimulation and hyperventilation. Normal interictal EEG activity, however, can be observed in patients with generalized tonic-clonic seizures (Porter et al., 1973).

## Initial Evaluation

The initial steps in the evaluation depend to a major degree on the patient's clinical status on first presentation to the physician. For example, the patient who arrives at the emergency department following a generalized seizure with fever and confusion is evaluated differently from the otherwise normal child who presents several hours after a generalized seizure. The former needs an urgent evaluation to look for an infectious etiology, such as meningitis or encephalitis, whereas the latter can be managed less hastily. This chapter deals with the evaluation and treatment indicated for patients with generalized seizures as their only presenting clinical sign.

In all children with their first seizure, a careful history should be obtained, with particular attention to whether the seizure was preceded by an aura or if the seizure had any focal features. A focal onset to the seizures, or Todd's paralysis, would suggest that the seizure was focal rather than generalized. However, primarily generalized tonic-clonic seizures can have lateralized findings such as version of the head or trunk or asymmetric myoclonus. A review of potential precipitating factors, such as sleep deprivation or photic stimulation, may be useful in counseling the patient and the parents. A past medical history of birth asphyxia or trauma, head injury, prolonged febrile seizures, meningitis, or encephalitis may offer etiologic clues indicating that the seizures have a partial onset. A history of other neurologic symptoms should be sought. Headaches, especially those associated with vomiting or occurring at night, should raise the possibility of a structural lesion.

Although neuroimaging appears to have reduced the importance of the neurologic examination, abnormal findings, even if subtle, may provide clues to the location of seizure onset and etiology of the seizures. For example, asymmetries in facial expression or strength may indicate focal deficits, even in the presence of normal neuroimaging findings.

Diagnostic studies ordered depend on findings during the history and neurologic examination. Children with an unremarkable history other than that for the seizures and with normal findings on neurologic examination typically require only an EEG and neuroimaging. An EEG should always be obtained because it may help differentiate focal from generalized seizures. Focal epileptiform activity or slowing would raise the possibility of a structural lesion.

Neuroimaging is recommended in all patients presenting with their first unexplained generalized tonic-clonic seizure, with the recognition that, in patients with normal neurologic examinations, the chance of finding a treatable lesion is quite low. Because generalized tonic-clonic seizures may have a focal onset with subsequent rapid generalization, however, the seizure may be incorrectly diagnosed as primarily generalized in type. In nonemergency settings, the imaging test of choice is a magnetic resonance imaging (MRI) scan. However, in young children, high-quality, artifact-free MRI often requires anesthesia. Although computed tomography (CT) scans can be used in acute situations to determine the presence of a mass lesion and hemorrhage, it does not provide adequate resolution to show subtle malformations of cerebral development.

The need for further diagnostic testing, such as metabolic and genetic screening and cerebrospinal fluid examination, depends on the clinical presentation. In the absence of mental retardation, developmental regression, or abnormalities on neurologic examination, these studies usually are not indicated following the initial seizure.

## Comorbidities Associated with Generalized Seizures

Although a major goal in the treatment of epilepsy is stopping the seizures, it is not the only treatment goal. Patients with epilepsy are at risk for a number of comorbidities. Comorbidity refers to the co-occurrence of two supposedly separate conditions that occur together more than by chance (also see Chapter 82). Depression occurs more frequently in patients with epilepsy than in the normal population, and thus epilepsy and depression are comorbidities. Comorbidities are not necessarily causal. For example, because epilepsy and depression are comorbidities does not mean that epilepsy caused the depression or depression caused the epilepsy. Rather, it is possible that both conditions have a common biological substrate or that another independent variable triggers one of the comorbidities. For example, epilepsy often leads to drug therapy, which could cause depression independently of the epilepsy.

Comorbidities associated with epilepsy include depression, suicidality, attention deficit hyperactivity disorder (ADHD), conduct disorders, anxiety, cognitive impairment and learning disabilities, and migraine (Camfield and Camfield, 2009).

Being aware of the comorbidities frequently associated with childhood epilepsy may influence the choice of antiseizure medicine used to treat the epilepsy. For example, lamotrigine and valproate may be helpful in treating both the primarily generalized seizures and mood disturbance. Likewise, topiramate and valproate can treat both seizures and migraine. On the other hand, antiseizure medications may exacerbate the comorbid condition. Topiramate can have adverse cognitive effects, and benzodiazepines and barbiturates can exacerbate ADHD and conduct disorders.

## Medical Treatment

The medical treatment of generalized seizures that have a partial onset and secondarily generalize is, in general, the same as the treatment for partial seizures. It is generally assumed that an antiseizure medicine that reduces the likelihood of focal seizures would also prevent focal seizures that secondarily generalize. However, it is possible that there may be a difference in the ability of an antiseizure drug to prevent secondarily generalization following the focal onset.

The major drugs typically used to treat primarily generalized tonic-clonic seizures include valproate, lamotrigine, levetiracetam, and topiramate. Although phenobarbital is effective in the treatment of primarily generalized tonic-clonic seizures, the profile of adverse side effects has reduced its use as initial therapy for primarily generalized tonic-clonic seizures. Although other antiseizure medicines such as lacosamide, zonisamide, perampanel, and clobazam have shown efficacy in primarily generalized seizures in children, additional studies are necessary.

## ABSENCE SEIZURES

Absence seizures, formerly termed petit mal seizures, are characterized by an abrupt cessation of activity, change in facial expression, and impairment of consciousness. Absence

seizures are not common, accounting for less than 10% of all seizure types. Absence seizures may be the most common seizure type to go undetected. The prevalence of absence seizures is highest during the first 10 years of life and then drops dramatically to a very low level. Absence seizures are more common in girls than in boys. Absence seizures can begin as early as the first year of life.

Absence seizures are classified as typical or atypical in type. Typical absence seizures are short, rarely lasting over 30 seconds; as with other generalized seizures, they are never associated with an aura or postictal impairment. The sudden onset of impaired consciousness, usually associated with a blank facial appearance without other motor or behavioral phenomena, is characteristic. The degree of impairment of consciousness is variable. Some children remember virtually everything that is said during the seizure, whereas for others, the entire duration of the seizure is “time lost.”

Although the absence seizure is commonly thought to consist only of staring, in fact the behavioral changes associated with the seizure type usually are more complex. Most absence seizures are accompanied by motor, behavioral, or autonomic phenomena, and seizures characterized by only staring and altered consciousness are unusual. Automatism, semipurposeful behaviors of which the patient is unaware and subsequently cannot recall, are very common with absence seizures. They either may be perseverative, reflecting continuation of preictal activities, or may arise *de novo*. Simple behaviors, such as rubbing the face or hands, licking the lips, chewing, grimacing, scratching, or fumbling with clothes, tend to be *de novo* automatisms. Complex activities, such as dealing cards, moving a chess piece, or handling a toy, are generally perseverative. Speech, if it occurs during the seizure, usually is perseverative and may be slow and slurred, but also may be totally normal. The longer the absence seizure lasts, the more likely automatisms are to occur.

Clonic or myoclonic components are common but may be quite subtle, most frequently consisting of blinking. Clonic activity also may be manifested by nystagmus, rapid jerking or trembling of the arms, or head nods. Alterations in muscle tone may lead to stiffening of the trunk or a fall.

Autonomic phenomena occasionally may be seen with absence seizures and include dilation of the pupils, pallor, flushing, sweating, salivation, and even urinary incontinence.

The frequency of absence seizures varies considerably from day to day and even from hour to hour. The number of absence

seizures varies significantly with different environmental situations. Seizures are more likely to occur during periods of inactivity than when the child is busily engaged in a task. Fatigue also may dramatically increase seizure susceptibility.

A majority of children with typical absence seizures have normal findings on neurologic examination, and when neurologic abnormalities are found, they usually are mild and nonprogressive. Most children with typical absence seizures have normal or mildly low intelligence. Compared with age-matched controls, children with absence seizures have lower general cognitive function, with impaired visual-spatial skills and memory disturbances. Children with absence seizures have higher rates of ADHD, behavioral problems, and psychopathology than in the normal population.

Typical absence seizures may be associated with generalized tonic-clonic seizures in 40% to 60% of patients. In most children, the generalized tonic-clonic seizures occur after onset of the absence seizures.

Although atypical absence seizures form a separate category of absences, overlap between the two seizure types is considerable, and they appear to represent a clinical continuum. Diminished postural tone, or tonic or myoclonic activity, is significantly more likely to be the initial clinical feature in atypical than in typical absences. Automatisms are less likely in atypical absences than in typical absences. Like typical absences, atypical absences have a distinct onset and ending, without auras or postictal symptoms. Although atypical absences usually are of longer duration than typical absences, a considerable amount of variability exists.

Atypical absences usually begin before the age of 5 years and often are associated with other seizure types and mental retardation. In children who have profound mental retardation, it may be difficult to detect subtle behavioral changes associated with the absence seizures. Many children with atypical absence seizures have Lennox–Gastaut syndrome (Widdess-Walsh et al., 2013).

The primary diagnostic considerations in the child referred because of “staring attacks” include absence seizures, focal seizures, and daydreaming (Table 66-5). Focal seizures are more common than absence seizures and also are manifested by an alteration in consciousness with staring, automatisms, changes in tone, and autonomic symptoms. Complex partial seizures tend to be longer and less frequent, but clinically no absolute distinguishing factor may be present. The presence of an aura or postictal impairment is strongly suggestive of a

**TABLE 66-5** Differential Diagnosis of Absence Seizures

Clinical and Laboratory Characteristics	Absence	Focal with Impairment of Consciousness or Awareness (Complex Partial Seizure)	Daydreaming
Frequency/day	Multiple	Rarely > 1–2	Situation-dependent
Duration	Frequently < 10 sec; rarely > 30 sec	Average duration > 1 min; rarely < 10 sec	Seconds to minutes
Aura	Never	Frequent	Never
Clonic component	Common; eye blinking common	Infrequent	Never
Postictal impairment	Never	Frequent	Never
Seizures activated by			
Hyperventilation	Frequent	Rare	Never
Photic stimulation	Frequent	Rare	Never
EEG			
Interictal	Generalized spike wave	Focal spikes, sharp waves	Normal
Ictal	Generalized spike wave	Rhythmic spikes, sharp waves, or slow waves	Normal

EEG, electroencephalogram.

complex partial seizure. In the child not on antiseizure medications, 3 minutes of hyperventilation usually precipitates an absence seizure. It is unusual for focal seizures to be precipitated by hyperventilation. Abnormalities documented on the EEG constitute the best confirmation of either seizure type.

Daydreaming is associated with boredom, can be “broken” with stimulation, and is not associated with motor activity. Absence seizures, however, also can sometimes be terminated with stimulation and tend to increase during periods of relaxation and tiredness. Normal findings on an EEG study that includes several trials of 3 to 5 minutes of hyperventilation virtually rule out absence seizures. Repeated studies or prolonged EEG monitoring occasionally may be necessary when diagnostic confusion persists.

## Initial Evaluation

The extent of the diagnostic evaluation required in patients with absence seizures is variable and depends somewhat on findings from the history and physical examination. All patients need a neurologic examination, 3 minutes of hyperventilation, and an EEG with hyperventilation and photic stimulation. Ideally the EEG should include sleep, recognizing this is sometimes difficult to achieve in children. Patients who have normal development, normal findings on neurologic examination, a history suggestive of typical absence seizures, and 2.5- to 4-Hz spike-wave discharges on an otherwise normal-appearing EEG require no further studies. Children with developmental delay, an abnormal neurologic examination, a history suggestive of atypical absences, or an EEG showing slow spike-and-wave (less than 2.5 Hz) discharges, background slowing, or focal epileptiform discharges should have an MRI and possibly more specific tests, such as meta-

bolic studies and a lumbar puncture (see Chapter 76). Children with refractory absences, especially if they are associated with developmental delay and a movement disorder, should be tested for glucose transporter type 1 deficiency syndrome, a condition with hypoglycorrhachia with normoglycemia.

## Electroencephalographic Findings

The EEG signature of a typical absence seizure is the sudden onset of 3-Hz generalized symmetric spike-and-wave or multiple spike-wave complexes (Fig. 66-2). The voltage of the discharges often is maximal in the frontal-central regions. The frequency tends to be faster, about 4 Hz, at the onset and may slow to 2 Hz toward the end of a discharge lasting longer than 10 seconds. Hyperventilation is a potent activator of typical absence seizures. Failure to induce an absence seizure with several trials of hyperventilation of 3 to 5 minutes' duration in a child not receiving antiseizure medication would make the diagnosis of typical absence seizures unlikely. Photic stimulation also may precipitate seizures, although the frequency of activation does not appear as high as with hyperventilation.

In atypical absences, the ictal EEG is more heterogeneous, showing 1.5- to 2.5-Hz slow spike-and-wave or multiple spike-and-wave discharges that may be irregular or asymmetric (Fig. 66-3). Interictal EEG findings usually are abnormal, with background slowing and multifocal epileptiform features (Holmes et al., 2004; Aghakhani et al., 2004; Crunelli and Leresche, 2002).

## Treatment

Medical therapy is recommended for children with absence seizures. Although not life-threatening, absence seizures may

**Figure 66-2.** EEG from a patient with typical absences. The technician said the phrase “green pizza” during the spike-and-wave discharge. After the absence seizure, the patient did not recall the phrase (calibration: 50  $\mu$ V, 1 second).

**Figure 66-3.** Slow, irregular generalized spike-and-wave discharges in a patient with Lennox–Gastaut syndrome and atypical absences (calibration: 50  $\mu$ V, 1 second).

lead to poor school performance, ridicule, and accidents. Because even brief generalized spike-and-wave discharges can affect cognitive function, it is therefore reasonable to begin drug therapy in most patients once the diagnosis is secure. Drugs of choice in absence seizures are valproate, ethosuximide, and lamotrigine.

## Prognosis

Approximately two thirds of children with childhood absence epilepsy can be expected to enter long-term remission (Wirrell et al., 1996; Wirrell, 2003; Berg et al., 2014). Favorable prognostic signs in absence seizures are a negative family history of epilepsy, normal EEG background activity, and normal intelligence. Nearly 90% of children with these characteristics will stop having absence seizures.

Juvenile absence epilepsy may occasionally persist into adulthood, however, and juvenile myoclonic epilepsy does not spontaneously remit. As a general rule, onset of generalized tonic-clonic seizures before absence seizures carries a poorer prognosis than that noted with the reverse order.

## MYOCLONIC SEIZURES

### Clinical Features

Myoclonic seizures are characterized by sudden, brief (less than 350  $\mu$ sec), shock-like contractions that may be generalized or confined to the face and trunk, or to one or more extremities, or even to individual muscles or groups of muscles. Myoclonic seizures result in short bursts of synchronized electromyographic (EMG) activity, which often involves simultaneous activation of agonist and antagonist muscles. The contractions of muscles are quicker than the contractions of

clonic seizures. Any group of muscles can be involved in a myoclonic seizure. Myoclonic seizures may be dramatic, causing the patient to fall to the ground, or quite subtle, resembling tremors. Because of the brevity of the seizures, determining whether consciousness is impaired is impossible. Although myoclonic seizures can sometimes be the only seizure type present, they can occur in combination with other seizure types, such as myoclonic-atonic and myoclonic-tonic.

Myoclonic jerks are so brief that they may be missed by parents and physicians. Once seen, diagnosis is usually not difficult. Myoclonic seizures may occasionally be confused with tics. Tics are repetitive, patterned motor activity, often involving multiple groups (see Chapter 98). Unlike seizures, tics can be voluntarily suppressed. Shuddering attacks are common in toddlers and consist of pronounced shivering. Typically, the child keeps the arms flexed and the shoulders adducted. The episodes last from seconds to minutes, and typically occur when the child is excited. Usually, both tics and shuddering attacks can be differentiated from myoclonic seizures. However, in cases in which the diagnosis is in doubt, an EEG can be useful. In both tics and shuddering attacks, the EEG is normal.

It is also important to recognize that myoclonus is not always an epileptic phenomenon. For example, sleep starts or hypnic jerks are normal physiologic events. On the other end of the spectrum, hereditary hyperekplexia and posthypoxic myoclonus are severe conditions not associated with epileptiform activity on the EEG.

### Electroencephalographic Findings

Myoclonic seizures are typically associated with generalized spike-and-wave or multiple spike-and-wave discharges on the EEG. Myoclonic seizures are frequently associated with enhanced photosensitivity.

## TONIC SEIZURES

Tonic seizures are brief seizures (usually lasting less than 60 seconds) consisting of the sudden onset of increased tone in the extensor muscles. If standing, the patient typically falls to the ground. Electromyographic activity is dramatically increased in tonic seizures.

Impairment of consciousness during the seizure is characteristic, although when seizures are brief, this change may be difficult to detect. Tonic seizures frequently are seen in patients with Lennox–Gastaut syndrome, a disorder consisting of a mixed seizure disorder, mental retardation, and the EEG findings of a slow spike-and-wave pattern (Arzimanoglou et al., 2009). The seizures usually occur more frequently at night.

Tonic seizures frequently begin with a tonic contraction of the neck muscles, leading to fixation of the head in an erect position, widely opened eyes, and jaw clenching or mouth opening. Contraction of the respiratory and abdominal muscles often follows, sometimes leading to a high-pitched cry and brief periods of apnea. The tonic contractions may extend to the proximal musculature of the upper limbs, elevating the shoulders and abducting the arms. Asymmetric tonic seizures vary in severity, ranging from a slight rotation of the head to a tonic contraction of all of the musculature on one side of the body. Eyelid retraction, staring, mydriasis, and apnea also may occur. Occasionally, tonic seizures terminate with a clonic phase. Unlike in generalized tonic-clonic seizures, however, the clonic phase is abbreviated. Postictal impairment, with confusion, tiredness, and headache, is common. The degree of postictal impairment usually is related to the duration of the seizure.

Tonic seizures typically are activated by sleep and may occur repetitively throughout the night. They usually are more frequent during nonrapid eye movement (NREM) sleep than during wakefulness and usually do not occur during rapid eye movement (REM) sleep. Arousal from light sleep may occur after a tonic seizure. Because the child often does not wake up during the seizure, these seizures often go undetected.

## Electroencephalographic Findings

The interictal EEG pattern in patients with tonic seizures usually is quite abnormal, consisting of slowing of the background, with multifocal spikes, sharp waves, and bursts of irregular spike-and-wave activity. The EEG ictal manifestations of tonic seizures usually consist of bilateral synchronous spikes of 10 to 25 Hz, of medium to high voltage, with a frontal accentuation. Simple flattening or desynchronization may also occur (Fig. 66-5). Occasional multiple spike-and-wave or diffuse slow-wave activity may occur during a tonic seizure.

## ATONIC SEIZURES

Atonic (astatic) seizures, or “drop attacks,” are characterized by a sudden loss of muscle tone. They begin suddenly and without warning and cause the patient, if standing, to fall quickly to the floor. Children with atonic seizures are more likely to fall backward than children with tonic seizures. Because muscle tone may be completely absent, the children have little means by which to protect themselves, and injuries often occur. The attack may be fragmentary and manifest as dropping of the head with slackening of the jaw or dropping of a limb.

At times, it may be difficult to distinguish epileptic from nonepileptic head drops. Children with head drops secondary

to seizures often have a change in facial expression and subtle myoclonic extremity movements associated with the head drops. Head drops with a rapid head descent, followed by a slow recovery to the upright position, usually represent seizures.

In atonic seizures, a loss of electromyographic activity is characteristic. Consciousness is impaired during the fall, although the patient may regain alertness immediately on hitting the floor. Atonic attacks are sometimes associated with myoclonic jerks, a combination that has been described as myoclonic-astatic seizures.

## Electroencephalographic Findings

Atonic seizures usually are associated with rhythmic spike-and-wave complexes varying from slow, 1- to 2-Hz, to more rapid, irregular spikes or multiple spike-and-wave activity. The hallmark of the EEG pattern in Lennox–Gastaut syndrome is the slow spike-and-wave discharge superimposed on an abnormal, slow background. The slow spike-and-wave or sharp-and-slow-wave complexes consist of generalized discharges occurring at a frequency of 1.5 to 2.5 Hz. The morphology, amplitude, and repetition rate may vary both between bursts and during paroxysmal bursts of spike-and-wave activity, and asymmetries of the discharge are frequent. The area of maximum voltage, although variable, usually is frontal or temporal in location. Often, sleep increases the number of epileptiform discharges, but these discharges may slow in frequency and become even more irregular than during the awake state. In REM sleep, the paroxysmal activity decreases markedly. Hyperventilation and photic stimulation rarely activate these discharges.

## Focal and Multifocal Seizures

Douglas R. Nordli, Jr.

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

### INTRODUCTION

Focal seizures originate in one region of the brain, where they may stay confined or spread to other areas. Focal seizures were previously referred to as *partial*, but this term created confusion when translated into other languages, and the International League Against Epilepsy (ILAE) has recommended that it no longer be used. If a discrete area of eloquent cortex is involved, the first manifestation may be an aura—something that only the patient can describe. If the seizure propagates into bilaterally distributed networks, the patient will likely become unaware of subsequent phases of the seizure. In the past this was referred to as the *complex* phase of the seizure. Other terms, including *dialeptic* and *dyscognitive*, have been used to describe some alteration of awareness and cognition. The simple term *unaware* might also suffice. Further diffuse spread of the ictus can result in secondary generalization with manifestations that are nearly identical to those of a generalized tonic-clonic seizure. When only the last portion of the seizure is witnessed, it may be impossible to discern if the onset was focal or generalized unless the patient can recall early declarative features.

Multifocal seizures arise from multiple locations and are not simply a composite of the individual focal seizures, but may be reflective of different underlying processes and therefore may respond differently to medications. Both focal and multifocal types have been underrecognized in children, but modern epidemiologic studies show that focal epilepsies account for about 60% of all seizure disorders (Berg et al., 1999). The behavioral manifestations of focal seizures relate not only to the region of the brain involved during the ictal discharge, but also to the maturation of the nervous system and the integrity of the pathways necessary for clinical expression.

### TYPES OF FOCAL SEIZURES IN CHILDREN

The ILAE Commission on Classification proposed a classification of seizures in 1981 (ILAE, 1981). This scheme was widely used for almost three decades and divided focal seizures into simple partial, complex partial, and partial with secondary generalization. Subsequently, another ILAE commission on classification proposed a substantial revision (Berg et al., 2010; Vendrame et al., 2011). In this revision, the term *focal* replaced the previous term *partial*, and the obligatory separation of partial seizures into simple, complex, and secondary generalized was discarded. This created some consternation, even though the committee proposed that descriptors, albeit slightly wordy, should still be used in the full characterization of seizures.

In adolescents and adults who can communicate normally, it may be useful to subdivide seizures by alteration of awareness. In the ILAE 2010 document, examples of such descriptors were given, including “without impairment of consciousness or awareness,” “with impairment of consciousness or awareness,” and “evolving to bilateral convulsive seizure.” The

reader will note that these terms roughly equate to the older terminology delineating simple, complex, and secondary generalized seizures.

### Alteration of Consciousness

Classifications that emphasize alteration of consciousness have substantial limitations in pediatrics. It may be very difficult or even impossible to accurately determine alteration of consciousness in the preschool child, even when children have the ability to communicate normally (Nordli, Kuroda, & Hirsch, 2001). In preverbal infants it is all but impossible. Simply because a child does not appear to alert to verbal or visual cues does not necessarily imply alteration of consciousness. Well-known examples are the focal seizures seen in children with rolandic epilepsy. An eye-witness will commonly infer that consciousness was altered in some daytime events because the child did not respond normally, but when one interviews the child, one realizes that awareness was completely preserved throughout the entire event, and the inability to speak was secondary to a selective anarthria. If classification schemes using awareness as the first branch point are widely adopted, another category of “awareness uncertain” may be a convenient way to approach the seizures in younger patients or those with limited ability to communicate.

### Semiologic Classification Schemes

Lüders and colleagues (1998) developed a classification system for seizures that has been used in many major epilepsy centers in a wide variety of countries. Others have proposed a similarly simplified semiologic classification system for use in the very young (Nordli et al., 1997). Neither of these schemes has yet been endorsed by the ILAE. Although seizures may sometimes be broadly classified using the most prominent and early feature of the seizure, the various combinations of features, patterns, and time course of the seizure cannot be adequately summarized in a single word or phrase. Nothing can replace a thorough and meticulous description of the seizure. Indeed, the historic narrative of the seizure, as described or observed by parents, is the single most helpful piece of information allowing proper diagnosis of the seizure disorder and should be recorded, as accurately as possible, with few or no editorial comments.

Still, certain features can be identified that increase the likelihood that a described event was a focal seizure, and these same features can be used to characterize the early and prominent features of the majority of pediatric focal seizures. This semiologic approach is simple, demonstrates good interobserver reliability (Nordli et al., 1997), and has a certain degree of sincerity in that it does not infer more than is possible from the clinical manifestations alone. The early manifestations are the most important because they are the closest to the source of the ictus and therefore provide the best localizing information. There is no doubt that the path the ictus takes may have a major influence on the degree of disability induced by

the seizure and therefore is not trivial, but the clinical analysis of the complex patterns seen during ictal progression is complicated, and it is important to keep in mind that some features of seizures may not be the direct manifestation of electrical stimulation of the telencephalon, but may be a result of disinhibition of deeper structures or networks. This may be particularly important when evaluating the semiology of frontal lobe seizures. Tassinari and colleagues (2005) make the point that some automatic motor movements may originate from deep structures that are preprogrammed motor movements (central pattern generators), remarkably conserved across species. Recent imaging work has indeed

implicated deeper gray-matter and brainstem circuits in the generation of tonic postures, spasms, and atonia. Accordingly, clinical features alone cannot always allow one to correctly diagnose a focal seizure. Rather, “focal seizure” is actually an electroclinical diagnosis. It usually is made following consideration of multiple factors related to the patient and the clinical event, but may require electroencephalogram (EEG) confirmation, particularly in the very young. To summarize, experience using video EEG monitoring suggests that certain clinical features tend to have focal ictal EEG correlates (Figure 67-1), and these may be used as a way to categorize focal seizures in pediatrics, including the very young, although

**Figure 67-1.** Typical interictal findings on electroencephalogram (EEG) in children with focal seizures. **A**, This EEG from a child with benign rolandic epilepsy of childhood (BREC) shows focal stereotypic spikes appearing on a normal background. Notice that each spike closely resembles the others in morphology and location, as is typical of idiopathic localization-related epilepsies. **B**, By contrast, this EEG from a child with an epileptogenic focal structural lesion in the left temporal region demonstrates pleomorphic spikes and background slowing in the same region. **C**, EEGs from children with multifocal seizures often show multifocal interictal epileptiform discharges.

**TABLE 67-1** A Simple Semiologic Categorization of Pediatric Seizures

Focal		Generalized	
	Aura Autonomic		Clonic Myoclonic
Elementary motor	Focal clonic Focal myoclonic Focal tonic Versive		Tonic Tonic-clonic Epileptic spasms Myoclonic-atic
Complex motor	Automotor Epileptic spasms with asymmetry Gelastic Hypermotor	Negative	Myoclonic-tonic Absence  Atypical absence Myoclonic absence
Negative	Dialeptic/dyscognitive  Behavioral arrest/hypomotor		Absence with eyelid myoclonia Atonic

confirmation sometimes requires electroencephalographic data (Table 67-1).

## Auras

Auras are special sensory or psychogenic phenomena that are perceived only by the patient. They occur in a variety of forms and have important localizing value. Although the concurrent ictal EEG often does not reveal clear electrographic expression in most patients, auras are believed by most authorities to be the manifestation of discrete focal seizures. When a somatosensory aura is specific and an ictal EEG correlate is present, the ictal discharge is often low-voltage fast activity localized over the corresponding region of the sensory homunculus. Other auras arising from limbic structures often are “indescribable,” or may have a fearful quality or include a feeling of epigastric discomfort. These discharges arise from subcortical structures, so the EEG may reveal little to no change, other than ipsilateral diffuse delta activity or a rhythmic theta-alpha pattern in the anterior to midtemporal region, particularly when the onset of activity is mesial temporal in location. Auras are supportive of the diagnosis of a focal seizure, especially when having certain clinical characteristics strongly localizing to a particular cortical area, although recent studies have reported the presence of auras in generalized seizures as well.

## Autonomic

Rarely, the only manifestation of a focal seizure is through the autonomic nervous system. Some examples include an increase in heart rate, oxygen desaturation, pallor, and piloerection in one region of the body.

## Automotor

Limb automatisms are semipurposive movements, such as rubbing or fumbling of the hands, or picking at the air, that may be seen in focal seizures. Oral automatisms, such as lip smacking, can occur with generalized absence seizures, but unilateral limb automatisms suggest a focal process. Well-developed distal limb automatisms are rarely seen in infants but become more common above age 6 years. When

unilateral, automatisms are another helpful sign, indicating the presence of a focal seizure, and are typically seen ipsilateral to the epileptic focus in older children and adults. Most often automatisms are probably coupled with some alteration of cognition, but this is not invariably the case. In infants and young children rigorous assessment of cognition is sometimes impossible.

## Behavioral Arrest or Hypomotor

In some infants and young children, the most conspicuous feature of a focal seizure may be the sudden, abrupt cessation of ongoing activity or a marked change in demeanor, as indicated by subtle but distinct changes in facial expression. Parents easily identify these features because they represent a clear paroxysmal alteration in the child’s behavior. Parents are particularly well attuned to the nature of their child’s habitual behavior, but these behavioral changes may be challenging for a person unacquainted with the child to identify on videotape. In the preverbal child, and in many children with special needs, it is impossible to ascertain alteration of consciousness reliably. Alteration of consciousness cannot be unambiguously inferred from behavior (e.g., daydreaming in school). To assess consciousness accurately, test items must be given and recall tested after the seizure. In children, this often is not possible, so the simple description of a behavioral arrest is more reliably used, rather than trying to infer if the patient was unaware during the seizure. Behavioral arrest seizures also have been described as hypomotor seizures. This description refers to a sudden reduction in the motor activity of the child. The electrographic ictal accompaniment often emanates from the temporal lobe or posterior quadrant and may be composed of monotonous rhythmic delta or theta-alpha patterns with an electrographic “crescendo” appearance, or low-voltage fast discharges that subsequently evolve to other rhythms (Figure 67-2). In children above age 3 years, behavioral arrest may accompany both focal and generalized seizures (absence seizures), so in isolation it is not a reliable indicator of a focal seizure; however, because absence seizures rarely occur in children less than 2.5 years of age, it is likely to be the correlate of a focal seizure in this age group.

## Clonus or Myoclonus—Focal

Hand or arm clonus (clonic seizure) or myoclonus is another reliable feature of focal epilepsy. This activity is easily recognized as ictal by the repetitive nature of the jerking in the case of clonus or the sudden isolated jerk of myoclonus. Clonic seizures can sometimes be distinguished from jitteriness or tremor by the inability to suppress the motion by passive restraint. Clonus is usually accompanied by runs of rhythmic spike discharges in the contralateral rolandic region, and it is a reliable indicator of a focal seizure. The EEG correlate of myoclonias is most often spikes or spike-wave discharges in the contralateral hemisphere.

## Dialeptic or Dyscognitive

Dialeptic or dyscognitive seizures are those in which the main manifestation is an alteration of consciousness. The term *dialeptic* was coined as a purely descriptive one, without the need to infer whether the underlying EEG correlate was focal or generalized (Lüders et al., 1998). Another largely synonymous term is *dyscognitive* (Berg et al., 2010), but because there are many aspects to consciousness and cognition, one could argue that a simpler option would be simply to state that the patient was unaware. In the author’s personal experience,

**Figure 67-2. Common infantile ictal patterns on electroencephalogram (EEG) in focal seizures. A,** EEG during a behavioral arrest seizure shows an ictal discharge in the left temporal region. Notice the rhythmic buildup of fast activity. Ictal discharges usually have an evolution in frequency, amplitude, and spatial distribution (like a crescendo in music). **B,** During a clonic seizure involving the left arm, the EEG demonstrates an ictal correlate consisting of repetitive spikes in the right central region. Notice that the ictal discharge remains very localized. **C,** EEG obtained during a versive seizure with eyes deviating to the right, or the same side as for the ictal discharge, shows a fast ictal pattern superimposed on some rhythmic slowing in the right posterior head region.

it is rare to diagnose pure dialeptic seizures of focal origin in infants and young children. Because consciousness and ongoing cognition are very difficult to assess in the young and because children tend to be more active when awake, the most conspicuous manifestation of a focal seizure with dialeptic features often tends to be an arrest of movement (hypomotor). There are times, however, when there is a constellation of features, including subtle posture, brief body movements, and slight version, that makes it difficult to segregate the seizure into one simple category, and if consciousness can be verified to be abnormal, as is often the case with older children or adolescents, than the terms *dialeptic* or *dyscognitive* can be used.

### Epileptic Spasms With Asymmetric Features

Spasms can be recognized by their tendency to recur in clusters, many times in an almost periodic fashion, with a fairly constant interval between successive individual spasms. Spasms have a quick or myoclonic component at the start, followed by a brief sustained posture (tonic phase), followed in turn by a relaxation. Spasms that are asymmetric, that occur in a child with hemiparesis or other focal pathology, or that are associated with marked interhemispheric asymmetries on EEG could be considered to be a form of focal seizures in that they may have a focal telencephalic trigger. In about 25% of patients with spasms, clear electrographic focal seizures can be detected before, during, or after the cluster. The EEG accompaniment of spasms often contains diffuse electrodecrements, even if they are preceded by clear focal seizures.

### Gelastic

Gelastic seizures are rarely seen but important to recognize because of their association with hypothalamic hamartomas. They may also be seen with lesions in the frontal lobe. They are characterized by brief epochs of "mirthless" laughter and may have subtle surface EEG correlates.

### Hypermotor

Hypermotor seizures usually involve a complex series of large movements, resulting in a violent appearance of the event. Although they have been noted to arise from the mesial frontal supplementary sensorimotor area, or other regions of the frontal lobe in adults, they may also be seen in temporal lobe seizures in children. Temporal lobe seizures in very young infants may show prominent coarse motor manifestations, but these tend to decrease with advancing age (Ray and Kotagal, 2005).

### Tonic

Tonic postures, both symmetric and asymmetric, are seen with focal seizures. It is surprising to observe how often symmetric tonic postures can occur as a manifestation of a focal seizure in infants, and also how unreliable asymmetries of tonic postures can be in localizing ictal onsets. It is possible that these tonic postures are generated in deeper brainstem or subcortical structures and are not direct manifestations of the ictal discharges. This finding would explain why some asymmetric tonic postures can be reversed by passive turning of the head during a seizure, in a fashion similar to the tonic neck reflex elicited in the newborn. As the child matures, symmetric tonic

postures are seen less frequently as a manifestation of a focal epilepsy. Instead, tonic postures become more asymmetric and show more lateralizing features.

### Versive

Pronounced and sustained lateral version of the eyes (as in a so-called versive seizure) is rarely encountered as an ictal manifestation in infants or young children. When present, version is another indicator of a focal seizure. In contrast with older children and adults, in whom the electrographic discharge often is best developed in the contralateral frontotemporal region, the ictal discharge in infants is more often in the ipsilateral occipital lobe.

### Ontogeny of Focal Seizures

The clinical expression of focal and multifocal seizures changes with age, in a more or less predictable fashion. Features that occur with more regularity with increasing age include aura, limb automatisms, dystonic posture, secondary generalization, and unresponsiveness. In contrast, the frequency of asymmetric clonus and symmetric tonic posturing decreases with age (Hamer et al., 1999; Acharya et al., 1997)

## EVALUATION AND MANAGEMENT

Although it is important to distinguish focal seizures from their generalized counterparts, this simple segregation is not sufficient to guide treatment. A broader understanding of the epilepsy syndrome, category of epilepsy, and etiology is even more important. A good example is Dravet syndrome. Infants with this condition will often have hemiclonic events early in their course, even though the EEG features may indicate a more multifocal process (Figure 67-3). If one focused only on the seizure type, one might correctly diagnose focal seizures and be tempted to select drugs that modulate the sodium channel (e.g., carbamazepine or phenytoin), but these medications may actually worsen the underlying sodium channel dysfunction causing the epilepsy and might very well make the patient worse.

If a precise epilepsy syndrome cannot be established, it may be helpful to consider the development of the child and the interictal EEG. If the child is developing normally and the EEG background is normal, then in most circumstances the EEG spikes should be rather stereotyped. If all of this is true for the particular case, it is most likely that one is dealing either with a familial epilepsy or a self-limited epilepsy, such as rolandic epilepsy or Panayiotopoulos syndrome.

If the child shows slowed development and the EEG background is slow, then a diffuse or multifocal encephalopathy needs to be considered. In this case the spikes will usually be multifocal and pleomorphic. A wide variety of conditions may cause this presentation, including metabolic disorders (Chapter 76) and de novo mutations. If these circumstances broader-spectrum agents will usually be more effective. The reader is referred to Chapter 77 focusing on medication.

Finally, if there is focal slowing, attenuation, or both, then a structural lesion needs to be considered. In this case there will often be focal pleomorphic spikes. Imaging should be obtained, and if multiple well-chosen medications have not helped, then a surgical evaluation should be considered (see Chapter 78).

**Figure 67-3.** Electroencephalogram (EEG) findings in Dravet syndrome in an infant. **A**, In the first year of life EEGs may be normal, although posterior spikes and polyspikes are sometimes seen, as in this child at 10 months. **B**, Later, generalized spike and polyspike-wave discharges are noted. This is the same child 2 years later.

## INTRODUCTION

Myoclonus, myoclonic seizures, and infantile spasms share many common features yet are seen in a wide variety of neurologic conditions. The precise definitions of each of these terms has also been somewhat controversial, but for this chapter we will use the definition proposed by Victor and Adams and define myoclonus simply as a “shocklike irregular jerk” with myoclonic seizures having a similar clinical appearance but also accompanied by neurophysiologic evidence of being cortically generated. The distinction between a cortically generated movement (myoclonic seizure) and a subcortically generated movement (myoclonus) is extremely important, especially when thinking about some of the progressive myoclonic epilepsies as many of these patients can manifest both myoclonus and myoclonic seizures. Infantile spasms, however, should not be confused with either, as the spasm itself is often a more complex constellation of movements with a myoclonic component.

Given this overlap, it is fitting to present myoclonic seizures and infantile spasms together as a continuum of events that occur in a developing nervous system. We will first discuss some of the more common pediatric epilepsy syndromes in which myoclonic seizures are often seen, followed by a more detailed discussion of infantile spasms.

## Epilepsy Syndromes With Prominent Myoclonic Seizures

Myoclonic seizures can be seen in a wide variety of pediatric epilepsy syndromes, including Lennox-Gastaut syndrome and childhood absence epilepsy, which are discussed elsewhere in this text. Our focus will be on those syndromes in which myoclonic seizures are a critical feature for the diagnosis. This includes benign myoclonic epilepsy in infants (BME), Dravet Syndrome (SMEI/severe myoclonic epilepsy of infancy), myoclonic-astatic epilepsy (Doose syndrome), and juvenile myoclonic epilepsy (JME).

### Benign Myoclonic Epilepsy of Infancy (BMEI)

BMEI was first described by Dravet and Bureau in 1981. The syndrome is characterized by brief, generalized myoclonic seizures with the predominant area of muscle involvement being the proximal upper extremities and usually occurs in children between the ages of 4 months and 3 years. These attacks often occur multiple times per day. Detailed EEG and polygraphic EMG recordings have shown that the myoclonic seizures are often associated with a flexor postural change and approximately 80% of attacks involve the upper limbs. A history of febrile seizures (30%) and a family history of epilepsy (39%) are relatively common.

### EEG

The ictal EEG discharge is often a generalized spike wave (GSW) that may be slower than 3Hz. Some infants may exhibit

photosensitivity at the onset of the syndrome, and the photic-induced myoclonic seizures are often more prominent than those that occur spontaneously.

## Treatment and Outcome

The overall prognosis of myoclonic seizures is excellent, with complete resolution in almost all children usually within 1 to 2 years of diagnosis. The majority of children also have normal neurodevelopmental outcomes, although some studies have reported impaired psychomotor development and behavioral disturbances if the child is not treated or if onset of the syndrome is less than 2 years of age. Those children with a prominent reflex component may have a more favorable neurodevelopmental outcome.

The medication of choice appears to be valproic acid (VPA) with 80% to 90% responding to VPA monotherapy, although high serum levels (greater than 100mg/dl) may be necessary. When VPA monotherapy does not provide complete control, adjunctive use of a benzodiazepine such as clonazepam or clobazam can be helpful.

### Dravet Syndrome

First described in 1978 by Charlotte Dravet, and termed severe myoclonic epilepsy of infancy (SMEI) but now more widely known as Dravet Syndrome, this occurs in normally developing children who experience prolonged febrile (longer than 20 minutes) or afebrile seizures, including hemiclonic seizures, during the first year of life. Afebrile, mixed seizures follow, and the emergence of myoclonic seizures is common but not necessary for the diagnosis. This syndrome is covered in more detail in Chapter 71.

### Myoclonic-Astatic Epilepsy of Doose (MAE)

These children present in early childhood with myoclonic seizures but with a prominent astatic component leading to falls. Although this syndrome does not always have a poor neurodevelopmental outcome, it remains an epileptic encephalopathy and if not appropriately treated can progress and lead to adverse neurodevelopmental sequelae or evolution into Lennox-Gastaut syndrome.

## ETIOLOGY

Genetic factors clearly play a role in the pathogenesis of MAE based on the high incidence of seizures (32%) in the siblings and parents in probands with the most common seizure type being absence. SLC2A1 mutations were found in 5%, suggesting genetic testing for GLUT-1 should be strongly considered.

## SEIZURE SEMIOLOGY

Onset of MAE is often between the ages of 2 and 6 years, and children are usually developmentally normal. There appears

to be a strong male predominance (70% to 90%). These children may begin experiencing unexplained “jerks” and “falls” occurring multiple times per day. These myoclonic seizures can occur in isolation but often are followed by a brief period of atonia, resulting in a dramatic fall in which the child appears to be propelled to the ground.

The atonic falls may be more subtle and the only manifestation of these may be a brief head nod or “head drop,” with or without a myoclonic jerk of the upper extremities. Absence seizures are quite common but often are accompanied by more prominent myoclonus of the proximal upper extremities.

## EEG

The interictal EEG findings are varied and can be normal. The most common findings are generalized 3 Hz spike-wave discharges as well as rhythmic 4 Hz to 7 Hz biparietal theta activity. Activation of generalized discharges during sleep is common, but generalized fast rhythms such as generalized periodic fast activity (GPFA) are uncommon. Focal EEG findings are uncommon and may suggest a less favorable prognosis.

## TREATMENT

The most commonly used and most effective antiseizure medicines have been valproate (VPA), lamotrigine, levetiracetam, topiramate, and benzodiazepines (clonazepam, clobazam, clorazepate). Felbamate is probably underutilized but can be effective against all seizure types. The combination of VPA with ethosuximide may be particularly effective especially if high doses of VPA are used.

The ketogenic diet has been shown to be as effective as other first-line agents in children with MAE and may be considered early in treatment.

## Outcome

Cognitive outcomes are highly variable and appear to be somewhat dependent on degree of seizure control, although even with fairly frequent seizures of multiple types there may still be spontaneous remission, usually after approximately 3 years (Oguni et al., 2002). The occurrence of tonic seizures may be a negative prognostic sign, although it remains unclear if these children may actually have an atypical form of Lennox-Gastaut syndrome rather than MAE.

## Juvenile Myoclonic Epilepsy (JME)

JME is a generalized epilepsy syndrome characterized by myoclonic seizures, generalized tonic-clonic seizures, and absence seizures. It is common, accounting for 26% of what had been previously considered the idiopathic generalized epilepsies and 10% of all epilepsies. The average age of onset is 15.1 years (7 to 28 years) with a slight female predominance.

**Seizure Semiology.** In the classic syndrome of JME, myoclonic seizures may precede the first generalized tonic-clonic (GTC) seizure by 6 to 12 months, although GTCs occur as the first seizure type in approximately one-third of patients. Photosensitivity is relatively common, occurring in approximately 30% of patients.

Myoclonic seizures often occur in the early morning hours shortly after awaking. Specific lifestyle features have been commonly associated with breakthrough seizures including sleep deprivation, stress, alcohol, and menses.

**EEG.** Patients with JME often have abnormal interictal EEGs with the most common finding being generalized 4 Hz to

6 Hz polyspike and wave (61%) or 3 Hz spike and wave discharges (14%). More prolonged (1 to 6 days; average 1 to 2 days) video EEG studies have shown EEG abnormalities of JME in 88% of patients. A photoparoxysmal response in treatment naïve patients is also common and has been seen in as many as 35% of patients.

**Treatment.** Valproate has long been considered the first-line agent with reports of up to 86% of patients becoming seizure free for 1 year. Valproate has also been shown to be particularly effective in those patients with photosensitivity. Women of childbearing potential must also consider the possible long-term cognitive effects on a fetus. Due to these concerns, many newer antiseizure drugs are also commonly used including lamotrigine, topiramate, zonisamide, and levetiracetam.

Benzodiazepines are widely accepted to have excellent antimyoclonic effects, but in JME only 43% of treated patients become free of GTCs. For this reason, benzodiazepines are not recommended as monotherapy but can be successful as add-on therapy when myoclonic seizures persist.

**Outcomes.** It has been widely accepted that JME was a life-long condition with a high rate of relapse if weaned off therapy; however, some recent long-term follow-up studies have shown conflicting results, and some patients with JME can successfully discontinue medications. The decision to discontinue medicine should be individualized with every patient, and a detailed discussion with specific attention to the frequency of life-style provoking factors is necessary for a safe and well-informed decision.

## Infantile Spasms

Infantile spasms is an age-dependent epilepsy syndrome that presents during infancy and is typically identified by clusters of spasms and an interictal EEG pattern known as hypsarrhythmia. Historically, West syndrome refers to the classic triad of spasms, hypsarrhythmia, and psychomotor arrest or regression. With a worldwide incidence of approximately 1 per 3000 live births, infantile spasms is the most prevalent epilepsy syndrome of infancy, and its emotional and financial costs to society are enormous.

Despite over 150 years of interest in this disorder, various aspects from terminology to treatment remain controversial, in large part because the pathogenesis is unknown.

## ELECTROCLINICAL FEATURES

Regardless of etiology, the syndrome manifests during a specific period of brain maturation, most often between 4 and 8 months of life and nearly always before 2 years (Riikonen, 1982).

## Spasms

The classic seizure type, referred to as an epileptic spasm, is characterized by symmetric, bilateral, brief contraction of the axial muscle groups. The electromyographic tracing during a spasm reveals an abrupt phasic contraction lasting less than 2 seconds, which may be followed by a less intense tonic contraction lasting from 2 to 10 seconds. Therefore this unique seizure type is longer than a myoclonic jerk and yet shorter than a tonic seizure.

Spasms typically occur in clusters, with a 5-second to 30-second interval between successive spells. The frequency of spasms may vary from only a few to several hundred per day. One common feature to note when taking a history is the common occurrence of spasms upon awakening and their rare occurrence during sleep.

Eye movements, consisting of deviation alone or followed by rhythmic nystagmoid movements, are also commonly seen during spasms. Changes in respiratory rhythm occur in the majority of patients, although alterations in heart rate are rare.

### Hypsarrhythmia and the Ictal EEG

The EEG hallmark of infantile spasms is hypsarrhythmia, a disorganized interictal pattern consisting of “random high voltage slow waves and spikes.” The spike discharges are usually multifocal, but when generalized, they are never rhythmically repetitive. A state-dependent EEG pattern, hypsarrhythmia is often present during wakefulness and quiet (non-REM) sleep and may be reduced or even absent during active (REM) sleep. Other EEG patterns including modified hypsarrhythmia or multifocal spikes can also be seen in children with infantile spasms.

Children with severe brain abnormalities such as tuberous sclerosis, Aicardi syndrome, and lissencephaly may not usually generate the typical hypsarrhythmic pattern. Asymmetric hypsarrhythmia may indicate the presence of a focal CNS lesion. Regardless of the specific pattern, however, any significant EEG background abnormality in a patient with clinical spasms may contribute to the epileptic encephalopathy, and all patterns should be viewed equally when considering approach to treatment.

The ictal EEG pattern varies, although typically shows a generalized, high-voltage, slow-wave transient followed by an abrupt voltage attenuation. Some children have focal seizures that are temporally related to clusters of spasms, a phenomenon that should raise suspicion for a structural brain abnormality and possibly a focal abnormality with EEG concordance.

### CLASSIFICATION

The classification of infantile spasms has been debated for years, though the International League Against Epilepsy (ILAE) Commission on Classification and Terminology published a revised recommendation for terminology and concepts related to infantile spasms and other seizure types (Berg et al., 2010). Spasms are neither generalized nor focal and remain a distinct seizure type.

The following etiologic classification has been recommended: (1) genetic, (2) structural/metabolic, or (3) unknown cause. As many epilepsies related to a structural brain malformation or inborn error of metabolism have an identifiable genetic cause this classification is presently under revision.

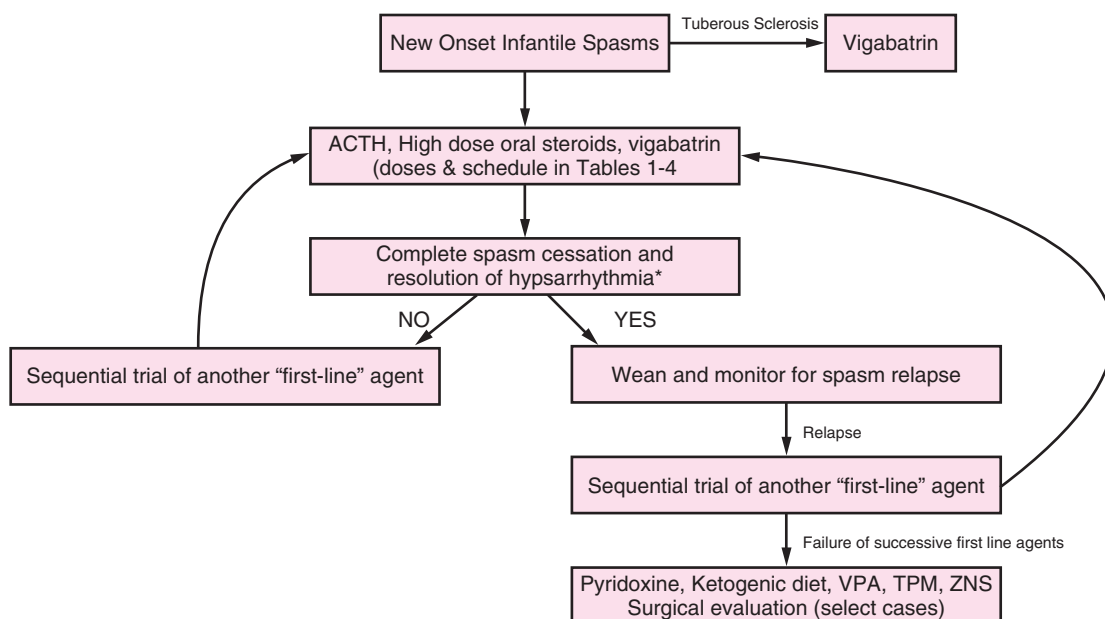

### ETIOLOGIC FACTORS

Gene mutations in key pathways of central nervous system development have expanded the genetic etiologies of infantile spasms. Examples include genes ARX, CKDL5, FOXP1, GRIN1, GRIN2A, MAGI2, MEF2C, SCL25A22, SPTAN1, and STXBP1 (Paciorkowski et al., 2011). Not every patient with these mutations will develop infantile spasms, but the phenotype is consistent enough to think of these as infantile spasm-associated genes with variable penetrance and expressivity. The early-onset epilepsies may be related to severity of mutation, though more data are needed to demonstrate if this is truly the case.

To evaluate the etiology and yield of investigations, 20 United States pediatric epilepsy centers prospectively enrolled all infants newly diagnosed with infantile spasms in a central database; 251 infants were enrolled. An underlying cause was identified in 64.4% of cases and included genetic causes in 14.4%. Genetic-structural causes were identified in 10%, including tuberous sclerosis, neurofibromatosis, and others. Congenital structural causes were identified in 10.8% and acquired structural causes in 22.4%. Metabolic causes were noted in 4.8% and infectious etiologies in 2.0%. Of note, among those with a defined etiology, the cause was evident on initial clinical assessment or MRI in 85.7%, whereas further genetic and metabolic studies were revealing in the other 14.3%.

### DIAGNOSTIC EVALUATION

An approach to the evaluation of infantile spasms is outlined in Figure 68-3. First, in a child with suspected infantile spasms, an EEG is needed to confirm the presence of hypsarrhythmia. Given the state-dependence of hypsarrhythmia, an extended EEG recording that captures at least one full sleep-wake cycle

\*In cases where clinical spasms have stopped but hypsarrhythmia continues, consider continuing therapy for 1-2 more weeks and then repeat EEG

Figure 68-3. Suggested treatment pathway for new onset IS.

**TABLE 68-3** Treatment With Intramuscular (IM) ACTH

Days	Dose—ACTH
1–14	75 U/m <sup>2</sup> twice daily <sup>#</sup>
15–17	30 U/m <sup>2</sup> in the morning
18–20	15 U/m <sup>2</sup> in the morning
21–23	10 U/m <sup>2</sup> in the morning
24–29	10 U/m <sup>2</sup> every other morning (3 total doses)
<sup>#</sup> If there is no clinical response by day 14, consider alternative treatment.	

should be performed in all cases. If the EEG remains normal with no features of hypsarrhythmia or its variants, the EEG should be repeated in 1 to 2 weeks, again capturing at least one full sleep-wake cycle.

## COURSE AND PROGNOSIS

Regardless of treatment, however, it appears that clinical spasms and hypsarrhythmia disappear in one-half of children by 2 years of age and in nearly all children by 5 years of age. Approximately 50% of children will develop other seizure types. In many patients who exhibit diffuse or multifocal cerebral dysfunction, the disorder evolves into Lennox-Gastaut syndrome.

Overall, the developmental outcome in infantile spasms is poor (Riikonen, 2010). Children with severe brain malformations tend to have worse prognoses. Early and complete control of spasms has been associated with improved neurodevelopmental outcome even when only evaluating infantile spasms of unknown etiology without confounding underlying diagnoses (O'Callaghan et al., 2011).

Children with infantile spasms due to Down syndrome, neurofibromatosis, and periventricular leukomalacia may have a more benign prognosis. Apart from etiology, the other factors that may translate into better long-term outcome include shorter lag time to treatment and use of hormonal therapy for spasms of unknown cause (Go et al., 2012). Regarding the type of treatment for spasms, developmental outcome, tested at 14 months and 4 years after spasms onset, was better after initial control of IS with hormonal therapy in those without an identified underlying etiology.

It is important to recognize that not all spasms of unknown cause will have a good outcome. In a retrospective series looking at long-term outcome of West syndrome, 50% of the group with no known cause had clear developmental impairment, despite early control of spasms. These adverse outcomes have not changed in several decades

## TREATMENT

The goal of treatment is to prevent or ameliorate the encephalopathy by stopping the spasms and improving the EEG background, yet the optimal treatment of infantile spasms has not been clearly defined. The Infantile Spasms Working Group has published a United States consensus report. This group supported ACTH or vigabatrin as the first-line treatments with proven efficacy (Pellock et al., 2010). It did endorse the use of high-dose corticosteroid in the treatment of spasms, but raised concern in that the combination of cessation of spasms as well as resolution of hypsarrhythmia on EEG has not been reported in studies on its use.

A treatment algorithm for infantile spasms based on available evidence of what are considered first line agents is shown in Figure 68-3. Although there remain no comparative effectiveness trials for these agents, sequential use is recommended. (Tables 68-3, 68-5 and 68-6)

**TABLE 68-5** Treatment With Oral Prednisolone UKISS Protocol

Days	Dose—prednisolone
1–14	10 mg oral 4 times daily <sup>#</sup>
15–19	10 mg oral 3 times daily <sup>*</sup>
20–24	10 mg oral 2 times daily
25–29	10 mg oral daily
<sup>*</sup> If there is no clinical response after day 7 (i.e., no 24-hour period free of infantile spasms), the dose can be increased to 20 mg three times daily. If done, the taper schedule from day 15 to 19 would be 10 mg 4 times daily and then proceed as in the table beginning on day 20.	
<sup>#</sup> If no clinical response by day 14, consider alternative treatment.	

**TABLE 68-6** Treatment With Oral Vigabatrin

Days <sup>#</sup>	Dose—Vigabatrin
1–3	50 mg/kg/day divided 2 times daily
4–6	100 mg/kg/day divided 2 times daily
>7	150 mg/kg/day divided 2 times daily
<sup>*</sup> Side effects (e.g., sedation, hypotonia) may necessitate slower titration.	
<sup>#</sup> If no clinical response by day 14, consider alternative treatment.	

Second-line treatments including conventional antiseizure medicines, as well as the ketogenic diet, have been used with variable success when first-line agents fail. Finally, fueled by advances in neuroimaging, surgical resection of focal lesions has emerged as a promising option for patients with medically intractable infantile spasms.

## Hormonal Therapy

In 2004, a practice parameter by the AAN and Child Neurology Society deemed ACTH “probably effective,” reaffirming the prevailing consensus that ACTH was the gold standard and in 2012, an update to the 2004 practice parameter produced by the American Academy of Neurology and the Child Neurology Society recommended low-dose ACTH, preferred over vigabatrin, particularly in cases in which the underlying cause is not known.

## ACTH

Several prospective, randomized trials of ACTH or cosyntropin of varying doses have shown 42% to 87% of patients experiencing cessation of spasms within 2 weeks of initiating therapy. Hypsarrhythmia resolved in 20% to 90% of patients, and relapse rates were 15% to 33%. Although there is no agreement about dose or duration of treatment, two randomized controlled trials comparing high-dose ACTH with low-dose ACTH did not show a significant difference in terms of spasm cessation. In a long-term follow-up study, there was no clear benefit of 150 IU/day compared with 40 IU/day. Given no clear consensus on the optimal treatment for infantile spasms and varying doses, the National Infantile Spasms Consortium (NISC), a United States multicenter initiative to improve outcomes through prospective data collection, was started. From 2012 to 2014, 238 infants were enrolled. Initial treatment, including ACTH, oral corticosteroids, vigabatrin, topiramate, levetiracetam, zonisamide, oxcarbazepine, clobazam, phenobarbital, and the ketogenic diet, was documented in 230 cases. Three-month outcome data was available for 205

children. ACTH led to remission in 48%, corticosteroids led to remission in 27%, and vigabatrin led to remission in 38%. Of the other treatments, only 5% achieved remission. This initial study has again motivated the need for a randomized clinical trial to identify best treatment practices.

## CORTICOSTEROIDS

The UKISS trial subanalysis showed that oral prednisolone was equivalent to synthetic ACTH (70% versus 76% spasm-free after 14 days, respectively). Although this study was not powered to determine a significant difference between the two groups, it had more subjects than prior studies and represents the only randomized controlled trial evaluating the effectiveness of high-dose oral corticosteroid. Incorporating UKISS results, a 2008 Cochrane review concluded that should oral prednisolone be used, “high dose” is recommended (Hancock et al., 2008).

## Vigabatrin

In patients with tuberous sclerosis, vigabatrin has been shown to be particularly effective in the short-term treatment of infantile spasms with more than 90% achieving complete spasm control. In contrast, short-term efficacy rates for all or non-TS infantile spasms range from 35% to 54%. Vigabatrin may be recommended as first-line therapy for patients with infantile spasms due to tuberous sclerosis. In a long-term follow-up study of 180 patients, vigabatrin terminated spasms in 56.9% of patients and did so within 3 to 7 days (mean 5.3 days), again suggesting that if a child does not respond to initial therapy, then rapid sequential therapy is indicated (Djuric et al., 2014).

## Surgical Therapy

Facilitated by advances in structural and functional neuroimaging techniques, surgical resection of focal or unilateral CNS lesions has emerged as an effective epilepsy treatment option in select patients with intractable infantile spasms. Epilepsy surgery for infantile spasms was fueled by the observation that positron emission tomography (PET) of glucose metabolism could identify focal cortical lesions localized to epileptogenic regions in infants with infantile spasms of unknown cause whose structural imaging was unrevealing, and that surgical resection was associated with a favorable outcome.

## Other Treatments

There are no randomized controlled trials of other antiseizure medications or alternative therapies for the treatment of infantile spasms, although limited evidence suggests that the ketogenic diet, valproate, topiramate, zonisamide, and pyridoxine may provide additional benefit in decreasing spasms and therefore are often used after hormonal therapy and vigabatrin.

The effect of these therapies on neurodevelopmental outcome is unknown. Without strong evidence to support a particular agent, the potential risks of each therapy should influence individual treatment decisions.

## LATE ONSET EPILEPTIC SPASMS

Although the focus of most of this chapter has been on infantile spasms that by definition occur during infancy, epileptic spasms can occur in older children though less is known about this clinical presentation. A few studies have described various

cohorts from 19 to 54 patients, and there are several features that distinguish late onset spasms from the classical infantile spasms. First, the interictal EEG does not show classical hypsarrhythmia. EEG backgrounds are still very abnormal, often showing both generalized and multifocal spikes with an anterior predominance in the temporal or temporofrontal regions. These cohorts also report a high incidence of asymmetric spasms. Underlying etiologies included tuberous sclerosis, diffuse cortical dysplasia, temporomesial hypoplasia, callosal agenesis, leukoencephalopathy, and hypoxic-ischemic encephalopathy. Response to treatment in these various studies has been variable. The agents that appear to be effective are similar to those used in infantile spasms including ACTH, hydrocortisone, and vigabatrin. In the studies that evaluated developmental outcomes, it is clear that late onset epileptic spasms is still an epileptic encephalopathy with only rare children having normal developmental outcomes.

Status epilepticus (SE) is one of the most common neurologic emergencies in the pediatric population (Chin, et al., 2006) and is associated with mortality, neurodevelopmental sequelae (DeLorenzo, et al., 1996), and subsequent reductions in quality of life. In this chapter, we will review the epidemiology, clinical presentation, treatment, and outcome of SE. Unless stated otherwise, we will refer to convulsive SE and will only briefly describe nonconvulsive SE.

## EPIDEMIOLOGY

Approximately 17 to 23 of 100,000 children experience SE every year with the highest incidence in children less than 1 year of age. In a large series in the UK, the overall incidence was 14.5 of 100,000 (95% CI: 11.5 to 17.6). The incidence was highest in children younger than 1 year (51 of 100,000; 95% CI: 35 to 66), and progressively decreased with increasing age: in children aged 1 to 4 years the incidence was 29 of 100,000 (95% CI: 19 to 35), in children aged 5 to 9 years it was 9 of 100,000 (95% CI: 5 to 11), and in children aged 10 to 15 years the incidence was 2 of 100,000 (95% CI: 0.75 to 3.5). If febrile SE is excluded, the incidence decreases by 25% to 40%. Children with SE have an overall mortality of approximately 0% to 3%. Additionally, a high proportion of children with SE develop subsequent epilepsy and severe cognitive deficits (Raspall-Chaure, et al., 2006).

## DEFINITIONS

The essential feature that differentiates SE from other seizures is duration. SE presents as a seizure that lasts longer than expected. The International League Against Epilepsy (ILAE) defines SE as “a seizure that shows no clinical signs of arresting after a duration encompassing the great majority of seizures of that type in most patients or recurrent seizures without interictal resumption of baseline central nervous system function.” The ILAE Task Force on Classification of SE proposed the following definition: “SE is a condition resulting either from the failure of the mechanisms responsible for seizure termination or from the initiation of mechanisms which lead to abnormally prolonged seizures (after time point t1). It is a condition that can have long-term consequences (after time point t2), including neuronal death, neuronal injury, and alteration of neuronal networks, depending on the type and duration of seizures.” This definition emphasizes the importance of time by defining two time points: t1—the time beyond which the seizure should be considered as “continuous seizure activity”; and t2—the time beyond which there is a risk of long-term consequences. How long a seizure or a cluster of seizures must last to be considered SE is a matter of discussion. The classical definition of established SE requires that seizures (continuous or intermittent without return to baseline mental status) last for a minimum of 30 minutes. However, seizures which last longer than 5 minutes are unlikely to stop spontaneously and may be referred to as

impending SE. Management at that time may be indicated to prevent the seizure from lasting 30 minutes at which time it may be producing secondary brain injury.

The classical 30-minute cut-off is based on the fact that approximately after 30 minutes of generalized seizures, the compensatory mechanisms fail against acidosis, hyperthermia, hyperkalemia, and cardiocirculatory collapse. Thus SE-induced irreversible neuronal damage occurs, and seizures become self-sustained and refractory to treatment. The 30-minute cut-off is consistent with epidemiologic studies such as the Richmond SE study, in which mortality for seizures lasting 10 to 29 minutes was 2.6% whereas mortality for seizures lasting longer than 29 minutes was 19%. However, the 30-minute cut-off may miss a window for optimal treatment effectiveness. Treatment in SE should not be delayed until patients reach the established SE stage when neuronal injury and pharmacoresistance have already occurred. The 5-minute cut-off emphasizes this window of opportunity for treatment by identifying seizures with a high risk of progressing to cause neuronal damage and becoming pharmacoresistant at a stage when treatment still can prevent these outcomes.

The 5-minute cut-off for SE is most frequently used in clinical practice as treatment should be initiated after 5 minutes of seizure duration. The 30-minute cut-off is more commonly used in retrospective investigations to study a relatively homogeneous group of patients in whom some degree of neuronal damage and in whom pharmacoresistance has already developed. There are limited studies comparing the clinical characteristics of impending and established SE. A series of 226 patients (135 adults and 91 children) compared seizures lasting 10 to 29 minutes with seizures lasting more than 29 minutes. Demographic characteristics such as gender, race, age, and etiology were similar between the two groups. In the 10- to 29-minute group, seizures stopped spontaneously in 43% of patients whereas in 57% did not. In a series of 445 children aged 1 month to 21 years with seizures lasting more than 5 minutes, a comparison was made between the 296 patients with seizures of 5 to 29 minutes duration and the 149 patients with seizures of 30 or more minutes duration. Patients with seizures of more than 29 minutes duration were younger at the time of seizure onset and were more likely to present with SE. However, there were no differences in seizure frequency, seizure types, presence of developmental delay, and electroencephalographic (EEG) abnormalities at baseline. In a population of 1062 children aged 1 month to 21 years of age with seizures, two different thresholds for SE were used: 5 minutes and 30 minutes. The risk factors for SE were similar when considering the 5-minute or the 30-minute thresholds. In summary, impending and established SE are probably a continuum and the different thresholds are arbitrary cut-offs. What is more, the 5-minute and 30-minute thresholds are essentially derived from studies on generalized seizures. The conceptualization as t1 and t2 emphasizes the need to estimate these times for different seizure types.

**TABLE 69-1** Frequency of the Most Common Etiologies of Pediatric Status Epilepticus

	Febrile Seizures	Acute Metabolic Derangement or Central Nervous System Infection	Remote Symptomatic	Acute Symptomatic on Remote Symptomatic	Low Antiepileptic Drug Levels
Chin, et al., 2006 (N = 226)	33%	17%	16%	16%	
De Lorenzo, et al., 1996 (N = 166)	52%*		39%		21%
Singh, et al., 2010 (N = 144)	32%	9%	18%		

\*Infections with fever

## ETIOLOGY

Most episodes of SE begin in previously healthy children in the out-of-hospital setting. In a large prospective study of 226 children with SE in the United Kingdom, 78% of cases were first-ever episodes of SE. Of those, 56% of patients had normal neurodevelopment at baseline, no history of epilepsy, and no neurologic deficits before the SE episode. The most common etiology of pediatric SE is febrile/infectious followed by other acute symptomatic causes (Table 69-1). Acute symptomatic etiologies are more frequent in younger patients, especially in patients younger than 1 year of age.

A variety of still unknown genetic factors might promote or protect patients from developing prolonged seizures. A study on 8681 twin pairs found a much higher rate of SE concordance in monozygotic than in dizygotic twins (0.38 versus 0). The genetic predisposition to prolonged seizures and SE is probably complex and multifactorial and susceptibility genes are still to be discovered in humans.

## CLINICAL PRESENTATION AND INITIAL MANAGEMENT

Any type of seizure may become prolonged and thus evolve into SE. Generalized tonic-clonic SE is the clinically apparent and life-threatening form of SE. Other forms include myoclonic, clonic, tonic, or absence SE. Seizures can be focal or more generalized. Some generalized seizures have a generalized onset whereas others secondarily generalize from initially focal seizures.

Regardless of the etiology and type, SE represents a life-threatening emergency that should be managed rapidly. Generalized tonic-clonic SE is associated with intense muscle activity with the consequent metabolic and cardiovascular demands as well as the risk of multiorgan failure if the needs to sustain intense muscle activity exceed the patient's reserve and if they are sufficiently prolonged. Focal seizures are associated with less metabolic demands but are equally harmful to the brain if sustained in time.

The initial therapy for SE includes maintenance of adequate brain oxygenation and cardiorespiratory function, identification and correction of seizure triggers such as hypoglycemia, electrolyte imbalance, lowered drug levels, infection, and fever, and prevention of systemic complications. In addition to the general management of any pediatric emergency, a main goal of SE treatment is to terminate clinical and electrical seizure as quickly as possible.

## TIME TO TREATMENT

### Rationale Behind the Need for Rapid Treatment

There are three major determinants of prognosis in SE: age, etiology, and SE duration (Raspall-Chaure, et al., 2006). Age

is a nonmodifiable factor. Etiology is usually not modifiable at least in the short term. In contrast, SE duration might be modified with appropriate and timely treatment management.

The current guidelines and protocols for the treatment of SE recommend rapid administration of antiseizure drugs. These recommendations are based on results from basic and clinical research. Animal models of SE have demonstrated that prolonged seizures cause brain damage independently from the underlying etiology. In addition, several clinical studies have demonstrated that prolonged seizures are associated with worse outcomes. In a study of 182 children with SE, for each minute delay from seizure onset to arrival at the emergency department, there was a 5% cumulative increase in the risk of SE lasting more than 60 minutes. A series of 45 episodes of pediatric SE compared 19 episodes treated with prehospital diazepam with 26 episodes not treated before hospital arrival; the duration of SE was shorter (32 versus 60 minutes) and the risk of recurrent seizures was lower (58% versus 85%) in the 19 episodes treated before hospital arrival. In a series of 157 children with SE, a delay of more than 30 minutes in administering the first antiseizure drug was associated with worse response to treatment (measured as time from the initiation of the treatment to the end of the clinical seizure activity). Another study reported 27 children in whom first line (benzodiazepine) and second-line (phenytoin or phenobarbital) medications were effective in terminating SE in 86% when seizure duration was less than 20 minutes at presentation and only in 15% when seizure duration exceeded 30 minutes. Studies in adults also suggest that a longer duration of SE is associated with a worse prognosis in terms of seizure duration, morbidity, and mortality. These results suggest that an early and appropriate treatment may markedly reduce the duration and improve patient outcomes.

## Changes in Neurotransmitter Receptors in the Seizing Brain

As seizures last longer, they become self-sustained and progressively more treatment resistant. The physiologic basis for these processes is only partially understood. In a series of surgical brain samples from three patients with refractory convulsive SE, three patients with electrical status epilepticus in sleep (ESES), and six patients with refractory epilepsy compared with brain samples from four autopsy controls who died without neurologic disorders, subunit composition of neurotransmitter receptors demonstrated the following patterns: elevated GluA1/GluA2 in the alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, increased GluN2B/GluN2A ratio in the N-methyl-D-aspartate (NMDA) receptors, and elevated  $\alpha 2/\alpha 1$  in the GABA receptors. These results are concordant with similar results from animal models and other human studies and the elevated ratios are known to promote excitation over inhibition. Further, when the brain is exposed to prolonged seizures, there is a rapid decrease in

the number of postsynaptic GABA<sub>A</sub> receptors and an increase in the number of functional postsynaptic NMDA receptors. This loss of inhibition and increase in excitation in the brain synapses promote self-sustaining of prolonged seizures and may explain the loss of efficacy of benzodiazepines over time in animal models of SE and the progressive pharmacoresistance to benzodiazepines with prolonged SE.

### Time Elapsed From Seizure Onset to Treatment Administration in SE

Whereas these data suggest the importance of rapid antiseizure drug administration in SE, a limited number of studies have evaluated the time elapsed from seizure onset to treatment initiation in SE. Paucity of data can be partially attributed to the fact that most seizures stop after a first medication is administered in the field or are managed in non-referral hospitals. Even in prolonged seizures it is difficult to measure the time elapsed from seizure onset to administration of antiseizure drug.

The few available studies on this topic suggest there are often important delays in treatment administration. In a series of 199 children with febrile SE the median time from seizure onset to administration of the first antiseizure drug was 30 minutes. In a retrospective study of 889 patients (625 adults and 264 children) with SE, approximately 60% of the patients received their first dose after 30 minutes and approximately 25% after 60 minutes. In a retrospective multicenter study of 542 episodes of convulsive seizures of 10 or more minutes duration in children, the median ( $p_{25}$  to  $p_{75}$ ) time from hospital arrival until administration of a nonbenzodiazepine was 24 (15 to 36) minutes. Among 82 adults with SE the time elapsed from seizure onset to administration of nonbenzodiazepine was 180 minutes. The primary outcome in a recent series of 81 children with refractory convulsive SE was the time elapsed from seizure onset to administration of medications. The median ( $p_{25}$  to  $p_{75}$ ) time elapsed from seizure onset to the administration of the first drug was 28 (6 to 67) minutes, to the second was 40 (20 to 85) minutes, and to the third was 59 (30 to 120) minutes. Further, the median ( $p_{25}$  to  $p_{75}$ ) time to administration of the first nonbenzodiazepine was 69 (40 to 120) minutes, and in the 64 patients with out-of-hospital SE onset, 40 (63%) did not receive any antiseizure medicine before hospital arrival.

These data suggest several areas for improvement in the time to treatment of SE including earlier detection and treatment of seizures, more widespread use of home and emergency medical system use of benzodiazepines, and rapid escalation in the administration of medications if seizures persist.

## TREATMENT OPTIONS

### Treatment Guidelines for SE

Most guidelines and protocols for the treatment of SE recommend a stepwise approach. The first step in the treatment of a seizure, as in any other emergency situation, is to secure the airway, ensure adequate breathing and circulation. Importantly, most seizures resolve spontaneously in less than 5 minutes and will not require rescue medication. However, when seizures last more than 5 minutes, they should be considered as impending SE, and treatment should be initiated immediately. Benzodiazepines are the first-line treatment and, among them, intravenous lorazepam is frequently the preferred option. When intravenous access is not available, intramuscular, rectal, intranasal, or buccal medication applications are potential alternatives. The first dose of benzodiazepines can be repeated if seizures persist. As seizures persist, however, they become progressively more refractory to benzodiazepines. Thus after 10 minutes, rather than administering subsequent doses of benzodiazepines, it may be useful to switch to a nonbenzodiazepine. Among those, the most commonly used antiseizure medication is intravenous fosphenytoin (or phenytoin). If seizures continue, then another nonbenzodiazepine is recommended with phenobarbital as the preferred option. Other nonbenzodiazepine medications that can also be administered intravenously are valproate and levetiracetam. However, once two appropriate doses of nonbenzodiazepine antiseizure drugs have been administered and/or seizure duration is longer than 30 to 60 minutes, initiation of continuous infusions with anesthetic therapy is recommended (Fig. 69-3) (Table 69-2). During this progression, it is important to consider and prepare for the next steps if seizures persist. This will ensure subsequent medications are available at bedside when needed.

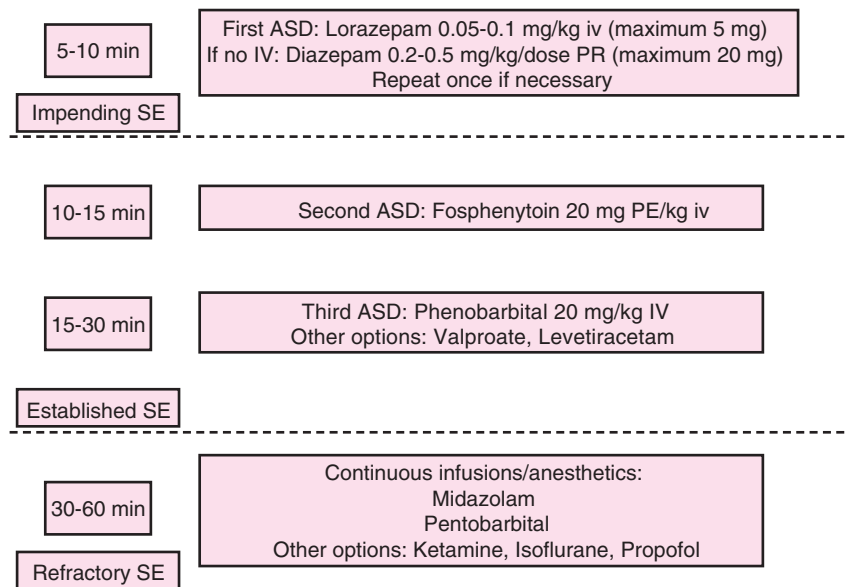

### Benzodiazepines as First-Line Treatment

Benzodiazepines are typically used as initial treatment for SE because of their wide availability, initial efficacy, and multiple routes of administration. In a double-blind trial, 205 adults with out-of-hospital seizures of at least 5 minutes duration were randomized to receive either intravenous lorazepam, intravenous diazepam, or a placebo. Seizures had been terminated on arrival at the emergency department in more patients treated with lorazepam (59%) or diazepam (43%) (no statistically significant differences in efficacy between lorazepam and diazepam) than in patients treated with placebo (21%). The rates of respiratory or circulatory complications were 11% for lorazepam, 10% for diazepam, and 23% for placebo. This landmark study established that treatment with

**TABLE 69-2** Recommended Initial Doses for SE

Drug	Dose	Maximum Dose	Route and Rate
Lorazepam iv	0.1 mg/kg	4 mg	iv push
Diazepam iv	0.3 mg/kg	10 mg	iv push
Diazepam rectally	0.2–0.5 mg/kg	20 mg	Rectal, bolus
Midazolam nasally	0.2–0.3 mg/kg	10 mg	Nasal, bolus
Phenobarbital iv	20 mg/kg	40 mg/kg or 1000 mg	2 mg/kg/min
Fosphenytoin iv	20 mg phenytoin equivalents/kg	300 mg phenytoin equivalents	3 mg phenytoin equivalents/kg/min
Valproate iv	20–40 mg/kg	40 mg/kg	3–6 mg/Kg/min
Levetiracetam iv	30–60 mg/kg	2500 mg	Over 5 min

**Legend:** iv: intravenous.

**Figure 69-3. Treatment algorithm for status epilepticus.** The first-line drug is usually a benzodiazepine (most frequently lorazepam). Sometimes it might be useful to try a second dose of benzodiazepines. However, when seizures last 10 minutes or longer the recommended treatment is fosphenytoin and for seizures of more than 15 to 30 minutes duration a second nonbenzodiazepine antiepileptic drug should be administered. The most commonly used is phenobarbital although other options include valproate or levetiracetam. When seizures last more than 30 to 60 minutes and the patient has not responded to prior medications SE can be considered refractory and switch to continuous infusions of antiepileptic drugs or anesthetic therapies is advised. Legend: ASD—antiseizure drug; iv—intravenous; kg—kilograms; mg—milligrams; min—minutes; PE—fosphenytoin equivalents; PR—per rectum; SE—status epilepticus. (Reproduced with permission from: Sánchez Fernández I, Loddenkemper T. Therapeutic choices in convulsive status epilepticus. *Expert Opin Pharmacother* 2015;16:487–500.)

benzodiazepines was more effective and even safer than not treating impending SE in the out-of-hospital setting. The Veterans Affairs Cooperative Trial—another large double-blind study—randomized 384 adults to receive one of four initial treatments for SE: lorazepam, phenobarbital, phenytoin, and diazepam followed by phenytoin. In this study lorazepam was superior to phenytoin, but in an intention-to-treat analysis, there were no differences among the four treatment groups.

### Lorazepam as the Preferred First-Line Drug for SE

Intravenous lorazepam has become widely regarded as the optimal first-line medication for SE. The results of the two previously mentioned studies conducted in adults are frequently extrapolated to children, although neither included children. In pediatrics, the preference of lorazepam as first-line therapy is largely based on the large North London series of 182 children with SE, in which treatment with intravenous lorazepam was associated with a 3.7 (95% CI: 1.7 to 7.9) times greater likelihood of seizure cessation than was treatment with rectal diazepam. However, it is important to note that this study was not only comparing medications (lorazepam versus diazepam) but also routes of administration (intravenous versus rectal) which may have different timeframes in terms of medication administration and absorption.

Multiple studies show the efficacy of benzodiazepines as first-line treatment for SE, but it is not clear if one benzodiazepine or route of administration is superior to the others. In a series of 48 children with prolonged seizures treated in the emergency department, there were no differences in the rate of seizure control between patients treated with intravenous diazepam (65%) and intravenous lorazepam (65%). In a double-blind study, 273 children with SE were randomized to receive intravenous diazepam (N = 140) or intravenous

lorazepam (N = 133). The primary efficacy outcome was cessation of SE by 10 minutes without recurrence within 30 minutes, and the primary safety outcome was the need for assisted ventilation. The rate of SE cessation (72% on diazepam and 73% on lorazepam) and the rate of requiring assisted ventilation (16% on diazepam, 18% on lorazepam) were similar for both medications. In a series of 76 episodes of pediatric seizures of at least 5 minutes duration treated with intravenous midazolam bolus doses of 0.1 to 0.2 mg/kg, seizure control was achieved with the first bolus in 40 of 76 (53%) patients, with a second bolus in 20 of 36 (55%), and with a third bolus in 8 of 16 (50%). The Rapid Anticonvulsant Medication Prior to Arrival Trial (RAMPART) randomized 893 patients (both children and adults) to receive intramuscular midazolam or intravenous lorazepam as a first-line, out-of-hospital treatment (Silbergleit, et al., 2012). Seizure resolution at the time of arrival in the emergency department was 73% in the intramuscular midazolam group, and in 63% in the intravenous lorazepam group (Silbergleit, et al., 2012). In a Cochrane review of three studies that included 264 patients, intravenous lorazepam was slightly superior to intravenous diazepam on cessation of seizures and not different in terms of requirement for ventilator support or other adverse effects. A less frequently considered option is intravenous clonazepam, which controlled SE in 16 of 24 patients in one study and 17 of 17 patients in a second study. In summary, intravenous lorazepam, intravenous midazolam, intravenous diazepam, and intramuscular midazolam have demonstrated similar efficacy and safety (Brophy, et al., 2012).

### Alternatives to the Intravenous Route of Administration

Intravenous lorazepam is the current first-line treatment for SE, but requiring intravenous access is a major disadvantage.

Most episodes of SE start in an out-of-hospital setting and, even when medical help is available, obtaining intravenous access in an actively convulsing patient can be challenging. Therefore other nonintravenous first-line treatments are being increasingly considered. A meta-analysis concluded that nonintravenous midazolam was at least as safe and effective as intravenous or nonintravenous diazepam in children and young adults. In a prospective study, 24 children with motor seizures of at least 10 minutes duration were randomized to receive intramuscular midazolam or intravenous diazepam. Patients in the midazolam group received medications sooner (mean: 3.3 versus 7.8 minutes) and had more rapid cessation of their seizures (mean: 7.8 versus 11.2 minutes) than patients randomized to diazepam. A series of 28 children with severe epilepsy at a residential school who presented with seizures of at least 5 minutes duration were randomized to receive buccal midazolam or rectal diazepam. In this series, buccal midazolam was shown to be at least as effective (75% of seizure control) as rectal diazepam (59% of seizure control) with no clinically important adverse events in any of the groups. A prospective randomized study of 92 children compared intranasal midazolam (0.2 mg/kg with a maximum of 10 mg) with rectal diazepam (0.3 to 0.5 mg/kg with a maximum of 20 mg) as home treatment of acute seizures. The median time from medication administration to seizure cessation was 3 minutes in the intranasal midazolam group and 4.3 minutes in the rectal diazepam group. There were no differences in the rate of complications between the two groups. A landmark double-blind noninferiority trial randomized 893 patients (both children and adults) to receive intramuscular midazolam or intravenous lorazepam as a first-line, out-of-hospital treatment (Silbergleit, et al., 2012). The primary outcome was absence of seizures at the time of arrival in the emergency department without the need for rescue therapy. As discussed previously, seizure resolution at the time of arrival in the emergency department was similar in the intramuscular midazolam group and in the intravenous lorazepam group (Silbergleit, et al., 2012). There were no significant differences in the need for endotracheal intubation (14% in both groups) or the proportion of seizure recurrence—11% in both groups. In this study, the time saved using the intramuscular route—1.2 minutes in the intramuscular midazolam group and 4.8 minutes in the intravenous lorazepam group—appears to at least offset the delay in the drug onset of action (3.3 minutes in the intramuscular midazolam group and 1.6 minutes in the intravenous lorazepam group). In summary, there are nonintravenous alternatives to lorazepam which have similar efficacy and are easier and faster to administer. Overall, the exact medication choice may be less important than administering whichever benzodiazepine is available by whatever route can be accessed most quickly.

## Nonbenzodiazepine Antiseizure Drugs

If benzodiazepines fail to control SE or SE has lasted for at least 10 minutes—at which point benzodiazepines may be less mechanistically likely to terminate seizures—a switch to nonbenzodiazepines is recommended. Although there are several nonbenzodiazepines available, evidence supporting one versus others is weak. Only a few studies have specifically addressed the efficacy of second-line medicines in SE. Their methodology and endpoints vary widely and most of the evidence on preferred nonbenzodiazepines comes from observational and retrospective studies.

At present, phenytoin (or fosphenytoin) is the recommended first option as a nonbenzodiazepine. The most common second option when phenytoin (or fosphenytoin) fails to control SE is phenobarbital. These choices are strongly

influenced by tradition as these drugs have been available for much longer than any of the newer antiseizure medicines. Therefore they are time-tested, and there is abundant literature on their efficacy and expected side effects. In the North London series of 182 pediatric patients with SE, treatment with intravenous phenytoin as a second-line therapy was associated with a nine times greater likelihood of seizure cessation compared with treatment with rectal paraldehyde. However, when phenytoin is compared with newer drugs, its position as first-line nonbenzodiazepine is unclear. A retrospective series of 167 adults with SE compared phenytoin, valproate, and levetiracetam as second-line agents (after failure of benzodiazepines as first-line drugs). Valproate failed to control SE in 25% of patients in whom it was prescribed, phenytoin in 41%, and levetiracetam in 48%. After adjustment for SE severity, this study showed that valproate was more effective than levetiracetam (or comparing levetiracetam failure with valproate failure: 2.69, 95% CI: 1.19 to 6.08) whereas there was no difference in the efficacy of phenytoin compared with valproate or phenytoin compared with levetiracetam. In a study of generalized convulsive seizures lasting more than 5 minutes which did not respond to a bolus of intravenous diazepam, patients were randomly assigned to either phenobarbital or valproate. Although differences in this study were not statistically significant, there was a tendency toward a higher rate of seizure cessation with valproate than with phenobarbital (90% versus 77%) with fewer associated clinically significant adverse effects (24% versus 74%). A series on SE randomly assigned 68 patients (including both children and adults) to valproate or phenytoin treatment as initial therapy. Seizures terminated in 66% of the cases in the valproate group and in 42% of the cases in the phenytoin group. As a second choice in refractory patients, valproate was effective in 79% and phenytoin was effective in 25% of the cases. There were no marked differences in adverse effects between the two groups. Considering the previously mentioned studies, newer antiseizure medicines such as valproate or levetiracetam deserve consideration as potential first-line nonbenzodiazepines for SE.

A meta-analysis compared the efficacy of phenytoin, phenobarbital, valproate, levetiracetam, and lacosamide to terminate SE persisting after administration of benzodiazepines. Considering phenytoin, there were eight studies reporting 294 episodes of SE in which phenytoin had a mean efficacy of 50% (95% CI: 43 to 66%). For phenobarbital, there were two studies reporting 42 episodes of SE in which phenobarbital had a mean efficacy of 74% (95% CI: 58 to 85%). For valproate, there were eight studies reporting 250 episodes of SE in which valproate had a mean efficacy of 76% (95% CI: 64 to 85%). For levetiracetam, there were eight studies reporting 204 episodes of SE in which levetiracetam had a mean efficacy of 69% (95% CI: 56 to 79%). There was insufficient detail regarding lacosamide to perform a meta-analysis, although lacosamide shows promising results controlling SE in approximately 45% to 68% of cases in some series.

In summary, multiple studies indicate that new drugs such as valproate and levetiracetam have similar, if not superior, efficacy than phenytoin (or fosphenytoin) and phenobarbital. Additionally, valproate and levetiracetam have potential practical advantages: in general, they can be administered faster than phenytoin (or fosphenytoin), have a better pharmacokinetic profile, and have a lower risk of hypotension and respiratory depression. Importantly, valproate is a generally safe drug in adults and children, but it can lead to serious toxicity in children with underlying metabolic disorders—often still undiagnosed when treatment decisions have to be made—or children under 2 years of age. The Established Status Epilepticus Treatment Trial (ESETT) is a large international randomized trial which aims to determine whether valproate and/or

levetiracetam are superior to phenytoin as nonbenzodiazepines for treatment of SE in children and adults. The Pediatric Status Epilepticus Research Group (pSERG) is developing a comparative effectiveness trial of the most efficacious second-line treatments for SE.

## Refractory SE

SE is considered refractory when it has not been controlled with appropriate doses of benzodiazepines and 1 or 2 doses of nonbenzodiazepine antiseizure drugs. Once SE is refractory, continuous infusions of antiseizure drugs or anesthetic therapies are often recommended. Initiation of treatment with anesthetic medications such as midazolam or pentobarbital may lead to respiratory depression and hypotension, so close cardiopulmonary monitoring is required and the patient should be in an environment in which intubation, mechanical ventilation, and blood pressure management can be performed if required. The most commonly used continuous infusions are midazolam, pentobarbital, and, less commonly in the pediatric setting, propofol. However, there is insufficient evidence to recommend any one in particular over the others.

One of the most frequently used initial continuous infusions is midazolam. Administration often involves a 0.2 mg/kg loading dose followed by 0.2 to 0.6 mg/kg/h infusion rate. Midazolam infusion may produce respiratory depression and hypotension, although hypotension may be less likely than with pentobarbital infusion. Thus the patient must be managed in a critical care environment with continuous cardiopulmonary monitoring. Tachyphylaxis often develops within 24 to 48 hours, so the infusion dose may need to be increased to maintain a constant pharmacologic action. If seizures persist, the midazolam dosage may be increased. Solely increasing the infusion rate may only very slowly raise midazolam levels, so repeating the bolus in addition to infusion rate increases are generally indicated. In a series of patients with refractory SE, continuous infusion of midazolam with a mean infusion rate of 2 µg/kg/min controlled seizures in 19 of 20 (95%) of children after a mean interval of 0.9 hours from infusion initiation (Sutter, et al., 2013). In another series of children with refractory SE, a continuous infusion of midazolam with a mean infusion rate of 3.1 µg/kg/min controlled seizures in 26 of 27 (96%) cases within 65 minutes of the midazolam infusion initiation.

Another common option is pentobarbital infusion. Administration often involves a 5 mg/kg loading dose followed by 1 to 5 mg/kg/h infusion rate. Pentobarbital may produce respiratory depression and hypotension, so the patient must be managed in a critical care environment with continuous cardiopulmonary monitoring. In a retrospective series of children with refractory SE treated with pentobarbital infusion with a mean loading dose of 5.4 mg/kg followed by an initial infusion of 1.1 mg/kg/h and maximum infusion of 4.8 mg/kg/h, 10 of 30 (33%) achieved sustained burst suppression without relapse during therapy. Of the patients who experienced seizure relapse, 12 of 20 (60%) eventually regained burst suppression. The rate of adverse effects in this series was particularly high, with hypotension requiring inotrope medications in 93% of patients, infection in 66%, metabolic acidosis in 10%, and pancreatitis in 10%. Another limitation of pentobarbital is its long half-life, which may make the weaning process challenging.

A third option for continuous infusion is propofol. Administration often involves a 2 mg/kg loading dose followed by 2 to 5 mg/kg/h infusion rate. Importantly, it may cause propofol infusion syndrome, a very severe and often fatal complication most often seen in critically ill children undergoing long-term propofol infusion at high doses. The mechanism underlying

propofol infusion syndrome may be propofol-mediated impairment of free fatty acid utilization and mitochondrial activity. An imbalance between energy demand and utilization is a key pathogenic mechanism that may lead to cardiac and peripheral muscle necrosis. The main clinical features of propofol infusion syndrome are cardiovascular collapse with lactic acidosis, hypertriglyceridemia, and rhabdomyolysis. As this syndrome is frequently lethal, propofol infusions with doses of at least 5 mg/kg/h are not recommended for more than 48 hours, especially in children. In a study of children with refractory SE, propofol infusion controlled 14 of 22 (64%) of episodes. In this series, propofol infusion had to be stopped in four patients: one patient had rhabdomyolysis, and three patients developed hypertriglyceridemia that normalized after stopping propofol.

## Super-Refractory SE

When SE continues despite one to two continuous infusions, it is considered super-refractory SE. There is no consensus on when SE should be termed super-refractory, but a proposed definition is "status epilepticus that continues for 24 hours or more after the onset of anesthesia, including those cases in which the SE recurs on the reduction or withdrawal of anesthesia." When patients are in super-refractory SE, several therapeutic approaches should be tried sequentially although evidence on their efficacy is generally limited to case reports or small case series (Table 69-3).

## Autoimmune SE and Immune Therapies

Autoimmune encephalitis is a rare etiology of SE. However, it is potentially treatable and should therefore be considered, especially when SE is refractory or super-refractory. Patients of any age who develop rapidly progressing symptoms, including a combination of seizures or SE, behavioral changes, and encephalopathy with no other explanation, should have serum and cerebrospinal fluid autoantibody evaluations. The suspicion or confirmation of autoimmune encephalitis should lead to consideration of treatment with immunotherapy such as steroids, intravenous immunoglobulins, or plasma exchange. The response to these treatments is variable, even when an autoimmune etiology is confirmed.

## OUTCOME

Children with SE have an overall mortality of approximately 0% to 3%. Considering only children admitted to pediatric intensive care units, the mortality is approximately 5% to 8%. Further, children surviving SE are at risk of lifelong sequelae, including cognitive and neurodevelopmental impairments, new-onset epilepsy, and recurrent SE. Overall, children with history of SE have a lower quality of life scores than children with similar epilepsy who have not experienced SE, even after correcting for demographic and clinical features known to affect quality of life. In addition to characteristics of the SE itself, other factors such as etiology, age, treatment, or treatment adverse effects have important influences on outcome.

Younger children have the highest rates of morbidity and mortality. In a series of 193 children with SE, neurologic sequelae occurred in 29% of infants younger than 1 year of age, 11% of children with ages between 2 and 3 years, and 6% of children older than 3 years. Given that there was no difference in outcome when these results were stratified by etiology, these data reflect the greater incidence of acute neurologic disease (associated with worse outcome) in younger age groups. Most deaths during hospitalization occur in children with acute or remote symptomatic causes and may not be

**TABLE 69-3** Treatment Alternatives for Refractory and Super-Refractory Status Epilepticus

	Comments	Adverse Events
<b>Thiopental</b>	Metabolized to pentobarbital	Hypotension Respiratory depression Cardiac depression
<b>Ketamine</b>	Mechanism of action particularly well-suited to treat refractory and super-refractory SE (NMDA receptor antagonist)	High intracranial pressure Hypotension Hallucinations
<b>Inhaled anesthetics</b>	High rate of complications Needs closed system (gas recovery)	Hypotension Infection Paralytic ileus
<b>Ketogenic diet</b>	Relatively safe (no respiratory and cardiocirculatory instability) Slow onset of action Requires skilled dietician	Gastroesophageal reflux Constipation Acidosis Hypertriglyceridemia
<b>Lidocaine</b>	Minor respiratory depression compared with other drugs	Cardiocirculatory instability Possible induction of seizures
<b>Hypothermia</b>	Only transitory control (cannot be a prolonged therapy)	Hypotension Cardiovascular instability Impaired coagulation (bleeding risks)
<b>Resective surgery</b>	Long-term treatment of seizures Not all patients are eligible	Surgical risks

Legend: NMDA—N-methyl-D-aspartate; SE—status epilepticus.

attributable to SE itself. Long-term mortality data also suggests that the etiology of SE is one of the main predictors for long-term survival. Further supporting the hypothesis that mortality is more likely related to the etiology than to SE itself, febrile SE is associated with a negligible mortality.

SE survivors have an increased risk of subsequent epilepsy, which is reported to occur in 13% to 74% of cases (Raspall-Chaure, et al., 2006). SE recurs in approximately 20% of cases within 4 years of initial presentation, with most recurrences during the first 2 years (Raspall-Chaure, et al., 2006). The occurrence of seizures and the recurrence of SE are influenced by the underlying etiology, with structural or metabolic lesions having the highest risk (Raspall-Chaure, et al., 2006).

Subtle neurocognitive dysfunction—such as focal neurologic deficits, cognitive impairment, and behavioral problems—occurs in patients who have experienced SE, but the contribution of etiology, duration, and other potential confounders has not been clarified.

In summary, SE is associated with substantial mortality and morbidity, including subsequent epilepsy and recurrent SE as well as neurocognitive deficits. The effect of SE itself on these adverse outcomes has not been elucidated, but it is possible that the primary etiology and the comorbidities are the main drivers of these outcomes.

## NEONATAL STATUS EPILEPTICUS

Several factors are important to consider in neonatal SE.

First, most neonatal seizures occur secondary to acute neurologic injuries such as hypoxic-ischemic encephalopathy, stroke, or infections. Neonatal epilepsy syndromes are much less common (Table 69-4). Because neonatal seizures typically reflect an underlying functional or structural lesion, the mortality and morbidity burdens are typically higher than in older children. In a series of 89 term newborns with clinical seizures, mortality was 7%, and 28% of the survivors had unfavorable long-term outcome defined as moderate to marked abnormalities in neurologic examination or cognition. In a series of 112 newborns with seizures (33 preterm and 79 term), mortality was 2.7%, and among the survivors, 28% had cerebral

palsy, 36% had epilepsy, and almost half of the patients had delay in at least two domains of development. In both, series etiology was a major predictor of outcome.

Second, diagnosis of neonatal seizures is challenging because many repetitive neonatal movements do not have an ictal EEG correlate and conversely because many electrographic seizures do not have associated clinical manifestations. A series of 20 video clips with repetitive neonatal movements—11 of them being EEG-confirmed seizures and nine being movements with no EEG correlate—were evaluated by 91 doctors and 46 other healthcare neonatal intensive care unit professionals. The average number of correctly identified events was 10 of 20 (50%). Further, clinical identification of neonatal seizures alone substantially underestimates their true incidence because approximately 80% of seizures detected on EEG have no clinical correlate. Further, antiseizure medicines may stop clinical seizures although seizures persist on EEG, a phenomenon termed electroclinical uncoupling. Therefore clinical observation alone may yield false positives (nonictal movement leads to administration and escalation of therapies) and false negatives (EEG seizures go undetected and thus untreated). Based on these data, the guideline of the American Clinical Neurophysiology Society (ACNS) on continuous EEG monitoring in neonates states that “conventional video-EEG monitoring is the gold standard for neonatal seizure identification and quantification and should be used whenever available for seizure identification and differential diagnosis of abnormal appearing, paroxysmal clinical events. It is the ideal tool to measure the exact number and duration of seizures, their site(s) of onset, and spatial patterns of migration.”

Finally, the definition of SE in newborns is not as straightforward as in older children or adults. One of the main factors in the SE definition is a prolonged seizure or prolonged cluster of seizures without interictal resumption of baseline central nervous system function between seizures. Most newborns with seizures have some degree of encephalopathy because of the underlying acute disorder producing the seizures, thereby making the evaluation of return to baseline neurologic function challenging. There is no consensus on the definition of SE in newborns although some studies have considered it to

**TABLE 69-4** Etiology of Neonatal Seizures in a Series of 112 Newborns (33 Preterm and 79 Full-Term)

Etiology	N (%)

be present when more than 50% of a 1-hour EEG epoch contains seizures, which may be a single continuous 30-minute seizure or a series of briefer seizures totaling 30 minutes. Regardless of how SE is defined in newborns, a higher seizure burden is associated with less favorable outcomes—even after controlling for potential confounders. Regarding treatment of neonatal seizures and neonatal SE, phenobarbital and phenytoin remain the preferred choices.

## NONCONVULSIVE STATUS EPILEPTICUS

Nonconvulsive status epilepticus (NCSE) broadly refers to prolonged seizure activity in the absence of major motor signs or to a change in behavior and/or mental processes from baseline associated with continuous epileptiform discharges in the EEG. Patients with developmental delay, recurrent seizures on multiple medications, and/or critically ill patients are at high risk for developing NCSE, and in these patients, changes in behavior or cognition can be particularly challenging to detect. The incidence of NCSE has been estimated in approximately 2 to 8 of 100,000, although difficulty in identifying NCSE and heterogeneous diagnostic criteria may yield both underestimation and overestimation. NCSE is a heterogeneous condition that can be broadly classified into subcategories: absence NCSE, complex partial NCSE, and NCSE in coma.

Absence NCSE consists of a prolonged state of drowsiness and confusion in which agitation, violent behavior, and hallucinations can occasionally occur. The EEG shows generalized EEG abnormalities markedly different from the interictal state. Relatively subtle myoclonic movements sometimes occur within this category.

Complex partial NCSE consists of periods of abnormal behavior or abnormal cognitive state including amnesia, aphasia, or hemiparesis in between complex partial seizures. EEG findings are focal with preferential involvement of the temporal and frontal lobes and include spike and wave, poly-spikes, and rhythmic slowing.

NCSE in coma consists of prolonged or recurrent electrographic seizures in patients in coma. A multicenter trial in the United States included 550 consecutive pediatric patients (1 month to 21 years) in pediatric intensive care units who underwent EEG monitoring. Electrographic seizures were found in 162 children (30%), of which 59 (36%) had no clinical correlate. In a subset of 98 patients from this study who underwent EEG monitoring after convulsive SE, 11 (11%) patients had electrographic-only seizures after termination of their clinically evident convulsions. A prior diagnosis of epilepsy and/or the presence of interictal epileptiform activity on EEG were identified as risk factors for the occurrence of electrographic seizures. Although risk factors may help identify subpopulations at high risk for seizures, some children with NCSE would have been undetected without EEG monitoring.

## SUMMARY

SE is a life-threatening emergency that should be controlled as soon as possible. Although SE is considered established after 30 minutes, the operational definition of impending SE at 5 minutes emphasizes the need of an early treatment. Most episodes of pediatric SE start in the out-of-hospital setting in previously healthy children, and the main etiology is symptomatic SE secondary to fever or systemic infection. Many children have acute symptomatic etiologies for SE, so careful evaluation for precipitating etiologies is essential. The initial management of SE consists of cardiorespiratory stabilization and monitoring followed by antiseizure drug to stop the seizures as soon as possible. Benzodiazepines, and in particular intravenous lorazepam, are the preferred first-line treatment, although other benzodiazepines should be considered when intravenous access is not readily available. If one or two doses of benzodiazepines have not controlled SE or more than 10 minutes have elapsed since seizure onset, administration of nonbenzodiazepine medication is warranted. Fosphenytoin followed, if necessary, by phenobarbital are the traditional initial choices in SE, but other agents such as valproate or levetiracetam have demonstrated at least similar efficacy in nonrandomized studies. Throughout treatment, it is important to anticipate the next needed medication so it can be available at bedside if needed. If SE persists after administration of a benzodiazepine and a second antiseizure drug, the patient is in refractory SE. Continued evaluation for underlying etiologies is essential, and initiation of anesthetic drug infusions is generally warranted, with careful monitoring and management of common cardiopulmonary adverse effects associated with these medications. Overall mortality in pediatric SE is approximately 0% to 3%, and sequelae are common. Although SE etiology is the main predictor of outcome, longer SE may also worsen outcome. Thus efforts to rapidly terminate SE as well as identify and manage any underlying treatable etiology are essential.

## 1.0 INTRODUCTION

The recent rapid advances in bedside video-electroencephalogram (EEG) monitoring, genetic techniques, and imaging modalities have markedly improved the identification and treatment of many epilepsy syndromes and their underlying etiologies. The term “electroclinical syndrome” has been used to designate a set of distinctive and recognizable clinical features, signs, and symptoms that define a specific clinical disorder. Often, this includes a typical age of onset, specific EEG characteristics, seizure types, and other features that permit the diagnosis of the specific syndrome. This is important to further guide management and prognosis. The 2010 revised International League Against Epilepsy (ILAE) classification stratified electroclinical epilepsy syndromes by typical age of onset (Table 70-1). There are four neonatal-onset electroclinical syndromes, two of which are benign: benign neonatal seizures and benign familial neonatal seizures. The other two neonatal epilepsy syndromes are early infantile epileptic encephalopathy and early myoclonic encephalopathy. In this chapter, these neonatal onset electroclinical syndromes will be discussed. For each syndrome, the clinical features, etiology, diagnosis, treatment, and prognosis will be detailed. Most neonatal seizures are often acute and symptomatic in response to a specific etiology such as hypoxic ischemic injury, central nervous system (CNS) infection or trauma, brain infarction, electrolyte disturbances, congenital brain malformations, and inborn errors of metabolism. Seizures due to neonatal-onset electroclinical syndromes are rare compared with acute neonatal seizures; however, prompt identification has implications that often are essential to guide further treatment and prognosis.

## 2.0 BENIGN NEONATAL SEIZURES

This is a benign electroclinical syndrome that is seen in neonates. It is also referred to as the *fifth day fits* or *benign idiopathic neonatal convulsions*.

### 2.1 Clinical Features

These seizures occur in term and late preterm infants born after an uneventful pregnancy, labor, and delivery. The prevalence is estimated to be between 4% and 38% of neonatal seizures with males constituting about 62% of the cases. Seizures occur within the first week of life, and 90% of the seizures occur between days 4 and 6 of life. Often, there is no family history of epilepsy, and the neonates are otherwise asymptomatic with normal neurologic examinations between the seizures. The presentation is in the form of repetitive seizures lasting from 1 to 2 minutes, sometimes recurring in clonic status epilepticus that last hours. Seizures may recur during a period of 24 to 48 hours but often do not persist beyond that period. Most frequently, seizures seen are unifocal clonic with rare focal tonic seizures.

### 2.2 Etiology

The pathogenic mechanism remains unclear with a hypothesis that a causal relationship may exist between rotavirus infections and benign neonatal seizures, but the virus was not identified in cerebrospinal fluid (CSF) (Plouin and Kaminska, 2013). Alternative theories implicate the role of a CSF zinc defect as a possible etiologic mechanism (Plouin and Kaminska, 2013).

### 2.3 Diagnosis

Diagnosis is based mostly on elements of the history and physical examination that are concordant with the expected clinical features. There is no characteristic ictal EEG pattern, but the interictal EEG may be normal or discontinuous or show multifocal sharp waves. A specific EEG pattern called *theta pointu alternant* is seen in 60% of the cases. This pattern may also be seen in cases with hypocalcemia, neonatal meningitis, and subarachnoid hemorrhage. This rhythm consists of nonreactive, discontinuous focal, rhythmic theta activity that may be mixed with sharp waves. The activity may shift between hemispheres, and this EEG pattern may persist for up to 2 weeks even after resolution of the clinical seizures (Mizrahi and Clancy, 2000).

The following criteria have been proposed for the diagnosis of benign neonatal seizures (Mizrahi and Clancy, 2000):

- Normal pregnancy and delivery
- Full-term gestation
- Appropriate for gestational age birth weight
- Apgar score greater than 7 at 1 minute
- Typical interval between birth and seizure onset (4 to 6 days)
- Normal neurologic examination before seizures and interictally
- Normal laboratory findings (including, but not limited to, metabolic studies, neuroimaging, and lumbar puncture)
- No family history of neonatal seizures or postneonatal epilepsy

### 2.4 Differential Diagnosis

It is important to differentiate benign neonatal seizures from other nonepileptic phenomena including tremors, benign neonatal myoclonus and hyperekplexia. Also, symptomatic seizures due to various etiologies need to be ruled out (Co, et al., 2007). A family history is important to differentiate this entity from benign familial neonatal seizures.

### 2.5 Prognosis

The expected outcome of these patients is favorable in terms of neurodevelopment and risk for postneonatal epilepsy, although long-term, follow-up studies are still lacking. Some

**TABLE 70-1** Electroclinical Syndromes Arranged by Typical Age of Onset

Age of Onset	Epilepsy Syndromes
Neonatal	Benign neonatal seizures Benign familial neonatal epilepsy (BFNE) Ohtahara syndrome Early myoclonic encephalopathy
Infancy	Febrile seizures; febrile seizures plus Benign infantile epilepsy Benign familial infantile epilepsy West syndrome Dravet syndrome Myoclonic epilepsy in infancy Myoclonic encephalopathy in nonprogressive disorders Epilepsy of infancy with migrating focal seizures
Childhood	Febrile seizures; febrile seizures plus early-onset childhood occipital epilepsy (Panayiotopoulos) Epilepsy with myoclonic atonic seizures Childhood absence epilepsy Benign epilepsy with centrotemporal spikes Autosomal dominant nocturnal frontal lobe epilepsy Late-onset childhood occipital epilepsy (Gastaut type) Epilepsy with myoclonic absences Lennox-Gastaut syndrome Epileptic encephalopathy with continuous spike-and-wave during sleep Landau-Kleffner syndrome
Adolescence— Adult	Juvenile absence epilepsy Juvenile myoclonic epilepsy Epilepsy with generalized tonic-clonic seizures alone Autosomal dominant epilepsy with auditory features Other familial temporal lobe epilepsies
Variable age at onset	Familial focal epilepsy with variable foci (childhood to adult) Progressive myoclonus epilepsies Reflex epilepsies

(Adapted from data in International League Against Epilepsy proposal for Revised Terminology for Organization of Seizures and Epilepsies, 2010. <http://www.ilae.org/Commission/Class/documents/ILAE%20HandoutV10.pdf>. Accessed March 2015)

studies suggested the presence of minor psychomotor deficits and the possibility of febrile and afebrile seizures.

## 2.6 Management

The treatment of benign neonatal seizures is controversial. More often, these seizures are treated as acute seizures as the workup is being conducted. Often, phenobarbital is started and then ultimately weaned as the seizures stop and the diagnosis is established. The controversy is that because most of the seizures are brief and self-limited, one may argue that no antiseizure medication may be needed.

## 3.0 BENIGN FAMILIAL NEONATAL EPILEPSY (BFNE)

This was classically thought of as a benign epilepsy syndrome in the neonatal period and was the first epilepsy syndrome for which the causative genes were identified.

## 3.1 Clinical Features

This is an autosomal dominant syndrome with a high degree (approximately 85%) of penetrance, the prevalence of which is estimated to be about 14.4 per 100,000. Seizures often start between days 2 and 3 in 80% of the cases in an otherwise healthy term infant, and usually by 1 week of life. Preterm infants may develop seizures later and rarely seizures may occur as late as 3 months (Miles and Holmes, 1990). Seizures are stereotyped starting with hypertonia and brief apnea. This is then followed by autonomic manifestations and oculo-facial and clonic movements of the limbs. Seizures are brief, lasting 1 to 2 minutes, and may be as frequent as 20 to 30 per day. A sample EEG recording of such a seizure is illustrated in Figure 70-1. The seizures may alternatively involve both sides. There is no report of myoclonic seizures, spasms, or generalized tonic-clonic seizures with this epilepsy syndrome (Plouin and Kaminska, 2013).

## 3.2 Etiology

Mutations in genes encoding the subunits of the potassium channels KCNQ2 (on chromosome 20q) and KCNQ3 (on chromosome 8q) are the etiologic factors contributing to benign familial neonatal epilepsy (BFNE). Although it was thought previously that these mutations often result in a benign epilepsy syndrome, recent advances in genetic testing have shown that KCNQ2, and rarely KCNQ3, mutations may result in a picture of severe encephalopathy severe encephalopathy often seen in infancy (Allen et al., 2014). The mutations seen in BFNE are thought to cause a reduction in the current amplitude through the potassium channels, which leads to a transient susceptibility to seizures. The more severe phenotypes of epileptic encephalopathy have been reported to be associated with loss of function as well as with dominant negative and gain of function effects.

## 3.3 Diagnosis

The brain imaging and metabolic and biochemical screening are usually unremarkable. The interictal EEG may also be normal or discontinuous, or may show focal or multifocal abnormalities. A theta pointu alternant pattern may also be seen. The ictal EEG (Fig. 70-1) often shows onset with bilateral flattening for few seconds coinciding with apnea and tonic activity. This is then followed by asymmetric discharges for 1 to 2 minutes coinciding with the automatisms and clonic activity. The diagnosis of BFNE often is made when there is a normal neurologic examination, family history of neonatal seizures, exclusion of other etiologies of neonatal seizures, and features consistent with seizures expected in BFNE with confirmation on gene testing.

## 3.4 Differential Diagnosis

BFNE is often a diagnosis of exclusion as a family history of neonatal seizures is needed to establish the diagnosis and is not always available. Similar to benign neonatal seizures, other etiologies need to be excluded including benign neonatal seizures. Genetic testing may also be done and can help confirm the diagnosis. (Table 70-2) compares BFNE and benign neonatal seizures.

## 3.5 Prognosis

Seizures abate between 1 and 6 months from onset, with about two-thirds remitting in the first 6 weeks. The risk of subsequent epilepsy has been found to be about 16% in some

studies. There is no increased risk of intellectual disability or learning difficulties otherwise.

### 3.6 Management

Seizures usually remit even without treatment but antiseizure medications are often used to shorten or stop recurrent seizures with options including benzodiazepines, phenobarbital, phenytoin, or levetiracetam. Often, it is recommended to stop treatment, if initiated, within 3 to 6 months.

## 4.0 OHTAHARA SYNDROME

This is also referred to as Early Infantile Epileptic Encephalopathy (EIEE) and is part of the spectrum of severe epileptic encephalopathies that may start in the neonatal period.

### 4.1 Clinical Features

The onset of Ohtahara syndrome is often within the first 10 days of life in the form of tonic spasms with a characteristic EEG picture of burst suppression. At times, intrauterine onset with increased fetal movements is suspected with onset delayed up to 3 months in some cases. A slight male predominance is present. The prevalence and incidence are not known.

The spasms often consist of tonic forward flexion that lasts 1 to 10 seconds often occurring in clusters 10 to 300 times per day. The spasms may be lateralized and may occur during wakefulness and sleep (Yamamoto et al., 2011). Soon after the onset of the seizures, the infant becomes hypotonic with poor activity, and psychomotor development is arrested with subsequent development of diplegia, spasticity, ataxia, or dystonia.

### 4.2 Etiology

The most commonly cited etiologic factors of Ohtahara syndrome consist of malformations of brain development. These include hemimegalencephaly, porencephaly, cerebral atrophy, Aicardi syndrome, olivary-dentate dysplasia, agenesis of mammillary bodies, linear sebaceous nevus syndrome, cerebral dysgenesis, and migrational defects (Beal et al., 2012).

Metabolic disorders may be seen in some cases of Ohtahara syndrome (although they are more likely to cause early myoclonic encephalopathy), including glycine encephalopathy (also called nonketotic hyperglycinemia), cytochrome C oxidase deficiency, Leigh encephalopathy, pyridoxine and pyridoxal-5-phosphate dependency, carnitine palmitoyltransferase deficiency, biotinidase deficiency, and mitochondrial respiratory chain complex I deficiency (Beal et al., 2012).

The recent advances in genetic studies have permitted the identification of a wide range of genes that cause EIEE (Table 70-3). Although many of these genetic EIEE present in the infantile period, many present neonatally also:

- EIEE1 caused by gene mutations in ARX—encoding the Aristaless-related homeobox protein involved in cerebral development and patterning—was first discovered as a cause of idiopathic EIEE in patients with early onset seizures in the neonatal or infantile periods with no associated brain malformations. These were due to mutations in the ARX gene outside the homeobox and those with polyalanine expansion mutations. Premature termination mutations and missense mutations within the homeobox of the ARX gene, however, were found to be associated with lissencephaly and abnormal genitalia. This disorder affects males. Females are carriers (X-linked recessive).

- EIEE2 caused by gene mutations in CDKL5—encoding cyclin-dependent kinase like-5 protein involved in regulation of other gene function including MeCP2—has also been described in neonates as early as 10 days of life presenting with generalized convulsions. This disorder predominantly affects females (X-linked dominant).
- EIEE3 caused by gene mutation in SLC25A22—encoding a mitochondrial glutamate carrier—may present in the form of migrating partial clonic seizures within the first 2 weeks of life along with hypotonia and brisk reflexes.
- EIEE4 caused by STXBP1 gene mutation—encoding syntaxin binding protein 1—presents as Ohtahara syndrome often as early as 3 days of age up to 4.5 months of age with tonic or tonic clonic seizures and profound global developmental delay and intellectual disability.
- EIEE7 caused by KCNQ2 mutations have been found to be present in patients with tonic seizures starting in the neonatal period before 2 weeks of age with diagnosis of Ohtahara syndrome.
- EIEE11 caused by SCN2A—encoding the alpha subunit of the voltage-gated sodium channel—may also present in the neonatal period with refractory focal and generalized seizures as early as the first day of life along with neonatal hypotonia.

Mutations of many of these genes and an expanding number of others, such as in the SIK1, CAK, BRAT1, and PIGA genes, may present as neonatal epileptic encephalopathy with classical features of Ohtahara syndrome, or at other times without burst suppression or tonic seizures but with markedly abnormal EEGs, and with drug-resistant seizures of other types, such as focal seizures.

### 4.3 Diagnosis

The diagnosis often involves identification of the seizures in the neonatal period. The EEG picture often shows a characteristic burst-suppression pattern. The EEG background consists of high voltage (150 to 350 microvolt) slow waves with intermixed multifocal spikes lasting 2 to 3 seconds with periods of suppression lasting for 3 to 5 seconds (Fig. 70-2). This pattern of burst suppression is continuous during wakefulness and sleep; this continuity at times helps distinguish Ohtahara syndrome from early myoclonic encephalopathy (Ohtahara and Yamatogi, 2003). Table 70-4 compares the two syndromes. During a spasm, the activity is more synchronized with a high-voltage slow wave seen followed by generalized fast activity.

The burst-suppression pattern disappears within the first 6 months of life and is often replaced by hypsarrhythmia with progression to West syndrome; it may later progress to a slow-spike wave EEG pattern with Lennox-Gastaut syndrome.

Brain imaging often confirms the presence of an underlying cerebral malformation. Metabolic screening and genetic testing should also be sought to help determine an underlying etiology. Metabolic workup similar to that described for early myoclonic encephalopathy and comprehensive epilepsy gene panels are often used, and whole exome sequencing may be needed in some cases.

### 4.4 Differential Diagnosis

Ohtahara syndrome is often confused with early myoclonic epilepsy given the similar EEG presentations at times and the overlap between the two syndromes. Table 70-4 shows the differentiating factors between the syndromes. Other differential diagnoses to consider may be early-onset West syndrome

or other causes of EIEE. It is also important to differentiate this syndrome from severe neonatal hypoxic-ischemic encephalopathy with burst-suppression pattern.

#### 4.5 Prognosis

Ohtahara syndrome is often associated with high mortality and morbidity. About half of the patients die in infancy and others develop permanent severe mental and neurologic deficits. Often, patients who survive may progress into West syndrome and later into Lennox-Gastaut syndrome with persistent high mortality and severe psychomotor delays.

#### 4.6 Treatment

Often treatment of the seizures proves to be challenging with the absence of effective treatment most of the time. Benzodiazepines, phenobarbital, phenytoin, levetiracetam, and topiramate are often used first. Ketogenic diet, after ruling out metabolic disorders that would contraindicate it, helps at times. Adrenocorticotropic hormone (ACTH) and steroids may be tried but are often of little benefit. Vigabatrin and zonisamide have been used with some success in small case reports. Consideration of surgical workup for cases with focal brain malformations may be worthwhile (Komaki et al., 2001).

Recently the identification of the genetic substrate of some of the syndromes presenting with EIEE has led to consideration of targeted therapy. Such studies are under investigation, including the use of retigabine, a neuronal potassium channel enhancer, in KCNQ2-related severe epileptic encephalopathy (Maljevic and Lerche, 2014) and quinidine in KCNT1 related epilepsies.

### 5.0 EARLY MYOCLONIC ENCEPHALOPATHY (EME)

This is the second of the severe epileptic encephalopathies that often presents almost exclusively in the neonatal period.

#### 5.1 Clinical Features

Early myoclonic encephalopathy (EME) starts very early on in life often within hours to days after birth. More than 60% start before 10 days of life, with rare cases presenting after the second month. There is no gender preponderance. The prevalence and incidence are not well-defined.

Often, the syndrome presents clinically with a triad of intractable seizures starting with erratic myoclonus followed by focal seizures and later by tonic epileptic infantile spasms. The erratic myoclonic seizures seen at onset are often segmental and fragmentary involving distal limb muscles. The neurologic examination is abnormal at onset in all neonates with encephalopathic picture. There is severe psychomotor arrest and progressive deterioration.

#### 5.2 Etiology

EME is mostly associated with inborn errors of metabolism, namely glycine encephalopathy (nonketotic hyperglycinemia), D-glycemic acidemia, methylmalonic acidemia, propionic acidemia, molybdenum cofactor deficiency, pyridoxine and pyridoxal-5-phosphate dependency, sulfite oxidase deficiency, Menkes disease, Zellweger syndrome, and hyperammonemia due to carbamyl phosphate synthase deficiency (Beal et al., 2012). Some cases are familial and others are

considered cryptogenic. No distinct genetic syndromes have been found in association with EME.

#### 5.3 Diagnosis

EME is suspected in patients presenting with erratic myoclonias with encephalopathy and an EEG picture of burst suppression. The burst suppression seen in EME is different from that of Ohtahara syndrome because the burst suppression is more accentuated during sleep and may not occur during wakefulness. Also, this pattern tends to persist throughout infancy. The bursts are often short (1 to 3 seconds) and the periods of suppression last 2 to 10 seconds. There is no associated EEG seizure activity when the erratic myoclonus is present, but seizure activity is recorded with the focal seizures and spasms when these occur subsequently in the course of this disease.

Brain imaging is often normal at the onset of the disease but progressive cortical atrophy may develop. Metabolic testing—particularly plasma and CSF amino acids and urine organic acids to evaluate for increased glycine and CSF to plasma glycine ratio—is often needed. A more extensive metabolic workup is often done to detect other inborn errors of metabolism causing EME. The workup often includes tests for blood amino acids, acyl carnitine profile, carnitine free and total, lactate, pyruvate, ammonia, biotinidase, pipercolic acid, and alpha amino adipic semialdehyde, as well as urine for organic acids, creatine, guanidino acetate, and sulfocysteine. Magnetic resonance spectroscopy may be needed for lactate and creatine peaks. CSF tests include amino acids, lactate, cells, glucose, neurotransmitter metabolites, 4-hydroxybutyric acid, succinyl adenosine, sialic acid, pyridoxal 5'-phosphate, 5-methyltetrahydrofolate, and alpha amino adipic semialdehyde. Gene testing can include targeted gene sequencing and deletion/duplication analysis, gene panels, or exome sequencing depending on the case.

#### 5.4 Differential Diagnosis

The differential of EME is similar to that of Ohtahara syndrome. Table 70-4 highlights some clues to differentiate the two syndromes.

#### 5.5 Prognosis

The prognosis is poor for patients with EME with about 50% dying within the first year. Almost all infants show progressive deterioration in their neurologic status and fail to develop milestones.

#### 5.6 Management

The erratic myoclonus often resolves within a few weeks, but the focal seizures are often refractory to treatment. When possible, etiology-specific therapies may be implemented. This may be in the form of sodium benzoate in cases of glycine encephalopathy or pyridoxine and pyridoxal phosphate trials in suspected pyridoxine related epilepsies.

### 6.0 CONCLUSION

The spectrum of neonatal electroclinical syndromes includes two benign syndromes (benign neonatal seizures [BNS] and benign familial neonatal seizures [BFNS]) and two highly encephalopathic syndromes (Ohtahara syndrome and EME), and potentially yet to be defined syndromes with predominantly focal seizures without burst suppression. Familiarity with the clinical presentation, diagnostic features, and

etiologies helps with early and appropriate diagnosis. This, in turn, facilitates prognostication and management. The rapid booming advance in genetic testing has helped uncover many genetic etiologies of these syndromes allowing for investigation of targeted therapies.

## INTRODUCTION

Epilepsies that begin early in life encompass a broad range of distinct etiologies with vastly different prognoses. Over one third of epilepsies beginning before 3 years of age will be pharmacoresistant, and these may have a devastating influence on cognition. Recognition of a specific electroclinical syndrome often informs decisions regarding therapy, including preferred medications, potential for resective epilepsy surgery, and ketogenic diet, and improves the understanding of the natural history of the seizure disorder.

This chapter will focus on the electroclinical syndromes seen in infants, addressing diagnosis, therapy, and long-term seizure and developmental outcomes.

## GENERALIZED SYNDROMES

### Myoclonic Epilepsy in Infancy

Myoclonic epilepsy in infancy (MEI) is a rare epilepsy syndrome that presents between 4 months and 3 years of age.

#### Seizures

MEI presents with brief 1 to 3 second myoclonic seizures during wakefulness and sleep. The myoclonic seizures may be subtle initially but increase in both frequency and intensity, often occurring in daily clusters during drowsiness. In nearly one third of infants, seizures are triggered by tactile, auditory, or photic stimuli, consistent with reflex myoclonus. Although no other seizure types occur at onset, generalized tonic-clonic seizures may occur later in childhood or early adolescence after the myoclonic seizures have resolved.

#### Other Neurologic Findings

Development and neurologic examination are normal.

#### Etiology

The etiology is unknown. A history of simple febrile seizures or family history of generalized tonic-clonic seizures may be present.

#### EEG Findings

The interictal EEG demonstrates a normal background with generalized spike and wave discharges and possible photoparoxysmal response. The ictal recording shows a burst of 3 to 4 Hz generalized discharge, associated with the myoclonic jerk.

#### Neuroimaging

Neuroimaging is normal.

#### Other Laboratory Studies

Other metabolic and genetic disorders presenting with infantile myoclonus must be evaluated (Tables 71-1 and 71-2).

## Differential Diagnosis

Epileptic spasms must be excluded. Semiology differs in that spasms are brief tonic contractions rather than myoclonic jerks and usually occur in clusters. Additionally, unlike West syndrome, developmental delay and hypsarrhythmia are not present. Both myoclonic-atonic epilepsy and Lennox-Gastaut syndrome include additional seizure types and EEG background slowing. Dravet syndrome should be suspected if there is a history of prolonged or hemiclonic febrile seizures. Non-epileptic myoclonus is not associated with EEG change. Metabolic disorders are typically accompanied by other seizure types, as well as developmental plateauing and regression (Table 71-2).

## Treatment

Valproic acid is the preferred treatment, but adverse reactions are more likely to occur in very young children. Therefore other medications, including benzodiazepines or levetiracetam, may be effective as first-line or adjunctive therapy.

## Outcome

MEI is usually self-limited and pharmacoresponsive. Occasionally, after resolution of the myoclonic seizures, other seizure types as well as cognitive impairment and behavior disorders may occur.

## Myoclonic Encephalopathies in Nonprogressive Disorders

Myoclonic encephalopathy in nonprogressive disorders presents with prolonged myoclonic status epilepticus in cognitively impaired children. This rare epilepsy syndrome has three subgroups based on etiology.

### Etiology

The first and most common subgroup is due to genetic etiology (often Angelman or Prader Willi syndrome). The second subgroup is due to malformations of cortical development such as polymicrogyria or is of unknown etiology. Children in the third subgroup have perinatal anoxic injury.

### Seizures and EEG

Seizures in the first subgroup occur between 1 month and 4 years of age and present with very frequent absence seizures with periorbital or perioral myoclonias, myoclonic jerks, and myoclonic absence seizures. This status epilepticus can last for years. The EEG shows rhythmic, generalized slow spike and wave discharges initially and then evolves to a quiet period with nearly continuous theta-delta frequency activity and superimposed spikes primarily activated by eye closure.

The second subgroup presents with bilateral positive myoclonic seizures that alternate with prolonged negative myoclonias. The EEG can be difficult to correlate with the positive and negative myoclonias due to subcontinuous, waxing and

**TABLE 71-1** Gene/Genetic Syndromes Associated With Infantile-Onset Epilepsies

Gene or Syndrome	Chromosome	Other Clinical Findings	Seizure Semiology	Interictal EEG Findings	Course
SCN1A	2q24.3	Severe cases: developmental delay, crouched gait, ataxia and pyramidal signs	Severe cases: Dravet syndrome with prolonged hemiconvulsive seizures triggered by fever before 18 months of age. Later on, other generalized and focal seizures Mild cases: GEFS + with febrile seizures and generalized or focal seizures	Generalized or focal/multifocal discharges Photoparoxysmal response may be seen	Severe cases: medically intractable, lifelong epilepsy Mild cases: Remission
Wolf-Hirschhorn	Partial monosomy 4p	Prenatal growth failure, severe delay, cleft lip or palate, beaked nose, hypertelorism, low-set ears	Focal, myoclonic, generalized tonic-clonic or atypical absence seizures	High voltage spike wave or slow waves or sequences of sharp waves in the centroparietal or occipital regions	Severity decreases with time
HCN1	5p12	Mild to severe intellectual disability, autistic features, behavior disturbances, ataxia	Onset of febrile or afebrile generalized or focal seizures in first year of life, followed by absence and/or myoclonic seizures		Medically intractable
STXBP1	9q34.1	Severe to profound delay, MRI may show hypomyelination, global atrophy or thinning of the corpus callosum	Early-onset tonic seizures, spasms or tonic-clonic seizures	Suppression burst or hypsarrhythmia	Seizures often intractable although rarely remit. Severe to profound developmental delay
SPTAN1	9q33-q34	Progressive microcephaly, spastic quadriplegia, severe intellectual disability, hypomyelination and diffuse brain atrophy on MRI	Spasms, generalized seizures	Hypsarrhythmia	Medically intractable
DNM1	9q34	Hypotonia	Infantile spasms, evolving to Lennox-Gastaut syndrome	Hypsarrhythmia, slow spike wave	Severe to profound intellectual disability, intractable epilepsy
SLC25A22	11p15.5	Hypotonia, microcephaly, abnormal electroretinogram	Myoclonic seizures, spasms	Suppression burst, hypsarrhythmia	Medically intractable
Trisomy 12p	12	Severe delay, short neck, prominent forehead, flat occiput, hypertelorism, micrognathia, low-set ears	Myoclonic or myoclonic absence, generalized tonic-clonic	3 Hz spike and polyspike	Seizures often respond to medications
SCN8A	12q13.1	Movement disorder	Clusters of focal or generalized seizures triggered by fever Spasms	Multifocal or generalized discharges	Often intractable
Ring chromosome 14	14	Severe delay, microcephaly, narrow face, high-arched palate, short palpebral fissures, flat nasal bridge, retrognathia, ocular anomalies	Symptomatic generalized epilepsy with onset in first year of life		
FOXG1	14q11-q13	Severe delay without microcephaly "congenital Rett"	Focal and generalized seizures	Slowing of background, focal and multifocal discharge	Often refractory

**TABLE 71-1** Gene/Genetic Syndromes Associated With Infantile-Onset Epilepsies (Continued)

Gene or Syndrome	Chromosome	Other Clinical Findings	Seizure Semiology	Interictal EEG Findings	Course
Inversion-duplication 15 syndrome	15	Moderate to severe delay, autism, microcephaly, mild occasional dysmorphic features	Epileptic encephalopathy resembling West or Lennox-Gastaut syndrome, occasional focal seizures	Hypsarrhythmia, slow spike-wave	Often refractory
Angelman	Partial monosomy 15q	Ataxia, tremor, minimal speech, severe delay, happy demeanor	Atypical absence, myoclonic, tonic-clonic, unilateral clonic, Focal dyscognitive	High-amplitude, symmetric, synchronous notched 2 Hz polyphasic slow waves or slow and sharp waves, particularly during slow wave sleep	VPA + BZDs helpful Seizure severity decreases over time
POLG1	15q24	Cerebral atrophy, liver dysfunction	Myoclonic, other focal and generalized seizures	Multifocal discharge with slowing	Refractory
CHD2	15q26	Intellectual disability, may have microcephaly	Fever sensitive generalized tonic-clonic seizures usually after age 1, later with prominent myoclonus and atypical absences	Generalized polyspike and wave discharges initially, later on may see focal or multifocal discharge	Mild–severe intellectual disability
PRRT2	16p11.2	Familial paroxysmal choreoathetosis or kinesigenic dyskinesia	Focal with or without secondarily generalized seizures in neurologically normal infants	Interictal EEG usually normal	Seizures usually pharmacoresponsive and self-limited
Miller-Dieker	17p13.3 deletion	Four layered lissencephaly, microcephaly, bitemporal narrowing, small, anteverted nose, micrognathia, high forehead, cardiac, renal and sacral anomalies	In first weeks to months, massive myoclonus and epileptic spasms are seen. Over time, focal and tonic seizures emerge as predominant seizure types	Prominent fast activity, although slowing is common in the first year of life	Seizures are refractory
KCNQ2	20q13.33	Usually normal infants but rarely may have moderate to profound delay Severe affected infants may have reversible T2 signal changes in the thalami and basal ganglia	Severe cases: early-onset tonic spasms, focal seizures, myoclonic seizures Mild: focal epilepsy in infants	Severe: suppression burst or hypsarrhythmia Mild: normal or focal discharges	Most cases are mild with self-limited seizure disorder and normal development Rarely, may present as early-onset epileptic encephalopathy
Ring chromosome 20	20	Mild–moderate delay, restlessness, aggression, nondysmorphic	Runs of atypical absence or myoclonic status epilepticus	Ictal: high voltage, 2–3 Hz slow activity with superimposed spikes maximal over frontal regions Interictal: normal or mild slowing/sharp waves	Seizures are refractory and don't remit with age
DEPDC5	22q12.3	AD inheritance with incomplete penetrance (50%–82%) May be associated with cortical dysplasias, often bottom-of-the-sulcus	Focal epilepsy (often frontal or temporal)	Focal or multifocal discharges	Heterogeneous—some cases have well-controlled epilepsy, others are intractable Rarely individuals may have intellectual disability, autism, psychiatric features

Continued on following page

**TABLE 71-1** Gene/Genetic Syndromes Associated With Infantile-Onset Epilepsies (Continued)

Gene or Syndrome	Chromosome	Other Clinical Findings	Seizure Semiology	Interictal EEG Findings	Course
CDKL5	Xp22	More common in girls but seen also in boys Severe developmental delay with hypotonia Acquired microcephaly in some cases. Impaired eye contact and gaze avoidance	Generalized tonic seizures beginning in first 10 wks, followed by spasm, atypical absences and myoclonic seizures	Interictal EEG normal early on, then see slowing of background and modified hypsarrhythmia	Intractable generalized seizures
PCDH19	Xp22.1	Girls only, intellectual disability, autism	Generalized tonic-clonic or focal seizures, typically occurring in clusters with febrile illness	Generalized or focal discharge	Intellectual disability, autism Seizures often medically intractable
Rett Syndrome (MECP2)	X q28	Normal early development followed by acquired microcephaly, autistic features, lack of purposeful hand movement with characteristic hand wringing	Generalized tonic-clonic seizures, other generalized and focal seizures	Slowing of background with multifocal and generalized epileptiform discharge	Often refractory
ARX	Xp22.13	Severe developmental delay and seizures in boys. Often associated cerebral malformations including lissencephaly, agenesis of corpus callosum. May have dystonia, spasticity	Spasms, other generalized seizures	Suppression burst, hypsarrhythmia	Usually refractory
SLC35A2	Xp11.23-p11.22	Moderate to severe intellectual disability, language impairment, early pubertal onset	Spasms, focal epilepsy	Hypsarrhythmia Electrical status epilepticus in slow sleep	Often intractable

**TABLE 71-2** Inborn Errors of Metabolism Associated With Infantile-Onset Epilepsies

Metabolic Disorder	Age at Onset	Clinical	Diagnostic Test	Prognosis	Treatment
Pyridoxine dependency	Birth to 1 year	Refractory seizures which may begin in utero, progressive encephalopathy, clinical and EEG response to pyridoxine	Increased AASA in CSF, serum and urine, confirm with ALDH7A1 genetic analysis	Variable, depending on duration of symptoms before supplementation	Pyridoxine 50–200 mg/d
Pyridoxal phosphate dependency	Neonatal	Refractory seizures, often in preterm infant, encephalopathy, clinical and EEG response to pyridoxal phosphate	Low P5P in CSF, confirm with PNPO genetic analysis	Variable, depending on duration of symptoms before supplementation	Pyridoxal-5-phosphate 30 mg/kg/d
Folinic acid responsive seizures	Neonatal	Refractory seizures, encephalopathy, clinical and EEG response to folinic acid, incomplete response to pyridoxal phosphate and pyridoxine	Increased CSF AASA and increased serum pipercolic acid, abnormal peaks on CSF neurotransmitter analysis	Variable, depending on duration of symptoms before supplementation	Folinic acid 3–5 mg/kg/d
Serine deficiency disorders	Neonatal to childhood	Microcephaly, cognitive disability, failure to thrive, spasticity, hypomyelination and brain atrophy on MRI, neonatal or absence seizures	Decreased serine on CSF and plasma amino acids	Variable, depending on duration of symptoms before supplementation	Serine 500–700 mg/kg/d +/- glycine supplementation

**TABLE 71-2** Inborn Errors of Metabolism Associated With Infantile-Onset Epilepsies (*Continued*)

Metabolic Disorder	Age at Onset	Clinical	Diagnostic Test	Prognosis	Treatment
Creatine deficiency	Neonatal and infancy	Developmental delay, seizures, autistic features, movement disorder, poor growth	Screen with urine testing for creatine and GAA, followed by definitive genetic testing for AGAT, GAMT or creatine transporter	Poor, majority with moderate to severe mental retardation	Creatine monohydrate 5–20 g/d
Untreated phenylketonuria	Neonatal and infancy	Growth failure, microcephaly, seizures, developmental delay, mousy odor	Increased Phe on plasma amino acids	Good if diagnosed and treated early	Phe restricted diet, consider BH4 trial to rule out tetrahydrobiopterin deficiency
Urea cycle disorders	Neonatal, later if partial enzyme deficiency	Vomiting, lethargy, coma, seizures, developmental delay, protein avoidance, diffuse white matter changes on MRI	Increased serum ammonia, abnormal serum amino acids and urine organic acids	Variable, depending on severity and duration of symptoms	Removal of ammonia with dialysis (if hyperammonemic crisis), sodium benzoate, sodium phenylacetate, arginine supplementation High carbohydrate, low protein diet with provision of essential amino acids
Glycine encephalopathy (Nonketotic hyperglycinemia)	Neonatal or infantile	Lethargy, hypotonia, hiccups, intractable seizures, apnea	Increased CSF and plasma glycine with CSF/plasma glycine >0.08	Poor, death usually within the first year	Benzoate (250–750 mg/kg/d), dextromethorphan Avoid valproate and vigabatrin
GABA transaminase deficiency	Neonatal-infantile	Intractable seizures, lethargy, irritability, severe delay, hypotonia, hyperreflexia, accelerated growth	Increased GABA in serum and CSF	Poor, death usually within the first 5 years	Symptomatic only
Sulfite oxidase deficiency and molybdenum cofactor deficiency	Neonatal or infantile	Intractable seizures, progressive neurocognitive decline, acquired microcephaly, MRI demonstrating leukoencephalomalacia and atrophy. Later onset forms may present with encephalopathy, focal findings and seizures after a febrile illness	Elevate sulfite levels on fresh urine. Low plasma homocysteine. Confirm with specific enzyme analysis of fibroblasts	Poor	Some patients may improve with vigabatrin, dextromethorphan. Some may improve with dietary restriction of methionine
Peroxisomal disorders	Neonatal or infantile	Hepatic disease, developmental delay, retinopathy, deafness, seizures, cortical migration defects	Abnormal very long chain fatty acids and/or phytanic acid	Variable, depending on phenotype	Symptomatic only
Menkes disease	Infancy	Developmental regression, seizures, particularly spasms, hypopigmentation of skin and hair, hypothermia, characteristic “kinky” hair	Low serum copper and ceruloplasmin. Confirm with ATP7A mutation analysis	Poor with progression to death typically within 5 years	Copper histidine supplementation and supportive treatment
Glutaric acidemia type 1	Infancy and childhood	Macrocephaly, acute neurologic decompensation with infection or febrile illness, characterized by hypotonia, opisthotonic posturing, dystonia or dyskinesia, seizures, encephalopathy. MRI shows widening of sylvian fissures	Increased urinary glutaric acid	Poor, although detection and treatment before decompensation may improve outcome	Low protein diet (low lysine and tryptophan) with carnitine supplementation

*Continued on following page*

**TABLE 71-2** Inborn Errors of Metabolism Associated With Infantile-Onset Epilepsies (*Continued*)

Metabolic Disorder	Age at Onset	Clinical	Diagnostic Test	Prognosis	Treatment
Biotinidase deficiency	Neonatal through childhood	Seizures, hypotonia, developmental delay, ataxia, dermatitis, hair loss, autistic behavior, optic atrophy	Low serum biotinidase	Outcome can be good if diagnosed and treated early	Biotin supplementation (10 mg/day)
Succinic semialdehyde dehydrogenase deficiency	Infancy and childhood	Developmental delay, ataxia, hypotonia, seizures, hyperactivity, behavior problems. Increased T2 signal in globus pallidus, dentate nucleus and subthalamic nucleus with cerebral atrophy	Increased gamma hydroxybutyric acid in urine. Confirm with enzymatic analysis or Aldh5A1 gene sequencing	Variable, treatment targeted at symptoms	Symptomatic
Congenital hyperinsulinism and hyperammonemia	Infancy and childhood	Epilepsy, intellectual disability	Postprandial hypoglycemia, hyperammonemia. Confirm by mutation analysis in glutamate dehydrogenase gene	Outcome can be good if diagnosed and treated early	Protein restriction, diazoxide
Tetrahydrobiopterin deficiencies	2–12 months	Cognitive regression, microcephaly, generalized seizures, irritability, dystonia, rash, basal ganglia calcifications	Elevated Phe on plasma amino acids, abnormal pterins and neurotransmitters in CSF	Outcome can be good if diagnosed and treated early	BH4 supplementation May need additional supplementation with neurotransmitter precursors based on type
Glucose transporter deficiency	Birth to early childhood	Seizures (infantile-onset focal or generalized, or early-onset absence epilepsy), microcephaly, developmental delay, acquired ataxia, paroxysmal dyskinesia	Low CSF/plasma glucose with normal or low lactate Confirm with SCL2A1 genetic testing	Variable, depending on duration of symptoms before treatment with ketogenic diet	Ketogenic diet
Cerebral folate deficiency	Childhood to adolescence	Intractable epilepsy, intellectual disability or regression, microcephaly, dyskinesias, autism	Low CSF methyltetrahydrofolate Further testing requires mutation analysis in FOLR1 gene, assessment for antibodies to folate receptors, and if workup for secondary causes of cerebral folate deficiency	Variable, depending on exact etiology and duration of symptoms before treatment	Folinic acid supplementation (0.5–5 mg/kg/d)
Mitochondrial disorders	Infancy to adulthood	Focal or generalized seizures, spasms, deafness, myopathy, lactic acidosis, ataxia, optic atrophy, hepatic dysfunction,	Elevated plasma and CSF lactate, may have evidence of cardiac, renal or hepatic dysfunction. Elevated lactate peak on MRS. Muscle biopsy, specific genetic analysis	Variable, depending on specific type	Avoid valproate Mitochondrial cocktail (carnitine, coenzyme Q, riboflavin) Ketogenic diet may be helpful in some conditions, e.g. pyruvate dehydrogenase complex deficiency (and contraindicated in others, e.g. pyruvate carboxylase deficiency)
Congenital Disorders of Glycosylation	Infancy to childhood	Developmental delay, hypotonia, failure to thrive, multisystem disease, inverted nipples and/or abnormal fat pads, cerebellar hypoplasia	Abnormalities in carbohydrate deficient transferrin analysis. Confirm with specific genetic analysis	Variable depending on etiology	Symptomatic

waning, multifocal, slow spike and wave discharges. The status epilepticus can become life-threatening, requiring intensive care.

Children in the third subgroup typically have mild neurologic impairment at baseline and experience only focal seizures. The myoclonic status begins between age 7 months to 5 years with rhythmic myoclonic jerking of the face and limbs. The EEG shows nearly continuous generalized or bilateral spike and wave discharges that can have a notched delta appearance. Over days to weeks, there is clinical deterioration with cognitive regression, frequent focal seizures, and movement disorders.

### Neuroimaging

Neuroimaging in the first subgroup, of genetic etiology, is normal. In the second subgroup, neuroimaging can be normal (unknown etiology) or show cortical malformations of variable severity. Imaging in the third subgroup is consistent with perinatal anoxic injury. Although there is clinical progression in this third subgroup, the neuroimaging remains unchanged.

### Other Neurologic Findings

Development in all children is abnormal at baseline. In the first two subgroups, there is severe neurologic impairment. In the third subgroup, the degree of neurologic impairment at baseline is mild but progresses over days to weeks with movement disorders appearing.

### Other Laboratory Studies

A comprehensive genetic evaluation as well as careful neuroimaging with epilepsy protocol to detect malformations of cortical development should be performed (Table 71-1). For those with unknown etiology, a comprehensive metabolic evaluation should be considered (Table 71-2).

### Differential Diagnosis

West syndrome can be excluded by differentiating the myoclonic seizures from epileptic spasms and the lack of hypsarrhythmia on EEG. Myoclonic status and similar initial EEG findings can be seen in Lennox-Gastaut syndrome and myoclonic-atonic epilepsy, making them difficult to exclude. However, other seizures typically seen with these syndromes occur much less frequently. Myoclonic seizures are a later occurrence in children with Dravet syndrome.

Identifying the underlying etiology can be helpful in differentiating this syndrome from progressive myoclonic epilepsies.

### Treatment

The seizures are pharmacoresistant. Mitochondrial disorders should be excluded before initiating valproic acid. The myoclonic status epilepticus is typically refractory to benzodiazepines and often requires intensive care unit therapy.

### Outcome

The myoclonic status epilepticus can resolve, often within 2 to 4 years; however, refractory brief absences and infrequent myoclonic seizures continue. Intellectual disability remains severe. Unfortunately, mortality due to status epilepticus is high in the second subgroup and survivors continue to have status epilepticus into adulthood.

## FOCAL SYNDROMES

### Epilepsy of Infancy With Migrating Focal Seizures

Epilepsy of infancy with migrating focal seizures is an early-onset epileptic encephalopathy that begins in previously healthy infants after the neonatal period but before the sixth month.

### Seizures

Initially, sporadic, focal seizures occur, with semiology suggestive of multifocal onset. Seizures may be accompanied by autonomic signs, including apnea, cyanosis, and flushing (Caraballo, et al., 2008). Seizure frequency and duration increase and frequently culminate in refractory status epilepticus requiring treatment with general anesthesia. After 1 to 5 years, seizures once again become sporadic and easier to control, although seizure clusters and intermittent status epilepticus can still occur.

### Other Neurologic Findings

At onset, children have normal neurologic examinations. As the seizures become refractory, hypotonia, loss of motor milestones, and subsequent developmental delay are noted in all infants. Progressive microcephaly, feeding issues, and decreased visual attentiveness are frequent.

### Etiology

The etiology is typically unknown with genetic causes found in a minority of children.

### EEG Findings

The interictal EEG can initially be normal, but over time, slowing and multifocal epileptiform discharges emerge. The ictal recording demonstrates variable electroclinical patterns (Fig. 71-5).

### Neuroimaging

At onset, neuroimaging is normal in all children. Over time, mild to moderate ventricular enlargement and possible mesial temporal sclerosis may evolve.

### Other Laboratory Studies

Extensive neurometabolic evaluations and, in most cases, genetic evaluations are normal.

### Differential Diagnosis

Structural etiologies such as cortical dysplasia should be ruled out with detailed neuroimaging. Infections such as meningoencephalitis and metabolic disorders can also present with multifocal seizures. Furthermore, both benign infantile epilepsy and benign familial infantile epilepsy can present at a similar age with focal seizures. However, these seizures are pharmacoresponsive and development remains normal in essentially all patients.

### Treatment

Although stiripentol, clonazepam, potassium bromides, and levetiracetam may be helpful, seizures are typically refractory to all therapies.

**Figure 71-5.** EEG during a focal dyscognitive seizure in an infant with epilepsy of infancy with migrating focal seizures demonstrating high amplitude delta frequency sharp waves over the right hemisphere initially (a), followed by involvement of the midline head regions as the right temporal region seizure discharge resolves (b), followed by independent left temporal discharge (c).

## Outcome

The outcome is typically poor with severe hypotonia, intellectual disability, refractory seizures, and high mortality, although there may be phenotypic variability.

## Benign Epilepsy of Infancy/Benign Familial Infantile Epilepsy

Infants with convulsive seizures and normal neurologic examination, with or without family history of similar seizures, can sometimes follow a benign course. These syndromes have now been termed "benign epilepsy of infancy (BEI)" and "benign familial infantile epilepsy (BFEI)" (Vigevano, 2005). The seizure semiology and outcome are similar for the two syndromes, thus they will be discussed conjointly.

## Seizures

The seizures in BEI and BFEI may initially be sporadic, but eventually occur in clusters. Within the cluster, seizures typically occur several hours apart, and the infant returns to baseline in between events. The semiology is variable and includes staring, unresponsiveness, behavioral arrest, eye deviation, head turn, apnea, and automatisms with or without generalized convulsions.

## Other Neurologic Findings

Neurologic examination and development are normal. Paroxysmal kinesigenic choreoathetosis and dystonia have been reported to coexist in individuals and families with BFEI. Later development of familial hemiplegic migraine has also been reported.

## Etiology

The etiology of BEI is unknown, and the diagnosis can be difficult to make with certainty at onset. Comprehensive metabolic and neuroimaging studies should be done to exclude other causes of early-onset multifocal epilepsy (Tables 71-1 and 71-2).

BFEI has been linked to chromosomes 2, 16 (PRRT2 mutations), and 19 and displays autosomal dominant inheritance with variable penetrance.

## EEG Findings

A normal interictal EEG is felt to be one of the characteristics of BEI and BFEI. Ictal EEGs have demonstrated focal onset in all seizures, including those with a generalized tonic-clonic component without focal semiology (Vigevano, 2005).

## Neuroimaging

Normal neuroimaging must be present for infants to be diagnosed with either BEI or BFEI. Malformations of cortical development may be difficult to detect on MRI before 2 years of age, so careful clinical follow up is needed to ensure the accuracy of this diagnosis.

## Differential Diagnosis

Careful evaluation must be undertaken to assess for malformations of cortical development or other structural causes, as well as potential metabolic disorders. The normal neuroimaging, normal interictal EEG, and normal development throughout the course of this epilepsy are helpful in securing the diagnosis. Furthermore, this is a pharmacoresponsive

syndrome, which would not be expected from epilepsy due to structural or metabolic etiology.

## Treatment

The seizure clusters are typically several hours apart and can continue for 1 to 3 days. Phenobarbital has been more helpful than benzodiazepines in aborting clusters, although doses higher than 10 mg/kg may be necessary. Multiple preventative medications have been tried and all appear to be beneficial.

## Outcome

Children with BEI and BFEI are able to discontinue antiseizure drug therapy by their early preschool years, without recurrence of focal seizures or emergence of new epilepsy syndromes. All children continued to have normal neurologic examinations and normal development. Recurrence of seizures or emergence of learning disorders/intellectual disability should prompt further evaluation.

## Hemiconvulsions, Hemiplegia, and Epilepsy Syndrome (HHE)

HHE is a rare condition that usually presents under age 4 years with prolonged unilateral convulsive status epilepticus in the context of a febrile illness followed by hemiplegia. Months to years later, intractable epilepsy emerges.

## Seizures

HHE typically presents initially with unilateral, clonic status epilepticus lasting for more than 24 hours. Severe autonomic symptoms can also emerge. The initial seizures are acute symptomatic seizures and, therefore are not epilepsy. This stage is called hemiconvulsions and hemiplegia syndrome (HHS).

Recurrent unprovoked seizures occur in two-thirds to three-fourths of children after months to years of seizure freedom, at which point the epilepsy is typically pharmacoresistant. The seizures are focal dyscognitive seizures arising from the temporal regions or from multiple foci within the affected hemisphere.

## Other Neurologic Findings

Most children have normal growth and development before onset of the seizure. Hemiplegia ipsilateral to the side of convulsive status epilepticus occurs and must last at least 1 week. Additional neurologic findings such as visual field deficits and aphasia may be seen.

## Etiology

The etiology for HHE is unknown. Even in those children with preexisting, structural abnormalities, the cause for the acute-onset, febrile, prolonged hemiconvulsion and subsequent hemiparesis is unclear. The febrile component and mild illness suggest that hyperthermia and inflammation are important contributors to the pathogenesis.

## EEG Findings

In the acute phase, EEG is important to ensure complete electrographic cessation of the seizure. The ictal EEG demonstrates rhythmic, high amplitude, 2 to 3 Hz slow wave activity bilaterally but higher over the affected hemisphere and often associated with rhythmic spikes and low amplitude fast activity contralateral to the clonic activity. Postictally, the slowing over

the affected hemisphere continues, whereas the unaffected hemisphere has gradual reappearance of normal background activity.

During the chronic phase, presurgical evaluation is often pursued for the intractable epilepsy. The interictal EEG typically shows multifocal spikes and sharp waves, typically most prominent over the affected hemisphere.

### Neuroimaging

Neuroimaging is essential for the diagnosis and should be done early. At the time of hemiconvulsive status epilepticus, the MRI reveals edema of the affected hemisphere maximally involving the subcortical white matter. There is hyperintensity on diffusion weighted imaging sequences that corresponds with decreased apparent diffusion coefficient. MRI angiography is normal. These MRI abnormalities are independent of any vascular territory and resolve within 1 month. Hemiatrophy and possible hippocampal sclerosis occur over weeks to months.

### Other Laboratory Studies

Additional studies to determine potential metabolic, vascular, infectious, or autoimmune etiology should be completed but are normal in these patients.

### Differential Diagnosis

Stroke can be excluded with neuroimaging that does not follow vascular territory, absence of hemorrhage, and normal vascular studies. Metabolic disorders such as mitochondrial cytopathies can present with stroke-like episodes and seizures, especially in the setting of illness. However, seizures due to acute stroke typically present first with motor deficit and then seizure.

Acute traumatic brain injury and neoplasm are also excluded by neuroimaging. The acute edema followed by profound hemiatrophy seen in HHE would make malformation of cortical development unlikely.

Infectious and autoimmune etiologies should be evaluated. Febrile infection-related epilepsy syndrome (FIRES) is characterized by onset of seizures that evolve to refractory status epilepticus in otherwise healthy, school-aged children during or shortly after a nonspecific febrile illness. Unlike HHE, cognitive deficit and pharmacoresistant epilepsy occur at onset.

Finally, Rasmussen's encephalitis typically presents with focal motor seizures and epilepsy partialis continua, but the onset of motor weakness is gradual as is the atrophy on MRI.

### Treatment

The treatment in the acute phase is supportive. There is no evidence that initiating chronic treatment with antiseizure drugs will prevent the later onset of unprovoked seizures. Presurgical evaluation should be pursued for pharmacoresistant seizures in the chronic phase.

### Outcome

Children with HHE are typically left with variable degrees of permanent motor and cognitive deficits.

The seizures in HHE are usually pharmacoresistant, but seizure control may be obtained through surgical resection. Those with proven temporal lobe onset have excellent seizure outcome after temporal lobectomy, even in the presence of more extensive imaging abnormalities. Multilobar resection or hemispherectomy may be needed in those with extratemporal onset or multiple ictal foci within one hemisphere.

## UNDIFFERENTIATED SYNDROMES

### West Syndrome

West syndrome is the most common epileptic encephalopathy in infancy, with an estimated incidence of 3 to 4.5 per 10,000 live births. It consists of a triad of: (1) epileptic spasms; (2) hypsarrhythmia on EEG; and (3) arrest or regression of psychomotor development. The onset of epileptic spasms is typically between 3 to 12 months of age.

### Seizures

Epileptic spasms involve a sudden flexion, extension, or mixed flexion-extension movement of the proximal and truncal muscles, lasting 1 to 2 seconds, and occur in clusters shortly after waking. Focal seizures may also be seen and suggest an underlying focal pathology.

### Other Neurologic Findings

Developmental delay is frequently evident, even before spasm onset. Focal or generalized motor findings, impairments in visual attention, and microcephaly are common. A dermatologic examination using a Wood's lamp should be undertaken to evaluate for neurocutaneous disorders such as tuberous sclerosis. Abnormalities such as organomegaly, unusual odor, or dysmorphic features would suggest the possibility of a metabolic or genetic etiology.

### Etiology

An obvious cause of spasms is identified in just over half of cases after initial clinical evaluation and MRI and in up to three fourths of infants after further investigations. Structural etiologies, including malformations of cortical development, tuberous sclerosis, and perinatal brain injury, are most common. Genetic etiologies are increasingly recognized (Paciorowski, et al., 2011). In contrast, metabolic etiologies are less frequent.

### EEG Findings

The classic finding on interictal EEG in West syndrome is hypsarrhythmia, characterized by very high amplitude (often up to 500 microvolts), asynchronous slow waves, and multifocal spikes and polyspikes. Absence of hypsarrhythmia in a child with a suspicious history does not rule out a diagnosis of West syndrome, and a prolonged EEG recording should be considered. Hypsarrhythmia may also be asymmetric in patients with focal lesions.

The typical ictal correlate of an epileptic spasm is a high voltage, often generalized sharp or slow wave followed by an electrodecrement, consisting of low amplitude fast activity.

### Neuroimaging

Brain MRI is a necessary test in all cases of West syndrome without known etiology. MRI reveals a cause in 35% to 41% of cases. If the initial MRI is normal and seizures persist, an MRI may be repeated every 6 months and should be redone after age 24 to 30 months, when myelination is more mature, to detect cortical dysplasia (Gaillard, et al., 2009).

### Other Laboratory Studies

In children without a clear etiology after imaging, further genetic and metabolic studies should be obtained (Tables 71-1 and 71-2). If imaging is suggestive of an inborn error of metabolism, an extensive metabolic investigation is warranted. In those with normal MRI, genetic testing, including comparative

genomic hybridization array, epilepsy gene panel, whole exome sequencing, or mitochondrial genetic studies, should be considered.

## Treatment

Hormonal therapy (ACTH or prednisolone) and vigabatrin have been proposed as first-line therapy for infantile spasms. Based on the evidence-based guideline from the American Academy of Neurology, ACTH may have greater short-term efficacy than vigabatrin once infants with tuberous sclerosis are excluded (Go, et al., 2012). Vigabatrin is the treatment of choice in infantile spasms due to tuberous sclerosis, with seizure cessation being seen in 95% of cases and may be effective in spasms due to focal cortical dysplasia. There is insufficient evidence to recommend other medications or the ketogenic diet as first-line agents.

Children with infantile spasms due to focal cortical structural abnormalities not controlled with hormonal therapy and vigabatrin should be expediently referred for possible surgical treatment, even with nonlocalizing EEG.

## Outcome

Most children with West syndrome have intellectual disability at follow up and are also at risk for autism (Widjaja, et al., 2015; Riikonen, 2001). The underlying etiology is the most critical predictor of developmental outcome. Additional factors predictive of better outcome include shorter duration from spasm onset to diagnosis, favorable response to initial therapy, absence of other seizures before infantile spasms, and absence of atypical spasms, focal seizures, or asymmetric EEG abnormalities.

Infantile spasms resolve in the majority of children by the early preschool years. However, 50% to 90% of cases develop other seizure types, most commonly either Lennox-Gastaut syndrome (27% to 50%) or focal/multifocal epilepsy.

West syndrome also carries a significant mortality risk. One large study that followed 214 children for a mean of 25 years reported that 31% had died; the most frequent causes of death included infection and complications of therapy (Riikonen, 2001).

## Dravet Syndrome

Dravet syndrome is a catastrophic childhood epilepsy syndrome that leads to intellectual disability and motor deficits (Brunklaus, et al., 2012). The estimated incidence is approximately 1 to 2 per 40,000 live births.

## Seizures

This epilepsy syndrome begins in the first 18 months of life with prolonged, hemiconvulsive seizures initiated by fever (often associated with vaccines) or hyperthermia. Over the next several months, recurrent febrile and afebrile seizures occur, often switching sides.

In early childhood other seizure types emerge, including myoclonic, atypical absence, and focal seizures. Obtundation status, in which children appear poorly responsive and have erratic myoclonus may also be seen and can persist for hours. Reflex seizures are frequent with the most common provoking factor being hyperthermia. Tonic seizures are unusual in Dravet syndrome.

## Other Neurologic Findings

Development is normal at epilepsy onset, but then there is a variable decline in developmental quotient over time. Autistic traits and hyperactivity have also been reported. A greater

degree of cognitive and behavioral impairment has been linked to higher frequency of seizures.

The neurologic examination is typically normal at epilepsy onset. However, ataxia and pyramidal signs, as well as crouch gait, may develop.

## Etiology

SCN1A mutations (mostly de novo) are found in 80% of patients. However, 5% show familial mutations in which affected relatives are mildly affected with a genetic epilepsy with febrile seizures plus (GEFS+) phenotype. The genetic finding must be correlated to epilepsy phenotype to reach an accurate diagnosis.

## EEG Findings

The EEG background is typically normal at epilepsy onset. After 1 to 2 years, patients show diffuse background slowing.

Epileptiform discharges, seen in a minority at onset, are most commonly generalized and may be triggered with photic stimulation. At age 2 to 5 years, an increase in generalized paroxysmal abnormalities, as well as emergence of focal and multifocal discharges, occurs.

## Neuroimaging

Neuroimaging studies are normal at presentation, although scans done later in life may show abnormalities, likely due to the prolonged seizures.

## Treatment

Dravet syndrome is extremely pharmacoresistant (Chiron, 2011). The goals of treatment are to avoid prolonged status epilepticus, reduce frequency of briefer seizures, and avoid problematic adverse effects of multiple agents used at high doses.

Sodium channel agents should be avoided as they exacerbate seizures. First-line therapy typically involves valproic acid, clobazam, or topiramate. Stiripentol is often considered if first-line therapy is ineffective and has been shown to reduce seizures and status epilepticus. Bromides and ketogenic diet have also been effective.

Isolated case reports and small studies have suggested possible efficacy of fenfluramine, verapamil, fluoxetine, cannabidiol, vagus nerve stimulation, and deep brain stimulation. Careful clinical trials are needed.

Caregivers of children with Dravet syndrome should be taught to administer a home dose of rescue benzodiazepine, and a treatment plan for management of prolonged seizures should be provided.

## Outcome

Seizures remain medically refractory. Many seizure types reduce or resolve by early adulthood, with brief, nocturnal, generalized tonic-clonic seizures remaining as the main seizure type. Most patients have moderate to severe disability and cannot live independently as adults.

There is an increased mortality rate in children with Dravet syndrome, with approximately 15% dying by early adulthood, and death is often seizure-related.

## Genetic Epilepsy With Febrile Seizures Plus (GEFS+)

GEFS+ is a common, familial electroclinical syndrome in which two or more family members have phenotypes consistent with this diagnosis (Scheffer and Berkovic, 1997).

Affected individuals exhibit variable phenotypes. The onset is typically between 6 months and 6 years of age.

### Seizures

At the mildest end of the phenotypic spectrum are children with febrile seizures alone, which may be recurrent, prolonged, focal, or occur in clusters. Next most common are those with “febrile seizures plus,” in which febrile seizures either continue beyond the age of 6 years, and/or afebrile seizures also occur. At the severe end of the spectrum are individuals with myoclonic-atonic epilepsy or Dravet syndrome. Some individuals may also present with temporal lobe epilepsy, with or without hippocampal sclerosis.

### Other Neurologic Findings

With the exception of rare cases on the severe end of the phenotypic spectrum, children with GEFS + are typically neurologically and developmentally normal.

### Etiology

GEFS + is usually inherited in an autosomal dominant manner with incomplete penetrance. GEFS + remains a clinical diagnosis, and genetic testing is not required.

### EEG Findings

EEG is not indicated in simple febrile convulsions but may be obtained in those with complex features—particularly focal or prolonged febrile seizures. An EEG is typically obtained in children with afebrile seizures, and the findings in GEFS + are heterogeneous. The background is typically normal, although diffuse slowing may be seen in individuals with severe phenotypes. In individuals with generalized seizures, the interictal recording typically shows generalized discharge, which can become fragmented in sleep. In those with temporal lobe epilepsy, focal discharge is seen.

### Neuroimaging

Neuroimaging is generally not required, particularly with generalized seizures, and is typically normal. Rarely, hippocampal sclerosis can be seen in patients with GEFS + and temporal lobe epilepsy.

### Treatment

Simple febrile seizures alone do not require prophylactic drug therapy. If febrile seizures are prolonged or clustered, caregivers should be taught to administer a home dose of rescue benzodiazepine therapy. Prophylactic antiseizure therapy for afebrile seizures should be geared toward the seizure type. Because many mutations in GEFS + may alter sodium channel function, sodium channel blockers may potentially be more problematic.

Children with epileptic encephalopathies such as myoclonic-atonic epilepsy or Dravet syndrome may also benefit from the ketogenic diet.

### Outcome

The majority of children with GEFS + have seizures that are easily controlled with medication. Seizures are typically self-limited and resolve at puberty. Rare individuals continue to have generalized seizures into adulthood. Development remains normal.

Children who develop myoclonic-atonic epilepsy are typically pharmacoresistant initially, but many ultimately become seizure free by middle childhood and have remission of their epilepsy.

## CONCLUSIONS

Epilepsies that begin in infancy are associated with high rates of pharmacoresistance and are commonly associated with neurocognitive impairment. Recognition of a specific electroclinical syndrome is imperative to: (1) understand the possible pathogenic mechanisms leading to epilepsy and allow more cost-effective, less invasive, and more streamlined investigations; (2) choose more efficacious therapies to control seizures and prevent associated comorbidities; and (3) better prognosticate long-term development and seizure outcome for families.

## INTRODUCTION

Electroclinical syndromes are important constellations of specific clinical history and electroencephalographic (EEG) findings with onset during a distinct time in brain development. Childhood is a particularly important stage of development in general and epilepsy specifically.

The electroclinical syndromes of childhood can be considered as three distinct categories depending on seizure onset localization. These include childhood generalized epilepsy syndromes, focal epilepsy syndromes of childhood, and a category best described as, “undetermined as to whether focal or generalized.”

Making the diagnosis of a specific electroclinical syndrome allows the clinician to provide specific diagnostic and therapeutic recommendations to the family and enhances counseling related to treatment response, remission rates, and potential psychosocial comorbidities.

## CHILDHOOD GENERALIZED EPILEPSY SYNDROMES

### Childhood Absence Epilepsy (CAE)

#### Clinical Characteristics

CAE is the most common pediatric epilepsy syndrome comprising 10% to 17% of all childhood onset epilepsies. Females are affected more frequently than males. The International League Against Epilepsy (ILAE) criteria include age of onset between 4 and 10 years that peaks between 5 and 7 years.

The main clinical manifestation of childhood absence seizures is an abrupt impairment of consciousness (without an aura) accompanied by one or more additional features including behavioral arrest, staring, eyelid fluttering, and/or hand automatisms followed by no significant postictal confusion or lethargy. The impairment of consciousness can be assessed at the bedside by asking the child to repeat a code word or perform a continuous motor task such as tapping. Absences can be provoked by hyperventilation. The duration of typical absence seizures has been reported as 9.4 plus or minus 7 seconds but with a range from 1 to 44 seconds. These seizures can be very frequent and occur at least daily but in the most severe cases can occur hundreds of times per day.

The ILAE Report on Terminology and Classification revised in 2010 distinguishes between typical and atypical absence seizures (Berg, et al., 2010). In contrast to typical absence seizures, atypical absences tend to have a less abrupt onset and offset, variable impairment of consciousness, and prolonged duration.

#### EEG Findings

The characteristic ictal electroencephalogram (EEG) of a typical absence seizure demonstrates generalized, bilaterally synchronous, spike and wave complexes with frontal predominance and repeating at 3 to 4.5 Hz (Fig. 72-1). There is a gradual slowing of the frequency from onset to termination. Often the onset is not truly bilaterally synchronous but rather

with one hemisphere preceding the other by a few milliseconds. A duration of 3 seconds is a clinically reasonable “rule” for distinguishing a burst from a seizure and provides an objective EEG measure when it is difficult to identify a clinical change (Glauser, et al., 2010). Interictal background activity is usually normal in patients with CAE although high voltage occipital intermittent rhythmic delta activity (OIRDA) has been reported in 15% to 38% (Holmes, et al., 1987).

#### Etiology

CAE is categorized as an idiopathic, and presumed genetic, epilepsy syndrome. Over the past 50 years multiple theories have been proposed to explain the generation of the diffuse spike and wave discharges that characterize absence seizures. Initially, the centrencephalic theory suggested that these rhythms were generated by cells in the midline thalamus that then projected diffusely to the cortex. Similarly, a more recent “thalamic clock” theory implicated the reticular thalamic nucleus as the generator that drives the cortical rhythms seen on EEG. Other investigators have highlighted focal cortical regions as generators for these seizures which then spread diffusely through corticocortical connections. The “corticothalamic” theory of generation highlights the interaction between oscillations in the thalamus and the presence of an excitable cortex that leads to the spike wave discharges. Investigations in animals and humans have highlighted the importance of focal cortical regions that may force larger areas of cortex into a pathologic state, which is then perpetuated by thalamocortical connections.

Genetics has been known to play a role in the development of CAE for over 70 years and recent work has highlighted the genetic complexity of this syndrome. Small populations of affected patients have been shown to have various mutations in genes coding for GABA receptor subunits, nonion channel proteins, and calcium channels.

#### Treatment

Before 2010 there were only a few, small, randomized, controlled trials completed to assess the most effective monotherapy for children with CAE, and none of them were categorized as Class I or II. These were insufficient for informing routine clinical practice. However, in 2010 a NIH funded double-blind, randomized, multicenter, comparative-effectiveness clinical trial compared ethosuximide, valproic acid, and lamotrigine as initial monotherapy in 446 patients with CAE. Significantly higher freedom from failure rates were seen at the 16 to 20 week visit in patients taking ethosuximide (53%) and valproic acid (58%) than those on lamotrigine (29%;  $p < 0.001$ ). In addition, dysfunctions of attention was seen less in the ethosuximide than valproic acid group (33% versus 49%;  $p = 0.03$ ). Taking these results together, the authors concluded that ethosuximide is the best initial therapy for CAE. However, this “best” therapy still failed in 47% of subjects (14% due to seizures, 24% due to intolerable side effects, 13% study withdrawal). At the 12-month mark of double-blind therapy, ethosuximide continued to demonstrate superior effectiveness compared with lamotrigine and less attentional toxicity

**Figure 72-1. Typical absence seizure.** EEG showing a typical absence seizure with generalized 3 Hz spike and wave discharges with a bifrontal predominance.

compared with valproic acid, reinforcing it as optimal initial monotherapy for CAE (Glauser, et al., 2013).

### Prognosis

Although often considered a “benign” epilepsy syndrome, CAE has a variable clinical course with far lower remission rates than other classic “benign” epilepsies such as benign epilepsy with central temporal spikes. Variable remission rates for CAE have been reported, ranging from 21% to 74%. Multiple prospective cohort studies have reported seizure free rates of 57% to 74% in their patients with CAE.

In those patients without remission of CAE, it has been reported that generalized tonic-clonic seizures (GTCs) develop in approximately 40% (range of 35% to 60%). These tend to occur between 5 and 10 years after the onset of absence seizures, when the children are between 8 and 15 years of age. Long-term follow up (median 7.0 years) of the NIH-funded CAE clinical trial cohort showed only 12% had experienced at least one GTC. Importantly, children who responded to initial ethosuximide monotherapy had a particularly low risk of developing later GTCs.

A consideration for patients with CAE is the possibility of accidental injury. This is a common problem with 20% of patients reported to suffer an injury during an absence seizure. The risk of accidental injury from an absence seizure has been estimated at 3% per person year.

Although clinical seizure outcomes in CAE can be favorable, these children have increased rates of neuropsychiatric comorbidities, including attention problems, depression, anxiety, low self-esteem, and social isolation. The 2010 CAE monotherapy trial reported normal overall cognition in the cohort, but 35% had pretreatment attention deficits that did not resolve, even when seizures were well controlled.

### Generalized Epilepsy With Eyelid Myoclonia (Jeavons Syndrome)

Eyelid myoclonia with absences is an epilepsy syndrome characterized by an absence seizure with special features. These

seizures consist of prominent jerking of the eyelids with an upward deviation of the eyes, often triggered by eye closure. Eyelid myoclonia with absences can occur as a part of idiopathic (Jeavons syndrome), cryptogenic, or symptomatic epilepsies. The ictal pattern of eyelid myoclonia with absences consists of diffuse 3 to 6 Hz polyspike and wave complexes. A generalized photoparoxysmal response can also be seen on EEG.

This syndrome has a likely genetic etiology given several reports of affected identical twins, but specific gene mutations are unknown. It is commonly thought that this syndrome is resistant to pharmacologic treatments. The most commonly used medications are valproic acid, ethosuximide, benzodiazepines, phenobarbital, and levetiracetam. Patients are counseled to avoid clear seizure triggers, and nonpharmacologic treatments such as wearing glasses with colored filters can be recommended. The long-term outcome of this syndrome is poorly understood but is typically considered lifelong and treatment resistant.

### Epilepsy With Myoclonic Absences (Tassinari Syndrome)

These seizures are characterized by absence seizures that are accompanied by severe, rhythmic, and bilateral clonic or tonic activity. Age of onset is 7 years (range of 1 to 12 years). A majority will have additional seizure types, most commonly GTCs and cognitive impairment is present in approximately 50% of patients. The ictal findings are difficult to distinguish from typical absence seizures, but jerks occurring at 3 Hz may be time locked to the spike component.

The cause is unknown but almost 20% have a family history of epilepsy. These seizures are usually considered pharmacoresistant. Medications used include those used to treat typical absence seizures. There is not much data about outcome; it seems a majority will convert to other seizure types over time, and cognitive impairment becomes severe, especially in those patients with frequent GTCs.

## Epilepsy With Myoclonic-Atonic (Formerly Astatic) Seizures (EMAS)

This epilepsy syndrome is characterized by multiple seizure types such as myoclonic-atic, absence, tonic-clonic, and tonic. Episodes of nonconvulsive and myoclonic status epilepticus have been reported. Age at onset has a peak of 3 years (range of 18 months to 5 years). The interictal EEG can be normal, but eventually frequent bursts of generalized spike and polyspike and wave discharges are seen along with central-parietal theta slowing. The EMG just after the jerk is often a brief silent period representing the atonic component.

EMAS is thought to have a predominantly genetic etiology. Studies have shown a relationship between EMAS and genetic epilepsy with febrile seizures plus (GEFS+). Initial pharmacologic treatment of EMAS usually consists of valproic acid, ethosuximide, or benzodiazepines, with those who are drug resistant considered for dietary therapy. If the atonic component is severe, then wearing a helmet should be considered. EMAS spontaneously remits in many (50% to 89%) patients. The remaining minority of patients can have intractable epilepsy with intellectual deficiency.

## Lennox-Gastaut Syndrome

### Clinical Characteristics

Lennox-Gastaut syndrome (LGS) is characterized by a constellation of symptoms and EEG findings, including: (1) multiple generalized seizure types such as atypical absence, tonic, atonic, and myoclonic; (2) diffuse slow spike and wave interictal pattern; (3) paroxysmal fast activity during sleep; and (4) cognitive abnormalities. Onset is usually by the age of 8 years, with a peak incidence at 3 to 5 years of age and a male pre-

dominance. Approximately 20% to 40% of cases have a preceding diagnosis of West syndrome.

Multiple seizure types can occur in LGS (Hancock and Cross, 2013):

1. Tonic seizures are the most common and can be bilaterally symmetric or unilateral.
2. Atypical absence seizures are also commonly seen and can have subtle clinical features with a gradual start and stop.
3. Atonic seizures are less common and are characterized by a rapid loss of muscle tone with symptoms ranging from subtle head drops to violent drops to the ground.
4. Myoclonic seizures have been reported with various incidences in LGS, from rare to up to one-third of patients.
5. Status epilepticus occurs in two-thirds or more of patients with LGS. Status can be either nonconvulsive or convulsive (tonic). Nonconvulsive status will typically consist of almost continuous absence seizures with intermittent tonic seizures that can last from hours to weeks.

### EEG Findings

The EEG posterior dominant background is slowed in the majority of patients with LGS and usually correlates with the degree of cognitive impairment. The characteristic interictal pattern is diffuse and slow: 2 to 2.5 Hz spike and wave complexes with a frontal predominance (Fig. 72-3). This most often occurs symmetrically, but a more focal or multifocal appearance can be seen. This interictal pattern may be absent at the time of initial epilepsy diagnosis, and in late childhood the interictal abnormalities may become more infrequent or resolve completely.

Paroxysmal fast activity can often, but not always, be seen during slow wave sleep and has been considered by some to

**Figure 72-3. Lennox-Gastaut interictal pattern.** Interictal EEG of a patient with Lennox-Gastaut syndrome showing slow, generalized 1 to 2-Hz spike and wave discharges with a bifrontal predominance.

be a diagnostic feature of LGS. The bursts typically are 10 Hz or faster frequency and are diffusely distributed with an anterior predominance. Careful review of accompanying video may reveal associated subtle clinical tonic symptoms.

The ictal patterns associated with LGS vary with the corresponding seizure types.

### Etiology

Up to 30% of patients with LGS have no known etiology, with normal development and brain imaging at the time of diagnosis. In the remaining patients, a presumed etiology can be determined from brain imaging, neurologic examination, genetic analysis, or metabolic testing. The more common etiologies associated with LGS are congenital brain malformations (focal cortical dysplasia, subcortical band heterotopia, perisylvian polymicrogyria, hypothalamic hamartoma), neurocutaneous diseases (tuberous sclerosis, hypomelanosis of Ito), meningitis/encephalitis, hypoxic ischemic encephalopathy, and genetic epilepsies (i.e., GEFS+).

### Treatment

Monotherapy with antiseizure medications is typically unsuccessful in patients with LGS and because of this polytherapy is often necessary (Montouris, et al., 2014). Five medications have demonstrated efficacy against the seizures associated with the Lennox-Gastaut syndrome in randomized, double-blind, placebo-controlled, adjunctive therapy trials: felbamate, lamotrigine, topiramate, rufinamide, and clobazam. Despite demonstrated efficacy, all these medications have potential adverse effects or specific practical considerations that need to be considered when selecting a medication. No one specific medication or combination of medications works for all patients with LGS. Finding the optimal combination of medications for LGS patients is a trial and error process. Commonly used medications without randomized double-blind, placebo-controlled, adjunctive therapy clinical trial evidence of efficacy against the seizures associated with LGS include: valproic acid, clobazepam, and zonisamide.

Nonpharmacologic treatments such as the ketogenic diet and vagus nerve stimulator (VNS) can also be effective in these children with treatment resistant seizures. The ketogenic diet has been associated with a greater than 50% reduction of seizures in approximately half of patients with LGS, with some patients having a greater than 90% reduction of seizures. Corpus callosotomy is a palliative treatment that may significantly reduce both atonic seizure frequency and severity.

### Prognosis

Prognosis for LGS remains poor despite the availability of new and varied treatments. Most patients have treatment resistant seizures along with significant cognitive deficits which limit their ability to live independently. Persistent daily seizures are present in the majority of patients (60% to 80%) with an early age of seizure onset (before 3 years) as a predictor of poor seizure outcome. Age at seizure onset seems to be a predictor for cognitive development, with earlier onset more likely to be associated with intellectual deficiency.

## CHILDHOOD FOCAL EPILEPSY SYNDROMES

### Benign Epilepsy With Centrotemporal Spikes (BECTS, or Benign Rolandic Epilepsy)

#### Clinical Characteristics

Benign epilepsy with centrotemporal spikes (BECTS) is a common pediatric epilepsy syndrome that is thought to

account for 15% to 23% of all childhood epilepsies. Seizures typically begin between 3 and 13 years of age with a peak at 7 to 8 years of age. Although the “typical” form has easily recognizable clinical features, there are many atypical features that can make an accurate diagnosis challenging. Seizures typically occur shortly after the child falls asleep or just before waking. Some patients will have seizures during both wakefulness and sleep, and approximately 25% may have seizures only during the waking state (Beaussart, 1972).

The seizures of BECTS also tend to be infrequent with the majority of patients having only a single seizure with relatively few (less than 10%) being reported to have frequent seizures (Loiseau, et al., 1988). When occurring during the awakened state, the seizure semiology is described as unilateral perioral paresthesias, unilateral jerking of the orofacial muscles, dysarthria, choking/gagging noises, expressive aphasia, and/or excessive drooling. Consciousness can be maintained as these symptoms occur. These symptoms can then self-resolve or evolve into secondary generalized tonic-clonic movements with loss of consciousness. When occurring during sleep, the semiology tends to be either unilateral facial jerking, often with drooling and/or choking/gagging noises, or secondarily generalized tonic-clonic movements. The seizures tend to be brief, lasting seconds to minutes, but there have been rare reports of status epilepticus in those with an atypical semiology. Post ictal Todd’s paralysis has been reported in 7% to 16% of children.

Aside from seizures, a wide range of cognitive and behavioral problems have been reported in patients with BECTS. General intellectual functioning (full scale IQ) is in the normal range, but these patients perform worse than age-matched controls on tests of language, visual-spatial skills, nonverbal and verbal memory, and attention. Behavioral problems are also more common in this population. Although the literature suggests that these cognitive problems are prevalent in BECTS, they are also commonly reported in patients with childhood epilepsy in general. The specific cognitive domain may vary, however, raising the possibility that specific epilepsy syndromes may be associated with specific neurocognitive phenotypes.

### EEG Findings

The characteristic EEG pattern of BECTS is high voltage, but blunted, spikes in the centrotemporal head regions that can be unilateral or bilateral and become more frequent during drowsiness and non-REM sleep (Fig. 72-6). A horizontal dipole can often be seen with maximal negativity in the centrotemporal region and maximal positivity in the frontal head region. The localization is most often unilateral although bilateral synchronous and asynchronous discharges can be seen. The localization of spikes can vary over time in the same patient. It has been reported that approximately one-third of patients will only have spikes during sleep. There is no known relationship between the frequency of spikes and the number of seizures. The background of the EEG is normal.

It is clear that centrotemporal spikes (CTS) can be seen in a significant percentage (up to 0.7%) of “normal” children with no history of epilepsy. The fraction of children with these EEG findings who then develop BECTS is unclear, but it is thought to be small. For this reason CTS can be considered an incidental finding in children without a clinical history concerning for seizures.

There have been many studies which suggest a possible negative effect of CTS, especially during sleep, on cognition, language, and behavior but none have provided clear proof of a direct relationship.

**Figure 72-6. Benign epilepsy with centrotemporal spikes.** Interictal pattern of a patient with BECTS during stage N2 sleep. Frequent high voltage spikes can be seen independently in the right centrotemporal and left centrotemporal head regions.

## Etiology

Typically, BECTS is not associated with any underlying structural brain abnormalities on routine visual analysis, although studies employing quantitative structural analyses have reported a variety of abnormal cortical thickness and atrophy. Genetic studies have suggested that BECTS has a genetic etiology with complex inheritance patterns, although noninherited factors also seem to play a major role. A few chromosomal loci and specific genes have been associated with the syndrome including the glutamate receptor, *GRIN2A*, as well as mutations in *RBFOX1/3* and *DEPDC5*.

## Treatment

Children with BECTS will have remission regardless of treatment, so pharmaceutical treatment can be avoided in many cases. The decision not to treat is based on the fact that the seizures in most are infrequent and tend to occur nocturnally when the children are in a safe location (i.e., in their beds at home). Occasionally, however, seizures are more frequent or occur during the day so that treatment is necessary. When used, medications include carbamazepine, valproate, clobazam, clonazepam, phenytoin, phenobarbital, gabapentin, and sulthiame.

## Prognosis

The long-term prognosis for BECTS is thought to be excellent with all patients achieving seizure remission and most by age 13 years. This remission has been reported to occur even when the seizures have been initially resistant to treatment. A recent study of patients 30 years after their onset reported that social outcomes were better for BECTS than other types of childhood onset epilepsy.

## Early Onset Childhood Occipital Epilepsy (Panayiotopoulos Syndrome)

The early onset form of benign occipital epilepsy of childhood is referred to as Panayiotopoulos syndrome. Onset is from 1 to 14 years of age with a peak age of onset from 3 to 6 years of age. These seizures, often prolonged and nocturnal, are associated with predominantly autonomic features including

nausea, vomiting, and tonic eye deviation, with consciousness usually preserved. In the majority these are followed by impaired consciousness and evolution to secondary generalized tonic-clonic movements. Occipital spikes are seen in approximately 40% of EEG recordings and may activate with sleep.

This syndrome likely has a genetic etiology, but most children lack a family history of epilepsy. Most patients do not require treatment because the seizures are relatively infrequent. Intermittent benzodiazepine use could be considered for those patients with prolonged events. The outcome of Panayiotopoulos syndrome is typically benign with most patients having between one and five lifetime seizures. Remission usually occurs within 1 to 2 years.

## Late-Onset Childhood Occipital Epilepsy (Gastaut Syndrome)

This syndrome begins in the later childhood years, with a peak between 8 and 11 years of age. Semiology consists of brief visual symptoms—commonly visual hallucinations in the form of colored circular patterns, lasting seconds to minutes. Brief ictal blindness can occur and consciousness often remains intact. Postictally, a severe headache can occur. In many patients the visual seizures are relatively frequent, occurring daily to monthly, but GTCS are rare. The interictal EEG shows runs of rhythmic bioccipital spikes and sharp waves, especially present upon eye closure and with resolution on eye opening.

Familial late-onset childhood occipital epilepsy is thought to be rare. Most patients require treatment, and carbamazepine can result in good seizure control; however, 40% to 50% may not be seizure free. Fifty percent to 60% of patients may have seizure remission within 2 to 4 years.

## CHILDHOOD EPILEPSIES UNDETERMINED WHETHER FOCAL OR GENERALIZED

### Epileptic Encephalopathy With Continuous Spike and Wave During Sleep (CSWS)

CSWS is a term that has been used interchangeably with electrical status epilepticus of slow sleep (ESES). This is an

epileptic encephalopathy that is a rare cause of childhood epilepsy. The diagnosis is typically made between 5 and 7 years of age. Various seizure types are possible, including GTCs during sleep, atypical absence, atonic, and myoclonic, but are often not the major feature. Global developmental delay or deterioration can often be seen as well as specifically selective regression of language. The hallmark EEG finding of CSWS is spike wave activity occurring during 85% of slow wave sleep.

The etiology is poorly understood with a minority of patients having identifiable structural abnormalities such as cortical dysplasia, polymicrogyria, and thalamic lesions in the neonatal period. Most clinicians agree that the ESES pattern should be treated, and the goal should be normalization of the EEG. Although there is no clear consensus on the optimal treatment, valproate, levetiracetam, high-dose benzodiazepines, and corticosteroids are most commonly used. Ketogenic diet or epilepsy surgery can be considered if these initial treatments fail. The prognosis for seizures in patients with CSWS is usually considered good; however, the prognosis of neurocognitive deficits is not as good. Approximately 50% of patients with average neuropsychological functioning and are able to live independently.

### Acquired Epileptic Aphasia (Landau-Kleffner Syndrome)

This is a rare syndrome of childhood, usually presenting between 3 and 7 years of age. The syndrome is characterized by loss of language skills in children who were previously normal. Attention and behavioral problems are very common.

The majority of children with acquired epileptic aphasia (Landau-Kleffner syndrome; LKS) (70%) also present with seizures of various types. The EEG in the awakened state often has a normal background and epileptiform abnormalities, typically in the central, parietal, and/or temporal head regions. During sleep, there is activation, and a pattern such as ESES can be seen.

It is likely that continuous discharges during sleep, especially in the perisylvian region, disrupt networks involved in normal language processing. It is likely that LKS is on the severe end of spectrum, which also includes BECTS and CSWS. Seizures usually respond well to treatment, and the treatment of choice is valproate with or without and adjunctive benzodiazepine. Corticosteroids or ACTH have been used in an attempt to normalize the EEG and prevent long standing language deficits. The long-term prognosis is unclear, although improvements of language ability seem to be related to the age of onset (prelanguage or postlanguage development), with early onset related to poorer prognosis.

### CONCLUSION

The electroclinical syndromes of childhood encompass a diverse collection of epilepsies, from benign to severe (Table 72-1). Childhood is a period of critical brain development, and disruption from seizures and/or electrographic abnormalities could induce lifelong deficits. Early and accurate identification of the electroclinical syndromes of childhood allows clinicians and parents to provide the most effective and appropriate treatments for these children.

**TABLE 72-1** Electroclinical Syndromes of Childhood

Syndrome	Age at Onset (peak)	Clinical Manifestations	EEG Findings	Treatment	Prognosis
Childhood Absence Epilepsy (CAE)	4–10 years (5–7 years)	Impaired consciousness Staring Behavioral arrest Automatisms	Diffuse SWDs 3–4.5 Hz	ETX VPA LTG	21–74% remission rate Neuropsychiatric co-morbidities

## INTRODUCTION

### Ontogenesis and Classification

Adolescence can be a formidable but exciting developmental period. However, when it is complicated by epilepsy it poses a great challenge for both patients and physicians. Adolescent medicine is confronted by immense physical, hormonal, and psychosocial growth occurring between the ages of 10 and 19. Early recognition and treatment of adolescent epilepsy are of paramount importance. The adolescent period also presents a unique set of challenges for seizure control, including medication compliance, pubertal changes, reproductive potential, sleep deprivation, social stressors, and driving (Appleton, 1999).

Adolescent-onset epilepsy can be classified into three broad categories. The first group is the genetic generalized epilepsies (GGEs), which are a heterogeneous group of epilepsy syndromes with substantial genetic influence. This group represents the most common classification of adolescent-onset seizures. The GGEs include juvenile myoclonic epilepsy (JME), juvenile absence epilepsy (JAE), generalized tonic-clonic (GTC) seizures on awakening, and generalized epilepsy with sporadic GTC seizures. The second group is composed of the progressive generalized epilepsies that the result of a structural-metabolic etiology. These include the progressive myoclonus epilepsies and characteristically portend a poorer prognosis compared with the nonprogressive generalized epilepsies. The third group consists of the focal epilepsies. These may be associated with a structural-metabolic pathophysiology, as is the case for temporal lobe epilepsy resulting from hippocampal sclerosis. Genetic and familial causes including mendelian inheritance patterns may also occur, as is the case for autosomal-dominant partial epilepsy with auditory features, autosomal-dominant frontal lobe epilepsy, and familial mesial temporal lobe epilepsy (Wheless and Kim, 2002).

### Epidemiology and Psychosocial Implications of Adolescent Epilepsy

Epilepsy syndromes in adolescents create a substantial health and psychosocial burden. In this age group, 4 in 1000 teenagers, representing a prevalence of 1.5% to 2% of the adolescent population, have epilepsy. In fact, it is one of the most common neurologic conditions in adolescence. Adolescent epilepsy contributes to substantial health-care costs and hospitalizations. In the United States, hospitalizations alone account for approximately one-third of the cost associated with epilepsy. Although there are annual changes in the number of epilepsy patients admitted to hospitals, an estimated 100,000 to 120,000 patients under 20 years of age with epilepsy are admitted to hospitals yearly. The majority of these hospitalizations occur in the adolescent age group. Moreover, grave complications, including injury, drowning, and sudden unexpected death in epilepsy (SUDEP), are real consequences faced by young people with epilepsy (Wheless and Kim, 2002).

Seizures may compromise social interaction, personal identity, career choices, relationships, and sexual maturation. Adolescents with epilepsy have greater rates of depression, anxiety, obsessive behaviors, anhedonia, and low self-esteem compared with adolescents who do not have a history of epilepsy. Additionally, when teens with epilepsy and their caregivers are surveyed, they report experiencing lost time from school and emotional instability as a result of their diagnosis, and approximately one-third of adolescents keep their diagnosis of epilepsy a secret. More than one-third of teens reported the expectation that seizures would hinder their lives, including employment and educational opportunities. These quality-of-life measures raise awareness that adolescent epilepsy is far from benign and can have a significant impact on those with epilepsy and their families (Wheless, 2002).

### Cognitive, Behavioral, and Compliance Issues

Aside from the real and perceived social stigma, there are additional cognitive implications for adolescent epilepsy. Those diagnosed with a GGE, including JAE or JME, tend to have mild cognitive dysfunction with normal intelligence quotients. In temporal lobe epilepsy, there is a diminution in the expected accumulation of learning and memory skills over time, particularly during the adolescent period, with persistent decreased performance in learning and memory-related tasks. Cognitive impairment is encountered with frontal lobe epilepsy, particularly if radiographic white-matter lesions are identified. A hallmark of progressive myoclonus epilepsy is cumulative neurologic disability with early-onset dementia. Finally, antiseizure drugs (ASDs) can have an independent negative influence on attention, memory, processing speed, and intelligence quotients. However, this is in contradistinction to the presumed benefit that these medications have on cognition if seizures are well controlled.

Compliance with medications can be a challenge when treating adolescent epilepsy. Because the reasons for not adhering to treatment are varied and patient specific, it is important for physicians to ask patients and their families about how they view taking medications to assist in identifying barriers to compliance. Effectively adhering to treatment, particularly early on, may increase the chances of becoming seizure-free. Simplifying ASD dosing and avoiding dosing regimens that require children to take medications during school are simple strategies that can improve compliance and reduce social embarrassment. Other recommended strategies include careful monitoring of ASD levels, patient and parent education, and social support.

Avoiding triggers is just as essential in this age group as medication adherence. In GGE, the recommendation to avoid flashing lights or video games that produce stroboscopic light stimulation is a pragmatic recommendation, especially for patients with photosensitivity. Improving sleep hygiene, addressing emotional and psychological stressors, and emphasizing the impact of substance abuse, including alcohol

consumption, are critical. Driving is also a teen-sensitive issue that needs to be addressed. State-specific regulations are available and carry different periods of abstinence for patients with epilepsy. Most careers or jobs are available to people with epilepsy, but employment requiring use of a weapon, such as law enforcement; public transport positions that require a class A or B license; or jobs that require a license to fly, such as airline pilot, should be discouraged. Proactive recommendations are crucial to provide realistic information for career choices.

## ADOLESCENT GENERALIZED EPILEPSIES

The genetic generalized epilepsies (GGEs) are the most frequent type of seizures of adolescent onset. The GGEs are polygenic disorders and represent a biologic continuum between epilepsy syndromes (Beghi et al., 2006).

### Juvenile Myoclonic Epilepsy

Juvenile myoclonic epilepsy (JME) is the most common GGE, representing 5% to 10% of all epilepsies, with a prevalence of 0.1 per 1000 persons (Wheless and Kim, 2002). The onset of JME occurs during adolescence, commonly between 12 and 18 years of age. It was initially described as “epilepsy with impulsive petit mal.” The stereotypical clinical features in all patients with JME consist of myoclonic jerks that often preferentially involve the upper extremities. The jerks involve sudden, irregular, nonrhythmic, lightening-like muscle contractions without loss of awareness, characteristically occurring upon awakening and in the early morning hours. Most individuals with JME exhibit a persistent tendency to manifest seizures as a lifelong condition, with a lower risk of remission (Figure 73-2). Additionally, more than 90% also have generalized tonic-clonic (GTC) seizures, and approximately one-third have absence seizures.

During the interictal period, the routine scalp electroencephalogram (EEG) may be normal. However, 4- to 6-Hz bilateral polyspike- and spike-and-slow-wave discharges are characteristic when observed in repeat or prolonged EEG recordings. Photosensitivity is common, with a photoparoxysmal

response observed in 30% of patients. Asymmetric electroclinical features are not uncommonly observed, including lateralized epileptiform discharges. Most abnormalities emerge during sleep and are precipitated by sleep deprivation. Additional triggers include alcohol consumption, menses, photic stimulation, and awakening from sleep. The hallmark features of the ictal EEG in JME include generalized symmetric frontocentral-predominant polyspike-and-wave discharges with a frequency between 10 and 16 Hz or slow-wave discharges between 2 and 5 Hz. The convulsion may occur independently or follow a crescendo increase in myoclonic seizures, with generalized polyspike-and-slow-wave onset transitioning into the usual pattern of generalized fast rhythms seen with GTC seizures.

### Juvenile Absence Epilepsy

Juvenile absence epilepsy (JAE) affects approximately 0.1 per 1000 persons and has a prevalence of 0.2% to 2.4% of epilepsy cases. JAE is responsible for 8% to 10% of all GGE cases. The typical age of onset ranges between 10 and 19 years but peaks around age 15. The clinical characteristics of the absence seizures in JAE are similar to those of childhood absence epilepsy (CAE). However, the seizures may be somewhat longer and are characterized by speech and behavioral arrest and loss of awareness. Absences may be accompanied by oral-buccal automatisms and repetitive hand movements and picking behaviors, suggesting temporal lobe involvement. However, the ictal EEG demonstrates a generalized 3- to 4-Hz spike-and-wave or polyspike-and-wave discharge. Similar to other GGEs, seizures may be triggered by sleep deprivation, alcohol consumption, and hyperventilation. Myoclonic jerks and generalized seizures often accompany JAE but are a less prevalent feature.

### Genetic Generalized Epilepsies With Convulsions

The GGEs also include those with GTC seizures alone. The syndrome of epilepsy with generalized tonic-clonic seizures on awakening (GTCS-A) may be challenging to separate from epilepsy with sporadic GTC seizures (Figure 73-6). These

**Figure 73-2.** Juvenile myoclonic epilepsy (JME) with generalized tonic-clonic seizures and absences. A 17-year-old with JME shows a 2-second burst of “fast” generalized bifrontally predominant spike and waves. Note the fragmented right frontal spike (arrow) and the 5.57-Hz interspike frequency. Longer bursts of greater than 3 seconds were intermittently associated with absence seizures. (Courtesy of William Tatum.)

**Figure 73-6.** Generalized tonic-clonic (GTC) seizures on awakening. Ictal electroencephalogram (EEG) of a generalized tonic-clonic seizure in a 20-year-old with genetic generalized epilepsy (GGE) manifest as recurrent GTC seizures on awakening. Note the single epileptiform complex and then the continuous myogenic artifact that follows the 8- to 10-Hz anterior-predominant activity. (Courtesy of William Tatum.)

seizures tend to start in the later adolescent period around age 16. However, the age range is between 6 and 28 years, with frequency estimates between 20% to 30% of GGEs. The seizure semiology involves GTC seizures alone, and in the case of GTCS-A, seizures occur within 1 to 2 hours of awakening from sleep. Some patients will also experience seizures in the evening during relaxation or just before falling asleep. Given the timing of these seizures, there appears to be a considerable circadian influence on seizure threshold. Consistent with an important role of sleep regulation in GTCS-A, alterations in the microstructure of the sleep-wake cycle have been observed in these patients.

The interictal EEG typically demonstrates a 3- to 4-Hz generalized spike-and-slow-wave discharge. First described in the mid-1930s, the presence of bilateral, synchronous, and symmetric generalized spike-and-wave activity is the electrographic hallmark of GGE on the EEG. As in the other GGE subtypes, these may be precipitated by sleep deprivation, photic stimulation, stress, and alcohol consumption. GTCS-A can occur with other seizure types, including “phantom” absences, which are absence seizures that go relatively undetected unless EEG is utilized to identify prolonged bursts of generalized spike-and-slow-wave discharges (Shian and Chi, 1994).

### Genetics of Nonmendelian-Inherited Adolescent Epilepsy

The genetics of adolescent-onset epilepsies is an ever-growing topic and has the capacity for providing putative targets for future drug therapies that may be more selective and seizure-subtype specific. JME is regarded as one of several genetic epilepsy syndromes with a complex inheritance pattern. Several gene mutations and loci have been associated with JME. Most of these genes encode for proteins or ion channels that modulate the balance between neuronal excitation and inhibition in cortical and thalamocortical circuits. Mutations in the *GABRA1* gene on chromosome 5 encoding the alpha 1 subunit of the gamma-aminobutyric acid receptor complex ( $GABA_A$ R) involved in synaptic inhibition were found in a large French Canadian family. Linkage analyses have also revealed an association between JME and genes on chromosome 3q26 encoding voltage-gated potassium and chloride channel subunits. Additional studies have identified associations with loci on chromosome 6 and 18. The *HLA* gene locus (EJM-1) on the short arm of chromosome 6 has been

associated with JME in several studies, although the neurobiological significance of this locus remains unclear. Variants in the *malic enzyme 2* gene located on chromosome 18 that indirectly regulates neuronal GABA synthesis may be involved in JME and other non-JME GGEs. The *CHRNA7* gene encoding the alpha 7 subunit of the nicotinic acetylcholine receptor and the *connexin 36* gene on chromosome 15 may be associated with JME in some families. Finally, a mutation in the *CACNB4* gene encoding the calcium channel beta 4 subunit on chromosome 2 was found in a JME patient. The heterogeneity of these genetic studies reflects the various genotypes involved in the phenotypic syndrome of JME. There is considerable overlap between the genes implicated in JME and those involved in juvenile absence epilepsy (JAE). Linkage analysis has found associations between chromosome 3, 6, and 18 in families and individuals with JAE. Similarly, there appears to be a genetic overlap between JME and GTCS-A, and long-term treatment is typically required. In addition, the seizures associated with GTCS-A can cluster with JME in families, suggesting a common genetic predisposition. In families with both absences and GTCS-A, there appears to be a link between expression of this GGE and the EJM-1 locus on chromosome 6 (Greenberg et al., 1995).

### Rare Mendelian-Inherited Progressive Generalized Adolescent Epilepsies

Progressive myoclonus epilepsy (PME) is a rare and heterogeneous group of inherited disorders that produce progressive neurologic dysfunction with dementia, ataxia, myoclonic jerks, and GTC seizures. This group accounts for approximately 1% of childhood and adolescent epilepsy syndromes and includes Unverricht-Lundborg disease, Lafora body disease, myoclonic epilepsy with ragged red fibers, neuronal ceroid lipofuscinosis, and others. These syndromes are accompanied by GTC seizures and action or stimulus myoclonus. The EEG pattern typically reveals generalized polyspike-and-wave and spike-and-wave discharges with photosensitivity.

Unverricht-Lundborg disease (ULD) is an autosomal-recessive disorder that presents between the ages of 6 and 16. In Finnish populations, the incidence is 1 in 20,000. Seizures are GTC and myoclonic jerks. The interictal EEG demonstrates progressively slower background activity with generalized anterior-predominant polyspike-and-slow-wave discharges. Dodecamer repeat expansions or point mutations in the cystatin B (*CSTB*) gene on chromosome 21 result in ULD. The

unique histopathologic feature of this disease that distinguishes it from the other forms of PME is the *lack of abnormal neuronal inclusions or systemic deposits*.

Lafora body disease (LBD) is an autosomal-recessive disorder presenting between the ages of 6 and 19; it is characterized histopathologically by polyglucosan intracellular neuronal inclusions, termed Lafora bodies, that stain positive with periodic acid–Schiff stain. Seizures consist of GTC seizures, visual phenomena, and scotomas, progressing to myoclonic jerks. These patients often go on to develop vision loss and a cerebellar syndrome. Mutations in the *NHLRC1* gene encoding laforin, a tyrosine phosphatase, located on chromosome 6q24 are responsible for LBD.

Myoclonic epilepsy with ragged red fibers (MERRF) is a disorder resulting from mutations in mitochondrial DNA that can present in the adolescent period through the second decade of life with myoclonus, generalized seizures, encephalopathy, and ataxia. The histopathology includes ragged red muscle fibers on Gomori trichrome stain with cytochrome c negative fibers. Additional neurologic features include diminished hearing and vision, neuropathy, and myopathy.

Neuronal ceroid lipofuscinosis is a heterogenous lysosomal storage disease that can present in early childhood up to adulthood. Most forms are inherited in an autosomal-recessive pattern and are classified as CLN 1 to 10. Mutations in 13 genes have been identified. Phenotypically, these patients suffer progressive intellectual disability, vision loss, dementia, ataxia, and pyramidal and extrapyramidal dysfunction. The EEG often demonstrates slowed background rhythm, with paroxysmal generalized bursts of spike-and-wave, polyspike-and-wave, or slow-wave discharges. The histopathology includes curvilinear, fingerprint, and granular osmiophilic deposits (Franceschetti et al., 2014; Wheless and Kim, 2002).

## ADOLESCENT FOCAL EPILEPSIES

Focal-onset seizures are more common than generalized. Of the focal epilepsy generators, the temporal lobe is the most epileptogenic region of the brain. Accordingly, temporal lobe epilepsy (TLE) is the most common form of localization-related epilepsy in adolescents and adults, accounting for 60% of all patients with epilepsy. Advances in neuroimaging have an immense bearing on the diagnosis of adolescent-onset focal epilepsy.

### Mesial Temporal Lobe Epilepsy Resulting From Hippocampal Sclerosis

Mesial temporal lobe epilepsy with hippocampal sclerosis was identified by the International League Against Epilepsy (ILAE) in the new classification system because of its prevalence and homogeneity (Berg et al., 2010). The onset of mesial temporal lobe epilepsy (mTLE) varies, and it can emerge during infancy through the third decade of life. Hippocampal sclerosis (HS) is composed of atrophy and gliosis of the amygdala, hippocampus, parahippocampal gyrus, and entorhinal cortex. Although HS can be bilateral, it is commonly unilateral, involving the dentate gyrus, CA 1 to 3, and subiculum. It may be easily visualized on qualitative high-resolution brain magnetic resonance imaging (MRI) as mesial temporal sclerosis. Characteristic features include hippocampal formation atrophy (Figure 73-8) and increased signal on coronal fluid-attenuated inversion recovery sequences or T2-weighted images.

mTLE can manifest various auras. Most commonly it presents with psychic and experiential phenomena of déjà vu, jamais vu, and fear. However, other autonomic and

abdominal auras, such as rising epigastric sensations, and olfactory and gustatory auras, such as pungent malodorous smells and bizarre tastes, may also occur. The ictal period is also accompanied by a fixed vacant stare with behavioral arrest and impaired consciousness over 30 to 60 seconds. Oral-buccal and bimanual automatisms are common and may consist of repetitive lip-smacking, swallowing, chewing, and picking or fidgeting movements of the hands. Amnesia for the event is typical for left temporal lobe epilepsy, and 30% of the time patients are repeatedly unaware that seizures have occurred. Focal seizures evolving to convulsions are infrequent in mTLE.

The interictal routine scalp EEG may demonstrate anterior temporal spikes or sharp waves occurring in more than 90% of patients during prolonged video-EEG monitoring. In one-third of patients they may appear bitemporally (Figure 73-8), with a regional temporal field that can be augmented by application of additional basal temporal electrodes. Intermittent focal temporal slowing may be seen with localizing value when present as temporal intermittent rhythmic delta activity. The typical ictal tracing demonstrates a unilateral regular rhythmic theta or alpha discharge of 5 to 9 Hz in the anterior temporal head region. When electrophysiological concordance correlates with ipsilateral HS on MRI, this pattern correctly lateralizes seizure onset in more than 95% of patients (Thom, 2014).

### Autosomal-Dominant Partial Epilepsy With Auditory Features

The onset of familial lateral temporal lobe epilepsy (fTLE) typically occurs in teenage or early adult life, but it may present earlier or later (range 4-50). The lateral form of familial TLE, also referred to as autosomal-dominant partial epilepsy with auditory features (ADPEAF), is associated with a missense gene mutation in the leucine-rich, glioma-inactivated 1 (*LGI-1*) gene on chromosome 10q22-24. Brain MRI and EEG are often normal. Simple auditory hallucinations are the hallmark of ADPEAF. Typically, simple sounds such as buzzing, clicking, or ringing may occur and are usually referred to the contralateral ear, although they may be bilateral. However, other visual, autonomic, psychic, and olfactory auras can be encountered in addition to more complex features described as singing, whistling, humming, and talking. Infrequently these sensations may progress to focal seizures with impaired consciousness, although they typically occur in isolation. Focal seizures that evolve to convulsions are usually rare and occur during sleep when present. The interictal routine scalp EEG in patients with fTLE is often normal, although it may reveal midtemporal focal slowing. When epileptiform discharges are encountered, they are temporal-occipital spikes or sharp waves. Seizures originate in or propagate into Heschl's gyrus in the primary auditory or auditory association cortices, with left frontotemporal and temporal onset.

### Autosomal-Dominant Nocturnal Frontal Lobe Epilepsy

Autosomal-dominant nocturnal frontal lobe epilepsy (ADNFLE) is an uncommon form of familial nonlesional focal epilepsy characterized by focal hypermotor seizures arising from the frontal lobe, classically during sleep. Although the age range for first seizures is between 1 and 30 years old, the mean age is during the early adolescent period around 12 years old. The seizures are brief, often complex, and usually occur in clusters during non-REM sleep, leading

**Figure 73-8.** Mesial temporal lobe epilepsy resulting from hippocampal sclerosis. A 16-year-old with a history of complex febrile seizure and seizure onset at puberty resistant to multiple antiseizure drugs (ASDs). Note the left hippocampal formation atrophy in 7A (circle) and bitemporal spike-and-wave discharges in 7B (arrows).

to misinterpretation as a parasomnia. Seizures may lead to simple arousals, wandering behavior, or more intense hypermotor movements involving bimanual-bipedal automatism with kicking, bicycling, flailing, or flinging movements. Vocalizations of moaning, crying, or gasping may also occur, simulating nocturnal panic attacks. The brain MRI and interictal routine scalp EEG are frequently normal. Video-EEG may be diagnostic when demonstrating electroclinical seizures of frontal lobe origin. The first gene identified was a missense mutation in a large Australian kindred in the alpha 4 subunit of the neuronal nicotinic acetylcholine (nACh) receptor (*CHRNA4*) located on chromosome 20 (20q13.2-13.3). Mutations of *CHRNA2*, *CHRN2*, and the sodium-gated

potassium channel gene *KCNT1* have also been associated with ADNPLE.

## TREATMENT

Obtaining seizure control is imperative to preventing morbidity and mortality associated with adolescent epilepsy.

### Treatment of Genetic Generalized Epilepsies

The majority of JME patients will require continued use of ASDs in adulthood. Carbamazepine, phenytoin, gabapentin, and vigabatrin may exacerbate seizures in JME and produce

myoclonic status epilepticus. Therefore these medications should be avoided in JME. Reproductive potential and pregnancy are significant factors in ASD selection. Valproate is a potent teratogen that is strongly associated with major congenital malformations. Therefore it should be avoided in females of childbearing potential. Levetiracetam and lamotrigine have emerged as the ASDs of choice for females with JME, although caution is necessary with lamotrigine because exacerbation of myoclonic jerks may occur. However, valproate is a very effective choice in adolescent males with JME. Treatment with valproate requires careful observation for idiosyncratic adverse effects, including serious rash, hepatopathy, and hemorrhagic pancreatitis. Additional monitoring for chronic changes, such as alopecia, tremor, weight gain, thrombocytopenia, and osteopenia, is important. Despite appropriate use of ASDs, 15% of patients will demonstrate pharmaco-resistant JME requiring multidrug therapy.

Absence seizures respond to treatment with ethosuximide, valproate, or lamotrigine. Ethosuximide targets the T-type calcium channels, thereby decreasing the excitatory drive of thalamocortical networks. If the patient has generalized convulsive seizures in addition to absences, valproate and lamotrigine are better choices. Most patients with JAE are well controlled on monotherapy. However, those refractory to monotherapy may require dual therapy and closer monitoring of ASD level. Valproate increases the serum concentrations of lamotrigine and ethosuximide, giving rise to clinical toxicity if coadministered. The most feared side effect of lamotrigine is Stevens–Johnson syndrome, but other side effects, such as insomnia, headache, incoordination, ataxia, and dizziness, also occur. Importantly, ASDs including phenytoin and carbamazepine in addition to gabapentin, pregabalin, and vigabatrin can aggravate absence seizures and precipitate absence status epilepticus and therefore should be avoided. Finally, adolescents and their parents should be counseled that although JAE can remit, it tends to be life-long, requiring long-term administration of ASDs.

GTC and GTCS-A tend to have a fairly good outcome. Most patients become seizure-free on ASDs. The majority of patients are able to be controlled with ASD monotherapy, but approximately 30% require polytherapy. In contrast, the treatment of PME remains problematic. The reason for this is likely twofold. First, broad-spectrum ASDs that are typically effective in generalized seizures, such as valproate, lamotrigine, topiramate, levetiracetam, zonisamide, and benzodiazepines, are unfortunately frequently ineffective in PME. Second, the underlying encephalopathy that develops as PME progresses requires supportive care and assistance when sleep, behavior, and mobility become compromised (Panayiotopoulos, 2001; Tatum, 2013).

## Treatment of Focal Epilepsies

In regard to treatment of focal seizures such as temporal lobe epilepsy, nearly two-thirds of patients will achieve seizure freedom with ASDs; however, those with HS have the worst prognosis for achieving medical control. Most ASDs are approved for use in patients with focal seizures. Newer ASDs have improved tolerability but provide little benefit once drug resistance becomes evident. Overly aggressive ASD use complicates the risk of serious adverse events and seizure-related morbidity and mortality. Furthermore, health-related quality of life is more difficult to improve over time. When focal seizures remain uncontrolled, epilepsy surgery needs early consideration. Anterior temporal lobectomy and selective amygdalohippocampectomy for refractory patients can be very effective and may improve quality of life. Newer minimally invasive techniques using stereotactic laser ablation are

evolving as a reasonable alternative to more invasive surgeries, which may minimize category-related object recognition and naming deficits following standard surgical approaches.

## ADDITIONAL DIAGNOSTIC CONSIDERATIONS

### Chronobiology

There is a significant influence of circadian periodicity on the timing and threshold for seizures. In adolescence, there are several epilepsies that present with early morning seizures, including JME and GTC seizures on awakening, similar to other seizures, such as those in ADNFLE, that are nocturnal. Additionally, many patients with adolescent-onset epilepsy may be provoked or aggravated by sleep deprivation. This phenomenon may involve light-sensitive neuronal activation of the suprachiasmatic nucleus, which can influence the activity of thalamocortical circuits and other epileptogenic networks, neurotransmitters, and hormones affected by sleep duration and circadian periodicity. Understanding the chronobiology of the epilepsies and the implications of circadian changes in neurotransmitter release and cortical excitation may enhance our understanding of the pathobiology of adolescent epilepsy syndromes. Furthermore, the interplay between sleep deprivation and circadian influences on seizure threshold could uncover targets for therapeutic intervention.

### Biomarkers

The advent of biomarker identification is a potentially high-yield area of future research. Structural biomarkers, such as hippocampal sclerosis or focal frontal lobe cortical dysplasia on high-resolution brain MRI, focal hyperperfusion on single-photon emission computed tomography (SPECT), and focal hypometabolism on positron emission tomography (PET), may augment presurgical planning when seizures are drug resistant. Serum and spinal fluid biomarkers such as heat-shock proteins could have the capacity to predict the natural history of epilepsy and treatment outcomes. Additionally, biomarkers may be powerful tools for the generation of newer, more complex animal models in future ASD research. The EEG is an indirect biomarker of epilepsy as well. For example, extending the EEG recording to include frequencies up to 500 Hz or more during invasive EEG required for presurgical evaluations in drug-resistant localization-related epilepsy has revealed high-frequency oscillations with pathophysiological implications for optimizing resection.

### Pharmacogenetics—The Horizon of Epilepsy Treatment

Molecular epilepsy genetics is a dynamic field that is creating a paradigm shift in how we think about epilepsy. Present-day candidate gene testing (e.g., LGI-1 in fTLE), gene panel testing (e.g., autoimmune limbic encephalitis), and array comparative genomic hybridization will probably evolve to whole-exome and whole-genome sequencing, especially when no candidate gene is suspected. These discoveries will expand mechanistic considerations for the many currently unexplained epilepsy syndromes, help identify mechanisms of drug resistance, and lead to more individualized ASD selection to personalize treatment. Perhaps in the future, genetic screening will assist in predicting patients who may respond better to one drug therapy as opposed to another. Finally, although the design of medications used to treat epilepsy has focused on remitting seizures, a more advanced approach to pharmacogenetics in epilepsy should focus on targeting the propensity

for seizures and natural history of lifelong or severe epilepsy disorders.

## CONCLUSION

There are age-specific electroclinical syndromes that occur in adolescence. In teens, other paroxysmal nonepileptic events, such as syncope, psychogenic nonepileptic seizures, migraine, and recreational drug abuse, that mimic epilepsy must be considered. The potential for misdiagnosis and misuse of ASDs during adolescence may account for morbidity, pseudodrug resistance from incorrect choice of medication, and impaired quality of life. Remaining sensitive to the pressures of this age group and providing information on driving, sexuality, use of drugs and alcohol, and compliance with ASDs is crucial for successful treatment of epilepsy. Many of the GGEs present during this age period and respond to the new-generation ASDs. Focal seizures should be treated aggressively with early surgical evaluation when drug resistance is identified.

## INTRODUCTION

The role of structural lesions is well recognized in cases of refractory focal epilepsy in children and adults. Although mesial temporal lobe epilepsy with hippocampal sclerosis, a common feature of refractory epilepsy in adults, also plays a role in pediatric epilepsy, there is a notable contribution in pediatric epilepsy from focal cortical malformations, ranging from small heterotopia to large hemispheric malformations, such as hemimegalencephaly. Our recognition of these lesions is likely to increase as neuroimaging continues to become more sophisticated. There are also reports of pathologic evidence of cortical malformation in surgical resections from patients with focal epilepsy without visible lesions on magnetic resonance imaging (MRI) (Sisodiya, 2004). Thus in this chapter we emphasize the role of cortical malformations in pediatric epilepsy and then discuss the more classical focal structural epilepsies associated with mesial temporal lobe epilepsy (MTLE), hypothalamic hamartoma, and Rasmussen encephalitis.

## FOCAL STRUCTURAL EPILEPSY WITH FOCAL MALFORMATIONS OF CORTICAL DEVELOPMENT

### Focal Cortical Dysplasia

One of the most common causes of focal structural epilepsy is focal cortical dysplasia (FCD). Although FCD is covered in Chapter 28, its prominence in the realm of focal epilepsy warrants discussion in this chapter as well. Neurologists often use the terms *FCD* and *cortical dysplasia* to include a range of abnormalities, from epileptic foci with microscopic cellular abnormalities to large hemispheric lesions visible on MRI. We will use the term *FCD* to refer to the specific malformations with pathologic abnormalities as described in the following section.

### Pathology

There are three major types of FCD: type I, with abnormal cortical lamination; type II, with abnormal cortical lamination plus dysmorphic neurons as the key additional feature; and type III, similar to type I but associated with an additional major finding (i.e., dual pathology), such as hippocampal sclerosis, developmental tumor, or vascular malformation. FCD type IIa is distinguished from type IIb based on the presence of enlarged “balloon” cells in the latter.

### Imaging Features

FCD is not well seen on computed tomography (CT), and even high-quality MRI may not detect small or subtle FCD. The presence of a focal lesion on MRI may influence the course of treatment of focal epilepsy in that lesional focal epilepsy may be amenable to focal resective surgery. Given the important role of FCD in focal epilepsy, it is necessary to use sensitive MRI techniques to maximize the detection of lesions such as FCD. Additional localizing techniques, including nuclear

medicine imaging, may be used when there is a high suspicion of a focal lesion.

The prototypical imaging features of FCD are seen in FCD type II, with blurring of the gray matter–white matter junction, abnormal gyral patterns, increased cortical thickness, and increased T2/FLAIR signal at the base of the lesion and in the underlying white matter, the so-called “T2 tail” that extends down to the ventricular surface. Type I FCDs may appear as blurring of the gray matter–white matter junction and subtle cortical thickening with irregular gyral morphology. These features may be more apparent in FCD type III when they are adjacent to other abnormalities, such as hippocampal sclerosis, although the other abnormalities may be so much more striking that the dysplasia may be initially overlooked.

### Clinical Features

In the pediatric epilepsy setting, FCD is most often seen as an isolated focal abnormality. FCD, and the related hemispheric lesion hemimegalencephaly (HMEG), may also be associated with neurocutaneous syndromes, including linear nevus sebaceous syndrome, Sturge–Weber syndrome, PTEN hamartoma tumor (Cowden) syndrome, and hypomelanosis of Ito.

Seizures, typically presenting in infancy or childhood, are often the presenting and chief clinical consequences of FCD. The cases and series in the literature are most often surgical series, reflecting refractory epilepsy. Intellectual disability and focal neurologic abnormalities may also be present, depending on the location and size of the FCD.

### Etiology

because the pathologic findings associated with FCD, tuberous sclerosis complex (TSC), and hemimegalencephaly (HMEG) share overlapping features, these disorders have increasingly been considered part of a spectrum, and their causes have been recently identified (Poduri et al., 2013). Indeed, the recently identified genetic causes of FCD support this assertion; genes in the mTOR-PI3K-AKT pathway have been implicated, including germline and somatic mutations in *MTOR*, *PIK3CA*, *AKT3*, *PTEN*, *DEPDC5*, and *NPRL3*. In addition, recessive mutations in the genes *CNTNAP2* and *OCN* have been identified as genetic causes of FCD.

### Management

Treatment of focal epilepsy as a result of FCD begins with antiseizure drugs suitable for focal epilepsy. Although FCD clearly plays a major role in refractory focal epilepsy, it is important to note that not all patients presenting with focal epilepsy attributable to FCD will have refractory epilepsy. Thus the prognosis of a child with focal epilepsy with MRI clearly showing FCD is not always that of refractory epilepsy requiring a surgical approach. Future prospective studies of patients with newly identified FCD are needed to determine the portion of patients with FCD that can be controlled by medication versus those who require surgical consideration.

FCD, particularly smaller and more subtle forms of FCD, may not be recognized on the initial MRI performed as part of the standard focal seizure evaluation. Thus any patient with refractory focal epilepsy with two or more unsuccessful attempts at treatment with antiseizure medications should undergo presurgical evaluation. This should include repeat MRI if no lesion was initially found, if possible using 3T MRI and protocols designed to enhance the detection of epilepsy-related lesions, including both FCD and hippocampal abnormalities.

Presurgical evaluation for patients with FCD follows standard presurgical practice and should include assessment of concordance of localizing features (e.g., seizure semiology, MRI, electroencephalogram [EEG] focality [interictally but more important ictally], nuclear medicine studies, in some cases magnetoencephalography) and assessment of possible deficits that might arise from surgery based on the location and extent of the lesion, neuropsychological evaluation, and in some cases diffusion tensor imaging identifying, for example, corticospinal tracts or arcuate fasciculus with respect to the FCD. Depending on the localization versus the possibility of deficit, invasive monitoring may be required. Furthermore, because the seizure-onset zone in some patients may be located adjacent to rather than directly in a focal malformation, invasive monitoring, such as subdural electrode recording, may be needed to best identify the source of the seizures and achieve the greatest chance of seizure freedom.

## Hemimegalencephaly

Hemimegalencephaly (HMEG) is a well-described disorder of abnormal brain development characterized by unilateral enlargement of most of one cerebral hemisphere (Flores-Sarnat, 2002). In its classic form, HMEG is characterized by unilateral cortical malformation, with the involved hemisphere enlarged and characterized by cortical dysgenesis, white-matter hypertrophy, and a dilated and dysmorphic lateral ventricle. The overgrowth and dysplasia may involve an entire hemisphere, part of a hemisphere, and/or part of the contralateral hemisphere as well, with no clear predilection for the right or left side. Various morphologic abnormalities outside the involved cerebral hemisphere have been reported, including ipsilateral cerebral vascular dilatation, ipsilateral and bilateral cerebellar enlargement with dysplastic folia, and ipsilateral olfactory nerve enlargement. Moreover, contralateral volume loss (or hemi-microcephaly) and white-matter abnormalities have been reported. Neuropathological findings include large neurons, cortical dyslamination with or without dysmorphic and ectopic neurons, heterotopia, balloon cells, and abnormal white matter.

## Neurologic Features

Classically, most children with HMEG have early-onset intractable epilepsy, unilateral or focal neurologic signs (such as hemiparesis), tone abnormalities, and severe intellectual disability. Intractable epilepsy usually begins within the first few months of life and is the most frequent and severe neurologic manifestation, occurring in up to 93% of cases. Seizures are typically focal in onset and almost always intractable to medical therapy. Likely because of the early age at presentation, HMEG is associated with infantile spasms in 50% of patients. Intellectual disability (ID) is often early and severe, although in a few cases it can be mild to moderate. Different degrees of hemiparesis are seen contralateral to the hemimegalencephaly. Macrocephaly is usually apparent at birth, and cranial asymmetry dependent on the degree of hemimegalencephaly may be evident. Occipito-frontal circumference

(OFC) may increase rapidly during the first few months, but subsequently the head size diminishes relative to the normal OFC curve, and patients may become normocephalic or microcephalic. Anatomic or functional hemispherectomy may improve both epilepsy and ID in selected patients, albeit with some complications given the often difficult anatomy involved. However, many patients do poorly with hemispheric surgery, possibly as a result of more widespread but asymmetric malformations (Vigevano et al., 1989).

## Neuroimaging

The MRI appearance of HMEG includes moderate to severe enlargement of one cerebral hemisphere, with enlargement of the lateral ventricle. In some, enlargement may be localized to the frontal or temporoparietal regions, but in others, it may extend to distinct regions of the contralateral hemisphere. A spectrum of cortical dysplasia is almost uniformly present, ranging from pachygyria to polymicrogyria, with cortical dysplasia often seen in the contralateral hemisphere as well (Barkovich and Chuang, 1990). Gray-matter abnormalities may include areas of thickening and simplification or overfolding, resembling pachygyria or polymicrogyria, respectively. Heterotopias are commonly seen as well. The underlying hemispheric white matter may be increased or decreased, with abnormal signal characteristics in some patients. The ventricular system is enlarged and/or dysplastic in most patients. Figure 74-1 (B, E, F) and Figure 28-4 (B-D) in Chapter 28 show variable degrees of hemimegalencephaly. EEG abnormalities are often extensive throughout the abnormal hemisphere, and a suppression-burst pattern can be observed in the most severe cases. Predictors of poor outcome are severity of hemiparesis, degree of MRI abnormality, and abnormal EEG activity.

## Nonneurologic Features

HMEG can be isolated or associated with somatic features such as focal or segmental body overgrowth and cutaneous vascular malformations, as has been reported in many individuals with Proteus syndrome, Klippel-Trenaunay syndrome (KTS), linear nevus sebaceous syndrome (LNSS), hypomelanosis of Ito, and neurofibromatosis. These associations, combined with recent molecular discoveries identifying mutations in the PI3K-AKT-MTOR pathway in these phenotypes, place HMEG, FCD, and diffuse megalencephaly within a broad spectrum of disorders associated with variable brain and body growth dysregulation.

## Etiology

Hemimegalencephaly was classically regarded as the result of an early disturbance in neuronal proliferation and migration. With the advent of next-generation sequencing (NGS), a number of genetic causes of HMEG have been identified. Mosaic (or postzygotic) gain-of-function mutations within key genes of the mammalian target of rapamycin (mTOR)-phosphatidylinositol-3-kinase (PI3K)-v-akt murine thymoma viral oncogene homolog (AKT) pathway have been identified in HMEG. These genes include *PIK3CA*, *AKT3*, *PTEN*, and *MTOR*.

Most of these mutations were detected in abnormal (surgically resected) brain tissue only, and were undetectable in peripheral tissues (such as blood and saliva). Mutations of the same genes have been reported with more focal malformations of cortical development, including FCD and diffuse megalencephaly (as occurs with megalencephaly capillary malformation syndrome and megalencephaly polymicrogyria-polydactyly hydrocephalus syndrome, discussed here and in

**Figure 74-1. Neuroimaging features of focal brain malformations associated with epilepsy.** **A**, FCD type 2a resulting from a mosaic mutation of *PIK3CA* (p.H1047R). **B**, Hemimegalencephaly resulting from two mosaic mutations of *PIK3CA* (p.E542K, p.T544N). **C**, MCAP syndrome resulting from a mosaic mutation of *PIK3CA* (p.M1043I). Note also severe ventriculomegaly and megalencephaly. **D**, Bilateral diffuse megalencephaly with cortical dysplasia (i.e., dysplastic megalencephaly) resulting from to a mosaic mutation of *PIK3CA* (p.E545K). Also note bilaterally enlarged and dysplastic ventricles, diffuse white-matter abnormalities, and bilaterally dysplastic basal ganglia. **E**, Hemimegalencephaly resulting from a constitutional (germline) mutation of *PTEN* (p.Y68H). **F**, Hemimegalencephaly resulting from a mosaic mutation of *AKT3* (p.E17K). **G**, Bilateral perisylvian polymicrogyria and mild ventriculomegaly resulting from a mosaic mutation of *PIK3R2* (p.G373R). **H**, Bilateral perisylvian polymicrogyria resulting from a constitutional mutation of *CCND2* (P281S). Also note megalencephaly, ventriculomegaly, and cavum septum pellucidum et vergae (features of MPPH syndrome). **I**, Tuberous sclerosis resulting from a constitutional mutation of *TSC1* (p.Gln301X). Note several subcortical tubers, subependymal nodules, mild ventriculomegaly, and periventricular white-matter T2 signal hyperintensities. This MRI is status following left frontal craniectomy for gross resection of a large left frontal subcortical tuber. **J-L**, Sturge-Weber syndrome (no mutation identified). **J**, T2-weighted axial image showing prominent subarachnoid spaces with diffuse cortical atrophy. **K**, T1-gadolinium (GAD) contrast axial image showing bilateral pial venous angiomas with leptomeningeal enhancement. **L**, Matching T2-weighted axial image further showing bilaterally prominent vessels in the subarachnoid spaces. MCAP, megalencephaly capillary malformation syndrome; MPPH, megalencephaly polymicrogyria-polydactyly hydrocephalus syndrome; MRI, magnetic resonance imaging. (**A** with permission from Jansen LA, Mirzaa GM, Ishak GE, et al. *Brain: a journal of neurology* 2015; **B-G** with permission from Poduri A, Evrony GD, Cai X, Walsh CA. *Science* 2013;341:1237758.)

Chapter 28). These heterozygous mutations lead to gain of function in pathway activity that regulates several cellular processes, including cell survival, growth, vascular development, and apoptosis (Figure 74-2).

Other less common patterns of focal megalencephaly with cortical dysplasia have been described, and various terms have been used to describe these patterns by distribution, such as total or diffuse HMEG, localized MEG (hemimegalencephaly), and multilobar cortical dysplasia (Table 74-1).

## FOCAL STRUCTURAL EPILEPSY WITH NEUROCUTANEOUS SYNDROMES

### Tuberous Sclerosis Complex

TSC, discussed in detail in Chapter 45, is commonly associated with focal epilepsy, with typically refractory epilepsy affecting 80% to 90% of children with TSC, often beginning in infancy in the form of infantile spasms. The majority of patients with TSC have mutations in *TSC1* or *TSC2*, resulting

Clinical entity	Pattern of involvement by neuroimaging	Severity
Dysplastic megalencephaly (DMEG) with segmental cortical dysplasia	Bilateral segmental cerebral and cerebellar hemispheres	
Total or diffuse HMEG	Cerebral hemisphere and unilateral cerebellum and brainstem	
HMEG (also called unilateral MEG)	An entire cerebral hemisphere	
Focal or localized MEG ("hemi-HMEG") <ul style="list-style-type: none"> <li>• Frontal lobe predominant (anterior quadrantic)</li> <li>• Occipital lobe predominant (posterior quadrantic)</li> <li>• Diffuse type</li> </ul>	Partial area of one cerebral hemisphere  Frontal lobe of one cerebral hemisphere Occipital, parietal and temporal lobe of one cerebral hemisphere	
Multi-lobar cortical dysplasia	An area of focal cortical dysplasia involving one or more cerebral hemispheres	
Focal cortical dysplasia	Focal area of abnormal cortical thickness and poor gray/white matter differentiation	

**Figure 74-2. Focal or segmental malformations of cortical development.** This figure illustrates the focal brain overgrowth entities described in the literature and their morphologic characteristics based primarily on the extent and distribution of the malformation seen in neuroimaging. These clinical entities include the following (from most diffuse to most localized): dysplastic megalencephaly, total or diffuse hemimegalencephaly, classic hemimegalencephaly, focal or localized hemimegalencephaly (also called hemi-hemimegalencephaly), multilobar cortical dysplasia, and focal cortical dysplasia.

**TABLE 74-1** Disorders Associated With Focal Structural Epilepsy, Clinical Features and Causes

Disorder	Neurologic Features	Somatic (Nonneurologic) Features	Cause	Gene	Constitutional Versus Mosaic
<i>With Focal Malformations of Cortical Development</i>					
Focal cortical dysplasia (FCD)	Laminar disorganization, dysmorphic neurons (IIa), balloon cells (IIb)	Typically none	Genetic	<i>MTOR, DEPDC5, PIK3CA, PTEN</i>	Mosaic
Hemimegalencephaly (HMEG)	Cortical dysgenesis, white-matter abnormalities, dysmorphic ventricles	Segmental overgrowth, vascular-lymphatic malformations, hypomelanosis of Ito	Genetic	<i>MTOR, DEPDC5, PIK3CA, PTEN, AKT3</i>	Mosaic
<i>With Neurocutaneous Syndromes</i>					
Tuberous sclerosis (TSC)	SEN, cortical tubers, hamartomatous lesions, calcifications	Hypopigmented macules, facial angiofibroma, Shagreen patches, subcutaneous nodules, café au lait lesions, subungual fibromas	Genetic	<i>TSC1, TSC2</i>	Constitutional, less commonly mosaic
Sturge-Weber syndrome (SWS)	Arachnoid hemangiomas, calcifications	Hemangiomas in the distribution of the trigeminal nerve	Genetic	<i>GNAQ</i>	Mosaic
Megalencephaly capillary malformation syndrome (MCAP)	Bilateral perisylvian polymicrogyria	Capillary malformations, somatic overgrowth, digital anomalies (syndactyly, polydactyly)	Genetic	<i>PIK3CA</i>	Mosaic
Hypomelanosis of Ito	HMEG or Dysplastic Megalencephaly	Hypomelanosis of Ito	Genetic	<i>MTOR</i>	Mosaic
HMEG, hemimegalencephaly; SEN, subependymal nodules.					

in overactivation of the mTOR pathway. Given the implication of this pathway in FCD and related disorders, early trials of mTOR inhibition to treat seizures in patients with TSC may extend to the many other mTOR-related forms of focal epilepsy.

## Sturge–Weber Syndrome

Sturge–Weber syndrome (SWS) is a neurocutaneous disorder characterized by aberrant vascular development affecting the skin, eyes, and meninges. Classic features include a facial capillary malformation, commonly in the distribution of the trigeminal nerve, sometimes involving the choroid of the eye, with secondary buphthalmos or glaucoma; leptomeningeal angiomas; secondary cerebral atrophy; sclerosis; and calcifications. Some affected individuals also develop subdural hematomas.

### Neurologic Features

SWS is often associated with severe neurologic sequelae, including epilepsy, intellectual disability, vascular headaches, glaucoma, hemianopia, and hemiparesis. Epilepsy is estimated to occur in 75% to 90% of patients and is most often focal, with onset typically in infancy or early childhood. Further, many individuals with SWS have focal neurologic symptoms such as hemiparesis.

### Neuroimaging

Leptomeningeal angiomas is unilateral in 75% of cases and bilateral in 25%. Secondary neuroimaging findings include cerebral calcifications, atrophy, and choroidal plexus hypertrophy, among others. Neuropathologic studies have demonstrated various abnormalities, including focal cortical dysplasia and polymicrogyria, some of which were subtle and undetectable on brain MRIs.

### Etiology

Recently mutations of the guanine nucleotide binding protein Q polypeptide (*GNAQ*) gene have been identified in SWS. Mutations were mosaic, detected predominantly in affected brain tissue. *GNAQ* encodes a G-class seven-transmembrane domain receptor that activates phospholipase C- $\beta$  and has downstream effects on the RAS signaling pathway.

### Clinical Management

Epilepsy is often refractory to antiseizure medications in SWS, often necessitating neurosurgical intervention, either hemispherectomy or focal resection. Several studies have shown that early surgery confers better seizure control and developmental outcomes. Some studies have proposed vertical extra-ventricular functional hemispherectomy to reduce the risk of postoperative hydrocephalus.

## Megalencephaly Capillary Malformation Syndrome

Megalencephaly capillary malformation syndrome (MCAP) is a multisystem disorder characterized by diffuse brain overgrowth or megalencephaly, with variable somatic features, including overgrowth and cutaneous vascular malformations. The severity of involvement varies widely, although most affected individuals have congenital-onset megalencephaly and cutaneous capillary malformations. Other somatic fea-

tures seen in this clinically recognizable syndrome include finger or toe syndactyly (most characteristically two- to three-toe syndactyly), postaxial polydactyly, and connective tissue dysplasia characterized most often by skin and ligamentous laxity.

### Neurologic Features

In addition to megalencephaly, approximately 60% to 70% of children with MCAP have cortical dysplasia, most commonly bilateral perisylvian polymicrogyria (BPP), predisposing affected individuals to epilepsy (Mirzaa et al., 2012). The extent of BPP varies widely from focal BPP involving the perisylvian regions only to extensive forms including the frontal and/or occipital poles. Approximately 30% of children with MCAP have seizures, including focal, generalized tonic-clonic, and myoclonic seizures. Epilepsy is usually well controlled on antiseizure medication. A fraction of affected individuals will also have ventriculomegaly predisposing to hydrocephalus, and cerebellar enlargement predisposing to cerebellar tonsillar ectopia. Therefore a fraction of individuals with this disorder undergo neurosurgical intervention for these complications (Mirzaa et al., 2012).

### Etiology

Mutations of the *PIK3CA* gene have been identified in the majority of individuals with MCAP (Riviere et al., 2012). Similar to HMEG, most identified mutations are mosaic (postzygotic), with the highest detection rates in affected tissues. There are several PI3K-AKT-MTOR-related pathway disorders that overlap MCAP and are variably associated with focal or generalized epilepsy. Some of these disorders lack vascular malformations and are therefore not neurocutaneous disorders per se.

Megalencephaly polymicrogyria–polydactyly hydrocephalus syndrome (MPPH) is a disorder that partially overlaps MCAP and is characterized by a tetrad of congenital-onset megalencephaly, polymicrogyria (PMG), postaxial polydactyly, and hydrocephalus. The most consistent features of this disorder are MEG and PMG, whereas polydactyly and hydrocephalus are seen less frequently. All reported individuals with this disorder have bilateral perisylvian PMG (BPP), and to date, 100% of reported children have epilepsy, including a subset with infantile spasms (Mirzaa et al., 2012). Mutations in three PI3K-AKT-MTOR pathway genes (*AKT3*, *PIK3R2*, and *CCND2*) have been identified in MPPH. Unlike MCAP and HMEG, most of the identified mutations are constitutional (detected in blood). However, mosaic mutations of *PIK3R2* have been reported in MPPH, and also BPP without megalencephaly.

## *STRADA* (LYK5)–Related Megalencephaly

Recessive mutations in *STRADA* (LYK5) have been identified in children with polyhydramnios, megalencephaly, and symptomatic epilepsy (PMSE) syndrome (Puffenberger et al., 2007). *STRADA* is part of a trimeric complex that phosphorylates and thereby activates the AMP-activated protein kinase (AMPK), which in turn activates the TSC1/TSC2 complex. Recessive mutations of this gene have been predominantly reported in children of Mennonite ancestry. Almost all affected children had early-onset intractable epilepsy, severe intellectual disability, and early death (between 6 months and 6 years of age). Seizures were focal in three children, including one child with epilepsy partialis continua. Two children died of seizure-related complications. Brain MRIs showed subependymal dysplasia, ventriculomegaly, and

multiple areas of high diffusion in the subcortical white matter. Neuropathology on one of the deceased children showed enlarged neurons with granular cytoplasm, areas of vacuolization in Purkinje cells and hippocampal neurons, and large dysmorphic cells in the frontal cortex, overlapping some of the histopathological abnormalities seen in FCD. Recently several individuals with PMSE were treated with sirolimus (rapamycin) and were found to have decreased seizure frequency and improvement in receptive language, suggesting that pathway inhibitors may be effective in this spectrum of disorders.

## FOCAL STRUCTURAL EPILEPSY WITH OTHER LESIONS

### Mesial Temporal Lobe Epilepsy With Hippocampal Sclerosis

Mesial temporal lobe epilepsy with hippocampal sclerosis (MTLE with HS), characterized by seizures involving the limbic structures, is known to have a major role in the pathophysiology of focal epilepsy in adults. MTLE with HS affects children as well, and recognition of this entity in children with refractory epilepsy may lead to earlier intervention with surgery.

#### Neurologic Features

Patients with focal epilepsy arising from the mesial temporal lobe structures often report auras, including rising epigastric or indescribable sensations or a sense of déjà vu. Alteration of consciousness during seizures and amnesia afterward are also common features. Other clinical features during seizures are oral, verbal, or motor automatisms (e.g., ipsilateral repetitive picking) and contralateral dystonic postures. Some seizures may secondarily generalize, often with contralateral head and eye version followed by contralateral clonus. Characteristically, the interictal EEG shows focal pleomorphic interictal epileptiform discharges in the anterior to midtemporal region.

#### Neuroimaging

The most common MRI findings are hippocampal atrophy and increased T2 signal in the hippocampus. The hippocampal pathology is best visualized on thin-cut, coronal sequences of an MRI. The entorhinal cortex volume is often decreased in patients with mesial temporal lobe epilepsy; however, this is not a predictor of postoperative seizure recurrence.

#### Etiology

The features of MTLE-HS are characteristic enough to be considered a specific syndromic diagnostic entity (Wieser, 2004). The typical onset of seizures is in adolescence but ranges between 4 and 16 years. MTLE is more common in adults, but it is seen in 1% to 5% of children and adolescents with epilepsy.

Many individuals have a history of recurrent or prolonged febrile seizures during childhood before the onset of MTLE. Hippocampal sclerosis and impaired growth of normal hippocampi are seen after febrile status epilepticus (Lewis et al., 2014). Genetics may also play a role because sodium channel gene mutations (e.g., *SCN1A*) in humans result in prolonged seizures. Other causes of HS include trauma, hypoxic events, and intracranial infection. The onset of seizures arising from the HS may be several years after the initial insult.

#### Medical Treatment

Antiseizure medications approved for focal epilepsy are the first-line treatment. Often patients will have periods of seizure remission, but these are often followed by a latency period and subsequent progression to medically intractable seizures.

#### Surgical Treatment

Temporal lobe surgery is effective for patients with intractable MTLE. Anterior temporal lobectomy yields a worthwhile improvement in 75% to 95% of patients, with approximately two-thirds becoming seizure-free. Up to a third of patients continue to have seizures after surgery. Accurate identification of pathologic features may aid in prognosis after surgical resection.

### Gelastic Seizures With Hypothalamic Hamartoma

Although a relatively rare entity, gelastic seizures are characteristic and often the presenting feature of a hypothalamic hamartoma. Gelastic seizures are one of the few seizure types arising from the diencephalon.

#### Neurologic Features

Gelastic seizures are episodes characterized by brief, frequent, and mechanical bursts of laughter. Facial flushing, pupillary dilation, and at times repetitive complex behaviors may accompany laughing. Additional seizure types, focal or generalized, may develop and are often medically refractory. Cognition remains normal in 35% to 40% of individuals; however, the spectrum of outcomes includes many with deterioration and severe cognitive deficits after the onset of epilepsy. Behavioral problems including aggression, anxiety, and mood disorders are prominent features.

#### Nonneurologic Features

Approximately 50% of children with hypothalamic hamartomas develop clinically evident precocious puberty. Hypothalamic hamartomas that are pedunculated are more strongly associated with precocious puberty and less likely to develop intractable epilepsy.

#### Neuroimaging

Hypothalamic hamartomas appear hyperintense in T2-weighted images and hypointense relative to gray matter in T1-weighted images. The size and location of the tumor are important features related to the severity of the syndrome. Intrahypothalamic hamartomas are strongly associated with gelastic seizures, whereas parhypothalamic hypothalamic hamartomas are associated with precocious puberty.

#### Etiology

Hypothalamic hamartomas can be isolated or part of a syndrome, including Pallister–Hall syndrome, oral-facial-digital syndromes, and Bardet–Biedl syndrome. *GLI3* mutations have been identified in a small proportion of isolated and syndromic causes of hypothalamic hamartomas.

#### Clinical Management

Although attempts with antiseizure medication are the mainstay of initial treatment, these are often ineffective at controlling gelastic seizures arising from hypothalamic hamartomas. Surgical resection can be curative or reduce seizure burden; thus, this represents a potentially treatable epileptic

encephalopathy. Radiosurgery and MRI-guided laser interstitial thermal therapy may be considered effective alternatives to traditional surgical approaches.

## Rasmussen Encephalitis

Rasmussen encephalitis—also known as chronic progressive epilepsy partialis continua of childhood—is a rare inflammatory disease characterized by intractable focal epilepsy, progressive hemiplegia, cognitive deterioration, and unilateral inflammation of the cerebral cortex.

### Neurologic Features

Median age of onset is 6 years, but it ranges from infancy to adulthood. A prodromal period may occur with mild hemiplegia and infrequent seizures. The acute stage is marked by frequent focal seizures in 50% of patients with epilepsy partialis continua. Untreated, ongoing inflammation occurs resulting in progressive cognitive decline, visual field deficit, and hemiparesis, typically over approximately a 1-year period. The residual stage is characterized by fixed neurologic deficits and often refractory epilepsy. Expressive aphasia can occur when the dominant hemisphere is involved. EEG features are variable in patients with Rasmussen encephalitis. Epileptiform discharges and high-amplitude delta slowing develop in the affected hemisphere. The contralateral hemisphere may also develop interictal discharges in more than half of patients, but these are rarely associated with bilateral disease. A consensus statement concluded the diagnosis of Rasmussen encephalitis can be made without a biopsy if patients display epilepsy partialis continua, unilateral EEG features, and imaging showing progressive atrophy.

### Neuroimaging

During the acute stage of disease, T2/FLAIR hyperintense signal and volume loss is often seen initially in the peri-insular region. Ipsilateral atrophy of the head of the caudate nucleus and putamen is often seen early in the disease. Serial MRIs typically show a high rate of progressive atrophy and loss over the cortical and subcortical structures during the acute phase.

### Etiology

The exact etiology of Rasmussen encephalitis is unknown, but pathologic studies are consistent with it being an immune-mediated disease. Both the adaptive and innate immune responses play a role in disease progression. Cytotoxic T lymphocytes are a major driver of pathogenicity in Rasmussen encephalitis. The antigen responsible for the T-cell-mediated neurotoxicity is yet to be identified. Antibody-mediated disease may play a role or be causative in a small subset of patients. Anti-GluR3 antibodies were identified in a small

cohort of patients, but no autoantibody has been found consistently in patients with Rasmussen encephalitis. Microglia activation is seen in areas of active disease. Unfortunately, it is not known if these findings are causative or secondary to an unknown trigger.

### Clinical Management

Antiseizure medications are often ineffective at controlling seizures. Immunomodulatory and immunosuppressive treatments show some promise at slowing down or halting progression of disease, but may delay referral to surgical treatment despite ongoing intractable epilepsy. Surgical hemispherectomy remains the only cure for seizures in Rasmussen encephalitis. Long-term seizure freedom is achieved in 70% to 80% of patients who undergo hemispherectomy. Motor and cognitive improvements have also been reported after surgical disconnection of the affected hemisphere. Homonymous hemianopia and hemiparesis may be present before surgery, but they may be worsened with hemispherectomy.

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Epilepsy is a spectrum of diseases that share a risk for recurrent, unprovoked seizures. The acquired epilepsies are those that result from either an external (e.g., traumatic brain injury [TBI]) or internal (e.g., stroke, infection, brain tumor) insult to the brain that triggers epileptogenesis, the process by which the “normal” brain is transformed at the molecular, cellular, and network levels, resulting in epilepsy.

The bulk of this chapter focuses on the epilepsies acquired following a TBI, stroke, or brain tumor (Hauser, Annegers, and Kurland, 1993). These three insults are often identified as the etiologies that account for the majority of the acquired epilepsies. It is often stated that neurocysticercosis is the most common cause of acquired epilepsy worldwide. Seizures are often the presenting symptom of neurocysticercosis. The estimated risk of recurrence after a first seizure is approximately 40%, and the risk of recurrence is approximately 70% after a second seizure. However, it has been suggested that the recurrence of seizures in this population is not the result of an epileptogenic process, but simply reflects a recurrence of acute symptomatic seizures provoked by the inflammation and edema created by a degenerating cyst. Further details of the neurologic consequences of neurocysticercosis resulting from an infection with the tapeworm *Taenia solium* can be found in Chapter 116, which outlines fungal, rickettsial, and parasitic diseases of the nervous system.

Another current controversy regarding the acquired epilepsies is the question of whether some cases of mesial temporal lobe epilepsy result from a hippocampal injury sustained during an episode of childhood febrile status epilepticus. Febrile status epilepticus accounts for approximately 25% of all cases of pediatric status epilepticus. Prior epidemiologic studies found a high correlation between a diagnosis of epilepsy and a prior history of febrile seizures; however, such studies could not address whether the febrile status epilepticus directly triggered the epileptogenic process or if the febrile status epilepticus was simply a marker that the epileptogenic process already occurred as a result of a prior insult or congenital abnormality. The question of the relationship between febrile status epilepticus, the infectious agent, prior developmental abnormalities of the hippocampus, hippocampal sclerosis, and the development of temporal lobe epilepsy is currently being addressed by the multicenter FEBSTAT study (Consequences of Prolonged Febrile Seizures in Children), a prospective study of children between 1 month and 5 years of age who experienced a first episode of febrile status epilepticus. The control group is composed of children who have experienced a febrile seizure that was not febrile status epilepticus. Current results include the finding that a developmental abnormality was more likely to be present in the children who had experienced an episode of febrile status epilepticus than in the control group, and, further, that there was electrographic and radiologic evidence of hippocampal injury resulting directly from the febrile status epilepticus in a small proportion of children. Several of these children within the febrile status epilepticus cohort have already developed epilepsy, and continued surveillance of this group is ongoing.

Further details of this landmark study addressing this important question can be found in Chapter 65 on febrile seizures.

Knowledge regarding the role of autoimmunity as a cause of acquired epilepsy is expanding. Antibodies to the voltage-gated potassium channel complex, contactin-associated protein-2 (Caspr2), and the N-methyl-D-aspartate (NMDA) receptor have been identified as causing epilepsy in a small proportion of children. Identification of an autoimmune antibody as the underlying cause of the epilepsy is important because there is a suggestion that these epilepsies may respond poorly to antiseizure medications and require immunotherapy. This developing area of autoimmunity and its links with limbic encephalitis and epilepsy are more completely reviewed in Chapter 119.

An epilepsy presumed to be the result of an infectious or postinfectious autoimmune process is febrile infection-related epilepsy syndrome (FIRES). This epilepsy commences with seizures evolving to status epilepticus in the setting of an intercurrent illness in children between 2 to 15 years with normal psychomotor development. The status epilepticus is typically refractory to standard treatment protocols and immunomodulatory agents, but may respond to the ketogenic diet. Unfortunately, after the status epilepticus is controlled, the child continues to have recurrent seizures refractory to antiseizure medications and has new-onset moderate to severe neurocognitive difficulties. The seizures are often lateralized, with prominent orofacial and limb motor features. The onset of the syndrome during an intercurrent illness led to the hypothesis that the chronic epilepsy is the result of an infectious or postinfectious autoimmune process. However, evaluation for an infectious, inflammatory, metabolic, or genetic etiology is typically negative, which has led to the hypothesis that FIRES is a chronic epilepsy with explosive onset of unknown cause, and not a remote-symptomatic epilepsy with an acute inflammatory antecedent.

## POSTTRAUMATIC EPILEPSY

TBI is defined by the presence of an alteration in brain function (e.g., loss of consciousness, confusion/disorientation, amnesia, focal neurologic deficit) or other evidence of brain pathology (e.g., imaging abnormality) that results from an external force. Examples of an external force include the head striking or being struck by an object, the head being subjected to a blast, a rapid acceleration/deceleration of the head that occurs in the absence of a direct force to the head (as may occur in a motor vehicle accident [MVA]), and penetrating injuries to the brain (e.g., gunshot wound). Traditionally, the severity of the TBI is classified as mild (which includes sports concussion), moderate, and severe. The current criteria used to determine the severity are based on a combination of the best available Glasgow Coma Scale (GCS) score within 24 hours of the injury, whether loss of consciousness occurred and its duration, whether posttraumatic amnesia was present and its duration, and the results of head imaging.

**TABLE 75-1** Occurrence of Late Posttraumatic Seizures in Children

Study	Cohort	Age (Years)	Follow-Up Period (Years)	N	Late Seizures (%)
Hendrick and Harris, 1968	Admitted	<15	4-12	4,465	1.3
Klonoff et al., 1977	Admitted	2.7-15.9	5	231	4
Appleton and Demellweek, 2002	Pediatric rehabilitation program	1.3-15.2	1.6-7 (median 4 yr)	102	9
Emanuelson and Uvebrant 2009	Population based	<18	10	109	11
Arango et al. 2012	Admitted (severe TBI)	0-17	≤2	270	16.9
Barlow et al., 2005	Admitted (inflicted TBI)	0.1-2.1	4.9 (average)	25	20

TBI, traumatic brain injury.

TBI is the leading cause of neurologic morbidity and mortality. The most common mechanisms of injury in the civilian population include falls, being struck by or against an object, and MVAs. In young children, nonaccidental trauma unfortunately remains a leading cause of severe TBI, whereas MVA and assault are common mechanisms in the adolescent age group.

### Early Versus Late Posttraumatic Seizures

Immediately or soon after the TBI, acute symptomatic seizures may be observed that occur in response to the temporary pathophysiological changes of synaptic, axonal, and glial function directly induced by the TBI. These early posttraumatic seizures have been reported in 1.6% to 42.5% of children and typically commence within the first 24 hours after the injury.

Seizures occurring 7 or more days after the injury have been defined as late posttraumatic seizures. In contrast to early posttraumatic seizures, the majority of late posttraumatic seizures are remote symptomatic seizures resulting from the permanent changes of brain function induced as a result of the TBI (i.e., epileptogenesis).

The International League against Epilepsy (ILAE) has recently proposed a new practical clinical definition of epilepsy that defines epilepsy as (1) at least two unprovoked (or reflex) seizures occurring more than 24 hours apart or (2) one unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years. Because the recurrence risk of late posttraumatic seizures is greater than 60%, the first occurrence of a late posttraumatic seizure can be considered the onset of the posttraumatic epilepsy.

### Epidemiology

The epilepsy that occurs following a TBI is most frequently characterized by seizures of focal onset. Studies performed on adult patients have documented that the seizures most commonly arise from the temporal or frontal lobe. In children, the data are more limited but also support that late posttraumatic seizures are predominantly focal. On occasion, epileptic spasms have been observed in children who are the victims of nonaccidental head injury.

Fortunately, posttraumatic epilepsy develops only in a minority of children who experience a TBI. In those studies in which children with a TBI have been followed for a minimum of 6 months, the occurrence of a late posttraumatic seizure has

varied between 1.3% to as high as 21.4% of the study population in those studies in which an unambiguous value could be determined (Table 75-1).

There is frequently a lag between the TBI and the development of the posttraumatic epilepsy. Although the risk for the onset of the epilepsy is highest in the first year after the injury, a small risk may persist for up to 30 years after the injury (Annegers, et al., 1998).

### Risk Factors

**Severity.** Large population-based studies have consistently demonstrated that the risk of developing posttraumatic epilepsy following TBI increases with injury severity. Specific markers of injury severity that have been correlated with an increased risk of developing posttraumatic epilepsy include the duration of loss of consciousness or amnesia at presentation, abnormal findings on head imaging (e.g., presence of a depressed skull fracture, cerebral contusion, subdural or intracerebral hemorrhage, midline shift, uncal herniation), focal abnormalities on neurologic examination, increased intracranial pressure, an acute-stage electroencephalogram (EEG) with focal abnormalities, and the need for multiple intracranial procedures (Christensen et al., 2009).

**Age.** When comparing children with adults, the risk of developing posttraumatic epilepsy after a TBI is greater in adults than in children. During childhood, the risk of developing posttraumatic epilepsy after a sustained TBI appears to be greater in the very young, which may reflect mechanism and severity of injury.

**Early posttraumatic seizures.** Early posttraumatic seizures tend to occur more frequently in children under 7 years of age than in adolescents and adults. The published incidence for early posttraumatic seizure in children varies between 1.6% and 42.5%. The high value of 42.5% was from a study performed using continuous EEG within an intensive care unit setting, and the next highest value of 30% was from a study of children with nonaccidental trauma. Risk factors for early posttraumatic seizures include injury severity (low GCS score), nonaccidental trauma, young age (<2 years), intracranial hemorrhage, prolonged loss of consciousness, and depressed or open skull fracture.

An association between the occurrence of early posttraumatic seizures and the later development of posttraumatic epilepsy has been well documented in multiple studies in both children and adults. In children, approximately 20% to 40% of children with early posttraumatic seizures will develop late posttraumatic seizures, compared with less than 5% of

children not observed to have an early posttraumatic seizure; therefore, children with early posttraumatic seizures are 3 to 9 times more likely to develop posttraumatic epilepsy.

With respect to early posttraumatic seizures, an important question is whether these seizures exacerbate the TBI and contribute to the epileptogenic process. If this were true, then prevention of these seizures may be expected to prevent or reduce the incidence of posttraumatic epilepsy. The best evidence that early posttraumatic seizures may directly lead to secondary injury comes from a convenience sample of adult patients with a TBI with a GCS score of 3 to 12 who both underwent continuous EEG monitoring at the time of presentation and had early and follow-up volumetric magnetic resonance imaging (MRI) of the brain. The degree of global atrophy was similar between those who did have seizures documented on the continuous EEG and those who did not. However, when the comparison was limited to the hippocampus, there was a greater degree of hippocampal atrophy in those with seizures, which was greater on the side ipsilateral to the seizure focus.

However, to date, only a single study that included both children and adults has demonstrated that prevention of early posttraumatic seizures with phenytoin reduced the risk of posttraumatic epilepsy. Other studies evaluating the prophylactic use of carbamazepine and valproate after TBI have failed to demonstrate a similar finding, and a meta-analysis of the best available studies of prophylactic treatment with either phenobarbital, carbamazepine, or phenytoin concluded that prophylactic antiseizure treatment did reduce the occurrence of early, but not late posttraumatic seizures (Schierhout and Roberts, 2001). Whether newer antiseizure medications, such as levetiracetam, or novel therapies, such as rapamycin, will prove effective is not yet known.

*Other.* A large population-based study identified family history of epilepsy as a factor that potentially increased the risk of developing posttraumatic epilepsy. Interestingly, single-nucleotide polymorphisms of the gene for glutamic acid decarboxylase type 1 have been linked to an increased risk of developing both early seizures and posttraumatic epilepsy. However, a genetic predisposition to posttraumatic epilepsy has not been demonstrated in all studies.

## Natural History and Treatment

The occurrence of late posttraumatic seizures has been associated with poor long-term outcomes. Posttraumatic epilepsy may also increase the risk for mortality. In a study of adults with posttraumatic epilepsy, 27% of the patients with late posttraumatic seizures died 8 to 15 years postinjury, compared with only 10% of those who had not developed posttraumatic seizures.

The optimal treatment and outcome of posttraumatic epilepsy is not well characterized in children. In a study of 50 adult patients ( $\geq 16$  years) with epilepsy and a history of head trauma, which was not better defined, only approximately 35% of the patients were seizure-free while taking antiseizure medications. In a study of children with nonaccidental trauma, 60% of the children were found to be intractable. When appropriate, epilepsy surgery should be considered because good outcomes for those with posttraumatic epilepsy have been reported.

## POSTSTROKE EPILEPSY

Stroke is recognized as an important cause of neurologic morbidity and mortality during childhood. The incidence of childhood stroke is estimated to be 2 to 13 per 100,000 children.

## Early Versus Late Poststroke Seizures

In the immediate stroke setting, acute symptomatic seizures, termed early poststroke seizures, may be observed. Early seizures are variably defined as those occurring within 7 days of stroke (Morais, Ranzan, and Riesgo, 2013; Hsu et al., 2014) or those occurring within 14 days of stroke onset. Early poststroke seizures occur in 22.3% to 58% of children who experience stroke, and these seizures frequently occur at the time of initial presentation or within 24 hours of stroke occurrence. In the setting of perinatal arterial stroke, early seizures occur in the neonatal period in 75% to 89% of neonates.

Remote seizures, termed late poststroke seizures, are also variably defined as those occurring 7 days or more after stroke occurrence or as those occurring greater than 14 days following the stroke. Late poststroke seizures are associated with a high risk of seizure recurrence, with 85.7% to 100% of children experiencing at least one seizure recurrence. Therefore, consistent with the ILAE's recent clinical definition of epilepsy, the first occurrence of a late poststroke seizure can be considered the onset of poststroke epilepsy.

## Epidemiology

Neonates and older children appear particularly vulnerable to developing poststroke epilepsy. Late poststroke seizures are reported to occur in up to 25% of children with stroke compared with only 3% in adults. Although the risk for developing poststroke epilepsy is greatest in the year following the stroke, the risk persists for many years.

## Risk Factors

Risk factors for developing poststroke epilepsy include younger age at the time of the stroke, cortical involvement, and early poststroke seizures. Although several studies have documented the association between the occurrence of early poststroke seizures and later development of poststroke epilepsy, there is no compelling evidence that prophylactic use of antiseizure medications following early seizures reduces the risk of late poststroke seizures (Fox et al., 2013).

## Natural History and Treatment

Poststroke epilepsy is frequently refractory to medical management. Several retrospective studies have found that almost 20% of these children will have multiple seizures per month despite treatment with antiseizure medications. Unfortunately, the literature is limited in terms of which antiseizure medications are best used in this setting, with limited head-to-head trials. In a prospective, open-label study evaluating the tolerability and efficacy of lamotrigine versus carbamazepine following a first poststroke seizure in adults, lamotrigine and carbamazepine were found to have equal efficacy, but lamotrigine was better tolerated. Similarly, in a multicenter, prospective, randomized, open-label study comparing the efficacy of levetiracetam versus carbamazepine in the treatment of adult patients with late poststroke seizures, levetiracetam and carbamazepine demonstrated equal efficacy, but levetiracetam was better tolerated because it caused significantly fewer side effects, including less adverse effects on cognitive functions.

When appropriate, epilepsy surgery should be considered because this treatment option has proved effective in treating intractable epilepsy related to perinatal vascular insults, with evidence for favorable long-term functional outcomes including improvements in independence, quality of life, cognitive development and motor skills.

## EPILEPSY ASSOCIATED WITH BRAIN TUMORS

Seizures and epilepsy are a frequent complication of pediatric brain tumors and their treatment and constitute a frequent reason for neurologic consultation.

Seizures may herald the initial diagnosis of a brain tumor in childhood or can occur as an acute result of the treatment or as a late treatment-related effect, occurring years after completion of treatment. New onset or recurrence of seizures in known brain tumor patients may raise concern for tumor progression/recurrence or treatment-related brain injury, in addition to other causes, including low antiseizure medication levels and metabolic dyscrasias.

The epilepsy associated with brain tumors likely results from multiple factors, including disruption of the peritumoral environment, altered expression of excitatory and inhibitory neurotransmitter receptors, change in glutamate uptake, tumoral edema, an adjacent scar, local hypoxia, acidosis, or metabolic changes.

### Epidemiology

Brain tumors are discovered in 1% to 3% of children with new onset of seizures, and seizures may precede the onset of other symptoms by several years.

### Risk Factors

Several factors affect the incidence of seizures, including age, location, histology, and grade of the tumor. Tumor pathology is associated with increased risk of seizures; specifically, slow-growing, infiltrative tumors such as dysembryoplastic neuroepithelial tumors (DNETs) and low-grade gliomas have the highest risk of seizure, with an overall incidence of up to 75% in adults and children. In addition, cortical lesions in the temporal, frontal, and parietal lobes are more often correlated with seizures than tumors in the occipital lobe or posterior fossa (Ullrich et al., 2015).

Causes of seizures related to brain tumor treatment include toxic-metabolic effects of chemotherapy (cyclosporin, asparaginase, imipenem), medication toxicity or withdrawal, radiation injury, renal or liver failure, latent non-central nervous system (CNS) infection, and electrolyte abnormalities (syndrome of inappropriate antidiuretic hormone [SIADH], hypoglycemia, hypomagnesemia, hypo- or hypercalcemia). The strongest association with seizures and chemotherapy has been reported with methotrexate, which is used to treat many pediatric cancers, including acute lymphoblastic leukemia, lymphoma, and sarcomas. Agents known to lower seizure threshold include cisplatin and vincristine because both of these agents can pass through the blood-brain barrier and can induce seizures secondary to electrolyte disturbances from hypocalcemia, hypomagnesemia, or hyponatremia.

### Natural History and Treatment

In a child with a brain tumor, the decision to initiate antiseizure medication must be considered with an interdisciplinary approach to determine whether medications are needed. In patients with a brain tumor but no prior history of seizures, the American Academy of Neurology (AAN) task force advised against the use of routine antiseizure medication prophylaxis for individuals with a primary brain tumor, except during the week following surgery (Glantz et al., 2000).

The choice of antiseizure medication is often challenging, particularly because many of the more traditional antiseizure

medications, such as phenytoin, carbamazepine, and phenobarbital, can affect metabolism of chemotherapeutic drugs by inducing increased activity of the cytochrome p450 system. This may result in decreased efficacy of antitumor therapy, decreased seizure control, and/or unexpected toxicity. By contrast, some data suggest that the antiseizure medication valproic acid may actually contribute an antitumor effect through action as a histone deacetylase inhibitor. In general, enzyme-inducing or enzyme-inhibiting antiseizure medications are less preferable. Newer medications, especially those without known drug-drug interactions, are becoming accepted as first-line seizure treatment in children who require ongoing seizure treatment (Wells, Gaillard, and Packer, 2012). Another important consideration is that the child with a brain tumor may be more susceptible to side effects of antiseizure medications, with an overall incidence of drug effects as high as 20% to 40%. Lastly, consideration of epilepsy surgery for refractory seizures may be appropriate for uncontrolled seizures in the setting of a brain tumor.

The decision to discontinue antiseizure medications in a child with a brain tumor who has achieved seizure freedom is dependent on several factors, including extent of surgical resection (incomplete resection is associated with higher risk for seizure recurrence), tumor recurrence, tumor location (temporal and cortically based tumors are associated with higher risk), and history of more than one prior tumor resection. Short-term treatment may be adequate during the perioperative period; however, the presence of residual and/or metastatic disease, abnormal EEG, and history of seizure at presentation may suggest the need for longer-term use of anticonvulsants.

## INTRODUCTION

The inherited metabolic epilepsies are a diverse group of disorders of inborn errors of metabolism in which epilepsy is a clinically significant, if not the presenting or predominant, component. They may be viewed within the rubric of genetic-metabolic epilepsies and bear special emphasis in this section on pediatric epilepsy because of their unique properties. In these disorders, the seizures and associated encephalopathy are generated based on the inborn metabolic error. In some cases, specific therapy directed at the metabolic error can lead to reversal of the epilepsy and encephalopathy, or at least a dramatically improved outcome. Yet prompt diagnosis and targeted intervention, beyond standard and nonspecific anti-seizure medications, are required in order to affect the prognosis in a salutary way.

Although individually rare, metabolic disorders in aggregate represent a substantial clinical problem—and challenge—in child neurology. They may present with various epilepsy phenotypes, including early-onset epileptic encephalopathy (including refractory neonatal seizures, early myoclonic encephalopathy, and early infantile epileptic encephalopathy frequently referred to as Ohtahara syndrome), infantile spasms, or mixed generalized seizure types in infancy, childhood, or even adolescence and occasionally adulthood. Although inborn metabolic diseases are covered elsewhere throughout this text in sections devoted to metabolism, those with special applicability to epilepsy, along with their epileptic aspects, are emphasized here with reference to more comprehensive discussions of single disorders as applicable.

## GENERAL PRINCIPLES

The inherited metabolic epilepsies are most likely to occur when seizure onset is in the neonatal, infantile, or early childhood periods (Box 76-3). A typical clinical presentation is that of a newborn with impaired feeding who is noted to ultimately become encephalopathic with hypotonia, lethargy, or respiratory distress. Myoclonic seizures are classic, although apneic episodes, oculofacial movements, grunting, and epileptic spasms are also well described ictal events. EEGs may show discontinuous patterns characterized by burst suppression (or suppression burst, e.g., in early myoclonic encephalopathy), continuous or frequent intermittent generalized sharp or spike wave activity, hypsarrhythmia or modified hypsarrhythmia, and multifocal spike discharges superimposed upon background disorganization, including loss of normal sleep architecture. A family history of consanguinity or a metabolic disorder is a strong contributing historical factor, and poor response to traditional antiepilepsy medication may be an important clue. The absence of a clear diagnosis to explain seizure onset is also helpful, but a suspicion of hypoxic-ischemic newborn encephalopathy, or the presence of structural abnormalities on neuroimaging, should not be taken as evidence of absence of an underlying metabolic disorder. In some cases imaging findings such as callosal dysgenesis in pyruvate dehydrogenase complex deficiency, intraventricular choroid plexus cysts in Zellweger syndrome, and enlarged

Sylvian fissures in glutaric aciduria type I are indeed suggestive of a specific underlying metabolic disorder.

These disorders can be classified in several ways. One rational approach is to consider what pathophysiologic mechanisms are likely most responsible for seizure generation such as impaired energy production, accumulation of toxic intermediates, neuronal storage products and cellular dysfunction, absence of vital vitamins (i.e., forms of vitamins that have similar chemical structure and physiologic vitamin activity) or neurotransmitters, or associated structural abnormalities (Box 76-2). On a clinical level, the disorders can be categorized based on typical age of onset, or most likely seizure type. Each of these methods contributes to our understanding of how these disorders may be associated with seizures and lead to an epileptogenic encephalopathy, meaning that the underlying disorder leads to inherent epileptogenesis and an ongoing encephalopathy that would require specific intervention aimed at the metabolic error to reverse or improve the phenotype. EEG is important in the diagnostic assessment and follow-up investigations of these patients but lacks the specificity to obviate investigations with imaging, metabolic profiles including plasma, urine, and CSF analyses, and genetic testing typically involving comparative genomic hybridization, gene sequencing panels relevant to the patient's phenotype, and, in some cases, whole exome sequencing when the earlier studies do not yield a diagnosis. There are, however, some EEG patterns that have a strong association with particular conditions—e.g., comb-like rhythmic waves in maple syrup urine disease, RHADS (repetitive high amplitude delta waves with spikes or polyspikes) in Alper disease associated with POLG mutations (Fig. 76-2), vanishing EEG in infantile type NCL, giant visual evoked potentials and photic responses in Lafora body disease, and certain entities known to present with common patterns such as burst suppression as in glycine encephalopathy and hypsarrhythmia in several of these disorders. One logical and practical approach to categorizing inborn errors of metabolism is to structure them based on whether the primary defect involves small or large molecules.

## SMALL MOLECULE DISORDERS

### Amino and Organic Acid Disorders

Amino and organic acidopathies present with seizures, typically myoclonic, and cognitive, behavioral, or motor disturbances resulting from the accumulation of toxic intermediaries, or possibly structural damage (Kölker, et al., 2008). Some may induce an epileptic encephalopathy.

EEG findings may include burst suppression, hypsarrhythmia, generalized spike wave discharges, and background slowing. These disorders are covered in detail elsewhere; aspects related to epilepsy are emphasized here.

*Methylmalonic Acidemia and Cobalamin Deficiencies.* Early myoclonic encephalopathy and epileptic encephalopathy have been associated with these disorders. The most common methylmalonic acidemia involving cobalamin is cobalamin C deficiency; individuals may present in infancy or early childhood with seizures, including status epilepticus and progressive

encephalopathy. Treatment with hydroxycobalamin is effective, including prenatal supplementation in affected families but may not reverse existing neurologic injury.

**Propionic Acidemia.** Epilepsy may present as infantile spasms with hypsarrhythmia or generalized seizures, including myoclonic in infancy or early childhood.

**Ethylmalonic Acidemia.** Ethylmalonic acidemia is usually lethal in infancy or early childhood and has a severe presentation including seizures, structural brain malformations, and often dermatologic findings, including petechiae and acrocyanosis. EEGs have multifocal spike and slow waves and background disorganization that may progress inexorably over time.

**3-Hydroxy-3-Methylglutaric Acidemia.** Seizures are linked in most cases to lactic acidemia or hypoglycemia and are associated with multifocal spike wave discharges on EEG. Some presentations show particular association with white matter lesions, dysmyelination, and cerebral atrophy on neuroimaging.

**Glutaric Acidemia type I.** The phenotype is macrocephaly, increased subarachnoid spaces, and progressive dystonia and

athetosis with striatal injury. Seizures can be a presenting sign and are seen during acute encephalopathic events. EEGs show background slowing with generalized spike-and-wave and mixed multifocal discharges. The antiepileptic valproate should be avoided because it is believed to affect acetyl CoA/CoA ratios and may exacerbate metabolic imbalance.

**Canavan Disease.** Canavan disease, caused by a defect of N-acetylaspartic acid (NAA) catabolism, presents with progressive epileptic encephalopathy with developmental delay, macrocephaly, leukodystrophy, and optic atrophy. Seizures typically begin in the second year of life, and treatment is primarily supportive.

**D- and L-2-Hydroxyglutaric Aciduria.** Severe cases manifest in the neonatorum with encephalopathy, intractable epilepsy, and cardiomyopathy. MRI findings include abnormal basal ganglia and thalamic signal intensity and agenesis of the corpus callosum.

The enantiomer, L-2-Hydroxyglutaric aciduria, is a disorder of alpha ketoglutarate synthesis. It presents with neurodevelopmental delay, generalized seizures, and progressive ataxia. Multifocal spike waves and burst suppression can be seen on

### BOX 76-2 Pathophysiologic Mechanisms Invoked in Inherited Metabolic Epilepsies

#### ENERGY DEFICIENCY

Hypoglycemia, GLUT1-deficiency, respiratory chain defects, creatine deficiency

#### TOXIC ACCUMULATION

Amino acidopathies, organic acidurias, urea cycle defects

#### IMPAIRED NEURONAL FUNCTION

Storage disorders

#### DISTURBANCE OF NEUROTRANSMITTER SYSTEMS

Glycine encephalopathy, GABA transaminase deficiency, SSADH deficiency, creatine synthesis/transport defects, serine synthesis defects, sulfite oxidase/Mb cofactor deficiency

#### ASSOCIATED BRAIN MALFORMATIONS

Peroxisomal disorders (e.g., Zellweger), O-glycosylation defects

#### VITAMIN/COFACTOR DEPENDENCY

Biotinidase deficiency, pyridoxine and PLP dependencies, folinic acid dependency, cerebral folate deficiency, Menkes disease

### BOX 76-3 Metabolic Epilepsies—Examples Based on Age at Onset

#### NEONATAL

Hypoglycemia, pyridoxine dependency, PNPO deficiency, glycine encephalopathy, organic acidurias, urea cycle defects, neonatal ALD, Zellweger, folinic acid dependency, holocarboxylase synthase/biotinidase deficiency, molybdenum cofactor deficiency, sulfite oxidase deficiency

#### INFANCY

Hypoglycemia, GLUT1-deficiency, creatine deficiency, biotinidase deficiency, amino acidopathies, organic acidurias, CDG, pyridoxine/P5P dependency, NCL1

#### TODDLERS

NCL2, mitochondrial disorders, lysosomal storage disorders, thiamine transporter deficiency (biotin-thiamine responsive basal ganglia disease)

#### SCHOOL AGE

Mitochondrial disorders, NCL3, progressive myoclonus epilepsies, thiamine transporter deficiency

**Figure 76-2.** EEG shows RHADS, or rhythmic high amplitude delta with (poly)spikes, in 11-month-old girl presenting with status epilepticus, abnormal occipital and thalamic signal on MRI, and compound heterozygosity for two disease-causing POLG1 mutations.

EEGs, and characteristic MRI findings include cerebellar atrophy, subcortical white matter loss, and T2-weighted hyperintensities in the cerebellar dentate nuclei, globus pallidi, and thalami.

**Fumaric Aciduria.** The disorder can present prenatally with polyhydramnios and cerebral ventriculomegaly and manifests in infancy and early childhood with epilepsy, neurodevelopmental delay, macrocephaly, opisthotonus, and vision loss. Status epilepticus is well reported. Diffuse polymicrogyria, decreased white matter, large ventricles, and open opercula have been identified on neuroimaging.

**Maple Syrup Urine Disease (MSUD).** Neurologic symptoms present in infancy and include cerebral edema and seizures. The EEG may show a characteristic comb-like rhythm. Treatment focuses on removing leucine from blood with dialysis or by reversing catabolism through feeding.

**Serine Synthesis Defects.** The clinical phenotype is congenital microcephaly, psychomotor retardation, and refractory seizures including hypsarrhythmia. Juvenile onset has also been reported, with presentation at school age with absence seizures and moderate developmental delay. Supplementation with oral serine and glycine has been reported to improve outcome, including prenatal intervention.

**Sulfide Oxidase Deficiency/Molybdenum Cofactor Deficiency.** Seizures, primarily myoclonic or tonic-clonic, begin in the first few weeks of life; they can be refractory to therapy and may develop into status epilepticus. EEG findings include burst suppression patterns and multifocal spike wave discharges, and neuroimaging results are usually profoundly abnormal, including diffuse cerebral edema evolving into cystic lesions and brain atrophy within weeks. Low total plasma homocysteinemia is associated with both, and hypouricemia due to secondary xanthine dehydrogenase deficiency can be indicative of Mb cofactor deficiency. Therapy has historically been symptomatic, predominantly with anti-seizure medications. There are later-onset forms that can develop a neurodegenerative pattern although recovery and developmental progress can occur. Decreased plasma uric acid can be a diagnostic clue in otherwise unsuspected late cases.

**Hyperhomocysteinemias.** The spectrum of neurologic dysfunction in homocysteine metabolism disorders is wide, including epilepsy, encephalopathy, peripheral neuropathy, ataxia, microcephaly, and psychiatric disorders. Focal seizures, stroke, neurodevelopmental delay, and cognitive deficiency, as well as psychosis are common neurologic findings. Pyridoxine, cyanocobalamin, folate, and a methionine restricted diet are used in cystathionine beta-synthetase deficiency, whereas high-dose hydroxycobalamin is useful in methionine synthase deficiency.

Autosomal recessively inherited deficiency of *methylene tetrahydrofolate reductase* (MTHFR) may present in early infancy with severe epileptic encephalopathy or infantile spasms, and evolve to Lennox Gastaut syndrome or status epilepticus. The methyl donor betaine may have a therapeutic role.

**Creatine Biosynthesis and Transport Deficiencies.** Creatine is an organic acid synthesized from L-arginine, glycine, and methionine and is critical in ATP production. Patients with deficiencies in creatine synthesis or transport present with early developmental delay, seizures, neurologic regression, intellectual disability, autistic behavior, hypotonia, and movement disorders. Females with heterozygous mutations of the X-linked creatine transporter gene may be symptomatic with more moderate intellectual disability, learning and behavior problems, and epilepsy. Approximately half of individuals with GAMT deficiency and most males with creatine transporter deficiency develop epilepsy. EEGs demonstrate generalized or multifocal spike discharges and background slowing.

## Fatty Acid Oxidation Disorders

Seizures can be a presenting sign of fatty acid oxidation disorders, a large category of diseases that particularly involve the CNS and other organ systems that have high energy demands. Metabolic decompensation can be triggered by physiologic stressors such as fasting, fever, or physical exertion, and symptoms can appear at any age. Acute crises resemble Reye syndrome, with cardiomyopathy and arrhythmia, as well as rhabdomyolysis and hypoketotic hypoglycemia.

## Mitochondrial Diseases

Epilepsy is common in mitochondrial disease and includes all seizure types. Myoclonic seizures are the most commonly reported, but *epilepsia partialis continua* and epileptic encephalopathy occur as well. Seizures are a logical consequence of mitochondrial dysfunction: deficient energy generation disrupts the active maintenance of neuronal membrane potentials, and seizure-induced cellular hyperactivity adds further oxidative stress to already deficient ATP generation. Up to 60% of patients with mitochondrial disease develop seizures, and many of these can be refractory to treatment.

**POLG1 Disease.** Mutations in the gene *POLG1*, which facilitates mitochondrial DNA replication, have been linked to a range of disease phenotypes, the most prominent being Alpers-Huttenlocher disease. This is a rapidly progressive encephalopathy with multiple seizure types (Wolf, et al., 2009). The syndrome has been associated with a pattern of Rhythmic High Amplitude Delta with Polyspikes on EEG (RHADS), typically most prominent over the occipital regions (Fig. 2) (Wolf, et al., 2009). Valproate has been associated with liver failure and *epilepsia partialis continua* in this syndrome.

**Myoclonic Epilepsy with Ragged Red Fibers (MERRF).** MERRF is a progressive mitochondrial disorder associated with prominent myoclonus, cognitive decline, optic atrophy, hearing loss, and myopathy (DiMauro and Schon, 2008). EEG findings include focal discharges, atypical spike- or sharp- and slow-wave discharges, and suppression of this activity during sleep. MELAS, or myoclonic epilepsy with lactic acidosis and stroke-like episodes, is associated with various forms of focal onset seizures, often occurring during the acute phase of a stroke-like episode, or described as *epilepsia partialis continua*, hemiclonic status, occipital status, and nonconvulsive status epilepticus.

**Leigh Syndrome.** Also known as subacute necrotizing encephalomyelopathy, this syndrome manifests with progressive hypotonia, spasticity, and brainstem failure and lesions in the basal ganglia, thalami, midbrain, and brainstem as well as cortical and cerebellar atrophy. Focal and generalized seizures, *epilepsia partialis continua*, and infantile spasms have all been described. A disorder that may simulate Leigh disease is biotin-thiamine responsive basal ganglia disease, an autosomal recessive disorder due to mutations of the thiamine transporter *SLC19A3* gene. Patients present acutely or subacutely with encephalopathy, ataxia, seizures, and a mixed pyramidal and extrapyramidal syndrome, including dystonia, quadriparesis, and hyperreflexia. MRI may show basal ganglia edema acutely and atrophy over time.

## Urea Cycle Disorders

The urea cycle, the metabolic mechanism for nitrogen detoxification and removal, is facilitated by six enzymes and a mitochondrial transporter and carrier. In the event of an enzyme or transport defect, the resulting hyperammonemia can lead to overwhelming encephalopathy, often accompanied by seizures that may be exacerbated by metabolic stresses such as

fever or infection. EEG monitoring should be initiated early in the course of acute treatment, as seizure activity is thought to be related to hyperammonemic crises or structural damage, and subclinical electrographic seizures are reported. Males with ornithine transcarbamylase deficiency typically present in the neonatorum and with high mortality, whereas female heterozygotes can vary in the severity and timing of presentation depending on hepatic lyonization.

## Disorders of Glucose Homeostasis

*DEND Syndrome (Developmental Delay, Epilepsy, and Neonatal Diabetes).* A syndrome that combines the problems of developmental delay, epilepsy, and neonatal diabetes is an epileptic channelopathy associated with mutations in potassium channel and sulfonylurea receptor genes (Shimomura, et al., 2007). These mutations permanently “lock in” the K channel in an open state, leading to insufficient insulin release and severe hyperglycemia within the first 6 months of life. Clinical manifestations include neurodevelopmental delay, dysmorphic features, hypotonia, and seizures starting as early as the neonatorum. Infantile spasms with hypsarrhythmia, as well as severe tonic-clonic and myoclonic epilepsies, are reported. Sulfonylureas are capable of bypassing the defective regulation of KATP channels and may improve the otherwise poor neurologic outcome (Shimomura, et al., 2007).

*Hyperinsulinism-Hyperammonemia (HI-HA).* HI-HA is a syndrome of congenital hyperinsulinism and hyperammonemia that has been related to activating mutations that affect GDH (glutamate dehydrogenase), affecting the insulin secretion pathway. These defects cause GDH to become insensitive to inhibition, resulting in excess ammonia production and insulin release and neurologic sequelae from hypoglycemic insults. The clinical constellation of generalized epilepsy, learning disorders, and behavior problems, in the context of hypoglycemia (both postprandial and fasting) and persistent hyperammonemia, is characteristic.

*Glucose Transporter 1 Deficiency.* Glucose transporter type I (Glut-1) facilitates the passage of glucose across the blood-brain barrier, and its dysfunction in the developing brain leads to the development of a metabolic encephalopathy. CSF shows hypoglycorrachia associated with normal plasma glucose and low-to-normal CSF lactate, measured in a fasting state. A wide array of phenotypes has been associated with this disorder, but 90% of affected children develop epilepsy (of various types, including absence, focal, generalized myoclonic, clonic, tonic, and nonconvulsive status epilepticus). Microcephaly, ataxia, and psychomotor delay may be present (De Vivo, et al., 1991), but patients may also suffer from epilepsy without any accompanying motor or cognitive deficiencies. EEG findings vary and may be normal but usually include either focal or generalized slowing or attenuation, or spike-and-wave discharges (generalized, focal, or multifocal).

Glucose transporter I deficiency has emerged as the leading metabolic indication for the ketogenic diet, a dietary therapy that replaces glucose with ketone bodies as the primary biochemical energy source. Response is rapid, even in the case of formerly refractory seizures, and treatment should be maintained long term. Additionally, there are certain compounds known to inhibit Glut-1, including phenobarbital, diazepam, methylxanthines (theophylline, caffeine), and alcohol, which should be avoided; valproate is generally avoided as well (Wang, et al., 2015).

## Vitamin Dependency States

*Pyridoxine, Folinic Acid, and Pyridoxal-5-Phosphate Dependent Epilepsies.* There are various epileptic encephalopathies related to vitamin B<sub>6</sub> metabolism, and pyridoxine-dependent epilepsy

(PDE) is the prototype, resulting from a loss of the biologically active pyridoxal-5-phosphate (PLP) due to a dysfunction of the protein antiquitin (ALDH7A1) (Mills, et al., 2006). PDE typically presents within the first hours after birth with serial refractory seizures responsive to pyridoxine administration. Improvement is significant and usually rapidly appreciable on EEG. Variants of the disorder that respond to folinic acid instead of, or in addition to, pyridoxine have also been described, as well as atypical cases with long asymptomatic periods or presenting later in infancy (i.e., weeks or months after birth).

PNPO, or pyridoxamine phosphate oxidase, deficiency is due to a defect in the enzyme PNPO, which synthesizes PLP from precursors pyridoxine-P and pyridoxamine-P. This syndrome is more typically associated with premature births and a distinct CSF profile compared with ALDH7 A1 deficiency pyridoxine dependency, although there is considerable overlap between the two including responsiveness to pyridoxine (Plecko, et al., 2014; Mills, et al., 2014).

*Cerebral Folate Deficiency (CFD).* Known as cerebral folate “deficiency,” albeit a dependency state as opposed to a dietary deficiency, CFD can be a common end result of diverse metabolic and genetic conditions. This may be due to one of multiple causes, including loss of function mutations in the folate FR1 receptor, blocking autoantibodies to the folate receptor, or disrupted uptake due to valproic acid. Secondary folate deficiency can also be seen in inborn metabolic diseases such as Rett syndrome, 3-phosphoglycerate dehydrogenase deficiency (a congenital serine biosynthesis disorder), and mitochondrial disorders such as Kearns-Sayre or Alpers disease.

Primary cerebral folate deficiency (CFD) is characterized by normal blood but low CSF levels of 5-methylhydrofolate (5-MTHF), the physiologically active form of folate. The common phenotype includes epilepsy, along with neurodevelopmental delay (or regression) and dyskinesias. In some cases, treatment with high doses of folinic acid (as opposed to folic acid, which has poor blood-brain barrier entry) has been reported to ameliorate seizures and improve neurologic function.

## Neurotransmitter Disorders

*Disorders of GABA Metabolism.* Seizures are an important problem in disorders of the synthesis or degradation of gamma-aminobutyric acid (GABA), the brain’s primary inhibitory neurotransmitter. The most common of these is succinic semialdehyde dehydrogenase (SSADH) deficiency, though GABA-transaminase deficiency—although extremely rare—has been more associated with a severe, progressive epileptic encephalopathy (Pearl, et al., 2009).

*Glycine Encephalopathy.* Glycine encephalopathy is an inherited disorder of glycine degradation resulting from defects in the mitochondrial glycine cleavage system (GCS). The majority of patients present with a severe neonatal-onset form, with primarily myoclonic and intractable seizures, hypotonia, apnea, and coma. Outcomes are generally poor, particularly in the presence of brain malformations such as corpus callosum hypoplasia. There are attenuated forms, lacking congenital malformations, with a better outcome. EEG findings include multifocal epileptiform activity, hypsarrhythmia, and burst-suppression patterns. Treatment with benzoate and a low-protein diet may reduce glycine levels in plasma, and combined antiseizure medical treatment is usually required.

## Purine and Pyrimidine Defects

Disorders of purine and pyrimidine metabolism may present with epileptic encephalopathies, including adenylosuccinase (adenylosuccinate lyase) deficiency which has a broad

phenotypic spectrum including neonatal seizures. Lesch-Nyhan disease, or X-linked hypoxanthine-guanine phosphoribosyl transferase deficiency, may result in epileptic seizures, but these can be difficult to distinguish from the extrapyramidal manifestations, specifically dystonic spasms, tremor, and myoclonus. Generalized tonic-clonic seizures are the most commonly reported epilepsy type. Treatment with allopurinol is essential for hyperuricemia and may provide some antiepileptic effect. Medication choices must weigh the possibility of exacerbating underlying behavioral irritability with levetiracetam and others. Topiramate and zonisamide are avoided due to the risk of nephrolithiasis.

## LARGE MOLECULE DISORDERS

### Disorders of Glycosylation

Disorders of protein glycosylation, due to defects in the synthesis of N- and O-linked glycoproteins, are characterized by multiple organ system dysfunction, developmental delay, hypotonia, and epilepsy. Certain of these disorders are associated with severe encephalopathy, particularly those involving alpha-dystroglycan, a protein component of the extracellular matrix, essential to muscle integrity. These are known as dystroglycanopathies. Examples that include frequent seizures are Walker-Warburg syndrome and Fukuyama congenital muscular dystrophy.

### Lysosomal Storage Disorders

Lysosomal storage disorders (LSD) involve defects in lysosomal enzyme function, lysosomal biogenesis, activation, trafficking, or membrane transporters. Over two thirds are neurodegenerative and some are associated with epileptic encephalopathy. Specific examples with active associated epilepsy are the neuronal ceroid lipofuscinoses, sphingolipidoses including Gaucher disease (glucocerebrosidase deficiency), and gangliosidoses, including Tay-Sachs disease (hexosaminidase A deficiency).

### Peroxisomal Diseases

As a participant in cellular detoxification, lipid metabolism, myelination, neuronal function, migration, and brain development, peroxisomes are essential for neuronal health. Nearly all peroxisomal disorders are known to impair neurologic function, though peroxisomes are present in almost all eukaryotic cells, and consequently the associated diseases will also manifest in multiple organ systems. The disorders may be classified as those of biogenesis, single enzyme deficiencies, or contiguous gene syndromes. Seizures occur particularly in the neonatal period and may be a result of cortical migration defects. Symptomatic treatment using anticonvulsants is the predominant therapy.

### Leukodystrophies

Genetic leukoencephalopathies, or inherited white matter disorders, are diseases that primarily affect myelinated structures in the brain and peripheral nervous system. The majority of leukodystrophies primarily feature motor dysfunction rather than encephalopathy, particularly early in the development of the disease. Epilepsy, however, can be a prominent symptom in certain classic leukodystrophies such as Alexander disease. This is associated with defects in the GFAP gene encoding astrocyte intermediate filaments. Early-onset forms of Alexander disease (Type I) frequently feature seizures, particularly associated with fever, that are difficult to control. The clinical

course of type I Alexander disease is normally progressive neurodegeneration involving megalencephaly, psychomotor retardation, and spastic paraplegia. Globoid cell leukodystrophy (Krabbe disease), metachromatic leukodystrophy, and hereditary leukodystrophy with spheroids are other examples in which epilepsy may be a prominent component of the phenotype.

## CONCLUSION

Epilepsy may be a prominent presenting feature, or major morbidity, of a variety of inborn errors of metabolism. The diagnostic evaluation and oftentimes therapeutic approach, however, are different than what would be considered the classic approach to evaluation and management of epilepsy. Early life onset and epileptic encephalopathies are especially characteristic.

These disorders have various degrees of treatability at present, with some requiring prompt diagnosis and intervention to avert otherwise potentially poor outcomes. Early myoclonic encephalopathy and myoclonic seizures represent a classic epilepsy syndrome and seizure type, respectively, associated with inborn errors of metabolism. Yet the phenotypic spectrum of epilepsy caused by hereditary metabolic disorders is wide and includes refractory neonatal seizures, early infantile epileptic encephalopathy (syndrome of Ohtahara), infantile spasms, and progressive myoclonic epilepsy, as well as syndrome variations such as early-onset absence epilepsy in glucose transporter deficiency. A careful approach to metabolic disorders is helpful to consider the various diseases that may present and develop into a severe epilepsy or epileptic encephalopathy.

The small molecule disorders include amino and organic acidopathies such as maple syrup urine disease, homocysteinemia, multiple organic acid disorders, and cobalamin deficiencies. Dietary intervention is key to preventing encephalopathy in maple syrup urine disease and glutaric aciduria, and hydroxycobalamin has a therapeutic role starting in prenatal intervention in cobalamin C deficiency. Neurotransmitter and fatty acid oxidation disorders may result in epileptic encephalopathies, and mitochondrial disorders present with a range of epilepsy phenotypes, including *epilepsia partialis continua* in polymerase gamma mutations. Cerebral folate deficiency appears to result from a variety of causes, but primary deficiency, associated with mutations of the folate receptor or blocking antibodies, has a phenotype of intractable generalized seizures in infancy which may respond to folinic acid.

Disorders of serine synthesis may respond to prenatal and postnatal supplementation with serine and glycine. There are several potassium channelopathies involving the pancreas and brain, presenting either with neonatal diabetes or hypoglycemia, with specific therapeutic implications. Glucose transporter deficiency appears to be the prototype of transport defects causing epilepsy and having specific therapy, in this case the ketogenic diet, and the disorders related to the pyridoxine vitamers, specifically pyridoxine and pyridoxal-5-phosphate, require prompt identification and therapy. Autosomal recessively inherited deficiency of MTHFR may be reversible with use of betaine, whereas other small molecule defects causing epileptic encephalopathy, for example, glycine encephalopathy and sulfite oxidase deficiency, have no specific therapy at this time.

Large molecule disorders involve a complex constellation of disorders of glycosylation, lysosomal storage diseases, and peroxisomal disorders. Although epilepsy represents significant gray matter involvement in neurologic disease, seizures can be a prominent aspect of leukodystrophies such as

Alexander disease. These hereditary disorders should be highly considered in the investigation of patients with severe epilepsies and epileptic encephalopathies, leading to specific diagnostic steps and, in some cases, potential therapeutic maneuvers to address the metabolic defect and improve the epilepsy and encephalopathy.

Rational management of antiseizure drug therapy in children requires an understanding of pharmacokinetics, pharmacodynamics, and toxicology of these agents. Pharmacokinetics is the study of drug absorption, distribution, metabolism, and elimination: that is, what the body does to a drug. Pharmacodynamics is the study of a drug's biochemical and physiologic effects: that is, what the drug does to the body. Children, much more than adults, have widely varying abilities to absorb, distribute, metabolize, and eliminate drugs. Evidence also exists that antiseizure drug pharmacodynamics in children differ from those in adults. Application of basic pharmacokinetic and pharmacodynamic principles to antiseizure drug therapy facilitates the attainment and maintenance of targeted serum concentrations, optimization of the clinical response, and control of drug interactions.

Adverse reactions often dictate the choice of an antiseizure drug and subsequent adjustment of therapy. An understanding of these reactions, including their differences and similarities among various antiseizure drugs, and the application of appropriate clinical and laboratory monitoring provide the tools needed for the clinician to prescribe antiseizure drug therapy rationally.

### PHARMACOKINETIC PRINCIPLES

Antiseizure drug absorption and elimination varies greatly among patients in the pediatric population, from neonates to teens. Potential sources of variability are numerous, and include drug formulation, behavior (compliance, diet, substance abuse), environment, and physiology. Physiologic variability may be related with the general health of the patient, but also with specific factors such as gender, age, maturation, and, in a few cases, pregnancy. In the management of pediatric patients with seizures, there is a concern with the effects of age and maturation on the pharmacokinetic profile of the antiseizure drugs. A drug's effect on a child's learning and behavior should also be a major determinant influencing the choice of an antiseizure drug. Age has the most influence on antiseizure drug elimination, metabolic pathways, and absorption. Factors such as protein binding and enzyme induction and/or inhibition are similar for children and for adults. Absorption may differ among similar formulations (such as tablets) from various manufacturers (e.g., carbamazepine) or with different formulations from the same manufacturer (immediate vs. extended release). Pharmacokinetic information for the antiseizure drugs is summarized in [Table 77-1](#) and [Table 77-3](#). See [online version](#) for more detail ([Anderson and Lynn, 2009](#)).

### PHARMACODYNAMICS

#### Dose–Response or Concentration–Response Concept

Substantial evidence exists that both the number of patients experiencing seizure control increases and the degree of seizure control for a given patient improves with higher antiseizure drug concentrations. The minimum effective

concentration defines the concentration at which the desired pharmacologic response is first observed and is not always the same in all patients. The intensity of response increases in direct proportion to drug concentration, until a response is maximized defining the maximum pharmacologic effect for that drug. With some drugs, such as phenytoin, further increases in concentration may reduce response (e.g., phenytoin-induced exacerbation of seizures). The incidence and severity of side effects also increase with drug concentration. The concentration at which side effects appear is usually, but not always, greater than the concentrations needed to achieve seizure control. The difference between concentrations that produce desired responses and those that produce toxic responses defines the therapeutic range.

### Tolerance

Tolerance is a phenomenon in which pharmacologic or toxicologic effect diminishes with chronic use, even at the same or increasing plasma concentrations. Different mechanisms for the development of tolerance have been recognized. Mechanisms of tolerance can be because of biochemical adaptation (e.g., upregulation or downregulation of receptor sites) or behavioral. For example, the effectiveness of benzodiazepine therapy diminishes over time, necessitating even larger doses. Behavioral tolerance is when patients become progressively insensitive to drug effect without any apparent biochemical change. For example, many patients initiated on phenobarbital or primidone exhibit mild neurotoxicity even at low plasma concentrations but later, at the same concentration, have no symptoms.

Tolerance can produce changes in clinical response that mimic certain drug interactions. For example, loss of seizure control may result from either tolerance, as in the case of clonazepam, or enzyme induction, which decreases concentrations of many antiseizure drugs. Differentiating between these phenomena is important in considering adjustments in drug therapy.

### PHYSIOLOGIC FACTORS AFFECTING DRUG DISPOSITION IN CHILDREN

#### General Considerations

Antiseizure drug pharmacokinetics and dosage requirements are influenced by the changing physiology of children as they age. The physiologic changes associated with maturation produce marked alterations in antiseizure drug pharmacokinetics. The variability with which children reach developmental milestones, along with genetic and environmental factors, causes antiseizure drug pharmacokinetics to vary substantially, even in children of the same age. As a result of the differences between children and adults, children require more frequent and larger doses relative to body size to attain targeted plasma concentrations. Although important age-related, quantitative differences in antiseizure drug pharmacokinetics are recognized, the pattern of drug-specific pharmacokinetics, such as

**TABLE 77-1** Formulations, Routes of Administration, and Bioavailability of Antiseizure Drugs

Medication	Available Formulation	Possible Route*	T <sub>max</sub> (hr)	Fraction Absorbed (F)	Special Problems
Acetazolamide	Tablet	PO	1–4	N/a	
	ER capsule	PO	3–6	N/a	
	Injectable	IV, IM	0.25	N/a	
Carbamazepine	Tablet	PO	3–8	0.79	Prolonged absorptive phase with variable T <sub>max</sub> ; induction results in earlier T <sub>max</sub> .
	Chewable tablet	PO	2	0.79	
	Suspension	PO, PR	0.5–3	0.7–0.9 estimate	Earlier T <sub>max</sub> results in higher C <sub>max</sub> , which can produce transient side effects.
	ER tablet	PO	3–12	0.89 relative to susp.	Tablet must be swallowed whole; do not crush or chew.
	ER capsule	PO	4–8	0.79	Capsules may be opened and the beads sprinkled over food, such as a teaspoon of applesauce or other similar food products. Capsules or their contents should not be crushed or chewed.
Clonazepam	Tablet	PO	1–8	0.85	
Clorazepate	Tablet	PO	0.7–1.5	0.91	
Diazepam	Tablet	PO	0.5–2	0.8–1	
	Concentrated oral solution	PO	0.1–0.5	0.8–1	
	Gel	PR	0.75	0.9	
	Injectable	IM, IV	1–1.5	0.8–1	IM absorption is slow and variable.
Ethotoin	Tablet	PO	2	N/a	
Ethosuximide	Syrup	PO	1.5–4	N/a	
	Capsule	PO	3–7	N/a	
Eslicarbazepine Acetate	Tablet	PO	1–4	1 relative to susp	
Ezogabine	Tablet	PO	0.5–2	0.6	Partially active N-acetyl metabolite (NAMR)
Felbamate	Tablet	PO	1–4	N/a	
	Suspension	PO	3.7	N/a	
Fosphenytoin	Injectable	IV, IM	0.5 (IM)	1	Fosphenytoin concentrations after IM administration are lower but more sustained than those after IV administration owing to time required for absorption of fosphenytoin from injection site.
Gabapentin	Capsule	PO	2–4	0.6–0.27	Gabapentin bioavailability decreases as dose increases.
	Tablet	PO	2–4	0.6–0.27	
	Solution	PO	2–4	0.6–0.27	
Lacosamide	Tablet	PO	1–4	1	
	Solution	PO	1–4	1

\*Primary and alternates.

saturation of absorption, protein binding, metabolism, and enzyme induction, is similar for children and for adults.

A number of physiologic and pathophysiologic processes can alter antiepileptic drug pharmacokinetics. Gastrointestinal disorders, particularly those that increase transit time, can alter the endothelial lining and decrease absorption. Antiepileptic drugs that are slowly absorbed, such as carbamazepine and phenytoin, are most likely to be affected. Physiologic stress, such as that associated with myocardial infarction, burns, traumatic injury, chronic inflammation, and surgery, increases  $\alpha_1$ -acid glycoprotein, resulting in greater binding with carbamazepine and carbamazepine-10,11-epoxide. Febrile illnesses may produce increases in phenytoin clearance that persist for several weeks, resulting in lowering of plasma concentrations by as much as 50%.

Renal failure can affect the excretion of antiepileptic drugs for which the kidney is the primary route of elimination. Both clinical response and plasma antiepileptic drug concentrations should be carefully assessed in patients with renal disease. Severe liver disease can alter the metabolism of antiepileptic drugs, resulting in accumulation of the parent drug. Antiepileptic drug metabolism appears to be well preserved in mild to moderate liver disease. Clinical response may vary, depending on the particular antiepileptic drug.

Plasma antiepileptic drug concentrations can fluctuate over a 24-hour cycle. The mechanism for this alteration is presumed to be a circadian rhythm in clearance (Cloyd, 1991; Italiano and Perucca, 2013).

## Neonates

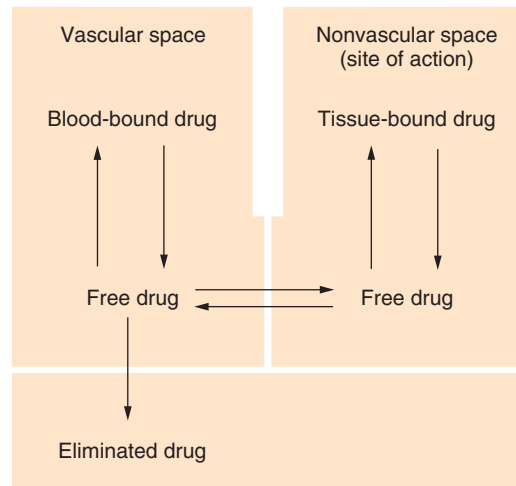

Gastric emptying time is irregular, absorption area is reduced, and biliary function is underdeveloped for several months or more after birth. These factors can contribute to erratic drug absorption. In addition, gastric pH is elevated, which may reduce the absorption of certain drugs, such as clonazepam. In contrast with the oral route, rectal absorption is reliable and efficient. Protein binding is reduced because of lower plasma albumin concentrations, whereas greater extracellular water and less adipose tissue can either increase or decrease volume of distribution (Vd). Reactions mediated by hepatic cytochrome P-450 enzymes reach and then exceed adult values within a few weeks after birth. By contrast, renal elimination of drugs and active metabolites may be lower than that in adults until the age of 6 months.

## Infants and Children

Gastric emptying time and intestinal motility are increased as children grow. Absorptive area, microbial flora, and biliary function begin to approach those in the adult. Also, gastrointestinal blood flow is greater than that in adults. These physiologic characteristics contribute to faster absorption of most drugs, resulting in earlier  $T_{max}$ . Plasma albumin levels are lower than adult values, particularly in infancy, resulting in an increased free fraction. Infants and children are capable of synthesizing  $\alpha_1$ -acid glycoprotein, which will alter the free fraction of drugs bound to this protein. Metabolism remains elevated for the first 2 years of life; in some cases, drug clearances may be 2 to 3 times the values seen in adults. Thereafter, metabolism slowly declines, reaching adult values at puberty. After the first 6 months of life, renal excretion is comparable with that in adults.

## DRUG INTERACTIONS

The clinical significance of pharmacokinetic interactions is determined by several factors, including concentration of the

**Figure 77-1.** Relationship of unbound drug in vascular and nonvascular compartments.

interacting drugs, the patient's seizure control, and presence of toxicity.

## Absorption

Concomitant therapy may influence absorption of antiepileptic drugs. For example, continuous tube feedings interfere with phenytoin absorption. Calcium- and magnesium-containing antacids appear to complex with phenytoin, decreasing its rate and extent of absorption. They should not be administered concurrently. Gastric pH affects the rate and extent of benzodiazepine absorption; thus, use of antacids and histamine  $H_2$  blockers may decrease the plasma concentration of these drugs.

## Protein Binding

In general, only the unbound drug is able to cross the blood-brain barrier and is in equilibrium with brain tissue and spinal fluid (Fig. 77-1; see also Table 77-3). Valproic acid and phenytoin compete for the same binding sites. Concurrent administration may decrease valproic acid and phenytoin binding. When this occurs, unbound concentrations briefly rise, potentially leading to clinical toxicity. Total phenytoin and valproic acid concentrations decrease; however, unbound concentrations rapidly reequilibrate to the original concentration. In general, phenytoin and valproic acid dosing does not have to be adjusted in these circumstances.

## Metabolism

Drugs interact in many ways, such as induction and inhibition of liver enzymes. Information on how drugs are metabolized may provide insight into the potential for a drug interaction. For example, if a drug is known to be an inducer or an inhibitor of a particular P-450 isoenzyme, it may be possible to predict if a medication will affect the plasma concentrations of a second drug that is metabolized by that P-450 particular isoenzyme when the drugs are given concomitantly. This approach may be particularly useful in predicting the interaction between the many new antiepileptic drugs being developed and other possible concomitant medications.

TABLE 77-3 Pharmacokinetics of Other Antiseizure Drugs

Drug	Age Group*	V <sub>d</sub> (L/kg)	Protein Binding (%)	t <sub>1/2</sub> (hr)	Route of Elimination	Active Metabolites	Initial Maintenance Dose (mg/kg/day)	Comments
Carbamazepine	N	1.1–2.6	65–70	7.2–27	Hepatic	Carbamazepine-10,11-epoxide	5–20	Therapy should be initiated at 30–50% of initial dose and increased as autoinduction occurs.
	C	0.8–2.0	75–85	5–26			15–20	
Clonazepam	C	1.5–4.4	80–90	22–33	Hepatic	None	0.05–0.2	Tolerance to antiseizure effect frequently occurs.
Eslicarbazepine acetate (ESL)	C	0.8–1	40 (A)	6–8	Hepatic	Acetate (ESL) eslicarbazepine	5–30 <sup>1</sup>	
Ethosuximide	N	0.69		32–41	Hepatic	None	15–40	
	C	0.7	<10	15–68				
Ezogabine	A	2–8	80%	7–8	Hepatic	NAMR	No pediatric data, adult dose 600–900 mg/day	
Felbamate	C	0.73–0.82 (A)	30	14–21 (A)	Hepatic 50–55%; renal 45–50%	None	15–45	
Gabapentin	C	0.6–0.8 (A)	0	5–7	Renal	None	10–15	
Lacosamide	A	0.6	<15	13	Renal 40%; hepatic 60%	None	8–12 <sup>1</sup>	
Lamotrigine	1–4 years	0.9–1.4	55	+ ind: 8 + VPA: 45	Hepatic	None	With VPA 1–5 With enzyme inducer 5–15	Slow-dose titration is necessary to lessen incidence of rash; see product information packet for details about titrating.
	5–10 years			+ ind: 7 + VPA: 66 24–31 (A)				
Levetiracetam	C	0.5–0.7	<10	5	Renal	None	10–60	
Oxcarbazepine	C	0.7–0.8	40 (MHD) 4.8–9.3 (MHD)		Hepatic	10-Hydroxy-metabolite (MHD)	8–10	
Perampanel	12–17 years	1.07	95	105	Hepatic	None	Not dosed based on weight, start at 2 mg	Bound to albumin and AAG; blood-to-plasma ratio 0.55–0.59
Phenobarbital	N	0.8–1	32	82–199	Hepatic 50–80%; renal 20–50%	None	3–4	
	I	0.6–0.9		37–73			4–5	
	C	0.7	40–55	21–75			2–3	

**TABLE 77-3** Pharmacokinetics of Other Antiseizure Drugs (Continued)

Drug	Age Group*	V <sub>d</sub> (L/kg)	Protein Binding (%)	t <sub>1/2</sub> (hr)	Route of Elimination	Active Metabolites	Initial Maintenance Dose (mg/kg/day)	Comments
Phenytoin	N	0.7–1.2	74–90	3–140	95% hepatic; 5% renal	None	4–6	Half-life varies with concentrations. Half-life varies with concentrations.
	C	0.7–0.8	87–93	1.2–60	95% hepatic; 5% renal	None	6–10 in younger children; 4–6 in children older than 10 years	
Pregabalin	A	N/a	0	4.6–6.8	Renal > 90%; hepatic <10%	None	No pediatric data Adult dose 150–600/day	
Primidone	C	0.43–1.1 (A)	20	4.4–11	Hepatic 60–70%; renal 30–40%	Phenobarbital PEMA	10–15	Therapy should be initiated at 30–50% of initial maintenance dose.
Rufinamide	C	0.8–1.2	34	6–10	Hepatic	None	10	
Tiagabine	A	0.74–0.85	96	5–13 Healthy (A)	Hepatic	None	0.375–1.3	
Topiramate	C	0.6–0.8	15	20–30 (A)	Renal >80%; hepatic <20%	None	1–3	
Valproate (valproic acid [VPA])	N	0.28–0.43	68–89	17–40	Hepatic 95%; renal 5%	2-en-VPA, 4-en-VPA, 2, 4-dien-VPA	5–10	
	I	0.2–0.34		6–8			10–20 (monotherapy), 20–30 (induced)	
	C	0.1–0.3	80–95	4–15			10–20 (monotherapy), 20–30 (induced)	
Vigabatrin	I	1.1	0	5.7	Renal	None identified	50–100	Vigabatrin is available as a racemic mixture; the S(+) enantiomer is the active enantiomer.
Zonisamide	A	0.8–1.6 h	40–60 h	63–69	Renal 40–50%; hepatic 50–60%	None	2–12 (C)	

MHD, monohydroxy derivative of oxcarbazepine; PEMA, phenylethyl malonamide; t<sub>1/2</sub>, half-life; V<sub>d</sub>, volume of distribution.

\*A, adults; C, children; I, infants; N, neonates.

<sup>†</sup>Being studied, not approved.

## DOSAGE FORMULATIONS AND ROUTES OF ADMINISTRATION

Antiseizure drugs are most commonly and conveniently given orally. However, use of an alternative route of administration is necessary. Oral administration is not possible, for example, before and during surgery, with acute severe trauma, when consciousness is impaired, or during gastrointestinal illnesses. Interruption of oral administration occurs in children during frequent bouts of vomiting and diarrhea. In acute emergencies, especially within medical facilities, some antiseizure drugs can be given by intravenous or intramuscular administration. The lack of parenteral formulations, mostly because of their poor solubility in water, creates a significant dilemma

for those persons on maintenance antiseizure therapy when oral administration cannot be continued. The rectal route of administration has been extremely useful for those situations, but water-insoluble antiseizure drugs are generally not well absorbed rectally.

See [Table 77-9](#) and online version for more detail.

## MONITORING ANTISEIZURE DRUG THERAPY

### Clinical Monitoring of Efficacy

Clinical assessment of patients is of paramount importance in the assessment of the effectiveness of therapy. The ideal response would be the total elimination of seizures without

**TABLE 77-9** Antiseizure Drugs Available for Rectal Administration

Drug	Treatment Usefulness	Dose (mg/kg/dose)	Preparation	Pharmacokinetics	Comments
Carbamazepine (CBZ)	Maintenance	Same as oral	Oral suspension (dilute with equal volume of water) Suppository gel (CBZ powder dissolved in 20% alcohol and methylhydroxy cellulose)*	Peak concentration 4–8 hr; 80% absorbed	Definite cathartic effect
Clonazepam	?Acute	0.02–0.1 mg	Suspension	Peak concentration 0.1–2 hr	Onset may be too slow for acute use.
Diazepam	Acute	0.2–0.5 mg	Gel	Peak concentration in ~45 min; concentration >200 ng/mL reached in 15 min	Well tolerated; nordiazepam accumulates with repeated doses.
Lamotrigine	?Maintenance	1.5–2 × oral dose	100-mg tablet crushed and suspended in 10 mL of water		Well tolerated
Lorazepam	Acute	0.05–0.1 mg	Parenteral solution	Peak concentration 0.5–2 hr	Well tolerated
Paraldehyde	Acute	0.3 mL	Oral solution (dilute with equal volume of mineral oil)	Effect in 20 min; peak concentration 2.5 hr	Moderate cathartic effect; use glass syringe
Phenobarbital	?Acute	10–20 mg	Parenteral solution	Peak concentration 4–5 hr; 90% absorbed	Onset may be too slow for acute use.
	Maintenance	Same as oral	Same as acute	Same as for acute	
Secobarbital	Acute	5 mg	Parenteral solution	Peak concentration 0.5–1.5 hr	
Topiramate	?Maintenance	Same as oral	200-mg tablet crushed and suspended with 20 mL of water	Peak concentration 2–3 hr; 95% absorbed	Well tolerated
Valproic acid (VPA)	Acute	5–25 mg	Oral solution (dilute with equal volume of water)	Peak concentration 1–3 hr	Definite cathartic effect
	Maintenance	Same as oral	VPA liquid from capsules mixed into Supocire C lipid base*	Peak concentration 2–4 hr; 80% absorbed	Well tolerated

\*Extemporaneously prepared using commercial product; all other preparations are commercial products given rectally.

any adverse effects of therapy. A satisfactory clinical response for many patients, however, might be substantial reduction of seizures with elimination of or decrease in adverse effects. One of the most common clinical errors is the premature interpretation of the clinical response. Assessment of seizure control requires an accurate record of seizure frequency and severity before and during therapy. Seizures may be eliminated, reduced, or increased in frequency, or become more or less severe during therapy. Patients with epilepsy have varying seizure frequency rates before therapy. The length of time required to assess clinical response varies with the frequency of seizures observed before beginning therapy. Patients with infrequent seizures need a longer period of observation on therapy to permit assessment of clinical response. Achievement of steady state with a new drug regimen is necessary to determine whether a medication has been given an adequate trial at any specific dose. The time to achieve a steady state varies considerably from drug to drug, depending on the drug's half-life. In every case, five half-lives must elapse before a steady state is reached.

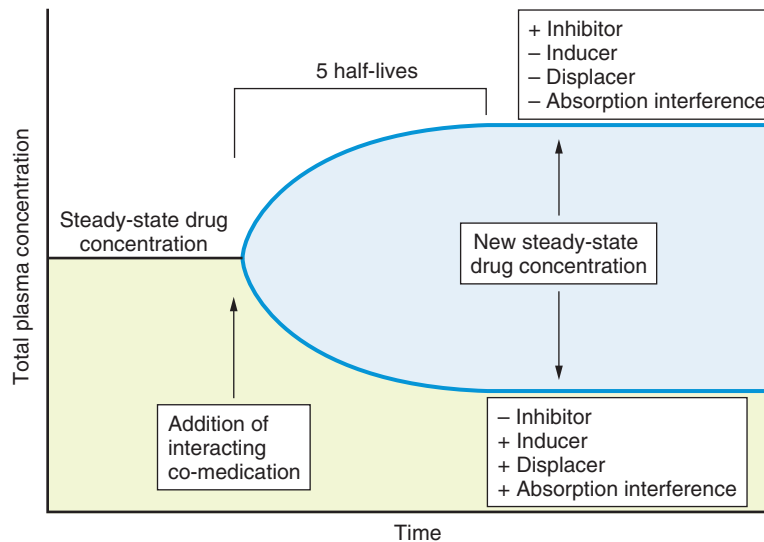

Interpretation of clinical response in patients in whom polypharmacy is necessary is especially difficult. Clinical

improvement or deterioration after the addition of a second antiseizure drug could be attributable to numerous factors. Such factors include the additive or synergistic effect of the two medications, the effect of the second drug alone, and the effect of the second drug on the metabolism and/or displacement of the initial drug. It is important to make clinical conclusions only after a steady state is reached with the new drug regimen. If improvement is obtained after the addition of the second medication, the clinician should attempt to taper and discontinue the first medication, to determine whether the clinical improvement is an effect of synergistic therapy or that of the second medication itself. Finally, it is necessary to remember that withdrawal of comedication might have an effect on the disposition of the remaining drug(s), which could influence clinical response (see Fig. 77-5).

### Clinical Monitoring of Adverse Effects

The clinical state of the patient is more important than laboratory testing for the assessment of adverse effects. It is possible to monitor clinical states continuously, whereas laboratory tests generally are obtained at arbitrary times; therefore,

**Figure 77-5.** Schematic of steady-state plasma concentrations of antiepileptic drugs when a particular antiepileptic drug is given alone or in combination with other medications.

impending organ dysfunction often may be detected earlier by clinical changes, rather than by laboratory tests. The most frequent adverse effects are dose related and often involve the nervous system. Common manifestations of adverse effects are cognitive changes and drowsiness, impaired attention, incoordination, ataxia, and diplopia. In addition to central nervous system adverse reactions, the liver also may produce signs of toxicity. Early signs of liver failure include anorexia, nausea, vomiting, lethargy, and abdominal pain.

## Monitoring of Drug Concentrations

### Interpretation of "Optimal Therapeutic Ranges"

Numerous factors should be considered in the interpretation of drug concentrations. Medications that have rapid absorption and clearance have wide fluctuation between dosing intervals. For example, the liquid formulation of valproic acid, especially when given to a child also receiving enzyme-inducing comedications, is rapidly absorbed and eliminated; therefore, a twofold fluctuation during dosing intervals is possible. Recording the time of the blood sample in relation to the last dose is needed to interpret laboratory results properly. Unexpectedly low concentrations are most frequently the result of poor compliance; however, they might be seen after the addition of an enzyme-inducing comedication. Very high drug concentrations are seen with administration of high doses, in persons with genetically low clearance or some disease states, or with use of enzyme-inhibiting comedications such as valproic acid (Perucca et al., 2001).

The terms *optimal drug concentration* and *target range* are preferred over "therapeutic range," for several reasons. First, these terms express the concept that the optimal dose and drug concentration need to be determined for each individual patient to balance seizure control and adverse events. Clinical effects and toxicity of antiepileptic drugs correlate better with drug concentrations than with total daily dosage. Published "optimal drug concentrations" are attempts to report ranges of concentrations at which many patients have improved seizure control without significant adverse effects. These ranges generally have not been determined by controlled studies in large populations.

### When to Obtain Drug Concentrations

It is useful to measure the antiepileptic drug concentration after the patient has reached steady-state dosing and optimal clinical outcome has been obtained. The time after dose of when the sample was drawn should be recorded in order to interpret where the concentration would be on a pharmacokinetic profile. The measured drug concentration could be considered the "optimal drug concentration" or the "target level" for the individual patient. Levels should also be obtained when a breakthrough of the seizure pattern occurs (i.e., a single seizure in a person usually well controlled, or a doubling of the usual seizure rate). If the level is lower than the individual's "target value," one needs to consider nonadherence or alteration in pharmacokinetics. For suspected nonadherence cases, the dose should not be changed, but steps should be taken to increase adherence (pill box, education, and so on) (Gardiner and Dvorkin, 2006). Illnesses affecting absorption or clearance can also be detected by comparing the current value with the "target level." Levels should be measured after changes in comedication once a new steady state has been reached to determine whether any changes in the levels have occurred. If a patient experiences an increase in seizures but the current concentration is at the "target," it is possible that the seizure threshold has changed or was underestimated, and changes in dose may be needed and a new "target level" should be established.

### What to Measure

Total drug concentrations generally are measured; however, it also is possible to determine levels of free or unbound drug, as well as of metabolites of the administered drug. Free drug concentrations correlate best with clinical effect and toxicity. In most cases, the ratio of free to bound drug is relatively constant for a particular patient; therefore, total drug concentrations usually are adequate. In certain instances, however, particularly with critically ill patients under intensive care, determination of free drug levels, especially for phenytoin and valproic acid, is essential. In such patients, many drugs are typically administered, increasing the likelihood that antiepileptic drugs will be displaced from protein-binding sites. The percentage of unbound valproic acid increases with higher

drug concentrations and with comedication, or when valproic acid is rapidly administered. When the bound fraction is doubled, the valproic acid free fraction may be eight times higher.

Occasionally, measurement of antiseizure drug metabolites is useful. With several antiseizure drugs, metabolites are clinically active and contribute to both response and toxicity. Phenobarbital is an active metabolite present during primidone therapy. Carbamazepine-10,11-epoxide is a derivative of carbamazepine and contributes to toxicity. Clinical monitoring of oxcarbazepine and eslicarbazepine acetate treatment is evaluated by measuring their primary metabolites.

### Laboratory Tests for Idiosyncratic Reactions

In an effort to identify patients in whom serious or potentially life-threatening adverse effects may develop, obtaining complete blood counts and chemistry profiles at routine intervals has become common practice. It is debatable whether routine laboratory monitoring can actually identify patients at risk for serious reactions or can identify significant adverse events better than clinical monitoring. Identification of life-threatening reactions is rarely made by routine laboratory screening of asymptomatic children. Fulminant or irreversible hepatic failure during valproic acid therapy is not reliably predicted by laboratory monitoring. Many reports, therefore, indicate that routine laboratory screening of asymptomatic patients is of little value. However, obtaining complete blood counts and chemistry profiles before, and then after, initiation of antiseizure drug therapy is reasonable. It is much more effective to caution patients and parents to obtain these tests immediately whenever there are signs of any possible reaction, such as unusual bleeding or bruising, significant loss of appetite, and jaundice. Testing for inborn errors of metabolism may be useful for identifying young children at risk for hepatic dysfunction from valproic acid.

### ADVERSE DRUG REACTIONS TO ANTISEIZURE DRUGS

The most frequent adverse drug reactions to antiseizure drugs are dose related, mild, and reversible. Less frequently observed but potentially more serious are the idiosyncratic adverse reactions, which generally are not related to dosage but may be attributable to individual peculiarities of drug metabolism, that is, lack of pathways to process toxic metabolites. Idiosyncratic reactions are almost never seen with antiseizure drugs that are not metabolized.

### Central Nervous System Adverse Reactions

The central nervous system adverse reaction profile for children is similar to that for adults. Most of the older antiseizure drugs and their active metabolites have similar side effect profiles, comprising of cognitive impairment, sedation, dizziness, diplopia, ataxia, headaches, and effects on somnolence. The effects of antiseizure drugs on cognitive function generally are concentration and dose dependent. Drug therapy is known to contribute to cognitive deficits, especially treatment with multiple drugs. Removal of antiseizure drugs frequently results in improved cognitive function and motor skills. It is important to recognize that reaction times, disordered attention, and impulsivity, even in untreated children with epilepsy, differ from those in control subjects. The differences in attention and reaction time, however, are small between children with mild, as opposed to severe, seizure disorders.

Side effects frequently occur in children who are given phenobarbital. Phenobarbital has been associated with a significant depression of cognitive function when it is used for treatment of febrile seizures in children. In a randomized, placebo-controlled, prospective study, children had lower mean intelligence quotient (IQ) scores both during and 6 months after stopping therapy with phenobarbital. Clinical tolerance does develop to some degree; however, an unacceptably high frequency of adverse effects from phenobarbital commonly is observed in children. The adverse effects are reminiscent of complaints present in attention-deficit disorders and include overactivity, aggressiveness, inattention, and irritability. The behavioral disorders are observed in 20% to 50% of children receiving phenobarbital for febrile seizures, and result in discontinuation of therapy in 20% to 30% of children. The presence of preexisting behavior problems, especially hyperactivity, is strongly predictive of adverse reactions during phenobarbital therapy. In a study of children receiving phenobarbital for febrile seizures, 80% of those with abnormal behavior before drug therapy reported aggravation of preexisting hyperactive behavior with phenobarbital, versus only 20% for children with normal pre-seizure behavior. In some cases, these adverse effects may resolve with continuation or with a lower dose of phenobarbital; however, discontinuation of therapy or alternative medication should be considered.

Some antiseizure drugs—gabapentin, felbamate, topiramate, lamotrigine, tiagabine, oxcarbazepine, levetiracetam, vigabatrin, and zonisamide—are thought to have fewer and less severe adverse effects; however, their adverse central nervous system effects are similar to those of the older antiseizure drugs. Although gabapentin has a good safety profile and seems well tolerated in adults, significant behavioral side effects are observed in some children. In other reports, aggression, hyperactivity, temper tantrums, and increased oppositional behavior developed in children taking the drug. Most, but not all, of these children had preexisting cognitive dysfunction, such as mental retardation, autistic features, or behavioral difficulties. The adverse cognitive changes resolved with discontinuation of gabapentin; if administration of the drug was resumed, the adverse cognitive changes tended to recur. In approximately 15% of children, decreased functioning in school, aggression, and other cognitive changes occurred within the first 4 months of initiation of topiramate therapy. A previous history of behavioral changes and concurrent lamotrigine therapy were associated factors. Central nervous system-related adverse effects from topiramate tend to decrease over time. Of greater concern are reports of the development of major depression, schizophrenic-like reactions, and organic psychoses in adults taking vigabatrin. A reversible acute psychosis has been reported in a child taking vigabatrin. Development of hyperkinesia, somnolence, and insomnia in children taking vigabatrin has been reported by a number of investigators.

### Gastrointestinal Effects

#### Weight Gain

A survey in children and adolescents taking valproic acid found the most common side effect to be weight gain; however, for many patients, the weight gain was "beneficial." The incidence of unwanted weight gain was 26% in adults and 15% in children and adolescents. An increase in weight was observed more than twice as frequently in females. Weight increase was independent of dose. Weight gain also was reported in children during therapy with carbamazepine and vigabatrin.

## Weight Loss

Sustained weight loss was reported in children on maintenance topiramate therapy. Seventy-five percent of children and adults during clinical research trials reported a loss of appetite and decrease in body weight while taking felbamate. Zonisamide also is associated with weight loss in children.

## Gastric Irritation

Signs of gastric irritation, with heartburn and indigestion, are seen with use of some antiseizure drugs. Gastric irritation during valproic acid therapy can be reduced with administration of lower doses or by taking medication with food. Use of enteric-coated preparations of valproic acid will enable most patients who did not tolerate valproic acid because of gastrointestinal symptoms (nausea/vomiting, eructation, heartburn) to resume valproic acid therapy. Aggressive medical intervention with antacids and H<sub>2</sub> receptor antagonists (other than cimetidine) has been helpful for some children with clinical signs of gastritis, allowing valproic acid therapy to continue.

Approximately 20% of patients receiving ethosuximide will demonstrate dose-related adverse effects, primarily gastric distress, vomiting, hiccups, and anorexia. Gastrointestinal disturbances also are encountered in 14% of patients taking carbamazepine, with symptoms of nausea, vomiting, anorexia, and constipation. Nausea and vomiting commonly are observed with felbamate.

## Gingival Hyperplasia

Gingival hyperplasia occurs in 10% to 20% of persons treated with phenytoin and is more frequent in young persons. It is observed more frequently in persons taking higher dosages, often appears 2 to 3 months after beginning therapy, and reaches its maximum severity in 12 to 18 months. Gingival hyperplasia generally resolves within 2 to 5 months after discontinuation or a reduction in medication. A vigorous program of good oral hygiene started before and continued during phenytoin therapy can be effective in minimizing gingival enlargement.

## Increased Seizures

Some patients, especially those with generalized or absence seizures, may experience an increase in seizure activity when carbamazepine, oxcarbazepine, or phenytoin is added. Vigabatrin also has been reported to increase seizure activity and even lead to status epilepticus. Aggravation of seizures occurred in 3% of children with generalized seizures, most often in those with nonprogressive myoclonic epilepsy, and was extremely unusual in children with partial epilepsies and infantile spasms. Phenytoin and carbamazepine may increase seizures associated with the Lennox–Gastaut syndrome, and gabapentin and pregabalin can increase or induce myoclonic seizures.

## Osteomalacia

Osteomalacia (rickets) may occur in patients taking antiseizure drugs. The cause of osteomalacia during antiseizure drug therapy appears to be multifactorial. Many antiseizure drugs presumably enhance hepatic conversion of 25-hydroxyvitamin D to biologically inactive metabolites. Clinically significant rickets seldom develops in ambulatory children on antiseizure drug therapy, or in institutionalized children who are not taking medication. On the other hand,

clinically overt rickets was observed in 10% of institutionalized children on phenobarbital and/or phenytoin. In these patients, sunlight was more important for the maintenance of serum 25-hydroxyvitamin D than were supplements of vitamin D.

In children, no correlation was observed between duration of antiseizure drug therapy and 25-hydroxyvitamin D levels. It was previously thought that older antiseizure drugs resulted in induction of vitamin D metabolism, resulting in decreased bone mineral density; however, the lack of correlation between vitamin D levels and bone mineral density suggests that other mechanisms are operative.

## Tremor and Movement Disorders

The benign essential type of tremor seen with valproic acid therapy begins within 1 month of initiating therapy and is dose dependent, occurring in some patients with blood valproic acid levels greater than 40 mg/mL. Reduction of tremor may occur with reduction of dose. Tremor also has been seen with use of lamotrigine and gabapentin.

## Other Effects

Hair changes have been associated with antiseizure drug treatment. Hair changes (thinning or wavy hair) are seen in 12% of children during valproic acid therapy. Additional dose-related adverse effects of phenytoin include hirsutism, coarse facial features, and acne, especially in children and teenagers. Pancreatitis has been associated with valproic acid therapy. Visual field changes, which may be irreversible, may occur with vigabatrin treatment. Topiramate has been reported to cause acute myopia and secondary angle closure glaucoma. Patients present with decreased visual acuity and ocular pain. In a majority of cases, immediate discontinuation of topiramate results in a resolution of symptoms. Hyponatremia occasionally is encountered in patients taking carbamazepine and oxcarbazepine. Hyperthermia and oligohydrosis have been reported in several children taking topiramate and zonisamide. Clinical signs included fever, decreased sweating, and exercise intolerance, which resolved in a majority of cases when topiramate or zonisamide was discontinued. Topiramate and zonisamide may cause nephrolithiasis. The risk is increased with topiramate or zonisamide treatment and the ketogenic diet.

## Anticonvulsant Hypersensitivity Syndrome in Children

### Clinical Features

The hypersensitivity syndrome is characterized by rash, fever, and malaise, generally occurring within the first several months of therapy. Certain types of rash may be particularly alarming, such as those of Stevens–Johnson syndrome or toxic epidermal necrolysis. Often hepatic involvement is part of the syndrome, and the liver is the most frequently involved internal organ. Affected children may present with hepatomegaly and elevations in serum transaminase levels. The involvement may progress to hepatic necrosis. Other systems may be involved, including kidney, lungs, bone marrow, and the lymphatic system.

### Pathogenesis

Although the mechanism of the hypersensitivity syndrome is not completely understood, current evidence implicates toxic metabolites (Glauser, 2000). The aromatic AEDs

(phenobarbital, phenytoin > carbamazepine > oxcarbazepine), lamotrigine, and felbamate have been more frequently implicated in causing this syndrome. Presumably, accumulation of toxic metabolites, such as reactive aromatic epoxide intermediates, precipitates the syndrome (Glauser, 2000).

### Prevention

Routine laboratory monitoring (i.e., with complete blood counts or liver function tests) will not prospectively identify which patients are at high risk for the development of an acute hypersensitivity reaction. Nevertheless, certain factors place some patients at high risk. Clinical profiles that identify patients at high risk for hypersensitivity reactions differ for specific antiseizure drugs (valproic acid, felbamate, and lamotrigine). When one of these drugs is being considered for a patient at high risk, one should proceed with caution. Alternative therapy, if possible, should be considered. Additional laboratory tests to screen for inborn errors of metabolism may be indicated when use of valproic acid is under consideration in children younger than 2 years. Families need to be advised that the child is in a high-risk category and counseled on the early recognition of the syndrome.

Although the identification of a high-risk clinical profile is the most inexpensive and practical way available to reduce the risk of hypersensitivity syndrome, various biomarkers also have been identified (Glauser, 2000). These biomarkers may indicate that some patients have genetic susceptibility to the accumulation of toxic metabolites because of deficient detoxification pathways. Studies in patients of Chinese ancestry indicate a strong association between the risk of developing toxic epidermal necrolysis and Stevens–Johnson Syndrome and the presence of HLA-B\* 1502. Clinicians may want to avoid use of carbamazepine in this population.

### Managing Adverse Effects

The clinician and the patient are faced with adverse effects approximately 30% of the time when antiseizure drugs are used, especially during initiation of therapy. In many instances, this rate is acceptable, especially when the patient and the physician mutually agree on which problems are most important to avoid. When no urgency exists, many adverse effects can be avoided during initiation of therapy by gradually increasing doses. In general, management of adverse effects depends on the problem. Most adverse effects are concentration dependent, and are less prominent at lower doses and blood concentrations. Seizure control may or may not be maintained at the lower dose; if not, the clinician and the patient need to consider whether a compromise is acceptable with regard to either increased seizures or increased adverse effects, or if alternative medication should be considered.

At times, toxicity is encountered only with high drug concentrations and is seen only at peak times; for these patients, it may be possible to avoid toxicity by more frequent and lower doses or by the use of extended-release formulations. Gastric irritation generally is dose dependent and may be managed in several ways. The amount of drug can be reduced; the effective dose to the gastric mucosa can be lowered by use of enteric-coated formulations, or the patient can be protected by use of H<sub>2</sub> receptor antagonists.

Idiosyncratic reactions pose another problem. Mild, asymptomatic elevations of liver enzymes do not mandate discontinuation of therapy if not in excess of 2 to 3 times normal values. On the other hand, Stevens–Johnson syndrome and toxic epidermal necrolysis, clinically symptomatic hepatotoxicity, pancreatitis, and most rashes are indications for immediate cessation of the responsible medication. If the rash was

mild, however, and especially if the patient had an otherwise favorable clinical response to the drug, a cautious rechallenge might be considered. Successful resumption of therapy has been reported in a number of patients, especially with valproic acid after that drug was discontinued, when a more gradual dose escalation was used.

### DISCONTINUATION OF ANTISEIZURE DRUG THERAPY

The decision to discontinue antiseizure drug therapy often is as challenging as the decision to initiate and continue long-term drug therapy. Many factors are considered in making these decisions, including the length of the seizure-free interval, drug history, presence of adverse effects, and the neurologic and epilepsy syndrome diagnosis of the patient. Numerous retrospective and prospective investigations are available. Ultimately, the decision to withdraw or to continue antiseizure drug therapy is that of the patient and family, and their perception of acceptable risk of recurrence often differs from that of the treating physician (Camfield and Camfield, 2008).

#### Benefits of Drug Discontinuation

The potential benefits of drug discontinuation are numerous. Most obvious are the immediate reduction in cost to the family and third-party payer with elimination of drug therapy and usually the reduction in associated expenses incurred by laboratory tests and physician and clinic charges. In addition, in many patients, the adverse, sometimes previously unrecognized, effects of antiseizure drug therapy are reversed. Patients who had been on phenobarbital, phenytoin, valproic acid, and topiramate had subtle improvement in various psychometric tasks, such as memory, vigilance attention, and visual motor performance, and in psychomotor speed, when therapy was discontinued.

#### Risks of Drug Discontinuation

The obvious risk of stopping antiseizure drug therapy is the recurrence of seizures. In most cases, seizure control can be regained with resumption of the previous drug therapy. Response to therapy after a relapse may be rapid and satisfactory. Chadwick and colleagues observed that approximately 90% of patients who experience seizures after antiseizure drug discontinuation have a 2-year remission after therapy is resumed. Thus control was usually but not always regained despite increasing doses of a previously successful drug regimen. A guideline has been published to assist the physician and the family considering discontinuation of antiseizure drug therapy. The conclusions were based on a MEDLINE search.

Families should discuss withdrawing antiseizure drugs with their neurologist once children have become free of seizures for 1 year or longer while on antiseizure drug therapy. Children whose EEGs have become normal have a somewhat better chance of successful withdrawal of therapy. However, there are critical life transitions when the risk of discontinuing therapy outweighs continuation. These are when children have been seizure-free and are eligible to begin driving, and when they are leaving home and transitioning to college or independent living. Finally, for some patients, withdrawal of antiseizure drugs is rarely successful—for example, those with abnormalities on neurologic examination or with certain seizure syndromes such as juvenile myoclonic epilepsy, Lennox–Gastaut syndrome, or infantile spasms.

Epilepsy is one of the most common chronic disorders facing children and adolescents. The overall prevalence of epilepsy has been estimated to be 5 to 8 per 1000. The cumulative risk of developing epilepsy from birth through adolescence is 1%. Unfortunately, only 60% to 70% of patients will achieve seizure freedom with antiseizure medications. The introduction of several new antiepilepsy drugs over the past 15 years has not changed the fact that approximately 30% to 40% of patients with epilepsy will be medically refractory.

The identification of a patient's specific epilepsy syndrome is one of the best determinants of prognosis. Some epilepsy syndromes are genetically determined and may have an excellent prognosis for remission. Other epilepsy syndromes, particularly the lesional epilepsies, are life long chronic disorders. Predictors for low probability of epilepsy remission include the following:

1. The presence of a symptomatic localization-related epilepsy secondary to a remote central nervous system injury
2. Abnormalities on neurologic examination or cognitive/motor delays
3. Persistent epileptiform abnormalities on EEG
4. Older age at onset

The longer epilepsy persists without control, the less likely is the chance of remission. If seizures remain inadequately controlled for longer than 4 years, then the chance of remission decreases to approximately 10%. The presence of multiple seizure types and frequent generalized tonic-clonic seizures also lessens the chance for complete remission. Approximately 60% of these patients will have focal onset seizures. Estimates by several investigators suggest that many of these patients are epilepsy surgery candidates. Currently, however, epilepsy surgery is underutilized in the treatment of intractable epilepsy, as shown by the fact that over the past 15 years, the mean duration of epilepsy before referral to a tertiary care epilepsy center for evaluation for epilepsy surgery was over 20 years.

The developing brain is highly susceptible to recurrent seizures. A growing body of evidence in animal models suggests that early seizures, even if brief and recurrent, can result in demonstrable structural and physiologic changes in the developing brain's circuitry, resulting in aberrant excitation and inhibition. Clinically, these defects may produce spontaneous seizures (epilepsy) and cognitive impairment, with the possibility of missed windows of developmental opportunity. In addition, chronic uncontrolled epilepsy in infants and children poses a significant risk for emotional, behavioral, social, cognitive, and family dysfunction. Population studies have demonstrated that epilepsy reduces life expectancy, and poorly controlled seizures further increase the risk of death in children and adults.

Both location and etiology play roles in determining prognosis of epilepsy surgery. In a meta-analysis of children who have undergone temporal lobectomy, the seizure-free rate overall was 76%, ranging from 52% to 100% depending on etiology (Englot et al., 2013a,b). A meta-analysis was also

done for extratemporal lobe resections, with an overall seizure-free rate of 56%.

Several studies have reported on cognitive function after surgery in children who have undergone temporal lobectomy (predominantly older children and adolescents). These studies have generally found that memory and intelligence are unchanged. A study of a small number of children who have undergone temporal and extratemporal resections looked at overall cognitive function pre- and postoperatively and found no differences. In a follow-up study of 24 children operated on before 3 years of age, younger age at surgery was correlated with an improvement in developmental quotient. Retrospective studies that combine temporal and extratemporal cases suggest that a reduction of seizure frequency, not necessarily complete elimination of seizures, resulted in significant improvements in family life, socialization, and behavior, as well as enhanced quality of life and developmental "catch up."

## HISTORICAL BACKGROUND

Epilepsy surgery substantially advanced in 1950, when Penfield published his article on 70 cases of temporal lobectomy. His neurosurgical career was devoted to the study of the clinical description of seizures and their correlation with the brain cortex. He used cortical mapping and stimulation in much the same way it is used today. He also recognized the substrates of epilepsy, particularly trauma and infection. His seminal clinical research has been instrumental in guiding the hands of contemporary epileptologists and neurosurgeons interested in the surgical approach to epilepsy.

In the past 30 years, dramatic improvements in brain imaging that identify specific anatomic substrates of epilepsy have sparked renewed interest in surgery for intractable epilepsy. Temporal lobectomy with amygdalohippocampectomy has become the standard of care in adult patients with intractable epilepsy emanating from the temporal lobe. The surgical success rate for a seizure-free outcome in these carefully selected patients approaches 80% to 90%. In a randomized, controlled trial of surgery for temporal lobe epilepsy compared with treatment with antiseizure drugs, 58% of patients demonstrated seizure freedom after 1 year compared with only 8% of patients treated with medications. Unfortunately, surgical success does not necessarily translate to an improved quality of life. The accumulation of years of low self-esteem, loss of independence, poor peer relations, and academic failure, coupled with high financial costs, often without benefit of full insurance coverage, translate to continued lack of employment and depression. The growing recognition of the real costs of epilepsy—medical, psychological, and educational—has led to increased interest in the early identification of children who might benefit from epilepsy surgery.

## INDICATIONS FOR EPILEPSY SURGERY

Practice guidelines for temporal lobe and localized neocortical resections for epilepsy have been proposed for adults. Criteria

have been proposed for referral and evaluation of children for epilepsy surgery, although there is currently insufficient class I evidence to produce a practice guideline (Cross et al., 2006). In determining whether a child is a candidate for epilepsy surgery, several key issues must be considered. The decision-making task must take into account the following:

- Failure of two or three antiseizure medications in achieving complete seizure control in a child or adolescent.
- Natural history of the epilepsy syndrome. The likelihood of continued intractability usually can be determined on the basis of the identification of a specific epilepsy syndrome.
- Identification of a known epileptogenic substrate. Lesional epilepsy in a young infant should prompt an evaluation for epilepsy surgery, even as the first medication is started. Young infants are particularly vulnerable to deleterious effects of epilepsy in the developing brain.
- Impact of epilepsy on the quality of life, as defined by cognitive and developmental parameters—now and in the future.

The proper classification of seizure type and epilepsy syndrome is crucial in the determination of whether or not a patient is an appropriate epilepsy surgery candidate.

The severe epilepsies of infancy and childhood are recognizable early, and affected patients should be referred to a tertiary epilepsy center for consideration for epilepsy surgery. These epilepsy syndromes are characterized by the tetrad of the following:

1. Multiple daily seizures
2. Medical intractability to standard antiseizure drug therapies
3. Cognitive/developmental stagnation or decline
4. Presumed or known epileptogenic pathology.

The epilepsies of infancy and childhood that have specific surgical indications include the following:

1. Sturge–Weber syndrome: Children with Sturge–Weber syndrome who have frequent, medically refractory seizures should be evaluated promptly for hemispherectomy. Clinical outcome studies indicate that early surgical resection can result in the elimination of seizures, improvement in cognitive abilities, and overall improvement in quality of life despite residual hemiparesis and visual field deficits.
2. Large unilateral or focal malformations of cortical development, such as hemimegalencephaly or unilateral schizencephaly: Hemispherectomy provides relief from seizures (especially in those patients with unilateral epileptiform abnormalities) and improved developmental outcome.
3. Symptomatic infantile spasms with focal malformations of cortical development, typically temporal-parietal-occipital dysplasia. These patients should be considered for early focal cortical resection. Clinical research has documented improvement in seizure control and enhanced developmental gains after epilepsy surgery.
4. Rasmussen syndrome: Rasmussen encephalitis is characterized by intractable focal motor seizures, often evolving into *epilepsia partialis continua*, cognitive decline, and progressive hemiparesis. The only definitive treatment for Rasmussen encephalitis remains hemispherectomy.

In addition to those with the aforementioned epilepsies of infancy and childhood, children with tumors and concomitant localization-related epilepsy should be considered for early surgical intervention.

Children with other types of lesional, symptomatic, localization-related epilepsy should also be considered as potential epilepsy surgery candidates. Common substrates of epilepsy include encephalomalacia, vascular malformations,

tubers, and malformations of cortical development (Harvey et al., 2008).

Patients who have generalized epilepsy syndromes may also be candidates for epilepsy surgery. Children with generalized or multifocal epilepsy should be considered for epilepsy surgery if data suggest an underlying focal generator for the epilepsy (Wyllie et al., 2007). Specifically, in the presence of a lesion on magnetic resonance imaging (MRI), the epilepsy syndrome is most likely to be attributable to symptomatic localization-related epilepsy with rapid secondary bisynchrony. In one study, children who had generalized discharges and focal lesions of early life onset had identical postsurgical seizure-free outcomes (72% seizure-free) to children with similar lesions and ipsilateral focal epileptiform discharges (Wyllie et al., 2007). Patients with tuberous sclerosis and medically refractory, symptomatic, localization-related epilepsy should also be considered for epilepsy surgery. If the presurgical evaluation points to a specific tuber, studies have shown that it can be successfully removed, with a significant improvement in seizure control.

Those children with intractable nonlesional extratemporal localization-related epilepsy represent the biggest challenge to the epileptologist but should still be considered for epilepsy surgery if their seizures remain intractable. The benefits of surgery must be weighed against the risks, especially the risk of neurologic deficits.

## PREOPERATIVE EVALUATION

Once a child has been selected as a possible epilepsy surgery candidate, further questions need to be addressed before epilepsy surgery can take place:

1. Can the epileptogenic zone be identified using video EEG, neuroimaging, and other modalities? Is there congruence of the data?
2. Will removal of the epileptogenic zone result in seizure freedom?
3. Can the epileptogenic focus be removed without causing unacceptable neurologic deficits? This requires accurate anatomic localization of eloquent cortex.
4. Will a delay in epilepsy surgery cause loss of developmental plasticity?

A multidisciplinary team is required for addressing the many issues surrounding the prospect of surgery in a child with chronic epilepsy. Epilepsy surgery itself may cure the seizures but will not necessarily address the family's other needs. The family of a child with medically intractable epilepsy has complex and diverse problems—not just medical but also developmental, educational, psychosocial, economic, and relational.

## Techniques and Technologies

### Seizure Semiology

Seizure semiology can provide insightful clues to the lateralization and localization of the underlying epileptogenic focus. The presence of versive, that is, forced turning, head movements, unilateral motor clonic activity, and eye deviation may constitute critical lateralizing information. Specifically, versive head movements typically indicate that the epileptogenic zone resides in the contralateral hemisphere. Seizures consisting of olfactory or gustatory hallucinations, followed by complex motor automatisms and staring unresponsively, are characteristic of involvement of the temporal lobe. It should be noted, however, that seizures emanating from the temporal lobe in infants and young children commonly are

**Figure 78-3.** Magnetic resonance imaging scans from a patient with focal cortical dysplasia of the posterior left parasagittal region. **A**, With T1-weighted imaging (TR = 24 msec/TE = 9 msec), thickening of the cortex and blurring of the white/gray matter are evident. **B**, The dysplasia is seen more clearly with fluid-attenuated inversion recovery imaging (FLAIR) sequencing (TR = 1100 msec/TE = 142 msec/TI = 2600 msec) (see text). TE, echo time; TI, inversion time; TR, recovery time.

associated with behavioral arrest, motor dystonic posturing, and fewer automatisms.

Frontal lobe seizures may present a challenge, as seizure semiology can vary greatly within the various regions of the frontal lobe (Bonini et al., 2014).

### Physical Examination

The physical examination, including attention to dysmorphic or neurocutaneous stigmata, can also provide very valuable lateralizing information. As with seizure onset or its evolution, a focal abnormality on physical examination may point to an underlying focal structural lesion. For example, a child with schizencephaly and focal seizures may have a subtle hemiparesis contralateral to the affected hemisphere.

### Electroencephalography

The surface EEG, including continuous video-EEG monitoring, is a critical element in the evaluation of children with epilepsy.

### Magnetic Resonance Imaging

- MRI scans have greatly enhanced the ability to detect epileptogenic lesions, especially focal cortical dysplasia. Examples of important new technologies are described below. Thin contiguous cuts of 1.5 to 1.6 mm in multiple sections of the cortex, in combination with a three-dimensional volumetric pulse sequence, provide the necessary resolution to detect small lesions that would be missed with conventional MRI. Quantitative volumetric analysis of the hippocampus allows determination of unilateral or bilateral hippocampal atrophy.
- The fluid-attenuated inversion recovery imaging (FLAIR) technique highlights lesions such as mesial temporal sclerosis and malformations of cortical development. This sequence produces a T2-weighted image that subtracts the cerebrospinal fluid signal (white and bright on T2), but retains the T2 signal in intraparenchymal structures [Fig. 78-3 and Fig. 78-4].

**Figure 78-4.** Magnetic resonance imaging scans showing coronal cuts through the temporal lobes, from a patient with left temporal hippocampal atrophy. **A**, The atrophy is seen best with T1-weighted imaging (TR = 24 msec/TE = 9 msec). **B**, Concomitant left temporal mesial temporal sclerosis is seen best with fluid-attenuated inversion recovery imaging (FLAIR) sequencing (TR = 1100 msec/TE = 142 msec/TI = 2600 msec). **C**, Middle panel represents the picture created on T2-weighted imaging (TR = 2000 msec/TE = 80 msec).

- Diffusion tensor imaging is an MRI technique that can identify white-matter tracts that may be disrupted in areas of cortical dysplasia and help in surgical planning.
- Multichannel coils (32 phased array and beyond and higher field strengths—3 tesla, 7 tesla, and greater), coupled with newer imaging sequences, including arterial spin labeling and susceptibility-weighted imaging, increase detection of focal cortical dysplasia.

### Single-Photon Emission Computed Tomography

SPECT has also enhanced the ability to identify the epileptogenic zone. Penfield and colleagues observed relative hyperperfusion in the epileptogenic zone during a seizure. Interictally, blood flow and metabolism are decreased. SPECT scan technology enables quantification of cerebral blood flow and identification of areas of relative blood flow change. SPECT images are reconstructed from data obtained by recording photon emissions from radiotracers injected intravenously. These radiotracers rapidly cross the blood-brain barrier because of their lipophilic nature and bind within minutes to the brain, producing an instantaneous picture of cerebral blood flow.  $^{99m}\text{Tc}$  ethyl cysteinyl dimer (i.e.,  $^{99m}\text{Tc-N,N}'(1,2\text{-ethylenediyl})\text{bis-L-cysteine diethyl ester}$ ), prepared as technetium  $^{99m}\text{Tc}$  bicisate (Neurolite), is the primary radio-isotope for this procedure. Logistically, Neurolite provides distinct advantages for ictal SPECT scans because it is a stable isotope tracer that can be mixed well ahead of the time of injection, as opposed to  $^{99m}\text{Tc-HMPAO}$ , which decomposes quickly in vitro and must be used less than 30 minutes after it is reconstituted. For ictal SPECT scans, a technologist or nurse trained in the delivery of these radioisotopes can sit at the bedside and deliver the Neurolite within seconds after the onset of a seizure.

Clinical research indicates that interictal SPECT studies alone have a relatively low sensitivity for identification of the epileptogenic focus in adults with temporal lobe epilepsy and even lower sensitivity with extratemporal epilepsy. Data pooled from several studies yield estimates of interictal SPECT sensitivity of 66% for temporal lobe epilepsy and 60% for extratemporal epilepsy localized by EEG (Knowlton, 2006).

Ictal SPECT scan data, however, have proved valuable with respect to localization of the epileptogenic focus. Ictal SPECT scans typically reveal an area of regional hyperperfusion that corresponds to the underlying epileptogenic focus, as verified by surgical pathology and surface EEG localization. Using data pooled from several centers, the sensitivity of ictal SPECT (as judged by EEG correlation) has been estimated at 90% for temporal and 81% for extratemporal epilepsy, with specificity at 77% and 93%, respectively (Knowlton, 2006).

Several techniques have been developed whereby the ictal and interictal SPECT scan data are coregistered with one another and the interictal image is subtracted from the ictal image, producing the area of true ictal hyperperfusion. This difference image, called a subtraction SPECT scan, is then coregistered with a three-dimensional representation of the MRI scan. Several studies have demonstrated that peri-ictal subtraction SPECT provides useful information for seizure localization in patients with focal malformations of cortical development, even when the MRI study is nonlocalizing (i.e., "nonlesional") (O'Brien et al., 2004). In a large series involving pediatric and adult epilepsy patients, if the site of the surgical resection was concordant with the subtraction SPECT localization (using technology that performs subtraction SPECT and then coregisters the results to a volumetric MRI), postoperative seizure frequency scores were significantly lower and postoperative improvement was greater. In summary,

SPECT scan technology, particularly subtraction SPECT, holds merit for localization of the epileptogenic zone.

### Positron Emission Tomography

PET is another imaging modality used for localization of the epileptogenic focus. It uses radiotracers labeled with specific positron-emitting isotopes ( $^{11}\text{C}$ ,  $^{15}\text{O}$ , and  $^{18}\text{F}$ ) to measure a variety of biochemical brain functions. Cerebral glucose metabolism is the most commonly measured parameter, using  $^{18}\text{F}$ -fluorodeoxyglucose (FDG) (see Fig. 78-9). Other tracers also can be used to measure cerebral blood flow, benzodiazepine and opiate receptors, pH, serotonin metabolism, and amino acid transport.

FDG-PET images are averaged over a 40-minute time interval, suggesting the limited value of this technique for ictal studies. The interictal images, on the other hand, are highly sensitive in focal onset seizures emanating from the temporal lobe. In several studies in adult patients with medically refractory epilepsy of temporal lobe origin, glucose hypometabolism in the temporal lobe correlated highly with localized ictal EEG and MRI abnormalities.

Analysis of nonlesional, extratemporal epilepsy in adult patients undergoing PET scans has provided data that are less definitive. In one recent analysis, the sensitivity and specificity of FDG-PET scans decreased to 40% in MRI-negative extratemporal cases. In children with refractory epilepsy, however, with poor localization on surface EEG and negative findings on MRI, FDG-PET may still provide useful information in identifying an underlying epileptogenic focus. Newer ligands have also been developed. In flumazenil PET scans, the flumazenil binds to benzodiazepine receptors. In the area of the epileptogenic zone, benzodiazepine binding appears to be decreased. In one clinical study, the flumazenil PET scan demonstrated a more restricted area of decreased binding than was apparent on the FDG-PET scan; the resection of this cortical region was associated with good surgical outcome. C-alphamethyl-L-tryptophan (AMT) PET scans have also been studied. AMT is an analog of tryptophan and a precursor for serotonin synthesis. Data suggest that the AMT PET scans may be useful in identifying the most epileptogenic tuber in patients with tuberous sclerosis, multiple tubers, and medically intractable epilepsy. Concordance of the epileptogenic tuber with increased AMT uptake has been observed in PET scans.

### Magnetic Resonance Spectroscopy

MR spectroscopy has been used in the study of patients with intractable epilepsy. Specifically, phosphorus MR spectroscopy measures phospholipid metabolism. In the region of the epileptogenic focus, investigators have found abnormal phosphocreatine to inorganic phosphate ratios. Proton MR spectroscopy can also measure regional abnormalities in lactate, N-acetyl-aspartate (NAA), creatine (Cr), and choline (Cho). Lactate levels increase during a seizure and remain elevated for several hours. Abnormal NAA/Cr and NAA/Cho ratios may serve as indices of regional cellular pathology. MR spectroscopy may have a role as an adjunctive noninvasive technique for assisting with the identification of the underlying epileptogenic zone.

### Magnetoencephalography

MEG is another technology that has been developed to improve the ability to identify epileptogenic foci. It measures tiny magnetic fields created by the electrical activity of the brain. Most institutions are using 128-channel MEG technology to enhance resolution. MEG offers several advantages over EEG. First, the magnetic fields are not attenuated by the skull,

scalp, and skin, in contrast to electrical potentials. Second, MEG is a monopolar measure and does not require a dipolar montage, eliminating the possibility of artifact associated with an “active reference.” Third, MEG provides high temporal resolution. Finally, MEG measures postsynaptic intracellular currents in the dendrites of neurons situated tangentially to the skull, whereas the EEG measures extracellular postsynaptic ionic currents.

Clinical research suggests that, although surface interictal EEG spike recordings may indicate multifocal activity, MEG can more precisely localize the underlying epileptogenic focus (Wheless et al., 1999). In this regard, MEG provides complementary data to EEG. MEG has been employed in children with intractable epilepsy to provide spatial information to be used in planning the excision area. MEG spike source clusters have been used to indicate the epileptogenic zone.

### Functional Mapping

If an underlying epileptogenic focus is identified, the next question to consider is whether the epileptogenic zone can be removed without causing unacceptable neurologic deficits. In infants and young children, this proves to be less problematic because of brain plasticity.

Classically, in the older child and adolescent, the amobarbital test (Wada test) is used in the preoperative evaluation for the lateralization of speech and language and to determine whether memory can be supported in the contralateral hemisphere. This test involves injecting amobarbital into either the left or the right internal carotid artery, in an attempt to transiently eliminate ipsilateral hemispheric function chemically and to determine which hemisphere is “dominant.” It is a time-consuming test that is invasive and provides a broad but nonspecific overview of hemispheric function.

Two other techniques used frequently to identify eloquent cortex are somatosensory-evoked potentials and cortical stimulation mapping. The measurement of somatosensory-evoked potentials has the advantage of being able to be applied successfully regardless of the state of the patient. This modality can be used in the operating room in the anesthetized patient, or in an awake and cooperative patient. Somatosensory-evoked potentials are used primarily to identify the sensorimotor cortex.

Cortical stimulation mapping is a useful, dependable, and safe technique to assess motor, sensory, and speech function. It involves the application of subdural electrodes followed by sequential electrical stimuli between two electrodes at various intensities and durations.

Although cortical stimulation mapping has yielded a tremendous amount of information about the localization of functions, several other emerging techniques are providing valid, noninvasive methods for mapping out functional areas of the brain. These techniques include functional MRI (fMRI) scans, MEG and magnetic source imaging, and transcranial magnetic stimulation.

fMRI is based on the fact that performance of a specific act will activate the anatomically appropriate cortex in the brain. With activation, a concomitant increase in blood flow occurs, resulting in a change in the paramagnetic properties of the affected cortex. This produces a signal that can then be detected by the MRI scanner. fMRI is a technique that is being increasingly used to map out eloquent functions, such as sensorimotor cortex and speech and language centers.

### Concept of Congruence

Under ideal conditions, identification of the epileptogenic focus is made by the congruence of data obtained during the

preoperative evaluation, with the precise localization based on seizure semiology, physical examination, surface ictal and interictal EEG monitoring, and MRI, along with additional studies as discussed above, that is, ictal and interictal SPECT, interictal PET, MEG, fMRI, MR spectroscopy, and transcranial magnetic stimulation. Each case must be individualized, with various combinations of the above procedures used at different centers.

The most complex cases are those of nonlesional extratemporal epilepsy. In these patients, placement of invasive subdural strips or grids or depth electrodes is generally necessary for precise localization of the epileptogenic focus.

## INVASIVE INTRACRANIAL ELECTROENCEPHALOGRAPHY MONITORING

There are noninvasive tools available to help identify the epileptogenic zone, defined as the minimum amount of cortical tissue that must be resected to produce seizure freedom. Defining the epileptogenic zone entails accurate seizure localization, mapping the extent of the epileptogenic zone, and assessing the functional status of the epileptogenic zone. When the noninvasive tools do not accurately achieve the goals of defining this epileptogenic zone in a patient with pharmacoresistant epilepsy, invasive intracranial electroencephalography may identify a clear resective surgical strategy. Indications for invasive monitoring include the following:

- No cortical lesion is detected on MRI.
- Data obtained from noninvasive evaluation are conflicting and do not clearly delineate the borders of the epileptogenic zone.
- There is a suspicion of multifocal epilepsy.
- Noninvasive data identify the epileptogenic zone being in close proximity or involving eloquent cortex.

Invasive monitoring is the placement of subdural grids and strips directly over the cortex. These disk electrodes are 2 to 5 mm in diameter and are embedded in silicon elastomer aligned in a linear fashion separated by 10 mm from center to center. Advantages of using subdural grids/strips include comprehensive spatial cortical coverage, which allows for accurate anatomic and functional mapping over the area of coverage. Limitations include inadequate and/or incomplete coverage of intrasulcal, deep cortical regions, and interhemispheric areas as well as difficulty covering multilobar and large functional networks.

Another invasive monitoring technique is the stereo-electroencephalography (SEEG). Its aim is to produce a three-dimensional spatial-temporal organization of epileptic discharges within the cortical and subcortical brain structures. This method is technically complex, using the Talairach stereotactic frame and the double-grid system in association with teleangiography to place depth electrodes, which are linear probes containing multiple cylindrical contacts (Gonzalez-Martinez et al., 2014). More modern and less complex methods of stereotactic implantation of depth electrodes, using a robotic arm, are emerging to make SEEG more feasible.

SEEG may provide an advantage in cases where the epileptogenic zone is hypothesized to be deep-seated or in a region that may be difficult to be adequately covered using subdural grids/strips. Examples of such regions include mesial temporal, perisylvian opercular, cingulate, orbitofrontal, and insular cortex (Gonzalez-Martinez et al., 2014).

A limitation to SEEG includes restricted ability to perform functional mapping, especially contiguous mapping in

eloquent cortex because of the limited number of contacts located on superficial cortex (Gonzalez-Martinez et al., 2014).

Complication rates range from 3% to 6% and include hemorrhage or intraparenchymal hematoma (Gonzalez-Martinez et al., 2014).

## TYPES OF SURGERY

Several types of epilepsy surgery are performed in children and adults, depending on the identification of the epileptogenic focus and its location and extent. The most common surgical procedures are as follows:

1. Temporal lobectomy
2. Cortical resection—lobar and multilobar
3. Stereotactic lesionectomy
4. Hemispherectomy—either anatomic or modified
5. Multiple subpial transection
6. Corpus callosotomy
7. Implantation of a vagus nerve stimulator
8. Minimally invasive surgical techniques

Temporal lobectomy is the most common epilepsy surgery performed in adolescents and adults. This procedure is almost exclusively a temporal lobectomy with amygdalohippocampotomy. Removal of the mesial temporal structures is correlated with a 90% chance of becoming seizure free in patients with mesial temporal sclerosis.

Extratemporal cortical resection is more commonly performed in children, often involving extensive lobar or multilobar resections. The extent of the resection is dictated primarily by the extent of the lesion. As the ability to identify focal cortical dysplasias and the concomitant epileptogenic zone improves, epilepsy surgical outcomes may also improve. Focal cortical dysplasias are a common cause of intractable partial epilepsy in children, accounting for 60% of the cases. The best predictive factors in successful surgical outcome in focal cortical dysplasia are completeness of the resection and the presence of an identifiable lesion on MRI brain imaging (Cross et al., 2006).

Stereotactic lesionectomy, performed in highly selected cases in children and adults, has a reported 50% to 60% chance of rendering the patient seizure-free. Outcome is improved if intraoperative electrocorticography is used to remove not only the lesion, but also the surrounding “epileptogenic zone.”

Hemispherectomy is performed in young children, including infants. The indications for this type of surgery are medically resistant epilepsies in which the substrate of epilepsy is limited to one hemisphere. Typical indications include Sturge-Weber syndrome, hemimegalencephaly or extensive unilateral cortical dysplasia, Rasmussen encephalitis, and (usually postinfarct) porencephaly.

Multiple subpial transection is a surgical technique that may be used when the epileptogenic zone overlies an area of functional cortex. Multiple subpial transection involves the disruption of connecting horizontal fibers, preserving vertical connections and avoiding resection of tissue. The technique is not as effective as cortical resection.

Corpus callosotomy is a palliative surgery that can reduce the seizure burden in carefully selected patients. It is most commonly used in children with Lennox-Gastaut syndrome, with the goal being reduction of tonic and atonic seizures, and can be highly effective. Although there is no consensus in the published literature, one series comparing anterior versus complete corpus callosotomy showed better seizure control in patients with complete corpus callosotomy. The use of a

complete corpus callosotomy, coupled with lateralizing strips, has been demonstrated to be effective in identifying an epileptogenic zone as part of a multistage surgery. Complications of corpus callosotomy include surgical complications, transient mild hemiparesis, and disconnection syndrome (apathy, urinary incontinence, and nondominant hemineglect). The risk for disconnection syndrome is greater in patients with higher cognitive function and older age.

Minimally invasive surgical techniques have emerged as potential alternatives to open epilepsy surgery because of the high costs of resective epilepsy surgery, the reluctance of patients and referring physicians to seek invasive surgery for definitive treatment, and surgical morbidities. These techniques include stereotactic radiosurgery, stereotactic radiofrequency thermocoagulation, and laser-induced thermal therapy (LITT).

Stereotactic radiosurgery involves delivering ionizing radiation to small foci deep within brain tissue while sparing damage to surrounding tissue. This technique has been used to treat lesions that are difficult to access, such as deep brain tumors and arteriovenous malformations. There are a few sources of focal ionizing radiation in clinical use, one of which is the Gamma Knife (Elekta AB), which consists of approximately 200 separate radioactive cobalt-60 sources housed inside a hemispheric chamber and focused to a single target.

Stereotactic radiofrequency thermocoagulation is a procedure that causes a permanent lesion by heating brain tissue until proteins denature. This technique uses a monopolar needle, inserting it into the surgical target under stereotactic guidance. After the needle is inserted into the desired focus, high-frequency current is injected, resulting in heating tissue at the electrode tip.

LITT, also known as MRI-guided thermal laser ablation, is tissue coagulation accomplished via laser delivery. Studies rigorously evaluating use of this technology are few. Though preliminary data for LITT are promising, use of LITT in epilepsy treatment is limited at this time.

Further surgical options as palliative procedures, namely, vagus nerve stimulation and responsive nerve stimulation, are discussed in the chapter on neuromodulation for epilepsy.

## GOALS OF SURGERY

With use of innovative, noninvasive technologies, the ability of the clinician to identify the underlying epileptogenic zone and achieve the elimination of seizures in patients with medically intractable epilepsy through surgery has improved. The goals of epilepsy surgery, however, may vary, depending on the epilepsy syndrome, the underlying pathophysiology, the cognitive and developmental status of the child or adolescent, and the identification and location of an epileptogenic zone.

## RESEARCH ISSUES: TRENDS FOR THE FUTURE

There are many unanswered questions that still need to be addressed in the pursuit of helping children with intractable epilepsy.

Future trends for exploration will involve several avenues of research: source localization and predictive EEG patterns for identification of the epileptogenic zone; expanded use of minimally invasive surgical techniques; and implantable devices that can detect predictive EEG patterns before a clinical seizure and deliver antiseizure medication or an electrical stimulus.

## INTRODUCTION

The twenty-first century has seen a rise of interest in neuromodulation, a term that describes the family of brain-stimulation techniques that alter brain function. Neuromodulation is particularly relevant in epilepsy, where seizures are resistant to pharmacotherapy in approximately one-third of all instances, a statistic that has not changed despite the introduction of more than 20 new antiseizure drugs in the late twentieth and early twenty-first centuries (Loscher and Schmidt, 2011). Accordingly, neurostimulation protocols are emerging as potentially valuable tools for seizure control.

Stimulating the nervous system to treat neuropsychiatric symptoms is not new. In the first century AD, the Roman physician Scribonius Largus documented treating headaches by applying electric torpedo fish to the head, and another Roman physician, Pedanius Dioscorides, in 76 AD applied the torpedo fish to a patient with epilepsy. As with brain stimulation in general, neuromodulation for epilepsy has advanced considerably in recent years, particularly as a set of palliative interventions in clinical epilepsy (Krishna et al., 2016). Neurostimulation protocols can be coarsely divided into either invasive or noninvasive. Among the invasive options, those that require surgical placement of a neurostimulation device are vagus nerve stimulation (VNS), deep-brain stimulation (DBS), and responsive neurostimulation (RNS). Noninvasive neuromodulation protocols include transcranial magnetic stimulation (TMS), trigeminal nerve stimulation (TNS), and transcranial direct current stimulation (tDCS). Although the most widely used neuromodulation approach to control seizures remains VNS, other technologies have become viable options for patients with intractable seizures.

## VAGUS NERVE STIMULATION

VNS is one of the oldest neuromodulation protocols for epilepsy. As early as 1937, Schweitzer and Wright demonstrated suppression of strychnine-induced convulsions by experimental VNS in cats. The first human patient to undergo VNS via an implanted stimulator became seizure-free in 1988. In 1997 the U.S. Food and Drug Administration (FDA) approved VNS for use in adolescents and adults with intractable focal seizures, and since then VNS has developed as an established adjunctive therapy for medically refractory epilepsy.

VNS involves surgical implantation of a generator beneath the skin of the upper chest. From there, a subcutaneous cable connection is made to the stimulation electrode terminals placed directly on the left vagus nerve. The VNS device has two common stimulation modes: scheduled stimulation with predefined ON and OFF periods and on-demand firing, in which the patient or caretaker can activate the device during a seizure with a magnetic switch. The most recent VNS models also have the capacity to program a threshold heart-rate change such that stimulation will be triggered by tachycardia associated with seizure activity. The VNS surgical procedure carries a relatively low risk. Stimulation-related

side effects such as cough, hoarseness, or throat discomfort are typically mild and can be relieved by adjusting the stimulation parameters.

The mechanisms by which VNS suppresses seizures are not fully understood. Anatomically, the vagus nerve carries both parasympathetic efferents to viscera and also visceral afferents that project diffusely to cortex and subcortical structures, particularly the thalamus, via the medial reticular formation, yet how these projections may modify seizure threshold is unknown. VNS may also activate unmyelinated nociceptive C fibers and lead to an arousal-like effect that is also associated with an elevation of seizure threshold. One study indicates reduced medial thalamus metabolic activity during the ON stimulation state in patients with favorable VNS effects, as assessed by single-photon emission computed tomography (SPECT). Results from another study that aimed to measure the effects of VNS on the cortical excitation:inhibition (E:I) ratio indicate that the VNS ON state corresponds to enhanced intracortical inhibition, as measured by paired-pulse transcranial magnetic stimulation (ppTMS; see discussion later in this chapter). A measure of scalp electroencephalogram (EEG) interregion synchrony in patients with successful VNS also identified desynchronization of cortical electrical activity as a possible VNS mechanism.

Overall, VNS results in modest seizure reduction. In adults with intractable seizures, a multicenter randomized controlled trial ( $N = 114$ ) measured seizure suppression after chronic stimulation or on-demand VNS activation by instructing patients to activate the device during a seizure aura. For chronic stimulation, subjects were randomized to one of two conditions: treatment (up to 3 mA, 20–50 Hz, 500- $\mu$ s pulse width, ON 30–90 sec, OFF 5–10 min) or active control (up to 2.75 mA, 1 Hz, 130- $\mu$ s pulse width, ON 30 sec, OFF 60–180 min). After 14 weeks of VNS, the treatment group experienced significant mean seizure frequency reduction (24% vs. 6%). In regard to the effectiveness of patient-controlled on-demand VNS activation by a portable magnet switch, there was no significant difference in efficacy between groups assigned to treatment versus control conditions (0-mA output programmed for magnet activation), although most subjects perceived seizure reduction with the on-demand intervention. A subsequent large ( $N = 196$ ) VNS trial with similar study parameters confirmed seizure frequency reduction in the treatment group receiving high stimulation compared with the control group receiving low stimulation (28% with high stimulation vs. 15% with low stimulation), with particular efficacy among patients with complex partial seizures (Handforth et al., 1998).

In pediatrics, the results of VNS trials have been mixed. A double-blind randomized controlled trial measured VNS efficacy in children ( $N = 41$ ) aged 3 to 17 years, 85% with focal epilepsy and 15% with generalized epilepsy. Seizure frequency and severity were monitored by diary and the National Hospital Seizure Severity Scale (NHS3). Participants were randomized to the treatment (0.25 mA, 30 Hz, 500- $\mu$ s pulse width, ON 30 sec, OFF 5 min) or active control (0.25 mA, 1 Hz, 100- $\mu$ s pulse width, ON 14 sec, OFF 60 min) groups. After the

initial phase, the treatment group received stimulation at the maximum tolerated current (up to 1.75 mA), whereas in the control group, the output current was initially increased during the clinic visit but was then restored to 0.25 mA. Although there was an overall reduction in seizure frequency and severity from baseline, there was no statistical difference in seizure reduction between the two groups.

Results from retrospective and open-label studies in children are more encouraging. One review of records in 69 children who had undergone insertion of VNS for intractable epilepsy identified a satisfactory outcome, as defined by an Engel class I, II, or III rating, in 55.0% of the sample, yet no change in seizures (Engel class IV) in 45%. An additional retrospective study reviewed patient records of 43 children with medically refractory epilepsy, aged 3 to 12 years, 46% with generalized seizures, 19% with focal onset seizures, and 35% with mixed types. The VNS output settings ranged from 0.5 to 2.0 mA, ON 30 sec, OFF 1.1 to 10 min (median 3 min). Postimplant seizure reduction was greater than 50% in 51% of the children. However, there was no relief of medication burden for any of these patients after VNS implantation. Yet another retrospective analysis of antiseizure VNS efficacy in 69 children at a single epilepsy center found an overall seizure frequency reduction of 50% at 6-month follow-up and 40% at 12 months. In this study, patients were classified as either high- or low-baseline seizure frequencies. Seizure frequency decrease in the low-baseline seizure frequency group ( $\leq 45$  seizures/month for 3 months before implantation) was 25% at 6 months but not significant after 12 months. However, in the subgroup with high-baseline seizure frequency ( $>45$  seizures/month), seizure reduction was significantly higher at 61% after 6 months and 69% at the 12-month follow-up. Taken together, these data indicate plausible VNS efficacy in pediatrics, although without confirmation by a large randomized controlled trial.

## ANTERIOR NUCLEUS OF THE THALAMUS DEEP-BRAIN STIMULATION

In the United States, DBS has been approved by the FDA for treatment of movement disorder symptoms such as tremor and dystonia since 1997. Although research into DBS efficacy as an antiseizure therapy dates back to the 1970s, it has yet to be approved by the FDA for seizure suppression. However, one specific form of DBS, in which stimulating electrodes target the anterior nucleus (AN) of the thalamus, is nearing approval. The rationale for AN stimulation is based in part on the AN role as the primary relay nucleus of the limbic system—the AN both receives major projection from the mammillary bodies of the hypothalamus and projects fibers to areas such as the cingulum, amygdala, hippocampus, orbito-frontal cortex, and hypothalamus.

The DBS procedure is similar to VNS in that a generator is implanted beneath the skin in the chest. However, the leads are bilateral and tunneled to connect with two stereotaxically placed intracranial electrodes. As with VNS, the surgical procedure is well tolerated, with few complications.

A favorable outcome with AN stimulation in a patient with intractable seizures was first reported by Upton and Cooper in 1985 and supported by subsequent small-scale studies, the results of which indicated both seizure suppression and an acceptable safety profile of AN DBS in epilepsy. The early AN DBS data then prompted a large multicenter randomized trial, Stimulation of Anterior Nucleus of Thalamus for Epilepsy (SANTE), in patients ( $N = 110$ ) with intractable seizures and baseline median seizure frequency of 19.5 seizures/month (Fisher et al., 2010). One month after DBS implantation,

subjects were randomized to two groups for the blinded phase of the study: treatment, in which the device was turned on at the start, and control, in which the device was turned on only after a 3-month blinded phase. The results from the SANTE trial are encouraging: 40% reduction in seizure frequency was identified in the treatment group, with stimulation parameters 5 V, 145 Hz, 90- $\mu$ s pulse width, ON 1 min, OFF 5 min, in comparison to 15% decrease in the control group. In a subsequent 12-month open label follow-up, in which stimulation settings could be adjusted to 7.5 V and 185 Hz, an overall 56% reduction in median seizure frequency was found, with 54% of subjects reporting at 50% or greater seizure frequency reduction. Moreover, in subsequent long-term follow-up, 14 patients (13%) were seizure-free for at least 6 months, 8 (7%) were free for 1 year, 4 (3%) for at least 2 years, and 1 (1%) remained seizure-free for more than 4 years (Salanova et al., 2015). AN DBS is approved for the treatment of refractory epilepsy in Europe and Canada but not in the United States at the time of this writing.

AN DBS complications in the SANTE trial cohort included infection (12.7%), hemorrhage (4.5%), status epilepticus (4.5%), and death (4.5%). Of the five deaths that occurred during the SANTE trial period, three were attributed to sudden unexpected death in epilepsy (SUDEP), either in the baseline or follow-up phase. However, no deaths were reported during the first month after surgery (Fisher et al., 2010). Additional adverse events reported during the blinded phase included depression (15%) and memory impairment (13%), which were the most common reported side effects in the active treatment group.

## RESPONSIVE NEUROSTIMULATION

Closed-loop responsive electrical brain stimulation is a novel treatment paradigm for epilepsy that involves implantation of subdural or depth electrodes in an epileptogenic brain region. In contrast to open-loop stimulation devices, the RNS electrodes are both stimulating and recording. The RNS electronics are self-contained in a cranial implant. EEG at the target is continuously monitored and recorded by the RNS computer. When electrical activity that signals seizure onset is detected, electrical stimulation with predetermined parameters is delivered via specified lead contacts, with the goal of disrupting the abnormal local electrical activity and either terminating an ongoing seizure or preventing seizure onset. The first implantable RNS device was FDA approved in the United States in 2013 as an adjunctive therapy in adults with medically uncontrolled focal onset seizures localized to one or two epileptogenic foci.

RNS safety and efficacy were established in three clinical trials: a 2-year primarily open-label safety trial ( $N = 65$ ), a 2-year randomized controlled trial ( $N = 191$ ), and a 7-year long-term extension study ( $N = 230$ ). In the pivotal multicenter randomized controlled trial, adults with refractory focal seizures were treated with a responsive neurostimulator connected to either depth or subdural leads at one or two pre-specified seizure foci. As in the SANTE trial, subjects were randomized 1 month after surgery into either the control or treatment group and followed for a 12-week blinded observation period, after which all participants entered an 84-week open-label period. During the first postsurgical month, both the control and treatment groups experienced a decrease in mean seizure frequency; notably, a postimplantation seizure reduction was also seen in the postsurgical month follow-up in the SANTE trial. Over the blinded evaluation period, mean seizure frequency fell by 38% in the treatment group compared with a 17% reduction in the control group. Of 102

patients assessed at the 2-year mark of the open-label period, 46% had at least 50% mean seizure frequency reduction. Both control and treatment RNS groups had similar improvements in secondary outcome measures, including quality of life, at the end of the blinded evaluation period. There were no significant differences in adverse events between the groups. The rate of intracranial hemorrhage was 4.7%, and 5.2% of subjects experienced implant site infection. There were 6 deaths in the pivotal 191-subject RNS controlled trial study: 4 attributed to SUDEP, 1 to lymphoma, and 1 patient with a history of depression who committed suicide (Morrell and RNS System in Epilepsy Study Group, 2011). Notably, mortality in this trial did not significantly exceed expected mortality rate in this vulnerable population.

## TRIGEMINAL NERVE STIMULATION

TNS (in some texts termed *external trigeminal nerve stimulation*, or *eTNS*), like VNS, is a means to access the antiepileptic capacity of cranial nerve stimulation. In contrast to VNS, TNS can be delivered noninvasively via cutaneous electrodes that activate branches of the trigeminal nerve, usually in the  $V_1$  distribution, where stimulating electrodes are positioned over the skin of the forehead. The mechanisms by which TNS may suppress seizures are not clear but, as in VNS, may relate to activation of the brainstem reticular formation and C-fiber stimulation that lead to an arousal state. TNS clinical trials were supported by early preclinical data that showed suppression of chemoconvulsant seizures in rats with high-frequency stimulation of the infraorbital nerve. These preclinical data prompted an open-label trial, which produced favorable results in 13 adults with intractable epilepsy. As with other neuromodulation protocols, data from a larger randomized control trial ( $N = 42$ ) were less impressive. In the phase II TNS trial, adults with intractable epilepsy were randomized to receive TNS with a bipolar transcutaneous gel-based electrode designed to stimulate the right and left branches of the ophthalmic and supratrochlear nerves (DeGiorgio et al., 2013). TNS in the treatment group was delivered at 120 Hz and a pulse duration of less than 250  $\mu$ s. The active control group received TNS at 2 Hz, pulse duration 50  $\mu$ s, ON 2 sec, OFF 90 sec. Subjects in both groups received stimulation for at least 12 hours per day and were followed for an 18-week trial period, with evaluation at weeks 6, 12, and 18. After 18 weeks of stimulation, 41% of patients who received active stimulation had more than 50% seizure frequency reduction, compared with 16% in the control group. Although an intergroup statistically significant difference was not found, patients in the treatment group had a significant within-group increase in responder rate ( $\geq 50\%$  seizure frequency reduction) over time, whereas patients in the control group did not. The TNS side-effect profile is favorable: no major adverse events were reported in the controlled TNS trial, apart from a transient (only at week 6 follow-up) increase in heart rate in the treatment group. At the time of this writing, TNS is approved in Europe and Canada and is under investigation by the FDA for approval in the United States.

## REPETITIVE TRANSCRANIAL MAGNETIC STIMULATION FOR SEIZURE SUPPRESSION

Therapeutic noninvasive brain-stimulation in epilepsy has been approached largely with two techniques: TMS and, to a lesser extent, tDCS. TMS is a method for focal noninvasive brain stimulation in which small intracranial electrical

currents are induced by a fluctuating extracranial magnetic field that is typically generated by a hand-held electromagnet. Repetitive TMS (rTMS), at a low frequency (0.3–1 Hz) can induce a lasting reduction in cortical excitability and has plausible antiseizure therapeutic utility. As with other forms of brain stimulation, the mechanisms by which rTMS may reduce cortical excitability and suppress seizures are only partially understood, but they likely resemble those of use-dependent long-term depression (LTD) of excitatory synaptic strength that follow electrical low-frequency cortical stimulation.

Encouraging open-label trials show a potential for seizure reduction by rTMS when applied over the epileptogenic region, or even when applied in a neutral scalp location, such as over the vertex. The positive response of some patients to stimulation outside of the epileptogenic zone, and in one series a favorable response of patients with primary generalized seizures to rTMS, raises the possibility that the rTMS antiseizure mechanism is not just local suppression of intracortical excitability, but rather a network effect whereby excitability is modulated at sites distal to the locus of stimulation (Shafi et al., 2015).

In contrast to the open-label data, placebo-controlled rTMS trials have yielded inconsistent results. The first trial, in patients with temporal lobe epilepsy (TLE), did not reveal an antiseizure benefit in patients with TLE. A second trial showed a significant seizure reduction and improvement of the interictal EEG in patients with intractable seizures attributable to cortical dysplasia. The third, which investigated rTMS in a mixed group of patients with either focal or primary generalized seizures, found that rTMS was no better than placebo for seizure reduction but that active treatment significantly reduced interictal EEG epileptiform abnormalities. However, the most recent large, randomized, single-blinded, controlled clinical trial ( $N = 60$ ) reveals a substantial effect: subjects randomized to a 2-week “high-intensity” treatment group (90% resting motor threshold, rMT; threshold to muscle activation) 0.5-Hz rTMS over the epileptogenic focus showed an 80% reduction in mean seizure frequency along with decreased interictal EEG discharges compared with the low-intensity (20% rMT) control group, with a mean seizure reduction of 2%. The antiseizure effects were relatively long-lasting and maintained up to 2 months after treatment.

The rTMS safety profile in the treatment of epilepsy is favorable. A 2007 review of the literature identified a crude per-subject seizure risk approximating 1.4% in patients with epilepsy undergoing rTMS. A subsequent case series also identified that in-session seizures during rTMS were most likely in patients whose seizure frequency exceeded one per day. The events were, in all instances, identical in semiology to a patient’s typical seizures and were of either typical duration or shorter than a patient’s native seizures. Further, any documented in-session seizures during rTMS thus far have not been correlated with a poor neurologic outcome or the absence of an rTMS response. Seizure exacerbation in patients with epilepsy by rTMS has not been recorded, and there are no instances of rTMS-provoked status epilepticus. The absence of reported seizure exacerbation appears to be a common finding independent of whether rTMS is administered interictally or during an ongoing seizure, as in *epilepsia partialis continua* (EPC). The incidence of the remaining rTMS-related adverse events (such as headache, neck pain, or tinnitus) is similar in patients with epilepsy to that which is described in healthy volunteers and in other patient populations. Last, rTMS appears to be safe and well tolerated in specialized populations with implanted VNS devices or with titanium skull plates, both of which are relatively prevalent in the population of patients with intractable seizures.

## DIAGNOSTIC TRANSCRANIAL MAGNETIC STIMULATION

TMS is unique among the neurostimulation techniques that are used in epilepsy in its potential as either a diagnostic or a therapeutic tool. For instance, neuronavigated TMS (termed *nTMS* in some texts) is an FDA-approved method for noninvasive presurgical mapping of the motor and language cortices. Another TMS protocol, paired-pulse TMS (ppTMS) is a means to measure the cortical E:I ratio and is emerging as a technique to either track disease severity or to measure the therapeutic effect of an intervention.

In presurgical motor cortex mapping, TMS is applied over the motor cortex and coupled with surface electromyography (EMG) such that TMS elicits an evoked muscle contraction in a contralateral limb muscle that is quantified by skin electrodes and the recording of a motor evoked potential (MEP). During presurgical mapping, the TMS operator, guided by a patient's brain magnetic resonance imaging (MRI), can test whether stimulation of a specified brain region evokes an MEP from a specific muscle group. These data are then registered to the patient's MRI to generate a precise motor map where the spatial resolution approximates that which can be obtained by intraoperative monitoring of the MEP. In addition to motor mapping, TMS offers a unique tool for mapping the language cortex. For language mapping, repetitive stimulation is delivered in trains to potential cortical language areas while a subject performs a linguistic task, such as object naming, and the operator then identifies regions where stimulation interrupts the task performance.

In a more experimental diagnostic TMS role, measures of the cortical E:I ratio can be derived from the MEP. Among these is the threshold to muscle activation, or motor threshold (MT). The MT, which is obtained by single-pulse TMS, likely reflects neuronal membrane excitability and is increased by anticonvulsants, such as phenytoin and carbamazepine, that block voltage-gated sodium channels. Other measures can be obtained from ppTMS protocols, where stimuli are delivered as closely-spaced pairs and the cortical response to a single test stimulus is modulated by the preceding conditioning stimulus. With ppTMS, measures of  $\gamma$ -aminobutyric acid (GABA)-mediated cortical inhibition and glutamate-dependent cortical excitability can be quantified. These metrics are affected preferentially by GABA-ergic drugs such as barbiturates and benzodiazepines. Taken together, these TMS measures can detect abnormalities in the E:I ratio in patients with epilepsy. In particular, pathologic suppression of intracortical inhibition as detected by ppTMS appears to be a common finding in patients with epilepsy and may in some instances reflect disease severity. A shift in the E:I ratio toward excess excitation occurs in the preictal period in patients with epilepsy, suggesting prospects for TMS in identifying periods of seizure vulnerability that could allow for prognosticating the timing and likelihood of seizure. Another potentially useful application of TMS may be to measure whether antiseizure drug treatment has shifted the E:I ratio in a favorable direction, and thus predict seizure control (Badawy et al., 2010).

The capacity to probe the E:I ratio by TMS may address an important unmet need for patients undergoing antiseizure therapies for which there are limited biomarkers to guide dosing or to aid in the identification of a favorable therapeutic effect in advance of a change in seizure count. As noted earlier, VNS may lead to an increase in intracortical inhibition that can be detected by ppTMS. TMS-derived intracortical inhibition measures are also enhanced by the ketogenic diet. Although the clinical utility of these findings will have to be determined in controlled trials, these data indicate a potential for diagnostic TMS to guide existing treatments for epilepsy.

## TRANSCRANIAL DIRECT CURRENT STIMULATION

tDCS modulates cortical activity by conductance of low-amplitude direct electrical current delivered through scalp electrodes. Applied to the mammalian cerebral cortex, cathodal tDCS induces a durable reduction in cortical excitability, whereas anodal tDCS increases excitability after a single session that typically lasts 20 to 30 minutes. In epilepsy, the capacity of cathodal tDCS to reduce cortical excitability has prompted research into this technique's potential. In contrast to other neurostimulation methods, tDCS amplitudes are insufficient to generate action potentials in the area of stimulated cortex, suggesting a mechanism of action reliant more upon modulation of ongoing neuronal activity than the induction of new neuronal activity.

The relatively low intracranial currents associated with tDCS likely, in part, account for its favorable safety profile. In contrast to other noninvasive neurostimulation techniques such as TMS, seizures have not been associated with tDCS in patients with epilepsy, and the remaining side effects are largely limited to skin irritation at the electrode sites. However, tDCS antiseizure efficacy and overall clinical utility in epilepsy are less established than in the aforementioned techniques.

Clinical tDCS data in epilepsy are limited, but a few reports suggest a realistic role for tDCS in seizure suppression. A randomized controlled study of adults with medically refractory epilepsy ( $N = 19$ ) referable to malformations of cortical development found that interictal epileptiform discharges on EEG were reduced by 64% for 30 days after one 20-min application of 1-mA cathodal tDCS over the seizure focus. In a pediatric study ( $N = 36$ ), children aged 6 to 15 years with refractory focal epilepsy were randomized to active (1-mA cathodal tDCS for 20 minutes) or sham control tDCS, in which current was applied only for 60 secs before the current was turned off. The results indicate that tDCS was well tolerated and corresponded to a significant decrease in the EEG spike frequency for up to 48 hours after stimulation. Clinical seizure reduction in this cohort was small (about 5%) but also statistically significant, supporting continued efforts to test whether multiple tDCS courses will result in a meaningful antiseizure effect.

The incomplete knowledge of the efficacy of human tDCS trials underscores the need for further preclinical studies that will help to inform future clinical tDCS study designs. Published reports using cathodal tDCS in animal epilepsy models show increased seizure threshold in focal electroshock and amygdala seizure kindling models. In an additional study, 7 days of cathodal tDCS treatment 1 day after pilocarpine-induced status epilepticus was shown to have an antiseizure and neuroprotective effect in rat pups. In a more recent experiment, cathodal tDCS was tested in the acute seizure setting that approximates status epilepticus to assess an immediate anticonvulsant effect. Electrographic seizure suppression was seen within minutes of stimulation in a rat pentylenetetrazole status epilepticus model. Of translational relevance for future clinical application, cathodal tDCS in this experiment worked synergistically with lorazepam to suppress seizures. These data indicate an important direction for neuromodulation research toward systematic testing of combination drug-device therapy in epilepsy (Dhamne et al., 2015).

## CONCLUSION

Given the incomplete efficacy of pharmacotherapy in epilepsy, the prospects for neuromodulation to play a significant role in patient management are rapidly improving. As with many technologies reliant on electronics, the neuromodulation tools available to patients, physicians, and investigators are

growing in abundance and are maturing in sophistication. Among these evolving protocols are established techniques such as VNS, techniques repurposed specifically for epilepsy such as DBS, and emerging technologies such as RNS and noninvasive brain stimulation. Novel neurostimulation tools are likely to be added to this short list in the future.

## Ketogenic Diets

James W. Wheless and Eric H. Kossoff

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Antiseizure medicines are the primary treatment modality and provide good seizure control in most children. However, more than 25% of children with epilepsy have either intractable seizures or suffer treatment-limiting adverse medication effects. Only a limited number of these children are candidates for surgical therapy. In addition, uncontrolled seizures pose a variety of risks to children, including higher rates of mortality, accidents, and injuries, as well as a greater incidence of cognitive and psychiatric impairment, poorer self-esteem, higher levels of anxiety and depression, and social stigmatization or isolation.

Thus effective treatment to control seizures is fundamental to improving overall outcome in childhood epilepsy. The ketogenic diet has proven to be an effective treatment for many children (and adults) with epilepsy (Kim and Rho, 2008; Neal et al., 2009; Stafstrom and Rho, 2004). In this chapter, the history of the development of the diet, current understanding of the biochemistry of ketone body formation and its relation to the anticonvulsant effect of the diet, considerations related to patient selection, and diet efficacy, complications, advantages, and disadvantages are reviewed.

### HISTORY

For centuries, fasting has been used to treat many diseases, including seizures; it was even used in biblical times (Wheless, 2004). Dr. Russell Wilder at the Mayo Clinic suggested in 1921 that a diet high in fat and low in carbohydrates could maintain ketosis and its accompanying acidosis longer than fasting and be maintained indefinitely. Wilder was also the first to coin the term “ketogenic diet.” The beneficial effects of this diet were initially recorded by investigators from Johns Hopkins University, the Mayo Clinic, and Harvard University. Until 1938, the ketogenic diet was one of the few available therapies for epilepsy, but it fell into disfavor when researchers turned their attention to the development of new antiseizure medicines. The ketogenic diet was also perceived as expensive, difficult-to-maintain, and less “modern” in many ways compared with drugs. Use of the ketogenic diet decreased greatly until it received national media attention in the mid-1990s. The creation of the Charlie Foundation ([www.charlifoundation.org](http://www.charlifoundation.org)) in 1994 by a parent of a child with epilepsy successfully treated with the diet has led to significant research and use. The year 2008 was an important one in the history of the ketogenic diet. Two randomized, controlled studies (one double-blinded) were published demonstrating efficacy of this approach. In addition, a consensus statement from 26 dietitians and neurologists at worldwide ketogenic diet centers was published in *Epilepsia* to help guide clinical management of ketogenic diet patients.

### EFFICACY

#### Efficacy of the Classic Ketogenic Diet

Initial reports began to appear in the 1920s and 1930s that documented the efficacy of the ketogenic diet. Over the next

60 to 70 years, many more clinical reports appeared (Lefevre and Aronson, 2000; Levy and Cooper, 2003). About one-half of children appear to have had an excellent response to the diet, defined by cessation or marked reduction (a greater than 50% reduction) in seizure activity. About 15% of children become seizure-free after initiation of the ketogenic diet and typically stop the diet after 2 years. Of those children who become seizure-free, a minority have recurrence after the diet is stopped. Risk factors that increase the likelihood of recurrence are epileptiform abnormalities on electroencephalograms (EEGs) obtained within 12 months of diet discontinuation, a focal abnormality on magnetic resonance imaging (MRI), lower initial seizure frequency, and tuberous sclerosis complex. Younger children as well as adolescents and adults do well on the diet.

In a 2010 single-center report, 104 infants (mean age 1.2 years) were started on the diet for mostly symptomatic and very refractory infantile spasms (mean 3.6 anticonvulsants tried). Nearly two-thirds (64%) had a greater than 50% spasm reduction, including one-third with at least 6 months of spasm freedom and EEG improvement. Those who were older age and had tried fewer anticonvulsants when the diet was started did better.

The diet may also be helpful for Dravet syndrome (severe myoclonic epilepsy of infancy). As part of the Korean multi-centered experience, Kang and associates retrospectively reviewed efficacy in 49 infants treated with the ketogenic diet. Only 1 of 14 children with severe myoclonic epilepsy of infancy was seizure-free at 12 months, but 56% had a greater than 50% seizure reduction. Caraballo and colleagues reported similar results, with 10% seizure-free and 55% achieving a greater than 50% seizure reduction at 12 months.

There have been several large studies demonstrating efficacy with the ketogenic diet. The first multicenter prospective study of the efficacy of the ketogenic diet was based on data collected at seven comprehensive epilepsy centers. All children in this study had intractable epilepsy, averaging 230 seizures per month. It was found that 10% of treated patients were seizure-free at 1 year. A greater than 50% decrease in seizure frequency was observed at 3 months in 54% of patients. This improvement was maintained at 6 months (53% controlled) and 12 months (49% controlled) after initiation of the diet. Patient age, seizure type, and EEG abnormalities were not related to outcome. Approximately 47% remained on the diet for at least 1 year. Reasons for discontinuation included insufficient seizure control, intolerable side effects, concurrent medical illnesses, or inability to tolerate the restrictive nature of the dietary regimen. Although the number of patients was small, the study demonstrated that the diet could be used effectively in different epilepsy centers with different support staff and that children and their families were able to comply with the diet when it was effective.

One of the largest prospective evaluations of the ketogenic diet was conducted in 150 consecutive children aged 1 to 16 years (mean age 5.3 years) (Freeman et al., 1998; Hemingway et al., 2001). The children were followed for a minimum of 1 year, had previously been on an average of 6.24 medications,

and were on a mean of 1.97 medications at the diet's initiation. Seventy percent of children had an intelligence or developmental quotient of lower than 69. The children averaged 410 seizures per month before the ketogenic diet. At 6 months, 71% remained on the diet, and 32% had a greater than 90% decrease in seizures. At 1 year, 55% remained on the diet, 7% were seizure-free, and 27% had a greater than 90% decrease in seizure frequency. There was no statistically significant difference in seizure control based on age, sex, or seizure type, although none of the patients had only focal seizures. Most of those discontinuing the diet did so because it was either insufficiently effective or too restrictive.

A randomized controlled trial of the ketogenic diet was performed in children aged 2 to 16 years. Children with various seizure types or epilepsy syndromes experiencing daily seizures were recruited. They were randomly assigned to receive the ketogenic diet immediately ( $n = 73$ ), or after a 3-month delay, with no other changes in their treatment ( $n = 72$ , control group). Children were also randomly assigned to the classic or the MCT ketogenic diet. After 3 months, the percentage of patients with baseline numbers of seizures despite treatment was significantly lower ( $p < 0.0001$ ) in the diet group (62%) than in the controls. The children in the diet group had a mean of 13.3 seizures per day at baseline; after 3 months of treatment, 1 was seizure-free, 28 (38%) had a greater than 50% reduction in seizures, and 5 (7%) had a greater than 90% reduction. Efficacy was the same for symptomatic generalized or symptomatic focal epilepsies. The most common adverse events were constipation, vomiting, lack of energy, and hunger.

The same authors reported on the 1-year follow-up of those children randomized to the classic or MCT versions of the ketogenic diet. Of the 125 children who started the diets, data from 64 were available at 6 months and from 47 at 12 months. At 12 months, there was no significant difference between groups in the number of patients achieving greater than 50% (17.8 versus 22.2%) or 90% (9.6 versus 9.7%) seizure reduction. There was no significant difference in tolerability of the diet, except increased reports of lack of energy after 3 months, and vomiting after 12 months, both in the classical group.

### Efficacy of the Ketogenic Diet for Adults

Many early studies and now several recent studies have evaluated use of the ketogenic diet in adults. Some revealed improved seizure control, but several reports have also concluded that the diet is not particularly beneficial in adolescents and adults with epilepsy. Reasons cited for this were poor dietary compliance, types of seizures seen in these age groups, and the developmental differences in the ability of the brain to use ketone bodies. Mady and associates reviewed their experience with 45 adolescents who had been on the ketogenic diet for an average duration of 1.2 years. They found no evidence to support the belief that the diet was not efficacious and was too restrictive in this age group. Adolescents with multiple seizure types did best, and those with simple and complex partial seizures had the poorest response. The retention rate for motivated adolescents on the diet was not significantly different than reports in younger children.

### Efficacy of Alternative Ketogenic Diets

In recent years, two alternative diet regimens that are less restrictive and perhaps more palatable have emerged: the modified Atkins diet and a low glycemic index treatment (Fig. 80-1). The modified Atkins diet is similar in fat composition to a 1 to 1 ketogenic ratio (grams of fat to protein and carbohydrate combined) diet, with approximately 65% of the

calories from fat sources; it can be started as an outpatient, with guidance from a nutritionist. It is started without a fast or admission, and carbohydrates are limited to 10 to 20 grams per day. Parents and patients are instructed to count carbohydrates (by reading food labels and carb-counting guides) in comparison to the weighing and measuring of foods typically used for the classic ketogenic diet. Protein, calories, and fluids are unlimited.

Subsequent studies in over 450 children, adolescents, and adults reveal that 45% have a 50% to 90% seizure reduction, and slightly over 25% have a greater than 90% seizure reduction (Table 80-5).

The low glycemic index diet includes approximately 20% to 30% of calories from protein and 60% to 70% from fat. Total carbohydrates are gradually decreased to 40 to 60 g/day (about 10% of calories), using foods with a low glycemic index. In a retrospective review of 76 children on the low glycemic index diet, there was a greater than 50% seizure reduction from baseline seizure frequency in 42%, 50%, 54%, 64%, and 66% of the group at follow-up intervals of 1, 3, 6, 9, and 12 months, respectively. Efficacy did not differ between partial onset and generalized seizure types. Increased efficacy was correlated with lower serum glucose levels at the 1-month and 12-month follow-up visits. Side effects were minimal, with only three patients reporting transient lethargy.

## MECHANISMS OF ACTION

Although clinical reports support the efficacy of the ketogenic diet, several theories have emerged to explain the diet's mechanism of action. Four major areas have been investigated: cerebral acidosis; water balance; the direct effect of ketones or lipids; and alteration in brain energy substrates. The importance of ketone body formation was recognized early in the search for the mechanism of action of the ketogenic diet. Animal models and human evidence suggest a prominent role of ketonemia. Despite its long history of use and proven value, the exact mechanism of action of the diet remains unknown.

### Oxidation of Fatty Acids: Ketogenesis

Ketonemia is essential for the ketogenic diet to work. Ketonemia occurs as a result of fatty acid oxidation during fasting or when on the ketogenic diet. Fatty acid biosynthesis (lipogenesis) takes place in the cytosol, whereas fatty acid oxidation occurs in mitochondria and generates adenosine triphosphate (ATP). The brain does not directly use fatty acids but readily oxidizes ketone bodies. Increased fatty acid oxidation leading to ketone body formation by the liver is characteristic of the ketogenic diet. Glucose, present in small concentrations, is necessary to facilitate ketone body metabolism. Acetoacetate, a ketone body constituent, continually undergoes spontaneous decarboxylation to yield acetone that is volatilized in the lungs and gives the breath a characteristic odor.

The liver is the only organ capable of synthesizing significant quantities of ketone bodies that are released into the blood (see Fig. 80-3). Once formed, acetoacetate cannot be significantly metabolized back to fatty acids in the liver because it lacks the enzyme 3-oxoacid-CoA transferase. This accounts for the net production of ketone bodies by the liver. Ketone bodies are then transported to and oxidized in extrahepatic tissues proportionately to their concentration in the blood. Oxidation and brain influx rates of ketone bodies are proportional to their blood concentration of approximately 12 mmol/L. At this level, the oxidative machinery and uptake mechanisms of the cell are saturated.

Glucose is the principal substrate for brain metabolism. Under certain conditions (e.g., ketogenic diet), the human

brain uses ketone bodies for fuel; the movement of ketone bodies into the brain is dependent on a monocarboxylic transport system. Acetoacetate and  $\beta$ -hydroxybutyrate (BHB), the two constituents of ketone bodies, are metabolized primarily in the mitochondrial compartment. In the brain, the main pathway for the conversion of acetoacetate to acetoacetyl-CoA involves succinyl-CoA. Acetoacetyl-CoA is split to acetyl-CoA and oxidized in the tricarboxylic acid cycle. Ketone bodies not only serve as a source of energy but also contribute to the synthesis of the neurotransmitters, glutamate and gamma-aminobutyric acid (GABA), and cerebral metabolic pathways normally dependent on glucose metabolism. Furthermore, fatty acid oxidation increases brain ATP concentration. Elevation of brain ATP concentration has been verified in an animal model of the ketogenic diet, suggesting that the ketogenic diet improves cerebral energetics. Increased alpha-ketoglutarate on the diet may also increase activity of the GABA shunt. Thus improved cerebral energetics, along with decreased excitatory (glutamatergic) and increased inhibitory (GABAergic) neurotransmission, may contribute to the efficacy of the ketogenic diet.

### Clinical Studies of Ketosis

Ketoneuria is necessary but not sufficient for ketogenic diet-induced seizure control. Urine ketones are commonly measured due to ease of testing and cost (versus fingerstick blood BHB meters) and typically the desired range is 80 to 160 mmol/L (large). Seizure control correlates significantly ( $p = 0.03$ ) with serum BHB levels greater than 4 mmol/L, although urine ketones of 160 mmol/L can be found when blood BHB levels exceed 2 mmol/L. Anecdotally, there are many children with fluctuating or low levels of BHB who maintain excellent seizure control, which has also been noted in studies of the modified Atkins diet and low glycemic index treatment. When using these latter two therapies, ketones may even be completely absent despite seizure control. Freeman and associates evaluated serum BHB levels of 35 children 3 months after diet initiation. There was a significant correlation between higher levels of BHB and seizure control. The mean serum BHB level in patients with greater than 90% seizure control was over 6 mM.

It is also accepted that the classic ketogenic diet produces the most ketone bodies. Ketones from the circulation are transported across the blood-brain barrier by facilitated diffusion, using a monocarboxylate transport system. The efficacy of the diet in childhood and the slightly lower efficacy in older children, and adults may be due to maturational changes in this transport system. A child's ability to extract ketones from the blood into the brain is 4 to 5 times greater than that seen in adults. MR spectroscopy has also been used to study changes in cerebral energetics induced by the ketogenic diet. Alteration of tricarboxylic acid cycle activity by ketosis, resulting in an increased adenosine triphosphate to adenosine diphosphate (ATP to ADP) ratio or greater cerebral energy, has been hypothesized to have an anticonvulsant effect. This hypothesis is supported by recent experiments in patients with Lennox-Gastaut syndrome that used MR spectroscopy (31P) to document improvement in cerebral energy metabolism on the ketogenic diet.

Additionally, during chronic ketosis, adaptive mechanisms are active that increase the cerebral extraction of ketone bodies. These mechanisms may be why ketosis develops promptly within several days after initiation of the diet, but the anticonvulsant effect may be delayed for 1 to 2 weeks. Once ketone bodies are extracted, it is postulated that there is a secondary biochemical change or a cascade of biochemical effects that has some form of anticonvulsant effect.

### Experimental Studies of Diets in Animal Models

At the present time, there are several animal models used to study the effects of the ketogenic diet. One of the most effective to demonstrate the diet's antiseizure effects is the 6-Hz model for inducing seizures. In general, these animal models demonstrate that the ketogenic diet provides protection for partial-onset seizures with secondary generalization and generalized myoclonic, tonic, and tonic-clonic seizures. The mechanism appears to be a lowering of neuronal excitability and a raising of seizure threshold.

A limited number of animal studies have investigated the effect of age at diet onset versus efficacy. The diet provides a greater level of seizure protection in younger animals, but older animals also demonstrate an elevated seizure threshold. Although it would seem intuitive that increasing ketonemia would correlate with diet efficacy, experimental studies have not revealed a positive correlation. However, rats that developed higher levels of ketosis also showed higher thresholds for seizure induction. Caloric restriction can significantly influence seizure threshold and augment the effects of the ketogenic diet on seizure control. Animal data support the hypothesis that a ketogenic diet enhances brain metabolism. Several animal models provide evidence that the ketogenic diet can prevent epileptogenesis and mediate neuroprotection. These studies also support the clinical observation that children can be gradually weaned off the ketogenic diet, resume a normal diet, and not experience loss of seizure control.

### SELECTION OF CANDIDATES FOR THE DIET

Many seizure types appear to respond to the ketogenic diet, but children with atonic seizures seem to particularly benefit. In general, however, several groups of children are widely accepted as potential candidates for treatment (Kossoff et al., 2009). These include the following groups:

1. Those with medically intractable seizures (failed at least two anticonvulsant drugs)
2. Those with poor tolerance of or significant side effects from antiseizure medicines
3. Those with intractable seizures who are being considered for epilepsy surgery (i.e., callosotomy; nonlesional, extra-temporal resections)
4. Those with specific neurometabolic disorders or neurologic syndromes (Box 80-1)

The ketogenic diet is a strictly regulated medical diet. Its success depends on the accuracy and consistency with which the regimen is carried out within the home. Continued support, monitoring, and education by an interdisciplinary team of professionals are necessary.

Approximately 20 years ago, the only metabolic disorders that were indications for use of the ketogenic diet were GLUT-1 deficiency syndrome and PDH (pyruvate dehydrogenase deficiency). Today, there are numerous other "indications" for the diet, and these potential candidates should be referred sooner in the course of their epilepsy. Table 80-1 of the 2009 expert consensus statement lists these conditions.

The ketogenic diet may be the preferred initial therapy in children with seizures and specific metabolic defects or seizures associated with specific neurologic syndromes (see Box 80-1 and Fig. 80-5). These specific metabolic disorders are reviewed in other sections of this book.

For some patients, the ketogenic diet is contraindicated (Box 80-2). When indicated, metabolic screens, including urine amino and organic acids, serum amino acids, lactate,

**BOX 80-1** Specific Conditions Treated With the Ketogenic Diet

- Glucose transporter deficiency syndrome (GLUT1-DS, *SLC2A1* gene, McKusick 138140)\*
- Pyruvate dehydrogenase complex deficiency (McKusick 312170)\*
- Infantile spasms
- Myoclonic-astatic epilepsy (Doose syndrome)
- Severe myoclonic epilepsy of infancy (Dravet syndrome)
- Associated with Leigh's syndrome
- Associated with lactic acidosis and cerebral dysgenesis
- Succinic semialdehyde dehydrogenase (SSADH) deficiency<sup>†</sup>
- Phosphofructokinase deficiency
- Mitochondrial respiratory chain complex defects
- Ketotic hypoglycemia
- Glycogenesis type V (McArdle disease)
- Acquired epileptic aphasia (Landau-Kleffner syndrome)
- Rett syndrome
- Tuberous sclerosis complex

\*The ketogenic diet is specifically indicated for these two metabolic disorders.

<sup>†</sup>Documented improvement in mouse model.

**BOX 80-2** Specific Contraindications to the Ketogenic Diet

- Pyruvate carboxylase deficiency
- Organic acidurias
- Selected mitochondrial disease
- Porphyria
- Defects in fatty acid oxidation
  - Short-chain acyl dehydrogenase deficiency (SCAD)
  - Medium-chain acyl dehydrogenase deficiency (MCAD)
  - Long-chain acyl dehydrogenase deficiency (LCAD)
  - Medium-chain 3-hydroxyacyl CoA deficiency
  - Long-chain 3-hydroxyacyl CoA deficiency
- Carnitine deficiency (primary)
- Carnitine palmitoyltransferase (CPT) I or II deficiency
- Carnitine translocase deficiency
- Glutaric aciduria, type II
- Pyruvate dehydrogenase phosphate deficiency

pyruvate, and carnitine profile, should be performed before starting the ketogenic diet. Lastly, children who do not have assured, stable nutrition should not be started on the ketogenic diet due to risk of malnutrition and/or weight loss. In many of these patients, the ketogenic diet is only recommended after a gastrostomy tube has been placed.

**Value of the EEG in Ketogenic Diet Prediction**

The predictive value of an EEG obtained before, during, or after initiation of the ketogenic diet is unknown. In a cohort of 29 children, 90% of children with normal pretreatment EEGs responded favorably to the diet, compared with only 12% with abnormal pretreatment EEGs.

Many studies have suggested improvement or normalization of the EEG after the diet has been implemented. A recent study showed that improvement in background slowing (described as "encephalopathy") after starting the diet was correlated with a greater than 95% seizure reduction, although surprisingly fewer interictal spikes was not. Kang and associ-

**BOX 80-3** Initiation of the Ketogenic Diet (Johns Hopkins Hospital Protocol)**HOSPITALIZATION FOR 3 DAYS****Day 1**

- Maintenance fluids without glucose
- Check urine ketones each void
- Check fingerstick blood glucose every 6 hr
- Simplify antiseizure medicine regimen; change to low carbohydrate or carbohydrate-free formulation
- Dietitian consultation
- Education
- After 12 to 24 hour fast, typically 5pm, begin ketogenic diet at half total daily calories using 4:1 ratio (3:1 in infants), with food as an eggnog or formula

**Day 2**

- 4:1 ratio (3:1 in infants), with one-half of total calories using eggnog for additional 2 meals then with dinner advance to full calories and a solid food meal
- Stop fingerstick blood glucose checks
- Continue education

**Day 3**

- Breakfast and lunch using typical ketogenic diet meals
- Ensure all medication prescriptions are provided and follow-up appointment made
- Discharge home

ates showed improvement in generalized epileptiform abnormalities more often than focal epileptiform discharges and a correlation between seizure control and EEG improvement. Caraballo also reported improvement in the EEG epileptiform abnormalities in children responding to the diet. In the randomized, double-blind study of the ketogenic diet, clinical seizure reduction and EEG improvements were quite different, especially for Lennox-Gastaut syndrome.

**INITIATION AND MAINTENANCE**

A comprehensive book on the evaluation and management of patients being considered for placement on the ketogenic diet has been published and subsequently revised in 2011. In addition, a videotape, "The Ketogenic Diet for Families, Dietitians, Nurses, and Physicians," and other resource material are available from The Charlie Foundation ([www.charliefoundation.org](http://www.charliefoundation.org)). Of importance, the manner in which the ketogenic diet is started can be highly variable, and yet maintain efficacy. The following is a brief overview of how the diet can be implemented.

**Prehospital Evaluation**

Once a child is considered a candidate for the diet, a screening evaluation by selected members of the team responsible for implementing the diet is initiated (e.g., dietitian, physician, nurse). The purpose of this evaluation is to educate the family and to assess their ability, on many levels, to carry out the rigorous and exacting program necessary to maximize the diet's success. At the same time, the different types of meal plans and foods that the child can eat are discussed, along with their preparation.

**Hospitalization**

The child is typically scheduled for elective admission to the hospital for initiation of the diet (Box 80-3). However, in

recent years, both retrospective and prospective studies have documented the feasibility of initiating the diet as an outpatient. The intense educational process afforded by inpatient initiation may be preferable for some families and ketogenic diet centers; it also may allow the families to have medications carefully reviewed, spend additional time with their treating neurologist familiarizing him/her with the epilepsy, and also to meet other families starting the diet at the same time (if admissions are done in a group). Additionally, inpatient initiation allows observation of the child to gauge the initial response to and the adverse effects of the diet. Parents are told to view this treatment as a 2 to 3 month trial. When effective, the ketogenic diet works quickly, typically within the first 1 to 2 weeks. If there is no seizure reduction after 3 months, the ketogenic diet can be discontinued. During this time, patients must adhere strictly to the diet, with proof of persistent ketosis. The frequency of seizures usually decreases gradually, but reversal of the effect may occur rapidly if the child cheats with carbohydrate-containing foods. If the seizures are improved, this usually is sufficient motivation for the parents to have the child adhere to the diet. If the child might have an underlying metabolic disease that could be exacerbated by the initial fast, an appropriate evaluation should be performed before initiating the diet.

The day before hospital admission, after dinner, the child begins fasting, with only noncaloric, noncaffeinated beverages given. Laboratory studies (complete blood count, platelet count, chemistry panel, fasting lipid profile, and antiseizure medicine levels) are obtained, either preferably a week before or at the time of admission. During this time, the child receives maintenance fluids but no foods (if fasting). Fingertick glucose levels are checked every 6 hours. The dietitian uses this time for further review of meal plans and the child's food preferences and eating habits with the parents. Recent studies have suggested no improvement in long-term seizure control with initial fasting or fluid restriction, and fewer adverse events with a nonfasting, gradual initiation.

On the first night of admission, the child is started on the ketogenic diet, using a 3 to 1 or 4 to 1 ratio (grams of fat to protein plus carbohydrate), depending on the child's age. A ketogenic eggnog or premade formula (several are in use) is often used for the initial feedings. The child receives three meals at one-half of the total calories on the second day and then is advanced as tolerated to full calories with solid foods on the final day. Before discharge, the parents may prepare their first ketogenic meal for their child under the supervision of the dietitian. At discharge, the parents have several meal plans for their child and are instructed to monitor the urine ketones on a daily basis and record all occurrences of seizures. Individual decisions are made during the hospital stay as to whether the antiseizure medicine regimen will be simplified. The child is given a prescription for sugar-free multivitamin, mineral, and calcium supplementation and instructed to begin this at home. Oral citrates are often prescribed empirically as well. Vitamin B supplements are given to prevent optic nerve dysfunction. Vitamin D supplementation and calcium prevent osteomalacia while on the ketogenic diet. The child is then seen regularly (typically every 3 months) for follow-up (Box 80-4). Special attention should be paid to the serum albumin and total protein concentration to make sure that the diet is providing enough protein. Cholesterol and triglyceride levels typically rise when the diet is started but usually decrease after several months and return to normal. It is not unusual to see minor elevations in the direct bilirubin.

Decisions regarding withdrawal of antiseizure medicines depend on the child's response to the diet and the family's wishes. Early reduction (during diet initiation or the first month afterward) of antiseizure medicines appears to be safe

### BOX 80-4 Ketogenic Diet Maintenance

#### 1 MONTH

- Adjust diet as needed
- Laboratory tests—complete blood count (CBC), platelets; SMA20; medication level(s); fasting lipid profile, serum lipid and carnitine profiles
- Clinic appointment with neurologist and dietitian for infants and other children (as necessary)

#### 3, 6, 9, AND 12 MONTHS

- Neurologist, dietitian, nurse
- Laboratory tests—CBC, platelets, SMA20; fasting lipid profile, serum lipid and carnitine profiles
- Antiseizure medicine level(s)
- Discussion about relative risk/benefit of ketogenic diet (consider wean at 1–2 years)

and well tolerated; however, it offers no definite advantage compared with a late taper. Benzodiazepines and phenobarbital are associated with a higher risk of seizure recurrence so should be tapered carefully. At follow-up, the dietitian also reviews the parental concerns about implementing the diet and makes adjustments in the meal plan, as necessary, to maintain the child in maximum ketosis. There are other methods to “fine tune” the ketogenic diet including ratio changes, calorie adjustment, fasting, and so forth, although the likelihood of improvement with these diet modifications is approximately 1 in 5.

In children who can be successfully withdrawn from anti-seizure medicine therapy and are seizure-free for 2 years on the ketogenic diet (about 10% of treated children), an EEG is repeated and the ketogenic diet is slowly withdrawn. A study of 183 children in whom the diet was discontinued determined that the speed of the wean did not matter: children tapered over several weeks did just as well as those in whom the diet was stopped more slowly. Children in whom there was a good, but not complete, seizure reduction with the diet (50% to 99% seizure reduction) were at highest risk for seizure worsening with the diet discontinuation. Should seizures worsen, many of these families elect to continue a low-carbohydrate diet versus new anticonvulsants.

### SIDE EFFECTS

It needs to be emphasized to parents and patients that the diet is a form of medical therapy, and as such, although it is relatively safe, it is not without side effects (Box 80-5). However, only 6% to 17% of patients discontinue the diet due to side effects; the vast majority are either treatable or even preventable. If the child has an unrecognized metabolic defect, a catastrophic event could occur during the fasting phase (see Box 80-2). Other adverse events can occur during the initial hospital stay, and, if recognized, are usually treatable. A number of side effects can occur during the maintenance phase. The most common side effect encountered is constipation. Renal stones have occurred in less than 5% to 10% of patients and can usually be easily managed. The risk of stone formation may be increased in younger patients (younger than 3 years of age) and those with hypercalciuria and low urine volume. Oral potassium citrate as a preventative supplement results in urine alkalization, decreasing the prevalence of kidney stones. Universal potassium citrate supplementation appears to be warranted.

Acetazolamide, topiramate, and zonisamide, as well as all carbonic anhydrase inhibitors, which, when combined with

**BOX 80-5** Possible Adverse Events During Initiation of the Ketogenic Diet

Adverse Event	Monitoring/Treatment Strategy
• Dehydration	• Encourage fluids (do not limit fluids to less than 75% of maintenance); intravenous fluids if necessary (without dextrose)
• Hypoglycemia	• Check blood sugars every 6 hr until diet is initiated; if symptomatic or blood sugar <30 mg/dl, give small amount (e.g., 1–2 oz) orange juice. Screen for metabolic errors in advance
• Vomiting	• Intravenous fluids; give orange juice

the ketogenic diet, predispose to metabolic acidosis. The ketogenic diet can be cautiously initiated in children on these drugs. However, the physician should be aware that, in some children, this may cause worsening of their metabolic acidosis, especially during ketogenic diet initiation and may require adjustments in the drug dose, adjustments in the diet, or the addition of oral citrates.

Fatigue occurs in many children during initiation of the diet but is prolonged in only a small number. The high fat content decreases gastric emptying, which promotes gastroesophageal reflux. This problem usually can be managed medically. Close attention to growth measurements, laboratory data, and medical supervision is indicated in infants on the ketogenic diet. Very young children (0 to 2 years) grew poorly on the diet, whereas older children (7 to 10 years) grew almost normally. A recent study of children who discontinued the diet years prior suggests that growth will catch up once the diet is discontinued.

Several laboratory abnormalities have been reported in children on the ketogenic diet, although none has been found to have clinical significance. Patients on the ketogenic diet are in a chronic acidotic state, putting them at risk for osteopenia. A single longitudinal study has evaluated the effect of the ketogenic diet on bone density, serum hydroxy vitamin D, and parathyroid hormone. A progressive loss of bone mineral content, resulting in osteopenia and osteoporosis, occurred with ketogenic diet treatment, despite improved serum vitamin D concentrations. Supplementation of vitamin D and calcium was not sufficient to prevent bone mineral content loss. Increased supplementation and periodic surveillance with dual energy x-ray absorptiometry may be needed to prevent or treat the loss of bone mineral content in children treated with the ketogenic diet. This compensated metabolic acidosis puts the young child, who becomes ill, at risk of becoming markedly acidotic, ketotic, or dehydrated. This can be addressed by forewarning parents to increase fluid intake during illness. Serum cholesterol and triglycerides may increase, especially during the first 6 months; they tend to plateau by 6 months, then decline and require routine monitoring. Patients on the diet and undergoing surgery should be evaluated for symptoms of bleeding tendency. Changes in the serum carnitine concentrations have also been described. Some believe a carnitine supplement should be given routinely, but this is highly debatable. Carnitine status should be monitored, although most children do not need supplementation. Supplementation with magnesium, zinc, calcium, vitamin D, and B vitamins is recommended to avoid deficiency-related disease states. The ketogenic diet is deficient in several

trace minerals, and if children are maintained on the diet for more than 2 years, these need to be supplemented.

Serious complications of the ketogenic diet are rare and typically have only been described in single case reports, including the occurrence of Fanconi renal tubular acidosis (in cotreatment with valproate), severe hypoproteinemia, marked increase in liver function tests (in cotreatment with valproate), cardiomyopathy, prolonged QTc, acute hemorrhagic pancreatitis, basal ganglia injury, scurvy, lipid pneumonia, and fatal propofol infusion syndrome. Selenium deficiency has been described with increasing frequency and some advocate for additional supplementation beyond standard multivitamins.

A single retrospective chart review reports maintenance of efficacy and tolerability with long-term use of the ketogenic diet (duration of 6 to 12 years, n = 28). The diet was well-tolerated after 6 years with maintained efficacy and little effect on serum cholesterol values. However, side effects of decreased growth (23 out of 28), kidney stones (7 out of 28), and fractures (6 out of 28) occurred; therefore careful monitoring with strategies to minimize these complications is suggested.

The ketogenic diet field is moving in the direction of adding vitamins and supplements empirically to the regimen of all children on the diet to prevent adverse effects before they occur. Although not mentioned in the 2009 consensus statement, many now advocate for universal treatment with oral citrates, selenium, extra vitamin D, laxatives, and even antacids. Several nutrition companies have created products that are designed for ketogenic diet patients such as NanoVM™ and FruitiVits™. Continued research into preventative supplements is warranted.

## ADVANTAGES (AND DISADVANTAGES) COMPARED WITH OTHER TREATMENTS FOR EPILEPSY

### Advantages

The ketogenic diet has several advantages compared with other medical therapies. Anecdotal reports have indicated that many of the children who are maintained on the diet are able to have their antiseizure medicines decreased or withdrawn. This usually results in the child being more alert and exhibiting better behavior. However, even children whose medications cannot be substantially lowered or withdrawn may have marked behavioral or cognitive improvements. This has occurred in children who have become seizure-free on the diet and had antiseizure medicines withdrawn, as well as in those whose seizures are only minimally improved and who have not had dramatic changes in their medication regimen.

For many families, the ketogenic diet provides a dramatic change in their role in the treatment of their children's epilepsy. The requirement for preparation and monitoring gives the parents an active role in the treatment of their children and a sense that what they are doing is directly influencing their children's epilepsy and psychosocial well-being. Only if the diet is ineffective can this become a disadvantage.

### Disadvantages

The most common reasons cited for discontinuation of the ketogenic diet are lack of efficacy, complications, noncompliance (especially in older children), and caregiver concerns. The ketogenic diet is a strictly regulated medical diet that requires an epilepsy team for success. It requires active participation by the parents and children. The work required on the part of the parents to initiate and maintain this rigorous diet may be considered a disadvantage.

The costs of ketogenic diet foods (especially dairy and meats) may be more expensive than that eaten previously (e.g., rice and grains). This is an issue as the diet is being expanded to developing countries.

Many physicians perceive the diet as unpalatable and difficult to initiate and maintain. However, modern nutritional labeling requirements and the use of computer programs allow the dietitian to construct a palatable diet, keeping the patient's food preferences in mind, and this permits a much more varied meal plan.

## THE KETOGENIC DIET IN THE 21ST CENTURY

Nearly a century has passed since the ketogenic diet was initially used, and many more therapies are now available for children with epilepsy. The ketogenic diet compares favorably with other new treatments that have been introduced to treat children with epilepsy. The question that remains unanswered is, "When, in the course of therapy for a child with intractable epilepsy, should the ketogenic diet be used?" For myoclonic-astatic epilepsy (Doose syndrome) and infantile spasms, the diet has been proposed even as a first-line therapy. If the child has an epilepsy syndrome that is often resistant to current therapy and if the seizures are not controlled on medication, the ketogenic diet should be mentioned as an alternative therapy at the time of the initial therapeutic discussions. This is especially true in children who are not good candidates for epilepsy surgery or whose parents do not wish their children to have epilepsy surgery.

Many children who are not seizure-free or who are not able to come off all antiseizure medicines are improved on the ketogenic diet. The improvement in seizure control or behavior and cognitive abilities is such that parents wish to continue the ketogenic diet. The ketogenic diet might be useful in other childhood neurologic disorders such as alternating hemiplegia of childhood or tumors of the nervous system. There is an expanding experimental literature suggesting that the ketogenic diet may treat several neurologic conditions.

As we approach the second century of the ketogenic diet, it is clear that clinical use, research, and parent/patient interest are at all-time highs. Dietary therapy is being used increasingly for adults, nonepilepsy indications, as a first-line therapy, and also for longer durations than in years past (Kossoff et al., 2011). As usage grows, we will continue to learn about this unique therapy and better define its place in the algorithm for treating epilepsy.

## 1. OVERVIEW

Pediatric psychogenic nonepileptic seizure (PNES) can be a difficult diagnosis to reach because of its clinical resemblance to epilepsy and prevalent medical and psychiatric comorbidities (Plioplys et al., 2014; Reilly, Menlove, Fenton, and Das, 2013). The patients, their families, and society bear an enormous cost if PNES is not diagnosed and psychiatric care provided in a timely fashion, or if inappropriate neurologic therapy is instituted. Misdiagnosis and mistreatment of PNES as epilepsy costs an estimated \$920 million annually in diagnostic evaluations, inappropriate administration of antiseizure drugs, and emergency department utilization. Although PNESs are not responsive to antiepilepsy medications or may even worsen with their use, patients with PNES take double the number of these medicines compared with patients with epilepsy. “Nonepileptic psychogenic status” was reported in 13.5% of youth with PNES who were treated with intravenous antiseizure medicines, received potentially dangerous invasive diagnostic studies, or underwent emergency intubation (Patel, Scott, Dunn, and Garg, 2007).

PNES is less frequent in children than in adults and most commonly found in 15- to 24-year-old individuals, with an incidence of 3.4 per 100,000. In children with suspected epilepsy, the prevalence of PNES ranges from 1% to 9% (Patel et al., 2007).

Clinically, paroxysmal nonepileptic events are either physiologic or psychological in origin. Physiologic nonepileptic events are associated with medical or metabolic issues, but they are not epilepsy. The differential diagnosis of physiologic paroxysmal nonepileptic events in children includes vasovagal or neurocardiogenic syncope, stereotyped movements, daydreaming, sleep myoclonus, hypnic jerks, tonic posturing, parasomnias, and movement disorders (Kotagal, Costa, Wyllie, and Wolgamuth, 2002). PNESs, the focus of this chapter, resemble epileptic seizures and present as a sudden, involuntary, time-limited alteration in behavior, motor activity, autonomic function, consciousness, or sensation. However, unlike epilepsy, PNESs do not result from epileptogenic pathology and are not accompanied by an epileptiform electrographic ictal pattern. PNES comprise 30% of all paroxysmal nonepileptic events in children (Vincentiis et al., 2006).

PNES are classified under DSM-5 diagnoses of Somatoform, Conversion, and Dissociation Disorders (American Psychiatric Association, 2013). A much smaller percentage (<5%) of patients intentionally produce their seizures, and these are classified as Factitious Disorder and Malingering, which are not psychogenic in origin. DSM-5 made changes in the criteria for Conversion Disorder, allowing clinicians to make a positive diagnosis based on symptom presentation. Also, the prior necessary criteria of presence of a psychological stressor and ruling out of intentional production have been modified from diagnostic criteria to a descriptive note, aligning the DSM system with ICD-10 (World Health Organization, 2004).

## 2. EVALUATION OF THE PATIENT

### Risk Factors

There are two main types or “causes” of PNES: posttraumatic and developmental. Posttraumatic PNES are thought to develop in response to acute or chronic exposure to traumatic experience(s), such as violence, severe personal medical illnesses or procedures, and physical, sexual, or psychological abuse. *Developmental PNES* refers to coping difficulties with daily tasks and milestones along the individual’s continuum of normal psychosocial development.

The demographic risk factor profile points to female predominance beyond adolescence; however, there is equal sex distribution in younger children (Patel et al., 2007; Reilly et al., 2013). The mean age of PNES onset is 12.9 years (Patel et al., 2007), but it can begin in younger ages. The youngest age of PNES onset described in the literature is 5 years (Reilly et al., 2013).

Youth with PNES have higher rates of medical comorbidities, including epilepsy, and take more medications (prescription and over the counter) than their siblings (Plioplys et al., 2014). In a retrospective chart review study, Patel et al. (2007) reported coexisting neurologic illness in 55% of youth with PNES. Headaches were found in 19%, past head trauma in 10%, and abnormal brain magnetic resonance imaging (MRI) findings in 21% of subjects (Patel et al., 2007). Comorbid epilepsy ranges from 29% to 61%, with higher rates noted in children younger than 12 years (Patel et al., 2007; Plioplys et al., 2014). Focal-onset epilepsy has been identified as the most common type, found in 45% to 80% of patients, with comorbid epilepsy and PNES (Patel et al., 2007).

Psychosocially, the most common risk factors for PNES in children are family discord, school problems, and interpersonal problems (Patel et al., 2007; Plioplys et al., 2014; Vincentiis et al., 2006). In contrast to adults with PNES, physical and sexual abuse are not reported as often in children (Patel et al., 2007; Plioplys et al., 2014; Vincentiis et al., 2006). Compared with their siblings, children with PNES have significantly more lifetime adversities, such as domestic or community violence, bullying, and serious personal illness, surgery, or medical procedures, but not physical or sexual abuse, or loss (Plioplys et al., 2014). It is possible that sexual and physical abuse may be underreported. These data, however, emphasize that common, everyday stressors can be traumatic for vulnerable children. Furthermore, Plioplys et al. (2014) demonstrated that previously described individual risk factors for pediatric PNES are interconnected and thus may have a cumulative effect.

In addition to the child’s individual vulnerabilities, family- and school-related factors play a significant role in the conversion process. Parents of children with PNES are often unaware or culturally unable to accept the psychological distress that children experience. As a result, parents do not recognize the

early signs of emerging psychopathology and do not provide necessary support and interventions. Moreover, parents of children with PNES may understand and accept physical somatic symptoms better than psychological ones; parents themselves report more somatization than parents of children with epilepsy. Somatization, the process during which physical symptoms are experienced in response to psychological stress, becomes an intergenerational family communication model.

A past history of chronic medical illnesses and treatment or frequent life adversities in a child who has fearful interpretation of physical body sensations, high levels of somatization, and ineffective coping increases the risk for PNES.

## History

Obtaining an accurate diagnosis of PNES is the essential first step for instituting proper therapy and avoiding unnecessary and potentially dangerous therapies. Acute neurologic events, such as head trauma, have not been found to be antecedents for PNES in children (Vincentiis et al., 2006). Typically, parents and patients cannot identify any specific triggers for the new onset of PNES, but recognize ongoing stress at school, home, or socially. Sometimes, a specific traumatic experience in the recent past, such as severe illness, medical procedure, abuse, or loss, can be identified.

A description of the events is obtained in assessing semiology. Clinical features of epileptic seizures and PNES overlap, however, and there is no one clinical feature that reliably distinguishes them. Subjective visceral, sensory, or psychic phenomena; alterations in responsiveness; and convulsive motor activity can be present in both disorders. Ictal presentations of PNES range from uncoordinated, disorganized motor activity to unresponsiveness without motor signs. Clinical differentiation between PNES and epilepsy has been based on other identifiers, such as the presence of preictal pseudosleep (where the patient reports being asleep, but electroencephalogram [EEG] shows the patient to be awake), geotropic eye movements (forced downward deviation of the eyes toward the floor, with head turning), eye closure, and postictal whispering with PNES, versus the presence of postictal headache and postictal nose rubbing (usually ipsilateral to the seizure focus) with epilepsy. The use of suggestion to both provoke and stop PNES is documented. With the issue of disclosure and informed consent, provocative procedures (e.g., saline injection, alcohol swab) have raised concern as a potentially unethical intervention, potentially compromising the trust in the physician–patient relationship. These maneuvers, however, have been demonstrated to have high specificity and positive predictive value.

## Differential Diagnosis Between Epilepsy and PNES

The distinction between physiologic nonepileptic events and PNES is based on the combination of thorough history, physical examination in the peri-ictal period, and neurophysiological monitoring. Other studies are used as adjuncts to video-electroencephalogram (vEEG), and the sensitivities and specificities for EEG, neuroimaging, and prolactin levels have been reviewed (Cragar, Berry, Fakhoury, Cibula, and Schmitt, 2002).

PNES are not associated with epileptiform discharges on vEEG recordings, the gold standard for diagnosis. Studies of interrater reliability in vEEG show moderate to excellent consistency for PNES diagnosis. Therefore diagnosing PNES without vEEG confirmation should not be practiced, no matter

how suggestive the clinical manifestation of a paroxysmal event may be. One study of epileptologists revealed a specificity of only 50% for seizure identification. In another study, prediction of the nature of unusual seizures by the admitting neurologist was accurate in only 67% of cases. When observing these events without accompanying EEG, determination from observations of unit personnel and neurologists was correct in less than 80% of episodes. Of note, PNESs were formerly referred to as pseudoseizures. Use of this term, however, has been discouraged given the negative connotations of “false” it conveys.

EEG abnormalities in patients with PNES do not necessarily confirm the diagnosis of epilepsy. For example, EEGs showing “sharpish waves” or paroxysmal slowing provide little support of epileptic seizures. Normal variants can also be misinterpreted as interictal epileptiform discharges in patients without epilepsy. A positive neurologic history, predominantly characterized as cognitive dysfunction, was present in almost half of children with PNES, and a positive family history of epilepsy was present in 35% of children with PNES (Patel et al., 2007). Although neurologic signs, symptoms, and history are important to note in seizure patients, they are in no way pathognomonic in distinguishing PNES from epileptic seizures. Three criteria in patients with PNES admitted for vEEG yielded a positive predictive value of 85%: (1) *at least two PNES per week*, (2) *refractory to at least two antiseizure medicines*, and (3) *at least two EEGs without epileptiform activity*. Using “the rule of 2s” and documenting seizure frequency, EEG abnormalities, and drug-treatment response before vEEG may help with definitive diagnosis of PNES. A paper commissioned by the International League Against Epilepsy provided diagnostic levels of certainty for PNES based on history, witnessed event semiology, and studies (with vEEG being the gold standard) (LaFrance, Baker, Duncan, Goldstein, and Reuber, 2013).

## Multidisciplinary Assessment Including Psychiatric Evaluation

The initial multidisciplinary assessment of PNES must combine both neurologic and psychiatric evaluations. Supplementing the psychiatric evaluation is the vEEG, to establish the diagnosis. Only ictal EEG can be used to differentiate PNES from epileptic seizures definitively at the individual level. After conducting a thorough history, mental status examination, and neurologic examination, a few neurophysiological and neurohumoral tests can be used to assist in the diagnosis of PNES and may include increased ictal prolactin, lower heart rate variability, and decreased oximetry. Neuropsychological and standardized self- and parent-report questionnaires do not distinguish PNES from epileptic seizures but can be used to identify cognitive, educational, emotional, behavioral, and family difficulties. For patients with other comorbid conversion symptoms, such as astasia abasia, tremor, weakness, vision problems, pain, stuttering, or physical/occupational/speech disorders, specialty evaluations may be indicated.

## 3. PSYCHOPATHOLOGY IN CHILDREN WITH PNES

As discussed earlier, the primary psychiatric diagnosis accounting for PNES is conversion disorder. Exceptionally rarely, children with PNES can have dissociative or factitious disorders when seizure-like episodes result from the dissociative states or sick-role-seeking behaviors. It can be difficult to correctly diagnose conversion disorder in a timely manner because

children often deny the underlying emotional conflict and associated distress and may perceive seizure-like symptoms as their primary and only problem. Limitations in recognizing and resolving underlying emotional distress are multifactorial and may be associated with the child's developmental characteristics, such as emotional immaturity and, ineffective problem solving, communication, and coping with stress.

Comorbid psychopathology is reported in 16% to 100% of youth with PNES (Caplan and Plioplys, 2010; Patel et al., 2007; Plioplys et al., 2014; Vincentiis et al., 2006). It is more frequent and severe in adolescents with PNES than in children younger than 13 years (48.6% vs 16%). Literature demonstrates that youth with PNES have significantly more lifetime emotional, behavioral, and learning problems than their siblings (Plioplys et al., 2014).

The most common comorbid psychiatric diagnoses in youth with PNES are mood disorders, such as anxiety (7%-84%), depression (19%-62%), and posttraumatic stress disorder (PTSD) (3%-25%), followed by disruptive behavior disorders, including attention deficit hyperactivity disorder (ADHD) (15%-29%) and oppositional defiant disorder (8%) (ODD) (Caplan et al., 2010; Patel et al., 2007; Plioplys et al., 2014; Vincentiis et al., 2006). A multisite PNES study reported that youth with PNES have significantly higher rates of PTSD than their siblings (25.5 % vs 2.9%), more lifetime adversities, and a higher mean number of adversities (Plioplys et al., 2014). A Turkish study of adolescents with PNES reported suicide attempts in 15% of PNES patients compared with none in a control group of adolescents with epilepsy.

Compared with their siblings, youth with PNES report higher levels of somatization and anxiety sensitivity, a tendency to view anxiety-related bodily sensations as dangerous (Plioplys et al., 2014). Fatigue, sleep problems, headaches, pain, weakness, and abnormal gait or muscle movements are commonly experienced by children with PNES. Secondary somatic symptoms reveal a more severe conversion disorder, and as patients become more functionally impaired, they receive more unnecessary medical investigations and treatments compared with PNES patients without symptomatic transformation. High social anxiety associated with performance fear and the presence of somatic symptoms have been reported in youth with PNES. In addition, adolescents with PNES display significantly lower self-esteem than healthy adolescents and those with epilepsy.

Data on cognitive problems in youth with PNES are inconsistent. Some studies identified cognitive and learning problems in 5% to 14.8% of the PNES subjects, whereas other studies using standard cognitive testing instruments have reported average IQ scores and no cognitive difference compared with siblings. However, clinical learning problems, as reported by patients, are identified in 14% to 67% of youth with PNES. These children demonstrate more school underachievement than patients with epilepsy and healthy control and have more medical and psychiatric illnesses, take more medications, and have more school absenteeism than their siblings (Plioplys et al., 2014). Rather than primary cognitive deficits, school absenteeism, cognitive impairment resulting from underlying medical and psychiatric disorders and treatments, and poor coping with stress may be contributing factors to learning difficulties and school-related stress.

#### 4. MULTIDISCIPLINARY TREATMENT MODEL

Timely PNES diagnosis and psychiatric treatment are associated with better outcomes and resolution of PNES episodes in children. However, PNES treatment can be a challenging process to all clinical services involved because of the hetero-

geneous PNES presentation, common symptom transformation to other types of somatic symptoms, high medical and psychiatric comorbidities, frequent use of urgent medical services, diagnostic procedures and treatments, and difficulties in obtaining adequate mental health services.

At the present time, there are no randomized, controlled treatment studies of pediatric PNES published. Despite the existence of treatment guidelines for PNES from expert consensus being available (Kerr et al., 2011), treatment of youth with PNES varies between providers. In adults with PNES, several randomized controlled trials provide evidence that cognitive behavioral therapy (CBT) alone (LaFrance et al., 2014) or a combination of CBT-informed psychotherapy and selective serotonin reuptake inhibitors (SSRIs) have been effective in decreasing PNES frequency (LaFrance et al., 2014).

Most importantly, treatment of pediatric PNES should be provided by a multidisciplinary team that includes a mental health professional (psychiatrist, psychologist, or social worker), a pediatric neurologist or epileptologist, and a primary care physician (PCP), with the school staff and family playing an active role. To assure the successful handover of PNES management from neurology to psychiatry, a transition process must be developed by both services. After the patient with PNES is discharged from the EEG monitoring unit to the outpatient setting, the mental health clinician should assume the primary PNES treatment and case management role.

#### The Role of the Neurologist

The primary role of the neurologist is to conduct a thorough diagnostic evaluation, to provide a sensitive diagnostic feedback to the family, and to discontinue or optimize antiseizure medicines in patients with comorbid epilepsy. Diagnostic feedback should be delivered to the patient and family together, ideally with a mental health clinician. The successful communication of the PNES diagnosis can be considered as the first and one of the most important therapeutic steps in PNES management (Caplan et al., 2010). In adults with PNES, a significant reduction of PNES frequency, visits to the emergency room, and other PNES-related healthcare use has been reported immediately after the PNES diagnosis is communicated and before the initiation of psychiatric treatment.

During the feedback, the neurologist should communicate that the seizures captured on the vEEG are not epilepsy, unambiguously confirm that the events are real and the patient is not faking them, and clearly state that PNES has a psychological origin. Viewing the typical events recorded during the vEEG evaluation can help parents accept this diagnosis, especially when the child also has epilepsy. For patients with PNES and comorbid epilepsy, the diagnostic feedback has to include a careful explanation of the differences between the epileptic seizures, which can respond to antiseizure medicines, and the PNESs that do not respond to antiseizure medicines and require different treatments, including psychiatric interventions with a mental health provider. The neurologist should recommend psychiatric care as the primary treatment modality. The neurologist together with a mental health clinician outlines a multidisciplinary treatment plan that involves changes in antiseizure medicines, behavioral management of the PNES, ongoing psychiatric treatment, and full transition to school and regular life routines.

The secondary role of the neurologist is to provide follow-up care during the antiseizure medicine taper and also after its discontinuation, especially in the transition period to mental healthcare. At the time of the initial PNES diagnosis, 50% to 95% of children take antiseizure medicines. In general, withdrawal from antiseizure medicines is safe; patients use

less “rescue” antiseizure medicine treatment and do not have an increase in events. However, the antiseizure medicine discontinuation process can be complex and may be negatively influenced by the clinician’s uncertainty about the PNES diagnosis; fear of making a clinical mistake, especially when nonspecific EEG findings are present; limited knowledge and experience with PNES; parental requests to continue antiseizure medicines; and lack of available psychiatric services.

In a recent national survey of 236 pediatric neurology clinicians, 96% were very willing to discontinue antiseizure medicine treatment in patients with PNES without comorbid epileptic seizures. Clinicians with sufficient knowledge of how to diagnose and treat PNES were less concerned about making a potential medical error and were less influenced by patient or parental requests to continue antiseizure medicines. The strength of clinicians’ decision to discontinue antiseizure medicines was significantly associated with patients having ongoing psychiatric care.

Continuity of neurologic care during and after antiseizure medicine discontinuation decreases parental anxiety, strengthens acceptance of the diagnosis of conversion disorder, and prevents further “doctor shopping” when seizure-like events linger or change into other somatic symptoms. It also supports patients’ transition to psychiatric care, especially during the early treatment, when rapport with the mental health clinician is still evolving and when some parents are still hesitant to accept the PNES diagnosis.

The neurologist or epileptologist also serves as a consultant to the other members of the treatment team because a majority of mental health clinicians and primary care providers have limited experience with PNES and may feel uncomfortable managing patients with dramatic, seizure-like symptoms. Often, mental health clinicians require backup support in communicating a behavioral PNES management plan to schools or athletic programs. To assure that youth with PNES return to regular school, athletic, and social activities, the mental health clinician together with the neurologist must provide letters to the school outlining the behavioral PNES management plan and instructing the school staff not to use the “seizure management plan” of calling paramedics and taking the patient to the emergency room.

### Basic Principles of Psychiatric PNES Treatment

Psychiatric treatment consists of the behavioral management of PNES, supporting the patient’s return to regular life activities, psychotherapy for conversion disorder, and treatment for comorbid psychiatric disorders using standard evidence-based psychopharmacological and psychotherapeutic modalities along with appropriate educational and family interventions (Caplan et al., 2010).

Treatment of conversion disorder is based on multimodal individual and family therapy because there is no evidence that antiseizure medicines or psychopharmacological agents, specifically antidepressants or anti-anxiety medications, have been effective. Most youth with PNES receive psychiatric treatment in the outpatient setting. Intensive outpatient treatment programs (day hospital) may be indicated if the child is not able to successfully reintegrate back to school within 2 to 3 weeks after receiving a PNES diagnosis, is not able to stay in school despite provided accommodations, or has severe comorbid psychopathology and nonsuicidal self-injurious behaviors. An inpatient psychiatric admission is recommended when patients are suicidal, are homicidal, have an unsafe family environment, are psychotic, or are undergoing investigation for newly disclosed abuse.

## 5. OUTCOME

Literature demonstrates that PNES outcomes in youth is more positive than in adults; 35% to 100% of youth achieve a full remission or significant reduction in PNES frequency over up to a 3-year follow up. Although systematic studies of factors associated with PNES remission or reduction in frequency in children are not available, shorter duration of illness, less severe psychopathology, absence of personality disorders, and earlier interventions may be contributing variables to improvement. Epilepsy, on the other hand, was associated with ongoing PNES in youth. Addressing the different psychological mechanisms may lead to symptomatic improvement in children with PNES.

### SUMMARY

Pediatric PNES is a high-impact disorder because of diagnostic and treatment difficulties resulting in medical interventions that do not treat the disorder, high economic cost and medical utilization, and the psychosocial burden to the patient and family. Early PNES diagnosis leads to timely psychiatric treatment and improved outcomes. Recent findings demonstrate the importance of screening for the broad range of interrelated risk factors that represent somatopsychiatric and adversity variables.

Manifestations of PNES range from uncoordinated, disorganized motor activity to unresponsiveness without motor signs. Identifiers that are helpful to distinguish PNES from epileptic seizures include the presence of preictal pseudosleep, geotropic eye movements, eye closure, and postictal whispering with PNES, versus the presence of postictal headache or nose rubbing in epilepsy.

The gold standard diagnostic approach includes comprehensive history, psychiatric assessment, and a vEEG recording capturing the event in question without an ictal EEG epileptiform correlate. Additional testing of ictal prolactin, heart variability, oximetry, and cognitive and psychological functioning can be used as supplemental, but not diagnostic, tests. Using the “Rule of 2s” (at least two PNES per week, refractory to at least two antiseizure medicines, and at least two EEGs without epileptiform activity) may help to identify a person who has PNES.

PNES treatment is multidisciplinary, with a mental health clinician taking the primary role, and includes neurologist/epileptologist, primary care physician, school staff, and family. PNES treatment starts while patient is still in the hospital with an accurate diagnosis of conversion disorder and sensitive diagnostic feedback provided by the neurologist together with the mental health clinician. Treatment of patients with PNES and comorbid epilepsy must address both disorders: Adjust the antiseizure medicines for epilepsy, and educate parents about the differences in management of the epileptic seizures and the PNES.

Ongoing neurology involvement beyond antiseizure medicine discontinuation is very important because it can decrease parental anxiety, strengthen acceptance of the diagnosis of conversion disorder, and prevent further “doctor shopping.” The neurologist must support patients’ involvement in psychiatric treatment and back up mental health clinicians in their work with family and school staff.

Children and adolescents with epilepsy and adults with childhood-onset epilepsy often have poor educational attainment, lower than expected occupational status, poorer perceived health, more behavior problems, and higher rates of social isolation. In most patients, one or more causes of poor functioning may be identified and, at times, remedied. The causes of cognitive and behavioral dysfunction are multifactorial. Underlying neurologic lesions or genetic syndromes such as channelopathies cause epilepsy and cognitive dysfunction. In other disorders, such as benign focal epilepsy of childhood, learning and behavioral disorders are more difficult to explain, and the relationship with seizures is almost certainly not causal.

## COGNITIVE AND BEHAVIORAL DISORDERS

### Cognitive Disabilities in Children With Epilepsy

Epilepsy is more frequent in intellectually disabled children than in the general population. Population-based studies of children with intellectual disabilities document the prevalence of epilepsy to be 15%–35%. Those with severe intellectual disabilities and cerebral palsy have highest epilepsy rates. Likewise, intellectual disability is more common in children with epilepsy than in children without epilepsy (Berg et al., 2008).

### Learning Disabilities and Academic Underachievement

Learning disability is diagnosed when academic performance in one or more areas falls below expectations and cannot be explained by cognitive level, sensory abnormalities, or lack of educational opportunities. Learning disabilities are more frequent in children with epilepsy, even accounting for sociocultural variables. Children with epilepsy are at higher risk for requiring special education services with the need being higher in children with remote structural/metabolic epilepsy and epileptic encephalopathies. However, almost half of neurologically intact children with cryptogenic or genetic epilepsies require special education services. A diagnosis of epilepsy provides sufficient cause to screen children for learning disability.

Academic underachievement in reading, writing, and mathematics has been reported in children with epilepsy, in comparison with their normal peers and children with chronic illnesses (e.g., asthma). It is unclear whether the relationship is a direct one, in which the epilepsy, seizures, or antiseizure medicines cause learning disability, or an indirect one, in which an underlying neurologic condition causes both seizures and abnormalities in perception, memory, and visual-motor skills. Detailed neurocognitive batteries in children with epilepsy demonstrate higher than expected rates of dyslexia, slowed processing speeds, and visual-spatial, attention, executive, and constructional difficulties. However, numerous

studies attempting to identify demographic, neurologic, and seizure-related risk factors for academic underachievement have shown inconsistent results. Posited risk factors such as inadequate seizure control, early age of onset, longer duration of epilepsy, and polytherapy are not universally associated with academic underachievement.

### Attention Deficit, Impulsivity, and Overactivity

Studies of children with epilepsy demonstrate a higher incidence of inattention, impulsivity, and slowed reaction time. This should not imply that clinical attention deficit hyperactivity disorder is extremely common in children with epilepsy, although the prevalence is probably somewhat higher than in the general population. As with overall cognitive function, simple cause and effect relationships are uncommon. Common neurobiological mechanisms and causative factors may be present in these two disorders. Antiseizure medications may positively and negatively affect attention and impulsivity. In rare instances, frequent seizures affect attention, and improved seizure control may ameliorate this problem. Anticonvulsants are unlikely to improve attention in children who have epileptiform discharges without clinical seizures.

If needed, treatment with stimulants, atomoxetine, or tricyclic antidepressants generally does not compromise seizure control. Bupropion may increase risk of seizures, particularly at high doses. Most pediatric neurologists avoid doses greater than 100 mg per day in these patients.

### Autism and Autistic Spectrum Disorders

Autistic spectrum disorders are associated with an increased incidence of epilepsy, but evidence that one causes the other is lacking. The risk for developing seizures in children with autistic spectrum disorders is highest during early childhood, with a second peak occurring in adolescence. Features of autism are common in children with epilepsy, regardless of cognitive ability. A number of syndromes are associated with a high incidence of autistic behavior and epilepsy (e.g., tuberous sclerosis, Angelman syndrome, and Rett syndrome), but the coincidence of seizures and behavioral symptoms is due to the underlying condition. A possible rare exception is the child in whom autistic behavior develops along with language regression, accompanied by an epileptiform EEG (continuous spike-and-wave pattern during sleep). This condition has been considered to be a variant of Landau-Kleffner syndrome. Behavior and language may improve with treatment.

### Psychiatric Disorders in Childhood Epilepsy

Little evidence exists to support the notion that severe psychiatric disorders are significantly more common in children with epilepsy. Although major psychiatric illnesses such as schizophrenia, obsessive-compulsive disorder, or affective disorders may coexist with childhood epilepsy, the prevalence is not

higher than expected (Dunn, Austin & Perkins 2009). Treatment of coexisting severe psychiatric disorder and epilepsy may be complex. Some antiseizure medications (carbamazepine, valproic acid) are beneficial in treatment of certain psychiatric disorders (e.g., bipolar affective disorders). However, treatment of epilepsy does not usually relieve symptoms of major psychiatric illness.

Mood disturbances are more frequent in adolescents and adults with epilepsy than in healthy peers. Depression and anxiety are common and frequently underdiagnosed and undertreated. Suicidal ideation also is more likely in children and adolescents with epilepsy.

### Behavioral Problems, Conduct Disorders, and Delinquency

Behavioral disturbances may be related to family factors and parental anxiety about epilepsy, rather than a primary result of epilepsy or the underlying disorder. Self-esteem is lower and behavioral problems are more frequent than in peers with or without chronic illnesses. Even in children assessed at the time of first seizure diagnosis, behavior problems are frequent, particularly in children who had previously unrecognized seizures. Children with epilepsy also have higher rates of oppositional–defiant disorder and conduct disorder.

Adolescents and young adults with childhood-onset epilepsy have slightly higher than expected rates of delinquency in a population-based Canadian study. It is uncertain whether this propensity is due to underlying brain disease with poor impulse control, stigma, lack of opportunity, or other socio-cultural factors. In contrast, a Finnish population-based study failed to find a similar relationship in males up to age 22 years.

### Cognitive and Behavioral Outcome of Specific Epilepsy Syndromes

#### Epileptic Encephalopathy, a Model of System Epilepsy

Advances in metabolic imaging, genetic analysis, and the development of animal models have provided significant understanding of the underlying pathophysiology in epileptic encephalopathies. One hypothesis is that the effects of a focal lesion may be magnified by interactions between cortical and subcortical structures. Disruption of subcortical arousal centers that regulate the early cortical development may lead to altered synaptic connectivity, which may affect cognitive development. Alternately, impairment of global interneuronal functions via genetic alteration of widely distributed potassium or sodium channels may manifest as developmental arrest and/or generalized slowing on EEG. Lastly, prolonged focal epileptic activity in sleep may interfere with local slow wave activity, therefore disrupting plasticity associated with regional learning and memory. Although seizures can contribute to these pathologic processes, they are unlikely to be necessary for development of the encephalopathy. Rather, they may be a symptom of the underlying lesion.

#### Infantile Spasms

Certain pediatric epilepsy syndromes (e.g., infantile spasms) have been associated with severe cognitive deficits. Many patients exhibit global developmental arrest as well as specific cognitive deficits, delayed speech and impaired visual–spatial function. Thirteen percent of children with cryptogenic infantile spasms exhibit persistent autistic features, and the rate is

higher in children with tuberous sclerosis. Effective early treatment may improve cognition and behavior. Other prognostic factors for better cognitive outcomes include sustained seizure control with the first medication, age at onset equal to or greater than 4 months, and absence of atypical spasms and partial seizures (Partikian & Mitchell 2010).

#### Epileptic Encephalopathies of Infancy

Many neonatal or infantile-onset epileptic encephalopathies (e.g., Dravet syndrome, Ohtahara syndrome, early infantile myoclonic encephalopathy, and migrating partial seizures of infancy) are associated with global developmental delays and regression. Delayed development and behavioral disorders such as autism and hyperactivity generally present by the second year of life.

#### Lennox–Gastaut Syndrome

Lennox–Gastaut Syndrome (LGS) describes a constellation of seizure types and a characteristic slow spike and wave EEG pattern, but etiologies are multifactorial, including both genetic and secondary symptomatic epilepsies. Intellectual disability is seen in nearly all patients, and behavioral problems including autistic spectrum disorders are frequent. Seizure patterns and EEG may evolve, making diagnosis in later adolescence or adulthood difficult if records from earlier childhood are not available. Long-term follow up reveals ongoing—and at times increasing—intellectual disabilities, deficits in motor speed, apathy, and perseverative behavior.

#### Electrical Status Epilepticus in Sleep and Landau–Kleffner Syndrome

Electrical status epilepticus in sleep is an EEG pattern associated with specific cognitive and language dysfunction. With continuous spike-and-wave activity in sleep, a typical decrease in the IQ or developmental quotient is noted. Approximately 40%–60% of children with continuous spike-wave sleep exhibit an expressive aphasia, which is in contrast to children with Landau–Kleffner syndrome, who present with verbal or auditory agnosia. In patients with Landau–Kleffner syndrome language may recover spontaneously, partially improve with therapy, or remain permanently affected despite EEG improvement.

#### Self-Limited Focal Epilepsies of Childhood

The syndrome termed benign childhood epilepsy with centro-temporal spikes (BECTS or benign Rolandic epilepsy) was thought to be benign, but increasing evidence suggests that a subpopulation may have impaired cognitive function and difficulties with visual perception, concentration, and short-term memory, impaired phonologic processing skills, and reading disability. Sleep disturbances are also more frequent than expected. Self-limited childhood epilepsy with occipital paroxysms has been associated with selective dysfunction in perceptive–visual attentional ability, verbal and visual–spatial memory abilities, visual perception, visual–motor integration, some language tasks, and reading, writing, and arithmetic abilities.

#### Childhood Absence Epilepsy

Cognitive dysfunction detected in childhood absence epilepsy includes deficits in visual sustained attention and execution of visual–motor tasks, verbal and nonverbal memory, and word fluency.

## EFFECTS OF ANTISEIZURE MEDICATIONS ON BEHAVIOR, ATTENTION, AND MOOD

### General Effects

Cognitive, psychiatric, and behavioral abnormalities in children with epilepsy are often attributed to medications. However abnormalities are commonly multifactorial in origin, with duration of epilepsy, etiology, seizure frequency, and antiseizure medications all affecting cognition and behavior. Most studies examining the impact of antiseizure medications on cognition and behavior are from adults. Randomized, prospective clinical research in children is limited. When applying adult data to children, several factors need to be recognized. Epilepsy occurring in the developing brain is likely to be substantially different from that in the adult in both its quality and response to treatment. In addition, most refractory epilepsies begin in childhood. These severe childhood epilepsies may have cognitive and behavioral abnormalities as a component of these syndromes.

Current research suggests that most medication-related cognitive adverse events are mild or difficult to document objectively, but idiosyncratic adverse behavioral and cognitive responses can occur with any medication. Risk of cognitive and behavioral effects generally increases with rapid titration, higher doses or serum concentrations, and polypharmacy. A few studies have randomized patients at the onset of seizures to monotherapy with an antiseizure medication. Most studies, however, are not randomized and monitor cognitive and behavioral effects when a medication is added or withdrawn (Mandelbaum, Burack & Bhise 2009).

### Psychotropic Effects and Adverse Psychiatric Effects

Psychopathology in epilepsy has a multifactorial etiology, and antiseizure medications provide only one of the potentially numerous contributing neurobiological factors. Investigation into the drug-specific adverse interactions is challenging in part because of methodological problems. There have been prior attempts when addressing the psychotropic potential of antiseizure medications to differentiate those that have positive from those that have negative effects.

Drugs that exhibit a *sedating* effect are typically characterized by fatigue and cognitive slowing. Examples include benzodiazepines, phenobarbital, tiagabine, valproate, and vigabatrin, all of which potentiate gamma amino butyric acid (GABA) inhibitory neurotransmission. Alternately, *activating* drugs—often with anxiogenic and antidepressant properties—usually attenuate glutamate excitatory neurotransmission. This rather straightforward model, however, does not address the complicating factors of the underlying epilepsy itself. Issues such as epilepsy severity or the presence of limbic system abnormalities may be important. Some features cannot be ignored, such as forced normalization, postictal psychosis, or release. The psychotropic effects of antiepileptic drugs are most likely related to their direct (e.g., mechanism of action, drug toxicity, drug withdrawal, polytherapy) and indirect mechanisms (e.g., epilepsy-related phenomenon or patient-related factors).

Recently concerns have been raised about potential for suicidal ideation or suicide in children and adults taking antiseizure medications. Most of the medications now contain warnings that suicidal ideation may occur. However, the risk of suicidality in patients who are treated with antiseizure medications for epilepsy is very low compared with use of the same medications for bipolar affective disorder or pain indications (Mula et al. 2013).

### Forced Normalization

The first publications regarding the concept of forced normalization date back to the 1950s. Patients with psychotic episodes were reported to have associated improvement or normalization of their EEGs. It was noted that drug withdrawal with subsequent seizure recurrence correlated with resolution of the abnormal mental state. Although several psychological profiles have been associated with forced normalization, psychosis is probably the most common. Anxiety, insomnia, and social withdrawal also have been reported. The exact incidence of forced normalization occurring in pediatric patients is unknown, but probably is very low.

### Mood Disorders

Mood disorders—depression in particular—are the most frequent psychiatric comorbidity in epilepsy but are often undiagnosed and therefore untreated. Epilepsy variables associated with depression include seizure type (temporal lobe epilepsy), seizure severity or frequency, and treatment. One study reported on specific features associated with medical therapy and depressive symptoms. These include enhanced GABA neurotransmission, folate deficiency, polytherapy, comorbid presence of hippocampal sclerosis, forced normalization, and a history of mood difficulty. Medications with GABAergic effect all have been linked with depression. There is also quite a substantial body of older literature linking depression and treatment with barbiturates.

Folic acid is an important cofactor for transmethylation reactions and monoamine metabolism within the central nervous system. Patients on polytherapy had low serum, red blood cell, or cerebrospinal fluid folate levels. Even greater deficiencies were found in patients with epilepsy and psychopathology. Antiseizure drugs such as carbamazepine and lamotrigine, which have a well-known positive effect on mood and behavior, have minimal impact on folate levels. On the other hand, barbiturates and phenytoin can depress serum or CSF folate levels.

### Psychosis

The reported frequency of psychoses related to treatment is approximately 1% to 2%, all occurring in medically refractory patients on polytherapy. It has been described with felbamate, vigabatrin, zonisamide, topiramate, tiagabine, and levetiracetam, suggesting that this phenomenon is not specific to a particular medication.

### Fear of Side Effects and Effective Medication Use

Despite the relative paucity of documentation of sustained adverse cognitive effects of antiseizure medications, parents may be under the erroneous impression that a particular medicine will “make the child retarded,” and may blame developmental problems that subsequently emerge on previous administration of antiseizure medications, or may avoid administration of these medications because of fear of disturbing the child’s behavior or development.

### Behavioral and Cognitive Effects of the Older Versus Newer Antiseizure Medications

Reviews of the adult literature suggest that there is no significant difference in efficacy, tolerability, and long-term retention between older versus new antiseizure medications. New medications approved over the last 30 years have generally undergone at least add-on trials in children, with some studies including behavioral and cognitive assessment. These newer

antiseizure medications have been reported to cause both positive and negative behavior changes. Very few have included behavioral or cognitive measures in properly designed, blinded monotherapy studies either in comparison with placebo or another antiseizure medication. This is particularly true for the most recently approved medications. Comparison of antiseizure medications across studies is further hampered by varying criteria for selection of the participants and use of differing neuropsychological tests and study designs.

### Phenobarbital

There are double-blind, placebo-controlled, long-term studies of the behavioral effects of monotherapy with phenobarbital for febrile seizures in infants and toddlers. Children on phenobarbital tended to have lower IQs or displayed IQ declines compared with control subjects. This is due in part to decreased processing speed and poorer attention, and the situation improves or reverses after discontinuation. There may be long-term effects on language skills and academic achievement, however. Its continued use as the drug of first choice in neonates has raised significant concerns and debates.

Phenobarbital can cause sustained behavioral difficulties, primarily overactivity, and can cause irritability and disturbed sleep, particularly in infants and toddlers. Estimates of the number of children who do not tolerate phenobarbital because of overactivity range from 5% to 25%. This is more frequent in toddlers and preschool-aged children.

### Phenytoin

There are no randomized studies examining behavioral and cognitive outcomes in children on phenytoin. Early reports that phenytoin caused generalized cognitive decline were later disputed when further data analysis and research found that the major effect of phenytoin was on motor speed. Other cognitive functions are relatively spared, if analyzed independent of response speed.

### Valproic Acid

In a recent prospective, randomized, blinded study of children with absence epilepsy, valproic acid adversely affected memory more so than ethosuximide or lamotrigine (Glauser et al. 2010). However, smaller earlier studies showed no memory or cognitive impairments. Valproic acid occasionally causes a confused state or psychosis. Hyperammonemia may result in mental slowing and encephalopathy.

### Carbamazepine

A recent open-label, prospective, randomized study of children with new onset partial epilepsy showed no decline in neuropsychological performance after 32 weeks on carbamazepine. Performance IQ, perceptual organization, and externalizing behaviors all improved (Eun et al. 2012). In addition, no cognitive impairment from carbamazepine was seen in two studies in children using a withdrawal design. One prospective study reported worsening reaction time and reaction time variability after treatment for 12 months.

### Oxcarbazepine

Three prospective, open-label studies have been performed in children on oxcarbazepine monotherapy; all have shown no cognitive impairment over a period of up to 6 months. In one study, cognitive effects were compared with carbamazepine and valproic acid in children ages 6 to 17 years with new onset partial epilepsy. In all treatment groups there was

improvement in mental processing speed and no cognitive impairment. Recently a study found statistically significant improvement in some cognitive and behavioral variables after 28 weeks on oxcarbazepine in children with new onset partial epilepsy.

### Lamotrigine

Since its introduction the United States in 1994, lamotrigine has received much attention with respect to its potential positive psychotropic effects. In adults with newly diagnosed epilepsy, lamotrigine has been reported to have fewer cognitive effects than carbamazepine, phenytoin, and topiramate. Significant improvements in behavior, cognition, and motor skills (unrelated to seizure control) also have been noted in children.

### Felbamate

Felbamate modulates glutamate neurotransmission and is generally "activating" rather than sedating. Sleep disturbances and overactivity have been reported, along with isolated instances of psychosis. Several studies found reduction in daytime drowsiness and increased alertness in children taking felbamate.

### Topiramate

Topiramate has been reported to cause significant cognitive difficulties in adult patients, with and without epilepsy, involving primarily word finding and verbal memory, particularly during initial treatment and titration. These adverse effects sometimes dissipate over time, particularly if the dosage is increased slowly. Studies have shown that a gradual introduction of topiramate does not necessarily prevent cognitive effects, and adverse effects on verbal fluency, verbal memory, and cognitive speed may persist until withdrawal of the medication.

### Zonisamide

There is one randomized open-label study of children with newly diagnosed epilepsy on zonisamide monotherapy. Children on low doses (3–4 mg/kg/day) showed improvement in several behavioral variables and no cognitive impairment after 28 weeks on zonisamide, whereas children on higher doses (6–8 mg/kg/day) displayed vocabulary impairment. In several observational studies, 26% to 61% of patients reported mild to moderate adverse events, with only a mild development of tolerance. Cognitive dysfunction—specifically attention, memory, and language changes—was reported in 2% to 11%. Reports from Japan suggest that psychotic episodes and behavior changes may occur in children.

### Levetiracetam

Prospective studies with adjunctive levetiracetam therapy in children have shown no cognitive impairment; however behavioral or mood abnormalities are common (up to 50% in one study) and often necessitate discontinuation (Schiemann-Delgado et al. 2012). A few anecdotal reports have described improved behavior in children with autism treated with levetiracetam, but in the same population, some children experienced increased aggressive behavior. Pyridoxine is sometimes added to levetiracetam to ameliorate mood-related symptoms based on empirical evidence.

### Clobazam

A randomized, double-blind, prospective, multicenter study addressed the cognitive tolerability of clobazam compared

with carbamazepine and phenytoin in children with newly diagnosed epilepsy and found no deterioration of intelligence, memory, attention, psychomotor speed, or impulsivity in children on clobazam.

### Gabapentin

Gabapentin occasionally has been reported to cause aggressive or agitated behavior. It was noted to cause no significant alteration of psychomotor or memory abilities.

### Vigabatrin

Mild and transient drowsiness, dizziness, and irritability are frequently reported with vigabatrin initiation, but do not appear to affect cognition in a strong, adverse way. Both a single review of the cognitive effects of vigabatrin and a monotherapy study comparing it to carbamazepine in adult patients with partial epilepsy showed no cognitive deterioration, and in fact reported improvement in tests of memory, psychomotor speed, and flexibility of mental processing.

### Lacosamide

Patients aged 16 to 74 years in a recent open-label lacosamide prospective study exhibited faster information processing reaction times at the second evaluation using a computerized visual searching task.

### Perampanel

Cognition was not specifically assessed during the clinical trials of this recently approved selective noncompetitive antagonist of the AMPA receptors. Fatigue, dizziness, irritability, and aggression were reported among the side effects, however. Perampanel carries a black box warning label of serious neuropsychiatric side effects, including homicidal ideation reported in several adult patients.

## MANAGEMENT OF COGNITIVE, SOCIAL, ACADEMIC, AND BEHAVIORAL PROBLEMS ASSOCIATED WITH EPILEPSY

Social acceptance and inclusion of children and adolescents with epilepsy is far from satisfactory, even when seizures are infrequent or fully controlled. In some cultural settings, diagnosis of epilepsy is not generally disclosed to friends or extended family. Despite laws guaranteeing disabled and medically impaired children full access to education, some schools discourage attendance by children with frequent seizures. Such prejudices may further impair social and academic function.

Assessment of the developmental, cognitive, academic, and behavioral status of the child and the social functioning of the family must be integrated into the management of a child with epilepsy. Although treatment generally will not alter the underlying cognitive capacity of the child, early intervention and referral to appropriate community and school resources will maximize function. Appropriate counseling may minimize later behavioral and adjustment difficulties.

### School Inclusion and Academic Planning

At times, parents report that a child with epilepsy is excluded from school programs, sent home repeatedly, or placed in a more restrictive class setting than is appropriate. The physician may need to intervene if a child is being denied appropriate educational experiences because of concerns about possible seizures. Having a treatment plan for seizures may be useful

in reducing the anxiety of school personnel. Any child with special needs or suspicion of learning disabilities should be thoroughly evaluated by the school, and have an individualized educational plan (IEP or 504 plan in the USA).

Local branches of voluntary organizations, such as the Epilepsy Foundation of America, may be helpful in providing informational programs to schools. In the United States federal law mandates inclusion of children with disabilities and medical conditions in educational programs in the least restrictive environment appropriate for the child's needs.

### Behavior Problems and Discipline

Behavioral problems and parent-child interaction should be addressed regularly. Parents may avoid disciplining a child with epilepsy out of fear that causing the child to become angry or upset may trigger seizures. Parents must be reassured that this is not the case. Even in children with well controlled seizures, parental anxiety may impair their ability to allow the child to take on age-appropriate behaviors such as sleeping in their own room, going out with peers, and participating in sports.

Significant abnormalities in behavior, activity, or attention warrant a more detailed evaluation. This may include psychiatric evaluation and/or psychometric testing. Psychometric testing, along with a clinical history gathered from parents, teachers, and patients, may be necessary to differentiate behavioral difficulties associated with coexisting ADHD from those due to family dysfunction, oppositional disorders, inappropriate parental expectations, and other factors.

### Peer Relationships, Teasing, and Social Isolation

Social isolation and poor peer relationships are a particular problem in school-aged and adolescent children with epilepsy and are difficult to address therapeutically. Nonverbal learning disabilities comorbid with epilepsy may make the child socially maladapted and target them for teasing by peers. Children may be particularly at risk for teasing and exclusion by peers if they have had seizures at school or are singled out by the need to take medication during school. Therapeutic or educational programs that emphasize social skills and assertiveness training may be helpful.

### Social and Occupational Adjustment of Adults With Childhood-Onset Epilepsy

Population-based studies from several countries document that adults who had childhood-onset epilepsy have impaired social functioning compared with their healthy peers. Employment is less frequent and included less skilled occupations; marriage is not as common, and social isolation is more frequent. Differences are more striking when adults have ongoing seizures, but are present even when complete remission or control has been obtained. Even when studies were restricted to adults with childhood-onset absence epilepsy, social functioning continued to be impaired in comparison with peers without epilepsy. Other studies of outcome in adults with childhood-onset epilepsy find substantial maladaptation as well, particularly in social and vocational function (Sillanpaa 1990). A Canadian study of adults evaluated 25 years after a diagnosis of juvenile myoclonic epilepsy documented a high frequency of social isolation, unemployment, and social impulsivity (Camfield & Camfield 2009).

Given these issues, vocational plans, postsecondary education, and appropriate goal setting should be discussed with adolescents who have epilepsy. Adolescents with

well-controlled epilepsy may be assured that their epilepsy will not interfere with career goals, with a few exceptions: military service, airlines, and public safety professions generally will exclude applicants with epilepsy, regardless of control. Some states will restrict commercial drivers' licenses, even with good seizure control. Appropriate resources for assessment, training, and placement should be identified in the community. In addition to school-based programs, local Epilepsy Foundation affiliates may be a good resource, as may the state department of vocational rehabilitation.

## INTRODUCTION

The recognition that children with epilepsy can die during seizures is not a new concept. However, the frequency and the circumstances of these tragic deaths have come under relatively recent scrutiny. This is attributable in part to the increased awareness of sudden unexpected death in epilepsy (SUDEP) and a desire to more accurately communicate to families the risks associated with the various types of seizures and epilepsy syndromes. The intent of discussion with the caregivers is to provide full disclosure regarding living with epilepsy and potential preventive measures to avoid mortality. This chapter focuses on mortality in childhood-onset epilepsy with the recognition that much of the literature addresses adults. The causes of premature mortality are divided into those that are directly related to seizures (e.g., status epilepticus) and those that are “comorbid” (e.g., etiology, pneumonia). We attempt to highlight those areas in which mortality in children differs from adults. The “bridging” literature is that which addresses epilepsy that starts in childhood, the consequences of which become apparent in the adult population.

## EPIDEMIOLOGY

Five relatively recent prospective cohort studies have defined the risks of mortality for children with epilepsy. Three of these are population-based studies (Nova Scotia; Finland; Rochester, Minnesota), and two are very close to population-based studies (Connecticut, the Netherlands) (Berg et al., 2013; Devinsky, 2011; Sillanpää and Shinnar, 2010).

All five studies have strikingly similar results, except for the findings about SUDEP in Finland (see following discussion). Each of these cohorts includes incidence cases only (new-onset epilepsy), except the Finnish cohort, which includes a mixture of incidence and prevalence cases. The *average* length of follow-up after seizure onset for the cohorts is 10 to 15 years, except in the Finland cohort, where the *median* follow-up was 40 years. Details of case findings of all children newly diagnosed with epilepsy and cause of death within these cohorts are summarized in Table 83-1.

The findings from these prospective cohort studies can be considered in five categories. First, children with epilepsy have a markedly increased risk of death. The standard mortality ratio (SMR) compares the death rate in children with epilepsy to that in the general population matched for age and sex and the time period under consideration. SMRs for children with epilepsy in four of the prospective cohorts range from approximately 6 to 8.5 (i.e., the risk of death for children with epilepsy in the next 10–40 years is 6–9 times that of the general population). Children without neurologic deficits and without symptomatic causes for their epilepsy have the same risk of death during follow-up as the general population (Nova Scotia; Connecticut; the Netherlands; Rochester, Minnesota). This remarkable and robust finding should have a major influence on the type of information about death that is shared with patients and families.

Second, the vast majority of deaths in children with epilepsy are not the direct result of seizures or SUDEP. They are the result of associated comorbid neurologic conditions, especially in those with swallowing difficulties resulting in aspiration pneumonia. Children with neurologic deficits sufficient to interfere with activities of daily living are markedly more likely to die than those with epilepsy but without neurologic deficits. Those with neurologic deficits were 22 times more likely to die in the Nova Scotia cohort over 20 years and 23 times more likely in the Connecticut study. In the Nova Scotia cohort, 20% of patients with serious comorbid neurologic conditions were dead within 20 years of seizure onset. Some but not all of the cohort studies included patients with progressive metabolic brain diseases (e.g., Menke’s syndrome). Here the epilepsy is a symptom, and the progressive brain disease leads inevitably to death. These patients are uncommon; hence, studies that excluded them come to similar overall conclusions.

Third, deaths directly from seizures are uncommon. Status epilepticus is the most frequent way in which a child may die of a seizure. In the Finland study, four deaths were from status epilepticus compared with one in the Nova Scotia study. The risk of death from status epilepticus may be higher in some epileptic syndromes, reaching 10% to 15% in Dravet syndrome. Accidents resulting from a seizure (e.g., a fall with fatal head injury) are even less common; however, drowning is more common in children with epilepsy than controls. The excess number of drownings presumably is the result of seizure events, although the events are usually not witnessed. In the Finnish study, there were a total of 60 deaths from all causes, and 6 (10%) were from drowning. The most common site of drowning is most likely the bathtub. This observation suggests that a shower might be a safer way of cleansing for people with epilepsy than a bathtub, provided that the shower drain is not easily occluded by someone falling on it. Hot water taps that may be knocked all the way open by a falling person are best avoided; pirouetting (screw-in, screw-out) taps are preferable and less likely to lead to a scalding injury. The degree of direct supervision that is reasonable for a child in the shower or bathtub is unclear and may depend on the child’s degree of seizure control. At the very least, it would seem prudent to have someone else in the household aware of when a child with epilepsy is bathing and to avoid locking the bathroom door. In general, most accidents that result from seizures do not appear to be easily preventable.

Drownings in swimming pools, lakes, or the ocean can only be prevented by avoiding swimming when seizures are not well controlled and providing a swimming “buddy” capable of intervening if necessary.

Fourth, suicide in people with childhood-onset epilepsy, although tragic, is not common (two cases in the Nova Scotia study and two in Finland, both cohorts with follow-up to age 36 and 50 years, respectively).

Fifth, SUDEP (see following section for definition) was very uncommon in the cohorts other than the Finnish. The number of SUDEP cases in the four cohorts, as updated by Berg et al.

**TABLE 83-1** Details of Methodology and Findings From the Five Cohorts

	Finland	Nova Scotia	Netherlands	Connecticut	Rochester
Methods and patient source	Prospective, population based, mixture of incidence and prevalence	Prospective, population based	Prospective, regional	Prospective, community based	Retrospective, population based
Years of cohort recruitment	1961–1964	1977–1985	1988–1992	1993–1997	1980–2009
Cohort size	245	686	472	613	468
Mean age at last FU or death*	39.5 y	19.2 y	20.7 y	23.3 y	16.7 y
Number of deaths from all causes	60	26	15	13	14
Number of deaths from SUDEP	23 (55%); none under 14 years of age	1 (at age 23 years)	2 possible SUDEP	1	1
Age range at death (years), all causes	0.1–50	0.5–30	2.1–26.9	1.8–28.7	0.2–21.7

\*All followed to death or  $\geq 5$  years after diagnosis.  
FU, follow-up; SUDEP, sudden unexpected death in epilepsy.

in 2013, was only 10 out of 2239 children with new-onset epilepsy. These children were followed for more than 30,000 person-years. None of those dying with SUDEP had epilepsy syndromes of childhood absence epilepsy, juvenile absence epilepsy, juvenile myoclonic epilepsy, or rolandic epilepsy.

As mentioned earlier, nearly 40% of the Finnish cohort were prevalence cases, which typically represent patients with more severe epilepsy. The rate of death for incidence cases was 5.3/1000 person-years and for prevalence cases was nearly twice as high at 9.6/1000 person-years. This suggests that the severity of epilepsy in the Finnish cohort may be higher than in the other four cohorts.

In the Finnish cohort there were 18 cases of SUDEP, confirmed by autopsy in 15. The median age of SUDEP was 25 years (range 4–49 years). The overall risk of SUDEP for a child with epilepsy over 40 years of follow-up was 7% and only 5% in those with “cryptogenic or idiopathic” etiology. It is important to note that there were no cases of SUDEP in patients with “cryptogenic or idiopathic” epilepsy who were younger than 14 years of age. Overall, SUDEP was very rare before young adulthood and was strongly associated with uncontrolled seizures. It would appear that persistent uncontrolled childhood-onset epilepsy is associated with an increased risk of SUDEP in adulthood. This important observation finding needs additional confirmation.

## SUDDEN UNEXPECTED DEATH IN EPILEPSY

Although the reality that people living with epilepsy died for unknown reasons had been known for some time, attention turned to SUDEP in the 1980s and was expanded in the 1990s after unexpected deaths in new antiseizure drug trials. This interest culminated in two sets of similar, but not identical criteria for SUDEP. The essential features common to both included deaths in people (children and adults) with the following characteristics: (1) known epilepsy, (2) no known other cause of death, (3) unexpected death, (4) death with or without a witnessed seizure (excluding status epilepticus), and (5) postmortem examination required for a definite diagnosis. Criteria were suggested to further classify cases as unlikely, possible, probable, and definite based on the strength of the information surrounding the death. In 2012 the research community recognized that the core criteria needed to be further clarified and expanded with a “unified” definition of SUDEP, which was outlined by [Nashef, So, Ryvlin, and Tomson \(2012\)](#) (Box 83-1). The additional features included specifying 1 hour

### BOX 83-1 Definition of Sudden Unexpected Death in Epilepsy (SUDEP) and Variants

- Definite SUDEP:** A sudden, unexpected, witnessed or unwitnessed, nontraumatic and nondrowning death, occurring in benign circumstances, in an individual with epilepsy, with or without evidence for a seizure and excluding documented status epilepticus (seizure duration > 30 min or seizures without recovery in between), in which postmortem examination does not reveal a cause of death.
- Definite SUDEP Plus:** Satisfying the definition of Definite SUDEP, if a concomitant condition other than epilepsy is identified before or after death, if the death may have been a result of the combined effect of both conditions, and if autopsy or direct observations/recordings of terminal event did not prove the concomitant condition to be the cause of death.
- Probable SUDEP/Probable SUDEP Plus:** Same as Definite SUDEP but without autopsy. The victim should have died unexpectedly while in a reasonable state of health, during normal activities, and in benign circumstances, without a known structural cause of death.
- Possible SUDEP:** A competing cause of death is present.
- Near-SUDEP/Near-SUDEP Plus:** A patient with epilepsy survives resuscitation for more than 1 h after a cardiorespiratory arrest that has no structural cause identified after investigation.
- Not SUDEP:** A clear cause of death is known.
- Unclassified:** Incomplete information available; not possible to classify.

(Adapted from [Nashef L, So EL, Ryvlin P, Tomson T. Epilepsia, 2012;53\[2\]: 227–233.](#))

as the limit in which to consider an event SUDEP after the terminal event and 30 minutes as the duration of status epilepticus to exclude the diagnosis, noting that death associated with drowning not associated with evidence of submersion should be considered “Possible SUDEP,” and creating new categories designated as “SUDEP Plus” to allow other possible etiologies of death (e.g., known cardiac disease) when the criteria for SUDEP have been met and “Near-SUDEP” to indicate that resuscitation prevented likely death.

## CLINICAL RISK FACTORS FOR SUDDEN UNEXPECTED DEATH IN EPILEPSY

To date it has been difficult to identify powerful risk factors for SUDEP (Tomson et al., 2008). Generalized tonic-clonic or focal seizures with secondary generalization appear to be important, especially if they occur during sleep (Walczak et al., 2001). There is a suggestion that children with comorbid neurologic deficits are at higher risk than those who are otherwise neurologically normal. A major theme has been the duration of epilepsy. As mentioned earlier, the Finland study noted an increasing rate of SUDEP after childhood onset if seizures persisted into adulthood. A review of published cases of SUDEP, noted only three studies with robust methodology, and calculated that the longer the duration of epilepsy, the higher the risk of SUDEP. Walczak et al. studied 4578 patients who had been admitted to several epilepsy monitoring units in the United States. During more than 16,000 person-years of follow-up, there were 10 definite and 10 probable cases of SUDEP. The odds ratio (OR) of SUDEP was 14 for patients with more than 30 years of epilepsy compared with those with less than 15 years.

Coupled with the duration of epilepsy are seizure severity and frequency. The lowest rate of SUDEP is seen in incidence (new-onset) cohorts, followed by prevalence cohorts, and then epilepsy clinics. The highest reported rates are in cohorts of refractory patients, especially those who have had unsuccessful epilepsy surgery.

## DISCUSSIONS ABOUT SUDDEN UNEXPECTED DEATH IN EPILEPSY WITH FAMILIES AND PATIENTS

One of the most contentious issues regards the “if, when, and how” relating to disclosure of SUDEP when taking care of people with epilepsy. The issues to be confronted include (1) the patient/family right to full disclosure of potential risks associated with seizures and (2) potential strategies to prevent seizure-related death. Reasons offered to not have this conversation are (1) concern about the psychological effects of this information, (2) inability to affect outcome, and (3) lack of need in low-risk populations (Morton, Richardson, and Duncan, 2006). The current practice of providers has been documented by several survey studies. A questionnaire of 738 British neurologists had a response rate of 52% ( $n = 387$ ) and revealed that only 31% discussed SUDEP with some or all of their patients, adults and children. In contrast, a survey of 250 British nurse specialists in which 58% returned questionnaires revealed that SUDEP education was provided by 50% of nurses. It should be noted that this was in the context of a 2004 national guideline from the National Institute of Clinical Excellence indicating that SUDEP should be discussed as part of the general education of people living with epilepsy. A subsequent study querying the SUDEP disclosure practice of physicians at a British regional epilepsy clinic revealed that this information was provided to 20% of all parents but increased to 63% of parents whose children had intractable epilepsy. In contrast, a questionnaire of these same parents revealed that 91% expected the pediatric neurologist to provide this information, and 67% wanted the information at the first visit (Gayatri et al., 2010). There was a significant disparity in what providers did and what parents wanted. Similar results have been found by focus-group qualitative research with Canadian parents who have children with different severities of epilepsy.

The findings from the epidemiologic and risk-factor studies noted previously suggest several things about the discussion

of SUDEP: (1) the topic should be discussed with the majority of patients/families at the time of diagnosis or soon thereafter, and (2) the risk for each child needs to be presented based on the available literature in children, which indicates that there are at least two types of discussions. The first is for those in the higher-risk population. These are children who have frequent generalized tonic-clonic seizures during sleep, underlying neurologic disorders that predispose to premature mortality, abnormal neurologic examinations, and significant intellectual disability. One of the purposes of the discussion in this group is to encourage adherence with aggressive therapies and to allow families to prepare for the worst of all outcomes. In contrast, the discussion with the lower-risk group (i.e., “benign” epilepsy syndromes, infrequent nonconvulsive seizures) is one of reassurance. These families should not live under the specter of possible death related to seizures that may have been brought to their attention by media or information intended for the higher-risk group.

*Mechanisms:* During the last decade it has been suggested that the primary “system” failure in SUDEP was either dysfunction of brainstem breathing centers, cardiac dysrhythmias, or “cerebral shutdown,” in which a seizure results in flattening of the electroencephalogram (EEG), referred to as postictal generalized EEG suppression, followed by lack of cerebral drive to cardiac and respiratory centers (Massey, Sowers, Dlouhy, and Richerson, 2014). It is acknowledged that the mechanisms underlying SUDEP are likely heterogeneous and that an individual’s genotype may predispose to this uncommon, but tragic event. The importance of respiratory dysfunction was highlighted in a recent study of deaths in epilepsy monitoring units in which the majority of deaths were preceded by tachypnea followed by apnea and cardiac arrest. Brainstem serotonergic dysfunction may play a critical role, as suggested by rodent experiments.

## PREVENTION OF MORTALITY RELATED TO SEIZURES

Although there are inadequate data specifically in the pediatric population, it is prudent to assume that reducing generalized tonic clonic seizures (GTCs) lowers the risk of SUDEP in children. The most direct evidence comes from a prospective case-controlled study from four epilepsy centers. Patients were all admitted to an epilepsy monitoring unit and then followed. There were no SUDEP cases in children. However, in adults, those who had at least four GTCs in the last year had an increased risk of dying from SUDEP by a factor of 8 compared with those with no GTCs. Another piece of evidence indicates that the most significant potential method of preventing SUDEP is reduction of seizures. This information comes from studies demonstrating decreased risk in a group of patients undergoing epilepsy surgery who were then seizure-free (0 of 199) compared with those who had recurrent seizures after surgery (11 of 194). It should be noted that both of these studies involved patients with more complicated cases than those of the typical community patient, as reflected by receiving their care in epilepsy centers and certainly those with intractable epilepsy requiring surgery.

A key assumption in the purpose of disclosing information regarding the risk of death and SUDEP specifically is that by doing so, the patient/family will be inclined to be more compliant with medications and/or pursue more aggressive therapies such as epilepsy surgery. The results to date have not been conclusive in this regard. One study of 39 parents living with a highly selected group of children with epilepsy indicated that this knowledge resulted in only a 31% increase in monitoring of antiseizure drugs. However, a survey of young adults

(18–20 years old) revealed that although 81% wanted to be informed of SUDEP, they had a fatalistic attitude, with no clear influence regarding therapy or lifestyle changes. This important study indicates that more than just disclosure will be required to change behavior with regard to adherence. At this point there is no direct evidence that increased adherence leads to decreased seizure frequency and decreased rates of SUDEP. Thus the recommendation to be adherent with treatment recommendations as a means of decreasing SUDEP is speculative, but logical.

It has not been proven that detection of seizures during sleep can avert SUDEP, but the results of two studies suggest that supervision during sleep may be protective. The first described 14 people who were enrolled in a residential school for 4 to 18 years and died of SUDEP when they were out of the facility. Because the students had nocturnal supervision (attendant available to respond to an auditory alarm) while at the school, it is possible that the supervision prevented deaths while the students were in the residential facility. The second was a case-control study of 154 individuals with SUDEP in whom an autopsy was performed and in which risk factors were compared with four controls for each case. It was found that nocturnal monitoring by a person 10 years of age or older in same room (odds ratio [OR]: 0.4, 95% confidence interval [CI]: 0.2–0.8) or precautionary measures such as a listening device (OR: 0.1, 95% CI: 0.0–0.3) were protective for SUDEP.

Based on the possibility that intervention might avert SUDEP, a significant amount of research has been directed to seizure-detection devices that could be used in the home (see Ramgopal [2014] for a recent comprehensive review). All of the issues that pertain to any diagnostic test (e.g., sensitivity, specificity) apply to seizure-detection devices and the feasibility of acting on the alarm. In addition to portable EEG systems with seizure-detection algorithms, widely varying devices have been proposed and include the following: accelerometers to detect motion (worn on the wrist, placed under the mattress, present as an app on a smartphone), audio and recording devices, and autonomic function (heart rate, sweat) monitors. Some devices have combined several modalities of detection, and others have utilized modern technologies (e.g., Bluetooth) for alerting someone who could intervene. The ability of dogs to detect seizures has been reported, but the sensitivity, specificity, and utility in the sleeping child have not been established.

To date, there are no definitive studies that establish that any monitoring device can reduce the risk of SUDEP. Based on the experience with sudden infant death syndrome (SIDS), it is likely that monitoring devices have a significant effect on family life and may possibly do more harm than good. Physicians should be cautious about recommending such devices for children with epilepsy.

A recent study has suggested that a preventive measure may be available that does not require a detection device. A systemic analysis of reported SUDEP cases found that 73% of the 253 cases where body position was noted occurred in the prone position; all 11 cases in video EEG reports were in the prone position. In 88 cases body position and basic demographics were available, and when stratified by age, 86% of patients under 20 years of age who died were found in the prone position. Thus an education effort targeted at those living with epilepsy similar to that implemented for SIDS might play a role in preventing SUDEP. However, patients may roll or be tossed from supine to prone during a convulsive seizure, so a “back to sleep” program may not be effective.

## PREVENTION OF MORTALITY NOT RELATED TO SEIZURES

As described in the Epidemiology section, the majority of children with epilepsy who suffer premature death die from a cause not related to seizures. Unfortunately, prevention related to an underlying neurodegenerative disorder, frequently of a genetic etiology, is limited to symptomatic care if a specific therapy is not available. Fortunately, suicide is uncommon in this population, but the clinician must be alert to signs of depression, which is the most common antecedent of suicide in people living with epilepsy. In contrast, drowning is preventable by supervision in the bathtub or shower and near bodies of water. Finally, infectious causes of premature mortality such as pneumonia and urinary tract infections are potentially preventable by clinical surveillance (particularly in intellectually disabled individuals) and rapid introduction of antibiotic therapy.

## CONCLUSIONS

Death in children with epilepsy is almost always related to the underlying neurologic disorder, not the seizures. Death from status epilepticus is rare but should be preventable. Death from accidents caused by seizures is also rare. SUDEP is fortunately rare in children with epilepsy, but the risk may increase if seizures persist into adulthood. The mechanism of SUDEP is likely multifactorial, and it can only be prevented by completely controlling seizures, especially generalized tonic-clonic seizures. Seizure-detection devices for home use are in development, but they remain of uncertain value. SUDEP should be discussed with families close to the time of epilepsy diagnosis.

## Headache in Children and Adolescents

Marielle A. Kabbouche, Joanne Kacperski, Hope L. O'Brien, Scott W. Powers, and Andrew D. Hershey

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

## INTRODUCTION

Headache is a common complaint among children and adolescents and is a common referral to neurologists, with migraine being one of the top five childhood diseases. However, it is frequently ignored by parents, teachers, and primary care providers as a significant problem, resulting in lost school days and social interactions. It is therefore essential for clinicians to have a thorough and systematic approach to the evaluation of headaches, because proper diagnosis and management can lead to improved outcomes and quality of life (Hershey, 2010).

The most common cause of recurrent, episodic headaches in children is migraine. Primary headache such as migraine and tension-type headaches are intrinsic to the brain, in contrast to secondary headaches caused by something else, such as head trauma, brain tumors, infection, inflammatory diseases or increased intracranial pressure. One of the first steps in the evaluation of headache is to exclude secondary causes. Evaluation begins by obtaining a thorough history, which includes the following elements:

1. Identification of any secondary etiologies
2. Timing, including when the child first began developing headaches, not just "bad" headaches
3. Headache characterization, including quality of the pain and the location, duration, severity, and frequency of the headaches
4. Associated features, signs, and symptoms
5. Warning signs that initiate or aggravate the headaches
6. Family history for headaches and also for medical, neurologic, and psychiatric illnesses

In addition to a complete history, a complete physical, neurologic, and headache examination is necessary. If abnormalities are observed, the cause of the abnormality needs to be determined. The neurologic examination is the most significant determinant if neuroimaging studies are warranted. In most patients, the initial evaluation and examination can be diagnostic and provide reassurance that additional testing is unnecessary. Once the diagnosis is established, a comprehensive treatment plan should be developed that includes a combination of pharmacologic and nonpharmacologic modalities.

## CLASSIFICATION

An international standardized set of criteria has been established to diagnose all headache disorders, the International Classification of Headache Disorders (ICHD) third edition (beta; ICHD-3b) ([http://www.ihs-classification.org/\\_downloads/mixed/International-Headache-Classification-](http://www.ihs-classification.org/_downloads/mixed/International-Headache-Classification-III-ICHD-III-2013-Beta.pdf)

[III-ICHD-III-2013-Beta.pdf](http://www.ihs-classification.org/_downloads/mixed/International-Headache-Classification-III-ICHD-III-2013-Beta.pdf)). The ICHD-3b is divided into three major categories: primary headaches, those that are diseases by themselves; secondary headaches, those caused or exacerbated by a secondary factor, and the cranial neuropathies; and other facial pains and headaches. In addition, an appendix contains criteria to be tested. ICHD-3b requires that all headache diagnoses should be included in the diagnostic list for that patient, thus describing the full phenotype.

## Migraine Without Aura

Patients can be given the diagnosis of migraine without aura using ICHD-3b criteria if they have had at least five recurrent, episodic headaches over the past year that last 2 to 72 hours untreated (<18 years old; 4-72 hours for adults); have two of the four features of pulsatile quality, unilateral location, worsening with activity or limiting activity, and moderate to severe in intensity; and are associated with either nausea, vomiting, photophobia, or phonophobia (all four symptoms can be present). Not all headaches need to meet all ICHD-3b criteria. They just need enough criteria to establish the diagnosis. There are special comments for children, including that sleep is considered part of the duration, associated symptoms can be inferred by parent or guardian based on the child's action, and location may be bilateral, namely, frontotemporal.

## Migraine with Aura

If the patient has a neurologic warning of an oncoming headache, migraine with aura should be considered. To make this diagnosis, ICHD-3b requires at least three headaches over the past year to be associated with an aura. The aura needs to be one of six types, visual, sensory, dysphasic, motor, brainstem, or retinal, that should have two of the following four features: lasting more than 5 minutes but less than 60 minutes (multiple auras can be additive), fully reversible, unilateral (dysphasia or aphasia is defined as unilateral), and the pain of the headache starts within 60 minutes (although it can be simultaneous, and the aura can occur when the patient has pain). What was formerly called basilar or basilar-type migraine is now recognized as a migraine with brainstem aura. Hemiplegic migraine (whether familial or sporadic) is also considered a migraine with aura and has an additional diagnostic hierarchy that can include the genetic identification of the polymorphism causing familial hemiplegic migraine.

## Chronic Migraine

When migraines become frequent (15 or more days per month), a diagnosis of chronic migraine can be included.

ICHD-3b requires at least 15 headache days per month for 3 months with at least 5 meeting ICHD-3b criteria and having at least 8 headaches per month that meet the ICHD-3b criteria for migraine that are responsive to migraine-specific medication or in the interpretation of the patient are migraine.

## Migraine Variants

Several migraine variants were included under the category of childhood periodic syndromes in earlier ICHD versions. In ICHD-3b, the limitation of childhood was removed, because it has been recognized that adults can learn from the experience of children, and the term has now been changed to *episodic syndromes that may be associated with migraine*. Within this larger category are recurrent gastrointestinal disturbance (cyclic vomiting syndrome and abdominal migraine), benign paroxysmal vertigo, and benign paroxysmal torticollis. In the ICHD-3b appendix, infantile colic, alternating hemiplegia of childhood, and vestibular migraine are included for testing to determine whether they should be included in or eliminated from future revisions. Please refer to the online version of the chapter for additional migraine variants.

## Tension-Type Headache

The other common primary headache in children is tension-type headache (TTH), which can be thought of as the opposite of migraine, and when migraine features occur, the ICHD-3b recommends defaulting to making a diagnosis of migraine. TTH can be divided into infrequent (<1/month), frequent (1-14 times per month), and chronic (>15 per month for ≥ 3 months). The ICHD-3b TTH criteria are recurrent headaches with at least 10 episodes in the past year, lasting 30 minutes to 7 days, with two of the following four headache features: nonpulsatile, diffuse in location, not worsened or aggravated by physical activity, and mild to moderate in severity. Clarification was added for differentiating migraine from TTH, and in contrast to the earlier discussion about being inclusive, if the diagnosis of migraine is made, the diagnosis of TTH should not be made.

## Trigeminal Autonomic Cephalalgia

The trigeminal autonomic cephalalgias (TACs) represent a group of primary headache disorders associated with excruciating head pain accompanied by autonomic features such as lacrimation, ptosis, rhinorrhea, and vasomotor changes. Cluster headache is an uncommon TAC in children and adolescents. The prevalence of childhood onset of cluster headache is approximately 0.1%. The diagnostic criteria require at least five attacks of severe unilateral orbital, supraorbital, and/or temporal pain, lasting 15 to 180 minutes, with a sense of restless agitation accompanied by ipsilateral conjunctival injection, lacrimation, nasal congestion, rhinorrhea, eyelid edema, forehead sweating, miosis, or ptosis. Cluster headaches may be episodic or chronic, and attacks occur in series that last for weeks or even months. A cluster may be precipitated by alcohol, histamine, or nitroglycerine. Males are three times more likely to be affected than females. Additional TACs include paroxysmal hemicranias and indomethacin-sensitive headaches.

## EPIDEMIOLOGY

The prevalence of any complaint of headache ranges from 37% to 51% in 7-year-olds, gradually rising to 57% to 82% by age 15. The prevalence of recurrent migraine is approximately 2.5% to 4.0% in younger children (under age 8 years),

which increases to approximately 10% in 5- to 15-year-olds and continues to increase to adult levels throughout the late-teen years.

The epidemiology of TTH is less well studied, because it is often complicated by a mixed-headache picture with migraine. Patients frequently have diagnoses of mild headaches as TTH and severe headaches as migraine.

For additional information, please see the online chapter.

## MIGRAINE PATHOPHYSIOLOGY

Migraine is a disorder of neurologic dysfunction with a strong genetic basis. The underlying pathophysiology is likely to be a complex, heterogeneous process, with the ultimate phenotype being a common appearance from multiple pathways. For a more complete review of migraine pathophysiology, please see the online chapter and the review by [Goadsby, Charbit, Andreou, Akerman, and Holland \(2009\)](#).

## EVALUATION OF THE CHILD WITH HEADACHES

Evaluation follows the traditional medical model and begins with a thorough medical history and complete physical and neurologic examination. The role of ancillary diagnostic studies, such as laboratory testing, electroencephalography (EEG), and neuroimaging, has been extensively reviewed. The American Academy of Neurology (AAN) Practice Parameter determined that there is inadequate documentation in the literature to support any recommendation as to the appropriateness of routine laboratory studies (e.g., hematology or chemistry panels) or performance of a lumbar puncture or an EEG unless a secondary headache is being evaluated ([Lewis et al., 2002](#)). At the end of the clinical evaluation, the clinician should be confident in narrowing the differential diagnosis and deciding whether or not there is a need for further testing.

## Neuroimaging

An imaging study is warranted if one or more of the following factors are present during the clinical interview (for a review of recommendations, see the online chapter):

- Subacute headache with rapidly progressive increase in severity
- New-onset headache in the immunosuppressed patient
- Headache of new onset in patients older than 50 years of age
- First or worst headache
- Associated systemic symptoms (e.g., fever or nuchal rigidity)
- Headache with focal neurologic abnormalities on examination

These guidelines apply to the general population. Because of the possibility of specific headache types in children, the following additional factors need to be considered:

- Headache of less than 1 month in duration
- Absence of family history of migraine/primary headache
- Abnormal neurologic examination
- Gait abnormalities
- Seizures
- Sleep-related headaches, vomiting, and confusion (headaches waking the child from sleep or intractable vomiting upon awakening)
- Children younger than 6 years old
- A history consistent with an occipital headache

In 1994, the AAN published its Practice Parameter on the use of neuroimaging in the evaluation of adults with headache

with normal neurologic examination and recommended that an imaging study is not warranted in patients older than 6 years with recurrent migraine when there is no change in pattern, no history of seizures, and an absence of other focal neurologic signs.

The recommendations for children were reported in 2002 by the AAN and the Child Neurology Society (CNS):

- Obtaining a neuroimaging study on a routine basis is not indicated in children with recurrent headache and a normal neurologic examination.
- Neuroimaging should be considered in children with an abnormal neurologic examination and in whom there are historical features suggesting recent onset of headache, change in the type of headache, neurologic dysfunction, and occipital location of the headache.

Based on the available current literature, imaging should be considered for the following factors:

1. Abnormal neurologic examination
2. Atypical headache presentation: vertigo, intractable vomiting, or headache waking the child from sleep
3. Headache onset within the last 6 months
4. Child of less than 6 years of age
5. No family history of migraine and/or primary headache
6. Occipital headache
7. Change in headache type
8. Subacute onset and progressive headache severity
9. New-onset headache in an immunosuppressed child
10. First and/or worst headache
11. Systemic symptoms and signs
12. Headache associated with confusion, mental status changes, or focal neurologic complaints

Computed tomography (CT) imaging can be acquired rapidly and is widely available in almost all emergency departments. It is highly sensitive in detecting acute hemorrhage. Magnetic resonance imaging (MRI) is more sensitive in evaluating the posterior fossa, an area of high incidence of pathology in children. MRI is also more sensitive for neoplastic and vascular disorders, ischemia, and infection. One should consider acquiring an MRI scan if an imaging study is considered necessary, unless an acute surgical lesion such as an intracranial hemorrhage is suspected.

## Lumbar Puncture

A lumbar puncture is indicated in the evaluation of headache in children as detailed in the AAN/CNS guidelines for headache evaluation when there is a suspected secondary etiology and any of the following features:

1. First and/or worst headache to evaluate for a subarachnoid hemorrhage, especially if suspicion is high and the CT scanning is negative
2. Headache with fever/nuchal rigidity or other signs of meningitis or meningoencephalitis
3. Headache in an immunosuppressed patient
4. Evaluation for increased/decreased intracranial pressure (pseudotumor cerebri/low-pressure headache)

A lumbar puncture is not indicated for routine diagnosis of a primary headache such as migraine or TTH.

## Clinical Laboratory Testing

Clinical laboratory studies are not needed in the routine evaluation of primary headache. Routine baseline testing can be of value before initiating preventive headache medications, and in monitoring of prescribed drugs for toxicity and compliance.

Low levels of vitamin B<sub>2</sub> and coenzyme Q10 have been associated with an increased frequency of headache.

## Electroencephalogram

Routine electroencephalogram (EEG) is not recommended.

For additional information on evaluation, please see the online chapter.

## MANAGEMENT OF PEDIATRIC MIGRAINE

Once the diagnosis of migraine is established and appropriate reassurances have been provided, a balanced and individually tailored treatment plan can be instituted. The first step is to appreciate the degree of disability imposed by the patient's headache. An understanding of the effects of the headache on the patient's quality of life will guide the decisions regarding the most appropriate treatment. Despite often experiencing significant disability, many children do not receive preventive therapy. One third of adolescents meet the criteria for preventive therapy, yet only 10% to 19% are offered treatment. Moreover, controlled clinical trials investigating the use of acute and preventive medications in children have suffered from high placebo response rates. As a result, treatment practices vary widely, even among headache specialists, as a result of the absence of evidence-based guidelines.

An AAN guideline has established the general principles for the management of migraine headache (Silberstein, 2000), which include the following:

1. Reduction of headache frequency, severity, duration, and disability
2. Reduction of reliance on poorly tolerated, ineffective, or unwanted acute pharmacotherapies
3. Improvement in quality of life
4. Avoidance of acute headache medication escalation
5. Education and enablement of patients to manage their disease to enhance personal control of their migraine
6. Reduction of headache-related distress and psychological symptoms

To achieve these goals, it is becoming increasingly clear that a balanced treatment plan must include biobehavioral strategies and nonpharmacologic methods in addition to pharmacologic ones. Biobehavioral treatments include biofeedback, cognitive behavioral therapy, stress management, sleep hygiene, exercise, and dietary modifications.

Biofeedback has shown effectiveness in adults and children in controlled migraine trials. Although the physiologic basis is unclear, data suggest that plasma beta-endorphin levels can be altered. Biofeedback commonly uses electrical devices that provide audio or visual displays to demonstrate a physiologic effect. Thermal biofeedback is the most commonly used technique, wherein children are taught to raise the temperature of one of their fingers. Children can use these methods to manage future headaches, allowing them to feel that they have greater control of their health.

Stress management and relaxation therapies use techniques such as progressive relaxation, self-hypnosis, and guided imagery. Controlled trials have reported relaxation therapies to be equally effective as propranolol in reducing migraine frequency.

Maintenance of healthy habits is an essential component of the treatment plan. Sleep disturbances occur in 25% to 40% of children with migraine. It remains unclear whether sleep disturbances increase the occurrence of migraine, whether frequent and intense migraine leads to sleep disturbances, or whether the two are unrelated. Current practice is to recommend good sleep hygiene (Miller, Palermo, Powers, Scher, and

Hershey, 2003). Exercise also is recommended, and a review of Internet websites serving headache sufferers reveals the common endorsement of regular physical activity. Extensive dietary restriction is not recommended. The once-popular elimination diets are now judged to be excessive, and they generally set the stage for a battleground at home when parents attempt to force a restrictive diet upon an unwilling adolescent. A more reasonable approach is to review the list of foods thought to be linked to migraine and invite the patient to keep a headache diary and see if a temporal relationship exists between ingestion of one or more foods and headache development. In addition to looking at what patients eat, it is important to encourage them to eat regular meals and to drink plenty of fluids. Many teenagers routinely skip breakfast. Missing meals is a common precipitant of migraine and is identified by adolescents as one of the leading triggers.

Caffeine warrants special mention. Caffeine influences headache frequency and may disrupt sleep and/or aggravate mood, both of which may exacerbate headache. Furthermore, caffeine withdrawal headache, which begins 1 to 2 days following cessation of regular caffeine use, can last up to a week.

## Pharmacologic Therapies for Migraine Headache

Pharmacologic management has been subjected to thorough review, but controlled data are limited (see the online chapter for a description of treatment studies).

### Acute Therapy/Outpatient Abortive Therapy

For the acute treatment of migraine, the most rigorously studied agents are ibuprofen, acetaminophen, and the triptans (Table 84-1), all of which have shown safety and efficacy in controlled trials. Almotriptan and rizatriptan are the only triptans approved by the U.S. Food and Drug Administration (FDA) for use in children and adolescents. Almotriptan has been approved for use in children ages 12 and above. The use of rizatriptan for pediatric migraine was approved for children ages 6 to 17.

In general, a nonsteroidal anti-inflammatory drug (NSAID) such as ibuprofen or naproxen sodium should be used as the first-line acute therapy. If this is not consistently effective, addition of a triptan may be warranted. Care should be taken to avoid overusing these medications, because they may cause medication-overuse headaches (see online chapter).

## Emergency Room Management of Migraine Exacerbation

Sometimes the headache continues despite acute outpatient therapy, and if it is disabling, a more aggressive approach may be needed.

*Status migrainosus* is an acute migraine attack lasting 72 hours or more. It is imperative to break this type of headache before it becomes intractable and unresponsive to acute therapy. The patient should initially be referred to an infusion center or the emergency department (ED) for therapy.

Therapeutic approaches vary because of the lack of guidelines for the treatment of acute refractory headache in children. Available treatments for status migrainosus in an ED include antidopaminergic medications (prochlorperazine and metoclopramide), NSAIDs (e.g., ketorolac), dihydroergotamine (DHE), antiepileptic drugs (e.g., sodium valproate), and triptan compounds.

**Antidopaminergic Drugs.** Prochlorperazine is very effective in aborting an attack in the ED when given intravenously (IV) with a load of IV fluids (Kabbouche, Vockell, LeCates, Powers, and Hershey, 2001). Results show a 75% improvement with 50% headache freedom at 1 hour and 95% improvement with 60% headache freedom at 3 hours. Prochlorperazine was compared with metoclopramide and a placebo in a well-controlled study; improvement in headache severity was 82% for prochlorperazine, 42% for metoclopramide, and 29% for the placebo.

The average dose of prochlorperazine is 0.15 mg/kg, with a maximum dose of 10 mg. The average dose of metoclopramide is 0.13 to 0.15 mg/kg, with a maximum dose of 10 mg, given intravenously over 15 minutes. These medications are usually well tolerated, but extrapyramidal reactions are more frequent in children. Patients experiencing symptoms or severe irritability and restlessness can be given diphenhydramine to control these side effects. Diphenhydramine does not prevent these side effects when given early.

**Nonsteroidal Anti-Inflammatory Drugs.** Ketorolac is often used in the ED as monotherapy (0.5 mg/kg, with a maximum of 30 mg) or in combination with other medications. Ketorolac alone results in 55.2% improvement, and the recurrence rate at 24 hours is 30%. When combined with Prochlorperazine, the response rate increases to 93%.

**Antiepileptic Drugs.** Sodium valproate is given as a bolus of 15 to 20 mg per kg intravenously over 5 minutes that can be

**TABLE 84-1** Selective Serotonin (5-HT<sub>1</sub>) Receptor Agonists

Generic Name	Trade Name	Route	Dosage
Almotriptan*	Axert®	Oral	6.25-12.5 mg at onset; may repeat in 2 h; no more than 2 doses in 24 h
Eletriptan	Relpax®	Oral	40 mg at onset; may repeat in 2 h; max 80 mg/d
Frovatriptan	Frova®	Oral	2.5 mg at onset; may repeat in 2 h; no more than 3 doses in 24 h
Naratriptan	Amerge®	Oral	1-2.5 mg at onset; may repeat in 4 h; not to exceed 30 mg/24h
Rizatriptan*	Maxalt® Maxalt-MLT®	Oral Disintegrating tablets	5-10 mg at onset; may repeat in 2 h; not to exceed 30 mg/24h
Sumatriptan	Imitrex®	Oral	25, 50, 100 mg at onset; may repeat in 2 h, up to 100 mg 6 mg at onset, may repeat dose in 1 h, up to 12 mg/d 20 mg, one spray in one nostril at onset; may repeat within 2-24 h; limited to two sprays/d
		Subcutaneous	
		Intranasal	
Zolmitriptan	Zomig®	Oral, nasal spray	2.5-5 mg at onset; may repeat in 2 h; not to exceed 10 mg/24h
	Zomig-ZMT®	Disintegrating tablets	

\*Almotriptan and rizatriptan are the only triptans with FDA approval for pediatric and adolescent migraine.

followed by an oral dose (15-20 mg/day) in the 4 hours after the infusion. Patients may benefit from a short-term preventive treatment with an extended-release form after discharge. Sodium valproate is usually well tolerated.

**Triptan Compounds.** An open-label study showed the effectiveness of subcutaneous sumatriptan. With a dosage of 0.06 mg per kg, overall efficacy was 72% at 30 minutes and 78% at 2 hours, with a recurrence rate of 6%. DHE, if recommended for recurrences, should not be given within 24 hours of triptan use. The triptan can be used in the outpatient setting, and the patient does not need referral to the ED (Table 84-1).

#### **Dihydroergotamine Use in the Emergency Department.**

Ergots are one of the oldest treatments for migraine. DHE is a parenteral form used for acute exacerbations. Its effect is attributable to 5HT<sub>1A-1B-1D-1F</sub> receptor agonist affinity and central vasoconstriction. DHE has a greater alpha-adrenergic antagonist activity and is less vasoconstrictive peripherally. Before treatment initiation, a full history and neurologic examination should be performed. Females of childbearing age should be evaluated for any concerns regarding pregnancy. DHE is used as a potent central vasoconstrictor to abort the vascular phase of the attack. One dose can be effective for an acute prolonged headache. Compared with valproate, the response was similar at 1, 2, and 4 hours for both therapies, with 60% improvement in headache severity; however, DHE was still effective in 90% of patients versus 60% for those patients receiving valproate at 24 hours. An additional study in 30 children using DHE for acute treatment showed an 80% response rate. Dosing ranged from 0.1 to 0.5 mg, considerably lower than dosages used for treating adults.

#### **Inpatient Therapy for Severe Debilitating Acute Exacerbation of Primary Headache**

Approximately 7% of children and adolescents will fail acute therapy in the ED and will require hospital admission for more intensive therapy. Inpatient treatment for status migrainosus has not been carefully studied, but clinical reports and reviews have been done in pediatric headache facilities, with positive results. These patients are usually admitted for a 3 to 5 days and receive extensive IV treatment. A child should be hospitalized when he or she is in status migrainous that was refractory to outpatient infusion center or ED treatment, or if the patient has an exacerbation of chronic severe headache. The goal is to control a disabling headache that has been unresponsive to other abortive therapies. Treatment protocols include the use of DHE, antiemetic medications, and sodium valproate.

**Dihydroergotamine Use in the Inpatient Setting.** Patients hospitalized for DHE treatment should be premedicated with 0.13 to 0.15 mg/kg of prochlorperazine a half hour before the DHE dose for up to three doses. If the patient continues to have significant nausea, the antidopaminergic medications are replaced by Ondansetron for the remaining treatments. The DHE dose is 0.5 to 1 mg (depending on age and tolerability) and is used every 8 hours until headache freedom. The first dose is halved and given a half hour apart to evaluate tolerability. When the headache ceases, two extra doses are given to prevent recurrence. The response to this protocol results in 97% improvement and 77% headache freedom. Response starts being noticeable by dose 5 and can reach its maximum effect after dose 10. Side effects include nausea, vomiting, abdominal discomfort, flushed face, and transient increases in blood pressure during infusion.

**Sodium Valproate.** Sodium valproate is used when DHE is contraindicated or has been ineffective. One adult study recommends the use of valproate as follows: bolus with 15 mg per kg followed with 5 mg/kg every 8 hours until headache freedom or up to 10 doses, whichever occurs first. An additional dose can be given after the headache ceases. This protocol was studied in adults with chronic daily headaches and showed an 80% improvement.

#### **Preventive Treatment**

Prophylaxis should be limited to those children and adolescents whose headaches occur with sufficient frequency and/or severity to warrant daily medication (Lewis, Diamond, Scott, and Jones, 2004). Treatment goals include reducing headache frequency and progression to chronic headache and lessening associated disability. Most specialists recommend a minimum of one headache per week or three to four headaches per month to consider prevention medication. Preventive treatment should also be considered if acute treatments are ineffective, not well tolerated, contraindicated because of other medical conditions, or overused, or if the patient has infrequent but severely disabling headaches.

The clinician and family must also establish a sense of functional disability before committing the child to a course of daily medication, because therapy should also aim to improve the overall quality of life. All patients warranting prevention should be provided with appropriate education regarding their diagnosis and treatment plan, thus enabling patients to manage their disease and enhance personal control of their headaches. Clinicians should discuss this long-term treatment plan so that families understand that the effort is often a long-term one, and response will not occur rapidly. It should be emphasized that the onset of improvement is often delayed in pediatric patients, and ideally these medications should only be used for a finite period of time. A goal of three or less headaches per month is recommended for a sustained period of 4 to 6 months. The dose of the medication should be titrated slowly to minimize side effects. Once an effective dose is achieved, relief must be sustained for 2 to 3 months before considering an alternative medication. Once these goals are achieved, a plan to slowly wean the child off the agent is also necessary.

A variety of medications are used to prevent migraine attacks, including antidepressants, antiepileptic agents, antihistamines, and antihypertensive agents (Table 84-2). The majority of these medications are extensively prescribed for other conditions, including depression, mood disorders, epilepsy, and other pain disorders, making their side-effect profiles well known. When selecting an agent, the clinician should take into account coexisting conditions. Clear instructions should be given to families regarding the medication's mechanism of action, potential side effects, and the importance of adhering to therapy. Clear titration instructions should be provided. It is important to remind families that it may take time, often several weeks, for the treatment to become effective. Slow titration over a period of 4 to 12 weeks may be necessary to assure that the child tolerates the medication with minimal adverse effects. If improvement is seen, the dose may be increased to achieve optimal control.

For specific details on preventive medications, please see the online chapter. The typical preventive medications are discussed next.

**Antidepressants.** Antidepressants are the mainstay of migraine prevention in adults; few studies have been performed in children. Yet they remain one of the most widely used medications for both age groups. Amitriptyline is the only tricyclic antidepressant for which studies have provided

**TABLE 84-2** Preventive Agents for Childhood and Adolescent Migraine

Agent	Dosing	Available Formulations	Commonly Encountered Adverse Effects
<b>Antidepressants</b>			
Amitriptyline	10-150 mg qhs (max 1 mg/kg/day)	Tablets—10, 25, 50, 75, 100, 125, 150 mg	Sedation, dizziness, constipation, decreased GI motility, increased appetite, weight gain, urinary retention
Nortriptyline	10-75mg qhs	Capsules—10, 25, 50, 75 mg Liquid suspension—10 mg/5 ml	Drowsiness, dizziness, constipation, increased appetite, orthostatic hypotension, QT prolongation (regular ECG surveillance necessary)
<b>Antiepileptics</b>			
Topiramate	1-10 mg/kg/day Typical dose 50 mg bid	Tablets—25, 50, 100, 200 mg Sprinkle caps—15, 25 mg	Paresthesias, somnolence, dizziness, anorexia, metabolic acidosis, cognitive/memory dysfunction, abdominal pain
Valproic acid	15-30 mg/kg/day	Tablets DR—125, 250, 500mg Tablets ER—250, 500 mg Sprinkle caps—125 mg Liquid suspension—250 mg/5 ml	Somnolence, nausea/vomiting, thrombocytopenia, tremor, alopecia, increased appetite, weight gain, emotional lability, lymphopenia, hyperammonemia, elevated pancreatic enzymes, PCOS, birth defects
Levetiracetam	500-1500 mg bid	Tablets—250, 500, 750, 1000 mg Liquid suspension—100 mg/ml	Somnolence, fatigue, irritability, mood/behavioral changes
Zonisamide	100-600 mg/day	Tablets—25, 50, 100 mg	Somnolence, dizziness, anorexia, nausea, irritability
Gabapentin	300-1200 mg tid	Tablets—100, 300, 400, 600, 800 mg Liquid suspension—50 mg/ml	Dizziness, sedation, ataxia, fatigue, peripheral edema
<b>Antihistamines</b>			
Cyproheptadine	0.25-1.5 mg/kg/day	Tablets—4 mg Liquid suspension—2 mg/5 ml	Drowsiness, fatigue, increased appetite, weight gain, dizziness
<b>Antihypertensives</b>			
Propranolol	2-4 mg/kg/day	Tablets—10, 20, 40, 60, 80 mg Tablets ER—60, 80, 120, 160 mg Liquid suspension—20, 40/5 ml	Fatigue, dizziness, constipation, hypotension, depression, exercise-induced asthma
Verapamil	4-10 mg/kg/day tid	Tablets—40, 80, 120 mg Tablets ER—120, 180, 240 mg	Constipation, dizziness, nausea, hypotension
Flunarizine*	5-10 mg qhs	Tablets—10 mg	Sedation, weight gain
DR, delayed release; ECG, electrocardiogram; ER, extended release; GI, gastrointestinal; PCOS, polycystic ovary syndrome. *Not available in the United States.			

consistent evidence of benefit in the adult population. In children, most research with amitriptyline has consisted of open-label studies, with no placebo-controlled trials, resulting in unclear dosing guidelines.

**Antiepileptic Drugs.** Antiepileptic agents are the most widely studied preventive agents for migraine in adults and children and include topiramate, valproic acid, levetiracetam, zonisamide, and gabapentin. Topiramate and valproate are approved by the FDA for headache prevention in adults, and topiramate became the first drug approved for migraine prevention in children ages 12 and over. Multiple retrospective studies have demonstrated a reduction in headache severity with antiepileptic drugs. More prospective studies are needed in children to assess efficacy and tolerability.

Data from several studies suggest that topiramate is effective in the preventive treatment of pediatric migraine, leading to its recent FDA approval. The effective dose in the pediatric population is not known, but a dose of 2 to 4 mg/kg/day is beneficial.

The preventive properties of valproate, levetiracetam, zonisamide, and gabapentin have also been examined, with few studies in children (see the online chapter).

**Antihistamines.** Cyproheptadine, an antihistamine with antiserotonergic properties, is commonly prescribed for pediatric migraine. It tends to be very well tolerated; its most significant side effects are sedation and weight gain, which specifically limit its tolerability in adolescents. Despite the lack of data, it is often used with target doses of 0.2 to 0.4 mg/kg/day and is considered a first-line option for children less than 6 years of age.

**Beta Blockers.** Propranolol and atenolol have been approved for the prevention of migraine in adults. Propranolol has long been used in children, but the results of this agent for preventing headache have been conflicting.

**Botulinum Toxin.** OnabotulinumtoxinA is effective for chronic migraine headaches in adults and was approved by the FDA in 2010. The prevalence of chronic migraines in children and adolescents, defined as at least 15 headache days/month for 3 consecutive months, is between 2% and 3%. The efficacy of OnabotulinumtoxinA in children and adolescents has begun to be evaluated.

**Nutraceuticals for Headache Prevention.** The use of dietary supplements, known as *nutraceuticals*, has become increasingly popular in the general population for the treatment of migraine and many other medical disorders and is often the preferred choice among parents of children and adolescents during discussions regarding preventive treatment. The decision to try nutraceuticals is based on the notion that they are often well tolerated, and families may view nutraceuticals as “natural” and may feel reluctant to start a conventional medication because of the concern for adverse effects. Also, conventional prophylactic medication may have failed for some patients as a result of ineffectiveness, toxic effects, or intolerable side effects. Furthermore, nutraceuticals are relatively inexpensive, and medical costs have become an increasing concern.

Some of the nutraceuticals that are used for headache prevention include riboflavin (vitamin B<sub>2</sub>), coenzyme Q10 (CoQ10), butterbur, *Petasites hybridus*, magnesium, and feverfew (see the online chapter).

## Nonpharmacologic Treatment

Patients with frequent headaches should be counseled on the importance of diet and lifestyle modification. Focus should include ensuring adequate sleep, staying hydrated, incorporating regular exercise, and maintaining a well-balanced diet. Cognitive behavioral therapy (CBT) and biofeedback-assisted relaxation training should be implemented early if headaches are disabling. These techniques are typically taught over multiple sessions, although they are also effective in a single session, and the patient is given a single recording for home use. For best results, patients must be motivated, because improvement could take several weeks. Implementation of CBT resulted in a significant reduction of headache days and migraine-related disability in pediatric patients (Powers et al., 2013). CBT has the potential of significant benefit, especially for overall improvement of mood and reduction of stress, without the concern of the negative side effects that often accompany pharmacologic treatments.

## SPECIFIC SECONDARY HEADACHE SYNDROMES

One of the keys to diagnosis of primary headaches is the lack of an identifiable etiology. When a secondary cause is suspected, appropriate investigation and treatment must be implemented. Confirmation of the diagnosis of a secondary headache can only be made after successful treatment of the underlying etiology. If treatment is not successful, further investigation is warranted.

Secondary headaches are headaches in which an underlying disorder initiates and perpetuates the headache. These headaches are less likely to be recurrent. When recurrent, it suggests that the underlying etiology has not been successfully managed or that the diagnosis is incorrect.

Principles for diagnosing a secondary headache include the following:

1. A known cause of the secondary headaches has been identified through history, laboratory testing, or neuroimaging.
2. A temporal and causal relationship exists between the identified disorder and the headache.
3. With implementation of effective treatment of the underlying etiology, the headache resolves or significantly improves.
4. Unless the secondary cause is episodic, the episodic headaches are typically primary.

Patients with primary headaches can also develop secondary headaches.

## Posttraumatic Headache

Headache following closed head injury (Chapter 102) or neck trauma in children and adolescents is one of the most common secondary headache syndromes, but has not been systematically studied (Kuczynski, Crawford, Bodell, Dewey, and Barlow, 2013). Epidemiologic data are not readily available. Headaches are common after mild traumatic brain injury or concussion and often occur with a constellation of physical, cognitive, emotional, and behavioral signs. The ICHD-3b classifies posttraumatic headaches as acute if lasting less than 3 months and persistent if lasting more than 3 months. This time period is consistent with ICHD-2 diagnostic criteria, although the term *persistent* has been adopted in place of *chronic*. Although the ICHD-3b criteria define posttraumatic headache as beginning within 7 days after injury to the head or after regaining consciousness, this 7-day cutoff is arbitrary, and some experts believe that headaches may develop after a longer interval (see the online chapter).

Acute posttraumatic headache must immediately raise concerns for traumatic brain injury, such as an intracranial

hematoma, subarachnoid hemorrhage, cerebral contusion, or skull fracture, and warrants neuroimaging, particularly if associated with alteration of consciousness, seizures, or a Glasgow Coma Scale score of less than 13. If focal neurologic symptoms or signs are present, evaluation for vascular injury (e.g., carotid dissection) may be indicated, and detection may require specific MRI sequences (magnetic resonance angiogram [MRA]). Cerebrospinal fluid (CSF) leaks following meningeal tears can lead to positional, or "ow-pressure, headaches.

Headaches developing after head trauma closely resemble primary headache disorders, most commonly TTH and migraine without aura, although some are referred to as "unclassifiable." Other headaches may resemble neuralgias such as occipital neuralgia, temporomandibular joint dysfunction, and, on rare occasions, cluster headache. Management should be relevant to the type of headache and focused on the clinical needs of the child. Referral for biobehavioral therapy for coping strategies may be necessary. As with primary headaches, adherence to treatment recommendations should be optimized.

Persistent posttraumatic headache may be part of a global postconcussive syndrome, with behavioral changes such as hyperactivity or hypoactivity, dizziness, tinnitus, vertigo, blurred vision, memory changes, sleep disturbance, irritability, and attentional disorders resembling attention deficit disorder (ADD)/attention deficit hyperactivity disorder (ADHD). The duration of symptoms is variable, with some patients having symptoms for more than 6 to 12 months.

Although headache is the most common symptom following concussion, there is a paucity of evidence regarding the safety and efficacy of headache treatments for posttraumatic headaches. These headaches can be difficult to treat, and management requires an appreciation of the degree of disability. There are no established guidelines for the treatment of posttraumatic headaches, and practices vary widely. There are currently no randomized controlled trials evaluating the efficacy of therapies for posttraumatic headaches in children or adults. Most proposed algorithms have been extrapolated from the primary headache literature, small uncontrolled trials, and expert opinion.

Similar to treating a child with a primary headache disorder, the goal of acute treatment should be a consistent response with minimum side effects and a rapid return to normal function. These treatments should be properly dosed and used as quickly as possible, while minimizing the potential for medication overuse. It should be incorporated into the child's life by providing the ability to receive these treatments in school or at home and without missing school or social activities. To avoid the development of medication-overuse headache (MOH), abortive medications should be used no more than 3 days per week. Triptans should be used fewer than nine times per month. From the characteristics of the headache, the clinician should make every effort to classify the headache type, because this may have treatment implications.

Patients with persistent posttraumatic headaches may require frequent analgesics, and although their use may be beneficial in the short term, rebound headaches are common and can complicate treatment and recovery. Because analgesics are commonly recommended, the risk exists that some susceptible patients will develop a medication-overuse pattern that causes a chronic headache syndrome. Several retrospective studies and case reports have addressed medication overuse as a potential cause of persistent posttraumatic headaches.

For persistent posttraumatic headaches, preventive medication may be indicated and typically includes those used for migraine. However, their efficacy has not been well studied.

## Idiopathic Intracranial Hypertension

Also known as pseudotumor cerebri, idiopathic intracranial hypertension (IIH) produces a global, daily, pounding headache and is an important consideration in the differential diagnosis of children presenting with a chronic daily headache. The incidence is 1 per 100,000, although the incidence in childhood is unknown. It appears to be more common in females and more common in obese individuals, although it does occur in males and in nonobese individuals. The pathogenesis of IIH is uncertain but may involve impairment of CSF reabsorption or CSF overproduction (see Chapter 105 and the online chapter).

For IIH headaches, there is a direct correspondence to increased intracranial pressure. The ICHD-3b establishes increased pressure as greater than 250 mm CSF measured by lumbar puncture performed in the lateral decubitus position and without sedative medications. The headache is typically relieved by reducing intracranial pressure. Typically, the pain is moderate and chronic and may be progressive. Headaches often resemble migraine or a tension-type headache. Physical activity, including the Valsalva maneuver and postural changes, can aggravate the pain. Neck stiffness and transient visual disturbances may be present.

Once an increase in intracranial pressure has been identified, other etiologies need to be investigated. IIH can be caused by multiple disorders, including endocrinopathies (e.g., hypothyroidism), Addison's disease, oral steroid use, pregnancy, medications (including tetracycline, sulfonamides, lithium, cyclosporine, and oral contraceptive agents), anemia, systemic lupus erythematosus, chronic sinopulmonary infection, and obesity, or may be idiopathic. In children, one should ask about vitamin A intoxication, either from excessive dietary intake or prescriptions, as in the case of adolescents seeking treatment for acne with retinoids.

Lumbar puncture not only provides critical diagnostic information, but also the relief of pressure usually provides a significant decrease in headache symptoms. The volume of CSF to be removed is controversial. Generally, removal of a sufficient volume to lower the pressure to about 200 mm H<sub>2</sub>O is beneficial and safe. Care must be taken to limit the risk of postlumbar puncture headache by keeping the patient recumbent for several hours following the procedure.

Acetazolamide can be used to lower CSF pressures, most likely as a result of a diuretic mechanism. Side effects are few but include paresthesias, polyuria, and sedation. The dose is typically 250 mg twice a day up to 1000 mg per day. There is an extended-release once-daily preparation available. Recovery is slow, over weeks or months. If obesity is a contributing factor, a weight-loss program is strongly recommended. If the visual symptoms are severe or progressive, or if there is visual compromise, ophthalmologic intervention may be necessary, with performance of an optic nerve sheath fenestration.

## Intracranial Hypotension

Headaches also can be caused by low CSF pressure (Chapter 105). The most typical example of this is headache following a lumbar puncture or other conditions that cause a tear in the dura mater, including penetrating trauma or cranial surgery. The typical clinical presentation is a headache that worsens with positional changes, especially upon standing, after a lumbar puncture. The cardinal clinical feature is orthostatic or positional headache, in which a severe, pounding, nauseating headache occurs immediately upon standing or sitting up from a reclined position. Importantly, symptoms resolve when the patient lies back down. Criteria include neck stiffness, tinnitus, hyperacusis, and photophobia. The CSF opening pressure is about 60 mm H<sub>2</sub>O in the sitting position. Although

the majority of headaches following a lumbar puncture resolve spontaneously, persistence of disabling symptoms may necessitate consideration of a "blood patch" or other technique to repair the source of the CSF leak; this may take 72 hours to be effective.

## Headache Secondary to a Brain Tumor

About two thirds of children with brain tumors will have headache as a presenting symptom. There is, however, no invariable profile for "brain tumor headache." A steady, gradual rise in intracranial pressure produces the chronic progressive pattern. On occasion, an anaplastic tumor or hemorrhage into tumor may cause an acute pattern. Several historic clues suggest space-occupying lesions, such as brain tumors, but such findings also may be present in other expanding masses, such as brain abscess, hematoma, or vascular anomalies. Headaches that awaken the child from sleep are a classic symptom of the dependent edema of intracranial lesions. Likewise, nocturnal or morning emesis, with or without headache, suggests increased intracranial pressure and is a particularly common symptom of tumors arising near the floor of the fourth ventricle. Head pain aggravated by exertion or the Valsalva maneuver suggests a mass lesion. In addition to headache, parents may note behavioral or mood changes, cognitive impairment, or declining school performance.

Accompanying symptoms may suggest localized disturbances of neurologic function. Ocular symptoms are common and include loss of vision (e.g., craniopharyngioma, optic pathway tumor) and diplopia (e.g., brainstem glioma, medulloblastoma). Disorders of coordination, such as truncal ataxia (e.g., medulloblastoma, ependymoma) or dysmetria (e.g., cerebellar astrocytoma), suggest posterior fossa tumors. The presence of seizures indicates cortical disturbances, often localized to the temporal lobes.

Key physical examination signs that indicate brain tumor include papilledema, abnormal eye movements, hemiparesis, ataxia (truncal or appendicular), and abnormal tendon reflexes.

## Chiari Malformation

Chiari malformations (type I) are among the most common incidental findings when performing MRI in children with headache, and they are a source of great controversy. Tonsillar ectopia of 5 mm or less is not considered pathologic. When symptomatic, children with Chiari I malformation may complain of occipital headache, neck pain or stiffness, arm weakness, and gait abnormalities. The headache may be aggravated by neck flexion or extension or the Valsalva maneuver. Basal skull abnormalities or scoliosis may be identified. In a retrospective MRI analysis of 49 children with Chiari I malformation, 57% of children were asymptomatic. Headache and neck pain were the most frequent complaints. Syringomyelia was detected in 14% of patients and skull-base abnormalities in 50%. The magnitude of tonsillar ectopia (5-23 mm) correlated with the severity score ( $p = 0.04$ ), but not with other clinical measures. Children with greater amounts of tonsillar ectopia on MRI are more likely to be symptomatic. Extreme care must be exercised before undertaking surgical decompression. MRI with CSF flow studies may help to determine whether suboccipital decompression is necessary.

## Metabolic Causes of Headache in Children

### MELAS

Mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS) constitute a mitochondrial disorder

characterized by migraine-like headaches, episodic hemiparesis, development regression/dementia, short stature, seizures, and cortical blindness. The initial presentation is seizures in 28% of patients, recurrent headache in 28%, gastrointestinal symptoms (emesis or anorexia) in 25%, limb weakness in 18%, short stature in 18%, and stroke in 17%. The age of onset is usually younger than 2 years in 8%, 2 to 5 years in 20%, 6 to 10 years in 31%, 11 to 20 years in 17%, 21 to 40 years in 23%, and over age 40 in only 1%.

Diagnosis requires stroke-like episodes, encephalopathy with seizures and/or dementia, mitochondrial myopathy (ragged red fibers on muscle biopsy), lactic acidosis, and clinical features such as recurrent vomiting. The disorder is caused by a point mutation in the mitochondrial DNA *MT-TL1* encoding tRNA<sup>Leu</sup>. With expanded genetic testing, the phenotype of MELAS is evolving (see Chapter 42).

## CADASIL

Cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is a mitochondrial disorder that usually affects young adults but on occasion can be seen in adolescents. It should be considered in adolescents with migraine with aura, in whom neuroimaging discloses subcortical infarcts and/or multifocal T2/fluid-attenuated inversion recovery (FLAIR) hyperintensities in the deep white matter. An autosomal-dominant family history of migraine, early stroke, and/or dementia may be present. The clinical spectrum is variable, but migraine headache occurs in more than one third of patients and may be the only manifestation. A recent case report described a 14-year-old girl with a 3-year history of episodic headaches, three episodes of right hemiparesis, persistent hypertension, negative family history, normal MRI, and a "Notch3" mutation. This report raises the possibility of screening for CADASIL in children with headaches and episodes of hemiplegia (hemiplegic migraine)

using skin biopsy and genetic testing for the Notch3 mutation, even when MRI is normal and family history is negative.

Breath-holding spells and reflex anoxic seizures are nonepileptic paroxysmal events. These events are benign, but can be frightening to parents and others observing an episode. It is important to differentiate these episodes from epileptic seizures so that the child is not inappropriately treated with antiepileptic medication.

Possibly the earliest report of breath-holding spells was published in 1737 by Nicholas Culpepper, who gave this description: "There is a disease ... in children from anger or grief, when the spirits are much stirred and run from the heart to the diaphragms forcibly, and hinder or stop the breath ... but when the passion ceaseth, this symptom ceaseth."

The clinical characteristics of breath-holding spells were well recognized and described in the pediatric literature in the 19th and early 20th centuries. More recent reports have provided a better understanding of the pathophysiology of these events.

## BREATH-HOLDING SPELLS

### Clinical Features

The term *breath holding* is a misnomer and implies that the child is voluntarily holding his or her breath in a prolonged inspiration. Breath-holding episodes actually occur during expiration and are involuntary. Breath-holding spells are not uncommon, with an incidence of 4.6% to 4.7%. The typical age of onset is between 6 and 18 months, although occasionally the onset may occur in the first few weeks of life. Fewer than 10% of children have an onset after 2 years of age. The frequency of episodes ranges from several times daily to once yearly. The spells are often spaced weeks to months apart at onset and increase in frequency to as many as several per day during the second year of life (Dimario, 2001). Breath-holding spells are classified by the color change manifested in the child during an event. Cyanotic episodes are more common than pallid episodes. In some instances, there are features of both cyanosis and pallor, and these are termed *mixed episodes*.

Cyanotic breath-holding spells are often precipitated by emotional stimuli, such as anger or frustration. The child typically cries vigorously, usually for less than 15 seconds, then becomes silent and holds the breath in expiration. The apnea is associated with the rapid onset of cyanosis. Some episodes may resolve at this point, but there may be a brief loss of consciousness and a period of limpness, followed by opisthotonic posturing. Recovery is usually within 1 minute, with the child having a few gasping respirations and then a return to regular breathing and consciousness.

Pallid breath-holding spells are usually provoked by sudden fright or pain. A fall with a minor injury to the head is frequently the precipitating event. An unexpected event or a surprise seems to play a role in triggering the spell. Sometimes the provoking event is not witnessed, and the child is found already in the midst of an episode. The child may gasp and cry, although it is usually for only a brief period of time. The child then becomes quiet, loses consciousness, and becomes pale. Limpness and diaphoresis are common accompaniments. Clonic movements of the extremities and

incontinence may occur with more severe and prolonged episodes. Cyanosis may occur during the episode but is much milder than with cyanotic breath-holding spells. The child typically regains consciousness in less than 1 minute but may sleep for several hours after the episode.

An association between behavior problems, emotional factors, and breath-holding spells has been discussed by many investigators. In the past, breath-holding spells were thought to occur in spoiled children or be a sign of a disturbed parent-child relationship. More recent studies of behavior in children with breath-holding spells compared with controls have found no differences in the behavioral profiles between the two groups, suggesting that breath-holding spells are nonvolitional and cannot be equated with a temperamentally difficult child.

Breath-holding spells generally decrease in frequency during the second year of life. By 4 years of age, 50% of children will no longer have episodes. Almost all will have stopped having episodes by age 7 to 8 years. Syncopal episodes occur in late childhood or adolescence in as many as 30% of patients with prior breath-holding spells.

Serious complications with breath-holding spells are exceedingly rare. There has been a report of a prolonged cardiac arrest in a patient with breath-holding spells. The few reported deaths may have been precipitated by aspiration or occurred in children who were at the severe end of the spectrum of breath-holders, often with structural abnormalities of the respiratory tract or complicated medical histories.

### Clinical Laboratory Tests

A detailed history of the event, including the precipitating circumstances, is essential in making the diagnosis of breath-holding spells. If the event was not witnessed from onset, important details may not be available. A video recording by the parents may be helpful in confirming the diagnosis. Usually, no laboratory tests are needed to make the diagnosis. An electroencephalogram (EEG) is usually not indicated, unless the convulsive activity after the breath holding is prolonged or the clinical description is incomplete and epileptic seizures cannot be definitively ruled out by historical features. If ocular compression is performed in patients with pallid breath-holding spells, there may be asystole on cardiac monitoring, and slowing or suppression of voltage on EEG (Lombroso and Lerman, 1967). Long QT syndrome is rare but should be considered as part of the differential diagnosis in a child with breath-holding spells. Patients with Long QT syndrome have episodes of loss of consciousness that may be induced by injury, fright, or excitement. An electrocardiogram should be considered in any patient with breath-holding spells.

### Pathophysiology

#### Cyanotic Spells

The pathophysiology of cyanotic breath-holding spells is complex and not completely understood. Cyanosis occurs

early in the episode, which is unusual during voluntary breath holding. In breath-holding spells, the breath is held in full expiration, which also is not typical with voluntary breath holding. An early study of a child during a cyanotic breath-holding episode with cinefluorography showed that the diaphragm was high, as would be seen in full expiration, and motionless during the period of apnea. Spasm of the glottis and respiratory muscles, with increased intrathoracic pressure, occurs during expiration. Increased intrathoracic pressure reduces cardiac output, causing a decrease in cerebral perfusion. Violent crying could lead to hypocapnia, which would also impair cerebral circulation.

Further evaluation of the prolonged expiratory mechanism in nine infants with cyanotic episodes that were usually triggered by noxious stimuli showed that the arterial oxygen saturation fell below 20 mm Hg within 20 seconds of initiation of the noxious stimuli. Loss of consciousness occurred after 30 seconds. Measurements of respiratory movements, airflow, and esophageal pressure, and, in some patients, microlaryngoscopy and chest fluoroscopy were obtained and documented no inspiratory flow during the period of apnea but continued expiratory muscle activity at low lung volumes with partial or complete glottic closure. No intracardiac shunt could be demonstrated. The rapid fall in arterial oxygen saturation was attributed to a lack of ventilation at a maximum expiratory position in the presence of a rapid circulation time. The authors hypothesized that central and peripheral neural respiratory control was functioning normally but was interfered with by a mechanical defect involving lung-volume maintenance. This defect could occur because of an excessively compliant rib cage, allowing alveolar collapse. This collapse, in turn, could lead to stretching of the airways and their stretch receptors, inappropriately simulating maximum lung volumes and thereby inhibiting further inspiration. Evaluations of prolonged expiratory apnea with krypton infusion scans demonstrated krypton outside the lung fields, without evidence of an intracardiac shunt, suggesting that there was intrapulmonary shunting that contributed to the rapid onset and severity of the hypoxemia.

The relation between breath-holding and chemosensitivity has also been investigated. Due to the difficulty of measuring chemosensitivity in toddlers, ventilatory responses to progressive hypercapnia and to progressive hypoxia were measured in subjects aged 11 to 50 who had a history of cyanotic breath-holding spells compared with a control group. The majority of persons with a history of cyanotic breath-holding spells had normal ventilatory responses. However, no one with a history of breath-holding spells had high normal responses to hypercapnia or hypoxia, as did some individuals in the control group. This study raised the possibility that ventilatory chemosensitivity may play a role in breath holding, but the ventilatory chemosensitivity may resolve with maturation.

The relation between breath-holding and cardiorespiratory control was studied in 71 infants with a history of breath-holding spells and age- and gender-matched controls. The median age of infants in the study was 14 weeks, which is younger than the typical age for onset of breath-holding episodes. The infants with breath-holding spells were significantly more often covered with sweat during sleep and wakefulness compared with control infants. One-night sleep studies were obtained in each infant. The infants with breath-holding spells had significantly less nonrapid eye movement (REM) stage III sleep, more indeterminate sleep, more nocturnal arousals, and more sleep-stage changes than the control infants. Airway obstructions during sleep occurred in 41 infants with a history of breath-holding, compared with six in the control group. The obstructions were generally short and not accompanied by significant bradycardia or oxygen

desaturation. The researchers concluded that there was a common underlying mechanism resulting in airway obstruction during breath-holding spells and sleep, which possibly involved the autonomic nervous system (ANS) because the ANS controls the patency of the upper airways. Another study of polysomnography in 14 children with cyanotic breath-holding spells showed an abnormal respiratory index in all, and ear, nose, and throat (ENT) examination showed upper airway narrowing. Adenotonsillectomy in this group of patients resulted in marked subsequent improvement in sleep-disordered breathing and resolution of their breath-holding spells.

Polysomnography has also been used to evaluate REM sleep in children with breath-holding spells compared with age-matched controls. The children with breath-holding spells had a significant decrease in ocular activity during REM sleep, especially during the last third of the night, compared with the controls. A relative elevation of cholinergic tone, compared with monoaminergic tone, is considered to be involved in the physiologic increase of REM sleep in the later cycles of the night. The vestibular nucleus and the medioventral caudal pons are believed to be involved in bursts of eye movements during REM sleep. The changes may indicate a functional disturbance in the pons of children with breath-holding spells. The study also suggests that the ANS is involved because of the more pronounced decrease in eye movement in the later cycles of the night, which are regulated by the ANS. Brainstem auditory evoked potentials in children with breath-holding spells have shown that the III-V and I-V interpeak latencies were significantly prolonged compared with controls also suggesting a disturbance in the brainstem.

Noninvasive evaluation of the ANS function in children with cyanotic breath-holding spells has been reported. Compared with controls, the breath holders had a significantly greater increase in pulse rate at 15 seconds of standing after rising from the supine position. Breath-holders also had a greater decrease in diastolic blood pressure without an increase in systolic blood pressure after standing from the supine position. These results suggest that in children with cyanotic breath-holding spells there is parasympathetic excess and subtle sympathetic excess, which mediates vascular resistance, arterial distensibility, and blood flow through the lungs. This sympathetic overactivity could cause the intrapulmonary shunting and subsequent hypoxemia.

There are reports of increased QT dispersion and cardiac repolarization changes in children with breath-holding spells. The significance of these findings is unclear but may also be a reflection of autonomic dysfunction.

### Pallid Spells

Excessive vagal tone leading to cerebral hypoperfusion is the underlying cause of pallid breath-holding spells. Observation of children during a typical episode reveals marked bradycardia or asystole. Ocular compression that triggers the oculocardiac reflex has been used to evaluate vagal tone in children with breath-holding. This maneuver results in transmission of afferent signals to the brainstem via the ophthalmic division of the trigeminal nerve and efferent parasympathetic signals via the vagus nerve. In 61% to 78% of children with pallid breath-holding spells, ocular compression resulted in an asystole of 2 seconds or longer, compared with 23% to 26% of children with cyanotic breath-holding spells (Lombroso and Lerman, 1967). Episodes that occurred spontaneously during cardiac monitoring were also associated with asystole. The asystole during spontaneous episodes is believed to be vagally mediated. When asystole is prolonged, a reflex anoxic seizure may eventually occur.

The role of underlying autonomic dysfunction in children with pallid breath-holding spells has been investigated in a small number of patients. Measurements of mean arterial pressures, pulse rates, electrocardiograms, and plasma norepinephrine levels were obtained in patients and controls during changes in position. The breath-holders had a statistically significant decrease in mean arterial pressure and an unsustained increase in pulse rate during the prone to standing maneuver. One child with pallid breath-holding spells had a plasma norepinephrine level that was 60% lower than the mean for both groups. Further evaluation of autonomic function was performed in children with either pallid or cyanotic breath-holding spells. Respiratory sinus arrhythmia, which is an established measure of vagal tone, was measured. There were no significant differences between controls and children with cyanotic breath-holding spells. The children with pallid spells, however, had a marked difference in respiratory sinus dysrhythmia, with less variability compared with controls and those with cyanotic episodes (DiMario et al., 1998). A comparative study of 24-hour Holter monitoring in children with severe breath-holding spells showed a lower mean heart rate and lower mean minimal heart rate compared with controls. Time domain measures of heart rate variability also showed significant changes in patients compared with controls. These studies suggest that there may be an underlying parasympathetic dysregulation in children with pallid breath-holding spells.

The role of anemia in the pathophysiology of breath-holding spells has been studied. Twenty-three percent of 102 children with breath-holding had a hemoglobin level less than 8 g/100 mL, compared with 7% and 2.6% in two control groups. Some studies did not find any significant difference in hemoglobin levels in the breath-holding group, compared with the control group. Asystole during breath-holding spells was prolonged in children with coexisting iron deficiency. There are reports of children with breath-holding spells and concomitant anemia, who had resolution of their spells with the correction of the associated anemia (Mocan et al., 1999; Orii et al., 2002). A child with pallid breath-holding spells associated with transient erythroblastopenia of childhood has been reported. The spells resolved after treatment with iron but before the anemia resolved. The effect of iron therapy on breath-holding spells has been investigated. Treatment and placebo groups were similar with respect to gender, age at onset, and frequency and type of spells, and had similar blood indices, including packed cell volume, mean corpuscular volume, saturation index, total iron binding capacity, and serum iron. At the end of the treatment period, 51.5% of the children treated with ferrous sulfate had complete remission of spells, and an additional 36.4% experienced a greater than 50% reduction. No children in the placebo group had total remission of spells, and only 5.9% had a greater than 50% reduction. As expected, the treatment group experienced significant improvement in the hemoglobin level and total iron-binding capacity. However, some children who were not iron-deficient had a favorable response to iron therapy, and some who were iron-deficient did not respond. Another study suggests that checking serum soluble transferrin receptor levels in children with breath-holding spells may be helpful in assessing iron status. An increase in serum soluble transferrin receptor levels is an early change seen in iron deficiency before anemia develops. Iron deficiency may play a role in the pathophysiology of breath-holding spells because iron is important for catecholamine metabolism and neurotransmitter function.

Other small studies have evaluated the role of the oxidant and antioxidant systems in the pathophysiology of breath-holding. Malondialdehyde, which is an indicator of free radical generation, was significantly higher in children with

breath-holding spells than controls. Glutathione peroxidase and superoxide dismutase, which remove oxygen radicals, and selenium, which acts as a cofactor for glutathione, were significantly lower in the patients.

## Genetics

In children with breath-holding spells, there is a positive family history of similar episodes in 23% to 38%, suggesting a possible genetic influence (Lombroso and Lerman, 1967). An evaluation of family pedigrees found that 27% of 114 proband parents and 21% of proband siblings had a history of breath-holding. Several families had some members with pallid spells and other members with cyanotic spells. The male to female ratio was 1:1.2 and the risk of transmission from parent to child was 50:50. There were seven instances of father-to-son transmission, ruling out an X-linked inheritance. Using a regression model for pedigree analysis, the inheritance pattern was consistent with an autosomal-dominant pattern with reduced penetrance.

## Treatment

The most important aspect of treatment of breath-holding spells is to reassure the family of the benign nature of the spells. It is important to emphasize that the episodes do not lead to intellectual disability or epilepsy. Although parents are inclined to pick up a child who is having a breath-holding spell, they should be instructed to place the child in a lateral recumbent position so as not to prolong the period of possible cerebral anoxia. Initiation of cardiopulmonary resuscitation should be avoided. Although anger and frustration are often precipitants for breath-holding spells, parents should be encouraged not to alter customary discipline for fear of triggering an episode. Parenting a child with breath-holding spells has been associated with more maternal stress than parenting a child with a convulsive seizure disorder, and parents of children with breath-holding spells are at risk for developing dysfunctional parenting behaviors. Referral of parents to professionals to help with stress and parenting skills should be considered in cases in which parental stress becomes evident (Mattie-Luksic et al., 2000).

Treatment with iron therapy should be initiated in any child who has iron deficiency anemia and should be considered in any child with breath-holding spells because children without anemia may have improvement in their breath-holding spells. The convulsive movements seen during breath-holding spells are reflex anoxic seizures, which are not epileptic and do not require antiepileptic treatment. There have been a few patients who have been reported to have prolonged seizures and even status epilepticus from breath-holding spells (Kuhle et al., 2000). It is presumed that these patients have a lowered seizure threshold and that hypoxia-ischemia triggered the seizures. These episodes have been termed anoxic-epileptic seizures. Treatment with antiepileptic medication may stop the seizure activity but not the breath-holding spells. Atropine (0.01 mg/kg 2 or 3 times daily) is effective for pallid breath-holding spells, but its use is rarely clinically warranted. Piracetam, which has a chemical structure similar to gamma-aminobutyric acid (GABA), has been used to treat children with breath-holding spells. Several studies using doses ranging from 40 mg/kg/day to 100 mg/kg/day have shown significant decreases or complete resolution of episodes compared with controls (Donma, 1998). Piracetam has not received approval from the U.S. Food and Drug Administration and is designated only as an orphan drug for use in refractory myoclonus. Levetiracetam, which is structurally similar to piracetam, did not affect the occurrence of breath-holding spells in a 10

month old child, but after treatment was initiated, the child no longer had asystole or unconsciousness with the episodes. In a retrospective study of six patients treated with fluoxetine, three had resolution of symptoms, and two had decreased frequency of episodes. A toddler with severe pallid breath-holding spells was treated with a combination of glycopyrrolate and theophylline and no longer had loss of consciousness but continued to have breath-holding spells.

## REFLEX ANOXIC SEIZURES

Reflex anoxic seizures are nonepileptic events resulting from cardiac asystole of vagal origin. Pain and surprise are common provoking factors for the events. Reflex anoxic seizures may occur with pallid breath-holding spells but also have been reported with minor blows to the occiput, expelling hard stools past an anal fissure, venipuncture, intramuscular injections, and seeing an intravenous scalp drip. Nonepileptic anoxic seizures may also occur after syncope, cyanotic breath-holding spells, or any event that results in a sudden reduction in cerebral perfusion or hypoxia.

### Clinical Features

Reflex anoxic seizures occur a few seconds after the provocation and are characterized by loss of muscle tone initially and later by tonic posturing. There may be opisthotonic posturing in some patients. A few jerks at the onset and end of an anoxic seizure may occur and probably represent myoclonic phenomena. A snoring type of inspiration or snort occurring close to the restoration of the cardiac rhythm is often noted. Urinary incontinence happens in approximately 10% of children with anoxic seizures, with bowel incontinence occurring less commonly. Other less common features include adverse head movements, limb quivering or twitching, agitation or fear, vomiting, and tongue biting. The color change seen with an anoxic seizure may be cyanosis or pallor, depending on the mechanism producing loss of consciousness. The duration of unconsciousness is almost always less than 1 minute. Most patients experience a rapid recovery of consciousness, but some will be dazed or disoriented for a short period. Some will be drowsy after an episode and may sleep. Occasionally, patients will have prolonged seizure activity after syncopal spells. These events, termed anoxic-epileptic seizures, are epileptic seizures triggered by hypoxia in patients with a lowered seizure threshold. A positive family history of epilepsy may make some children more prone to anoxic-epileptic seizures (Horrocks et al., 2005).

### Pathophysiology

The mechanism of reflex anoxic seizures has been studied by using ocular compression with EEG and cardiac monitoring. Ocular compression induced asystole in susceptible patients. If asystole lasted 3 to 6 seconds, there were no clinical symptoms and the EEG demonstrated only desynchronization. When asystole lasted 7 to 13 seconds, slow waves appeared and were usually associated with altered consciousness. If asystole was prolonged for 14 seconds or more, there were often myoclonic jerks or tonic posturing. The EEG during this time reveals no electrocerebral activity. With return of cardiac activity, there was again high-voltage slow-wave activity on the EEG with return of normal activity over 20 to 30 seconds. At no time during EEG monitoring were epileptiform discharges present. Some patients have had spontaneous episodes or episodes triggered by other stimuli, such as venipuncture during EEG and cardiac monitoring, and have demonstrated similar changes to those seen with ocular compression. Ocular

compression increases vagal tone, with the afferent pathway involving fibers from the trigeminal nerve originating from the cornea, iris, and eyelids. In contrast, episodes induced by exteroceptive stimulation, such as pain and emotion, have afferent fibers in various sensory pathways. In both situations, the vagal reflex centers are located in the brainstem in the nucleus ambiguus. The efferent pathway involves the cardio-inhibitory fibers of the vagus nerve that depresses heart rate.

### Clinical Laboratory Tests

Diagnosis of reflex anoxic seizures is usually made by obtaining a history of the episode. Details about the precipitating circumstances and onset are essential. Parents may state that their child had a seizure, and a careful description of the movements and posture, length of the episode, and recovery period will be helpful. Usually, no laboratory tests are needed, although consideration should be given to obtaining an electrocardiogram to evaluate for a cardiac cause if the episodes are not typical. Rarely is it necessary to obtain an EEG. If there are atypical clinical features and an EEG is performed, ocular compression may be helpful in confirming the clinical diagnosis.

### Treatment

Treatment of reflex anoxic seizures focuses on explaining the nature of the event to the parents and reassuring them that the episodes are not epileptic seizures and do not need treatment with antiepileptic medication. In more severe cases, atropine, theophylline, and transdermal scopolamine have been helpful. Cardiac pacemaker implantation has also been useful in the rare patient with severe recurrent episodes (Sartori et al., 2015). Children with reflex anoxic seizures are at risk of bradycardia during surgical procedures, and modifications in the anesthesia protocol may be warranted.

Paroxysmal disorders, including epilepsy and syncope, represent one of the most common neurologic problems in the pediatric population. However, autonomic disorders like postural orthostatic tachycardia syndrome are only now becoming recognized in increasing numbers in children and adolescents. Their disease characteristics, diagnostic criteria, and therapies are still evolving and remain largely undefined.

## SYNCOPE

Syncope is defined as the temporary loss of consciousness and postural tone resulting from transient and diffuse cerebral hypoperfusion, followed by spontaneous recovery with no neurologic sequelae. In the young patient, syncope often results from a fall in systolic pressure lower than 70 mm Hg or a mean arterial pressure of 30 to 40 mm Hg. The event is typically preceded by a prodrome lasting several seconds to 1 to 2 minutes, with distinctive premonitory features such as nausea, epigastric discomfort, blurred or tunnel vision, muffled hearing, dizziness, lightheadedness, diaphoresis, hyperventilation, palpitations, pallor, cold and clammy skin, and weakness. Although syncope is commonly a benign self-limiting event, it may rarely be the first warning sign of a serious underlying cardiac or noncardiac disease. Furthermore, the term "syncope" may have different meanings to different people; therefore specific questions should be asked to help differentiate cardiac from neurologic, psychogenic, and metabolic conditions.

## Epidemiology

Syncope is a common clinical problem affecting 15% to 25% of children and adolescents. Its true incidence, however, remains unknown. According to Sheldon and colleagues, the most common age for a child's first vasovagal syncopal episode is approximately 13 years. The recurrence rate of syncope ranges from 33% to 51% when patients are followed up to 5 years.

## Etiology

Syncope may result from cardiovascular or neurologic causes (cardiovascular-mediated or neurally mediated syncope). Each of these categories accounts for about 50% of adult syncope, but, in children, cardiovascular-mediated syncope is less frequent than it is in adults. The differential diagnosis of pediatric syncope is given in Box 86-1.

## Cardiovascular-Mediated Syncope

Cardiovascular-mediated syncope has a higher mortality and a higher incidence of sudden death than neurally mediated syncope. It is therefore imperative to distinguish syncope from seizures and to triage patients with syncope due to malignant cardiac causes for urgent and appropriate investigations and management. Risk factors that suggest structural or

conduction heart defects are given in Box 86-2. Cardiovascular causes of syncope in children are given in Box 86-3.

## Neurocardiogenic Syncope

Neurocardiogenic syncope, previously known as vasodepressor, vasovagal, or neurally mediated syncope, is the most common cause of syncope and also the type most commonly confused with epilepsy. The history that suggests this type of benign syncope includes triggers such as postural changes, prolonged standing or sitting, obnoxious stimuli (anger, pain, sight of blood), and a positive family history.

## Clinical Features

The patient's history, physical examination, and electrocardiography (ECG) have a combined diagnostic yield of about 50%. A prodromal phase of presyncope consists of lightheadedness, blurred vision, epigastric discomfort, nausea, pallor, or diaphoresis. When present, these clinical features help to differentiate syncope from epilepsy. A detailed history usually reveals contributory environmental factors before the loss of consciousness and postural tone. These environmental factors include upright posture, prolonged standing, change in posture (orthostasis), crowding, heat, fatigue, hunger, or a concurrent illness. Emotional or stress factors, such as venipuncture, public speaking, "fight-or-flight" situations, pain, and fear, are also commonly identified (Driscoll et al., 1997). The loss of consciousness is usually brief, lasting from a few seconds to 1 to 2 minutes, followed by rapid spontaneous recovery without neurologic deficits. During the ictus the patient may have tonic posturing, myoclonic jerking, or a brief clonic seizure rarely associated with incontinence. The postictal period may be accompanied by persistent nausea, pallor, diaphoresis, and a generally "washed-out" appearance. Complete recovery usually evolves in less than an hour.

Distinguishing between neurocardiogenic syncope and seizure is the most common clinical dilemma and a frequent source of diagnostic error. In distinguishing patients with syncope due to cardiac causes, a history or physical signs of cardiac disease can be 95% sensitive for a cardiac etiology. Patients with pseudosyncope and pseudoseizures typically use the events consciously or unconsciously to avoid an unpleasant emotional situation. Most of these patients are young females. A very high number of events, episodes without injury, and florid symptomatology are typical. Furthermore, in these patients, recovery after a syncopal event is often prolonged (10 to 30 minutes), despite a supine posture. In true syncope, consciousness returns within 1 minute of lying down, and unconsciousness for more than 5 minutes is rare.

The evaluation of syncope may therefore result in unnecessary and costly investigations. A complete evaluation would include neuroimaging studies, electroencephalography (EEG), ECG, echocardiography, Holter monitoring, and selected hematologic and metabolic testing. Despite extensive

investigations, more than 40% of patients with recurrent syncope do not have a specific diagnosis.

## Pathophysiology

There is no consensus concerning the mechanisms underlying the vasovagal reaction, but several theories have been proposed (Grubb and Kosinski, 1996). The ventricular theory (Fig. 86-1) proposes that, among predisposed individuals who experience recurrent syncope, excess peripheral venous pooling on prolonged standing results in diminished venous return. Decreased cardiac ventricular filling activates mechanoreceptors located mainly in the inferoposterior wall of the left ventricle, which send afferent impulses via C-fibers to the dorsal nucleus of the vagus. Arterial baroreceptors and carotid sinus afferent activation may also contribute to the complex pathophysiology of syncope. These inhibitory cardiac and arterial receptors mediate increased parasympathetic activity, and inhibit sympathetic activity that results in bradycardia, vasodilatation, and hypotension (Bezold-Jarisch reflex) (Shen and Gersh, 1993). In individuals susceptible to recurrent syncope, a “paradoxical” reflex bradycardia and peripheral vascular dilatation occur (Grubb and Kosinski, 1996). The previous emphasis on parasympathetic (vagal) output is shifting to sympathetic withdrawal as the main mechanism responsible for the bradycardia or asystole (cardioinhibitory response) and hypotension (vasodepressor response) that accompany neurocardiogenic syncope. Although parasympathetic-mediated

bradycardia remains a contributory factor in syncope, the responsible phenomena are vasodilatation and hypotension.

## Diagnostic Evaluation

The patient history is the cornerstone on which the diagnosis of syncope is made. Important historical details to take from patients are given in Box 86-4. On clinical examination, blood pressure and heart rate should be taken in the supine and upright positions, noting any orthostatic hypotension with or without an increase in heart rate. Special attention should be paid to detecting cardiac anomalies. An ECG should be obtained on all patients who present with syncope, especially if it is recurrent or occurs with exercise. All patients with recurrent syncope, family history of syncope, or sudden unexplained death should be referred to cardiology for further evaluation. This may include echocardiography and a Holter or event monitor.

## Tilt-Table Testing

Until the mid-1980s, the diagnosis of neurocardiogenic syncope was made primarily by a careful and detailed patient and family history, the physical examination, and an ECG. Tilt-table testing as a potential diagnostic tool for neurocardiogenic syncope was introduced only in 1986 after the groundbreaking report by Kenny and associates. A number of reports have since emerged, attesting to the utility of the test in reproducing syncopal episodes in patients who are predisposed to neurocardiogenic hypotension and bradycardia.

Despite criticisms, the tilt-table test still continues to enjoy popularity as a noninvasive and physiologically appropriate neurophysiologic test for the diagnosis of neurocardiogenic syncope.

The test is done by positioning the patient head upright at an angle of 60 to 80 degrees for 10 to 60 minutes on a tilt table with a supporting footboard. A tilt-table test result is positive when the symptoms of syncope or presyncope are reproduced. To standardize the test, the duration of head-up tilting has been increased to 45 minutes or 2 standard deviations (SD) of the mean time required to reproduce syncope.

Experience with tilt-table test among pediatric populations is limited. Of note, the tilt-table test has been used in children as young as 3 years of age.

In addition to heart rate and blood pressure monitoring during tilt-table testing, concomitant EEG recording may be used to differentiate anoxic from epileptic seizures. More controlled studies and standardization of degree and duration of tilting are necessary to validate the tilt-table test as a safe, practical, and useful diagnostic tool for neurocardiogenic syncope in children.

## Treatment

Once a diagnosis of neurocardiogenic syncope is confirmed, treatment requires counseling of the patient and his or her parents. The benign nature of these events should be explained to allay concerns about epilepsy or sudden death. Most patients presenting after a single uncomplicated syncopal event require simple reassurance, education about the disease, and advice on recognizing prodromal symptoms and how to avoid provocative situations—in particular, prolonged standing, sudden postural changes, dehydration, and irregular meal times. If a prodromal phase is consistently present, the patient may be taught to recline or sit to avoid injury from a fall. Supplemental fluids and electrolytes are usually beneficial; up to 2000 to 3000 mls per day are recommended for adolescents. Patients should be instructed to increase dietary salt,

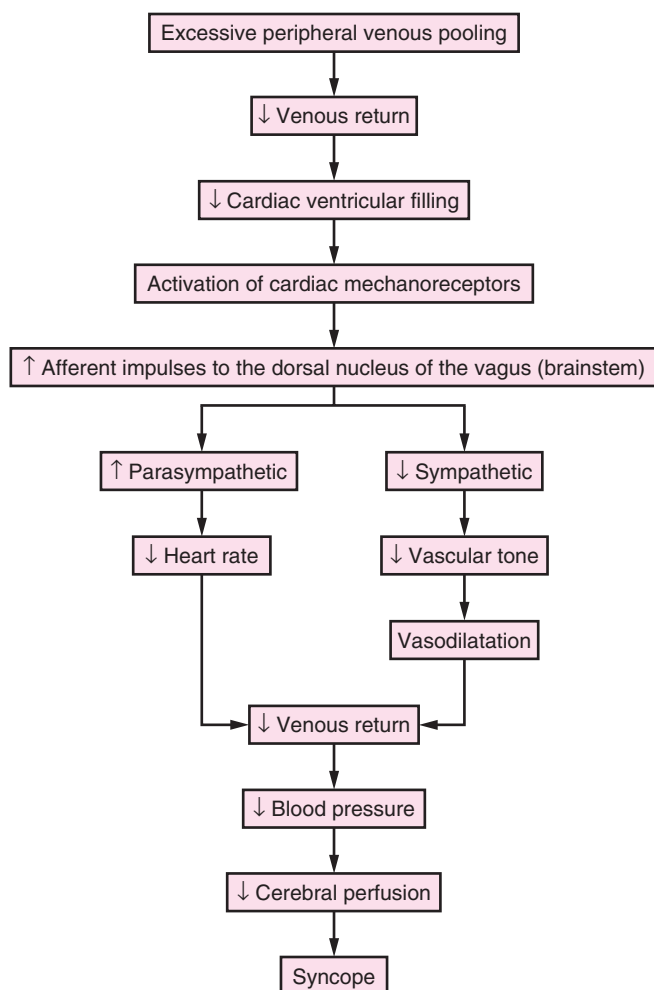

Figure 86-1. The pathophysiology of syncope.

**BOX 86-6** Medications for Treatment of Neurocardiogenic Syncope\*\***BETA-ADRENERGIC BLOCKERS**

- Atenolol 1–2 mg/kg/day
- Metoprolol 1–2 mg/kg/day
- Propranolol 0.5–4 mg/kg/day
- Nadolol

**ANTICHOLINERGICS**

- Disopyramide 10–15 mg/kg/day
- Hyoscine
- Propantheline
- Scopolamine

**ALPHA-ADRENERGIC AGONISTS**

- Midodrine 5–10 mg tid
- Methyphenidate 5–10 mg use three times a day
- Ephedrine
- Pseudoephedrine 60 mg—use two times a day

**SEROTONIN RECEPTOR REUPTAKE INHIBITORS**

- Fluoxetine 10–20 mg/day
- Sertraline 25–50 mg/day

**MINERALOCORTICIDS**

- Fludrocortisone 0.1–0.3 mg/day

\*\*Pediatric doses are given for those medications used in children for whom dosages have been recommended.

(Data from Grubb and Kosinski, 1996; Lazarus and Mauro, 1996; Raviele, et al., 1996; Sra, et al., 1997.)

either as salt tablets up to 10 g per day or the liberal use of salt with meals (Box 86-5).

If, despite these conservative measures, the syncopal episodes become refractory, pharmacologic therapy may be tried. Favorable but not consistent response to treatment has been reported with  $\beta$ -adrenergic receptor antagonists,  $\alpha$ -adrenergic receptor agonists, anticholinergic agents, theophylline, serotonin reuptake inhibitors, and mineralocorticosteroids (Box 86-6). Beta blockers, fludrocortisone, and midodrine, an  $\alpha$ -adrenergic agonist, are often prescribed in children, but none of these agents has shown a consistent therapeutic benefit in clinical trials. Some authorities currently recommend low-dose midodrine as a promising first-line therapy for vasovagal syncope in children (Stewart, 2006). When using fludrocortisone, combine with increased salt intake for an optimal effect.

**Prognosis**

The prognosis for recovery is excellent in neurocardiogenic syncope. Most patients show spontaneous resolution of their syncope and presyncope within the first year after onset; 5% to 10% will, however, continue to show symptoms over an extended period of time, often up to 5 years.

**Convulsive Syncope**

A brief tonic or, rarely, a clonic seizure may occasionally accompany syncope. Most convulsions consisted of tonic spasms (65%), characterized by eye rolling, nuchal rigidity, arm flexion, and clenched fists, followed usually by prompt recovery. Other types of convulsions were myoclonic (23%), clonic (6%), and tonic-clonic (6%). Convulsive syncope results from cerebral ischemia and is not indicative of an epileptic predisposition. The EEG reveals diffuse slowing,

followed by loss of electrocerebral activity; epileptiform activity is absent. Rarely, an epileptic seizure is triggered by syncope, and in such cases, the EEG reveals epileptiform activity.

**Reflex Syncope**

Syncope that is triggered by specific factors or events is known as reflex or situational syncope. The most common of these among infants and children is breath-holding spells. These are discussed in greater detail in a chapter elsewhere in this book. Another related but distinctive type of reflex syncope—pallid breath-holding spells or pallid infantile syncope—is frequently confused with breath-holding spells. A simple and more appropriate designation for this type of paroxysm is reflex syncope.

In reflex syncope, the antecedent event is minor trauma before loss of postural tone and consciousness. The rapid or immediate onset of syncope after minor trauma or other unexpected painful stimuli differentiates reflex syncope from breath-holding spells. There is general agreement that reflex syncope attacks do not represent epileptic seizures, but the mechanism responsible is less clear. Some refer to these events as reflex anoxic seizures.

**Situational Syncope**

Other triggering factors associated with syncope include cough, deglutition (cold liquids), defecation, diving, micturition, sneezing, trumpet playing, weight lifting, hair grooming, and the Valsalva maneuver. These events are more common in adults than in children and are referred to as situational syncope. Hair-grooming syncope is an uncommon type of situational syncope among adolescent females; hair pulling or scalp stimulation activates the trigeminal nerve and the syncope is often followed by a brief seizure activity.

**Hyperventilation Syncope**

If the syncope is preceded by paresthesias, lip tingling, and anxiety or panic, consider hyperventilation as the cause. Loss of postural tone and consciousness during hyperventilation is thought to result from cerebral vasoconstriction induced by hypocapnia. This type of syncope is discussed in more detail elsewhere in the book.

**Suffocation or Strangulation Syncope**

Meadow syndrome (Munchausen by proxy) is a rarely suspected cause of syncope. A caretaker induces loss of consciousness by obstructing the infant's airway using a pillow or by pressing the infant's face against the caretaker's trunk. In other cases, compression of the neck by strangulation results in cerebral hypoxia and, after repeated attempts, brain damage.

**Metabolic and Drug-Induced Syncope**

When syncopal episodes begin with a slow onset and gradual recovery, consider a toxic or metabolic cause, such as hypoglycemia, alcohol, or drugs (illicit or prescribed). Among the medications that can cause syncope are those that induce ventricular tachycardia or cause hypotension. Cardiovascular medications (vasodilators and antiarrhythmics), psychotropics, diuretics, and glucose-controlling medications are the most common drugs associated with syncope. Alcohol and illicit drugs (cocaine and marijuana) can cause syncope by several mechanisms, including exacerbation of a supraventricular or ventricular tachyarrhythmia. Drug-induced syncope is common among the elderly but rare among children.

However, illicit drug use is increasing significantly in the younger age group. Urine and plasma toxicology screens often provide clues to this diagnosis.

## Psychogenic Syncope

One of the most important causes of syncope in pediatric patients, in particular adolescents, is psychogenic syncope. Several features help distinguish psychogenic syncope from neurocardiogenic syncope (Benbadis and Chichkova, 2006):

1. Episodes are extremely frequent (sometimes several episodes per day).
2. The episodes are usually not associated with injury and lack any of the usual precipitating or triggering factors.
3. Patients experience onset of syncope in the supine position.
4. Patients fail to regain consciousness rapidly after a syncopal event (occasionally taking as long as several hours), during which time there are no cardiovascular or neurologic abnormalities, and resumption of the supine posture does not terminate the event.
5. Finally, patients manifest remarkable indifference to their syncope. During tilt-table testing, these patients may suddenly faint without any changes in their heart rate and blood pressure.

A detailed psychosocial history may provide clues about the possible mechanisms involved. Many of these individuals turn out to have conversion reactions, most frequently secondary to sexual abuse. A useful clinical maneuver in the unresponsive patient whose eyes are closed is to touch the eyelashes gently. This touch elicits a blink reflex in the conscious patient and alerts the examiner to the underlying psychopathology. Appropriate referral to a behavioral specialist or pediatric psychiatrist should be made for further evaluation and management.

## POSTURAL ORTHOSTATIC TACHYCARDIA SYNDROME

### Introduction

Of several autonomic disorders in children the most intriguing is postural orthostatic tachycardia syndrome (POTS), a disorder of unknown etiology in which patients exhibit orthostatic intolerance (OI) associated with significant tachycardia (Moodley, 2013). OI is a constellation of symptoms and signs provoked by standing upright and relieved by recumbence. Symptoms of OI included dizziness, lightheadedness, near syncope, syncope, headache, nausea, vomiting, blurred vision or transient “blackout” or “whiteout” of vision, diminished concentration, hyperpnea, tiredness, and leg weakness (Box 86-4). Symptoms of sympathetic activation include palpitations, chest pain, vasomotor skin changes and warm feeling, tremulousness, increased sweating, anxiety, and occasional sympathetic or autonomic storms.

POTS is one of the most common manifestations of OI and is now being increasingly recognized in children and adolescents. According to current criteria for adults, POTS consists of symptoms of chronic OI and sustained increase in heart rate (HR) of 30 beats per minute (bpm) or more, or an absolute HR of 120 bpm or more, or both within 10 minutes of active standing or head-up tilt. The diagnostic criteria for orthostatic intolerance and POTS in adults are not appropriate for children and adolescents, and new criteria for these disorders in this age group have recently been proposed. A heart rate increment of 40 bpm or more is now considered the

required increment for a diagnosis of POTS in children and adolescents (Singer et al., 2012).

Patients with POTS occasionally faint, but unlike OI from autonomic failure, significant orthostatic hypotension is unusual. In fact the blood pressure in POTS may actually increase upon standing secondary to a hyperadrenergic response.

POTS is a multisystem disorder with heterogeneous clinical features and pathophysiology that can be severe and quite disabling with significant effect on the daily quality of life; patients suffer significant functional impairment, yet many of these patients are misdiagnosed as having psychiatric disorders like severe anxiety, panic disorder or depression.

Although POTS has been reported in adults more than a century ago, the condition is rarely reported in children. The first report of POTS in adolescents was in 1999 by Stewart and associates; currently, it affects millions of Americans, particularly young women.

## Clinical Features

Patients are typically female with a 5:1 female to male ratio and the vast majority of the patients are Caucasian. POTS is relatively uncommon in preadolescent children and more typically affects females between the ages of 15 to 50 and therefore roughly span the ages from menarche to menopause.

Patients with POTS experience chronic and daily symptoms of OI and sympathetic overactivation. These symptoms are commonly exacerbated by heat and exercise. In addition they may experience a myriad of other somatic symptoms including migraine, abdominal pain, cognitive dysfunction, fatigue, sleep disorders, weight loss, and poor exercise tolerance. Moreover, associated anxiety, panic attacks, depression, and other psychiatric disorders add to the complexity of this syndrome and contribute to the disability and poor quality of life in these patients (Jarjour, 2013).

The prevalence of POTS is unknown. In adults, it is estimated to be at least 170 in 100,000, but there are no prevalence data for children.

Early studies suggested that approximately 50% of pediatric patients with POTS have an antecedent illness typically a virus such as infectious mononucleosis, rickettsia, trauma, surgery, or extreme physical activity (Johnson et al., 2010). How these triggers affect the autonomic nervous system is unclear. Many children have severe gastrointestinal dysfunction and chronic debilitating fatigue. Patients complain of poor exercise tolerance and low energy level even at rest, typical of patients who are deconditioned such as in patients who have had prolonged bed rest (Low et al., 2009).

## Pathophysiology

POTS represent a syndrome rather than a single disease entity in which no etiology is found despite exhaustive diagnostic testing. Common to all its variants is a final physiologic pathway involving excessively reduced venous return to the heart when in the upright position. The related symptoms of POTS are thought to be secondary to excessive central hypovolemia, and the signature tachycardia may therefore result from related reflex parasympathetic withdrawal and sympathetic activation. The chest pain reported by some patients with POTS and the electrocardiographic wave changes sometimes seen may be secondary to cardiac sympathetic overactivity.

Furthermore factors that reduce compensatory response to decreased thoracic blood volume such as dehydration and hemorrhage can simulate and exacerbate symptoms of POTS.

Additional pathophysiological mechanisms in POTS include defective “skeletal muscle pump,” especially in the legs and buttocks. Ambulation is therefore always encouraged for the reduction of POTS symptoms.

Several authors have attempted to classify POTS into one of several phenotypes based on clinical and laboratory testing. A recent study of 152 patients by Thieben and associates described three groups of patients with POTS:

### I. Hypovolemic and Deconditioned POTS

This was the most common type confirmed by urinary sodium excretion of less than 100 meq/24 hours. Patients with this type of POTS have decreased plasma volume associated with venous pooling in the legs and mesenteric bed during standing upright or tilt. These patients tend to respond well to increased fluid, salt, and exercise treatment measures (Johnson et al., 2010). Jarjour and colleagues found a high prevalence of low iron stores and mild anemia in patients with POTS and neurally mediated syncope, as well as hypovitaminosis D in patients with POTS (Jarjour, 2013). Patients with hypovolemic POTS often complain of extreme fatigue and fibromyalgia-type symptoms with decreased exercise tolerance (Jarjour, 2013). Physical deconditioning is often present in patients with POTS either as the primary etiologic factor or may be secondary to POTS symptoms (Benarroch, 2012).

### II. Hyperadrenergic POTS

This type of POTS is characterized by excessive increase of plasma norepinephrine and a rise of blood pressure (BP) on standing. Hyperadrenergic POTS is defined as POTS associated with systolic BP increment of 10 mm Hg or more within 10 minutes of head-up tilt, and an orthostatic plasma norepinephrine of 600 pg/ml or more. The absolute heart rate increment is often 120 beats per minute or more. These patients often have prominent symptoms of sympathetic activation such as palpitations, anxiety, tachycardia, tremulousness, pallor, excessive sweating, migraine type headaches, chest pain, and vasomotor skin changes (Low et al., 2009).

Autonomic or sympathetic storms may occur in a subset of these patients with extreme rise in BP, anxiety, headache, excessive sweating, and other features of sympathetic overactivation (Jarjour, 2013). Secondary hyperadrenergic POTS has been associated with mast cell activation disorders and norepinephrine transporter deficiency. In patients with hyperadrenergic POTS, the possibility of hyperthyroidism or a catecholamine secreting tumor such as pheochromocytoma should be considered (Benarroch, 2012). Laboratory studies should include plasma and urinary metanephrines and, if elevated, imaging studies to rule out pheochromocytoma (Benarroch, 2012).

### III. Neuropathic POTS

The term “neuropathic POTS” describes a subgroup of patients who have partial distal autonomic neuropathy, a length-dependent pattern that especially affects larger fibers in the lower limbs (Benarroch, 2012). Distal postganglionic sudomotor denervation can be demonstrated with the quantitative sudomotor axon reflex test and the thermoregulatory sweat test demonstrating sudomotor denervation to the foot and toes (Low et al., 2009).

An acute or subacute autonomic neuropathy may be caused by autoimmunity, as is the case with autonomic

ganglionopathy due to antibodies directed against the nicotinic ganglionic acetylcholine receptor. The symptoms come on gradually and involve orthostatic hypotension, significant GI dysfunction, bladder dysfunction, and anhidrosis. This form of POTS is uncommon in children.

## Comorbidities in POTS

Many patients with POTS experience chronic symptoms not easily explained by postural intolerance or excessive tachycardia. These associated symptoms include:

### I. Visceral Pain and Dysmotility

A significant percentage of patients with POTS experience visceral symptoms referable mainly to the gastrointestinal tract and bladder. Nearly 80% of children with POTS have abdominal pain, and 60% have recurrent nausea and vomiting (Chelimsky and Chelimsky, 2013). Other associated symptoms include bloating, diarrhea, constipation, and bladder symptoms (Benarroch, 2012).

### II. Chronic fatigue, Neurocognitive Disorders, Insomnia, and Fibromyalgia

Chronic fatigue, neurocognitive disorders, sleep disturbances, decreased exercise intolerance, and fibromyalgia have been frequently associated with POTS.

### III. Nutritional Deficiencies

Several studies have shown that nutritional factors can affect symptoms in patients with dysautonomia. In patients with POTS and neurally mediated syncope, low iron stores and mild anemia were detected, as well as low vitamin D and B12 levels (Jarjour, 2013). The mechanisms by which iron deficiency and hypovitaminosis D and B12 affect autonomic function are unclear (Johnson et al., 2010).

### IV. Headache

Moderate to severe headaches with or without migraine features, orthostatic headaches and chronic daily headaches are commonly reported by both adult and pediatric patients with POTS.

### V. Ehlers-Danlos Syndrome (EDS)

EDS is a heterogeneous disorder characterized by skin hyperextensibility, joint hypermobility, and connective tissue fragility. Studies have linked joint hypermobility syndromes such as EDS with POTS, but the mechanism of this association remains unclear.

## Clinical and Laboratory Evaluation

Patients with POTS require a multidisciplinary evaluation and multimodality treatment (Low et al., 2009). The first and most important step in the evaluation of patients suspected of POTS is to obtain a detailed history followed by a thorough physical examination, including a complete neurologic and cardiac examination in addition to bedside orthostatic measurements.

The physical examination is invariably normal except for the bedside orthostatic measurements that may show excessive postural tachycardia. Examination could also reveal signs

**BOX 86-12** Pharmacological Management of POTS

- I.  $\beta$ -adrenergic antagonists
  - Atenolol 1–2 mg/kg/d
  - Metoprolol 1–2 mg/kg/d
  - Propranolol 0.5–4 mg/kg/d
  - Nadolol
- II.  $\alpha$ -adrenergic agonists
  - Midodrine 2.5–10 mg tid
  - Pseudoephedrine 60 mg bid
  - Methylphenidate 5–10 mg tid
- III. Mineralocorticoids
  - Fludrocortisone 0.1–0.3 mg/d
- IV. Pyridostigmine 30 mg bid
- V. Selective serotonin reuptake inhibitors
  - Fluoxetine 10–20 mg/d
  - Sertraline 25–50 mg/d

of venous pooling (edema) or excessive sympathetic activity (such as cold, clammy hands) (Benarroch, 2012). Other clinical signs include hypermobile joints, hypotonia and, tissue-paper-thin skin as seen in EDS. The history and physical examination will guide practitioners in choosing the diagnostic studies that apply to a given patient. Box 86-10 provides details of the laboratory evaluation of suspected POTS.

## Treatment

Pediatric POTS is best managed by a multidisciplinary team (neurologist, cardiologist, gastroenterologist, gynecologist, psychologist, geneticist, psychiatrist, and the pain rehabilitation team). The treatment is difficult and based largely on adult studies because of a lack of pediatric specific studies. Patient and family education is a fundamental aspect of POTS management; deconditioning is significant and significantly affects school attendance and education.

Initial treatment includes increasing fluid and salt intake. Most patients require about 2 to 3 L of water per day; and more than 5 g of salt per day. Avoid excessive caffeine intake as it increases diuresis and promotes hypovolemia. Thermotabs may be a substitute if ordinary salt tablets are not well tolerated.

Physical countermeasures such as leg crossing or active contraction of abdominal or buttock muscles may produce small increases in mean arterial pressure to maintain an adequate cerebral blood flow (Benarroch, 2012).

In all patients with POTS and physical deconditioning, aerobic exercise and resistance training are exceedingly helpful during their rehabilitation. Patients should be well hydrated before, during, and after exercise (Johnson et al., 2010).

In patients with POTS, blood pooling or standing occurs both in the abdomen and lower limbs. Some patients may therefore benefit from wearing supportive garments such as knee-high, thigh-high, or waist-high tight support stockings with a pressure of 30 to 40 mm Hg. Box 86-11 outlines the nonpharmacologic management of POTS.

If despite these conservative measures the patients continue to have symptoms, pharmacologic therapy may be tried (Box 86-12). Low-dose beta blockers such as metoprolol, labetalol, and propranolol are commonly used, primarily to control heart rate. These medications are reported to be particularly effective in patients with hyperadrenergic POTS.

As inappropriate control of peripheral vascular resistance has been postulated as a cause of POTS the use of  $\alpha$ -agonists

( $\alpha$ -1, midodrine hydrochloride, pseudoephedrine  $\alpha$ -2, clonidine) can improve orthostatic intolerance, reduce venous pooling, and suppress the related tachycardia. Avoid taking  $\alpha$ -agonists within 4 hours of a prolonged supine posture, including sleep, to prevent supine hypertension.

Fludrocortisone (0.1 to 0.3 mg daily) is a mineralocorticoid often used in combination with other medications for the treatment of POTS. Fludrocortisone promotes intravascular volume expansion and at the same time induces potassium excretion; thus serum potassium levels need to be carefully monitored and potassium supplements provided when necessary. Fludrocortisone needs time to work, so 2 or more weeks should be allowed between dose increases.

Other medications have been used in POTS with mixed results and mainly in adults. These include vasopressin (DDAVP); erythropoietin, clonidine, methylphenidate, octreotide, selective serotonin reuptake inhibitors, serotonin norepinephrine reuptake inhibitor (venlafaxine), and pyridostigmine (Johnson et al., 2010). Pyridostigmine is thought to be particularly helpful in patients with hyperadrenergic POTS (Johnson et al., 2010). Starting dose is 30 mg twice daily. Clonidine, an  $\alpha$ -receptor agonist, is a useful drug for the treatment of sympathetic storms as it works by inhibiting central venous system sympathetic out flow.

Patients with neuropathic POTS who are seropositive for autoimmune autonomic ganglionopathy or neuropathy may respond well to immunotherapy.

## CONCLUSIONS

Systematic studies of autonomic disorders in children and adolescents are relatively new. The disease characteristics, diagnostic criteria, and therapies are evolving and remain largely undefined.

As with all chronic illnesses, psychological and psychiatric comorbidity adds to the difficulty in the optimal management of these patients. Deconditioning is commonly associated with POTS, adding to its disability. In some centers, up to 50% of patients with POTS are placed on SSRIs because of the high burden of psychological and psychiatric comorbidity. Psychological counseling and participation in a chronic pain management program are useful adjuncts in the rehabilitation of patients with POTS. There are limited long-term outcome data for children and adolescents with POTS. Most available studies however, suggest an overall good potential for recovery in newly diagnosed adolescents compared with adults with newly diagnosed postural orthostatic tachycardia syndrome.

Many childhood sleep disorders have paroxysmal onset and offset. It is therefore not uncommon that these episodes may be interpreted as parasomnia or seizures. In this chapter, common sleep disorders that may mimic parasomnia and epilepsy are emphasized.

## A. PARASOMNIAS

According to the International Classification of Sleep Disorders, third edition (ICSD-3), parasomnias are defined as undesirable physical events or experiences that occur during entry into sleep, during sleep, or during arousals from sleep (American Academy of Sleep Medicine [AASM], 2014). They are classified as (1) disorders of arousals from nonrapid eye movement (NREM) sleep, (2) parasomnias associated with rapid eye movement (REM) sleep, and (3) other parasomnias (AASM, 2014).

Lists of the parasomnias and disorders mimicking parasomnia are provided in [Table 87-1](#) and [Table 87-2](#), respectively.

### I. Disorders of Arousal from NREM Sleep

Disorders of arousal from NREM sleep are the most common parasomnias in the pediatric population. Most disorders of arousal occur during slow-wave sleep (SWS) as incomplete transitions into wakefulness, and are characterized by automatic behavior, altered perception of the surrounding environment, and a variable degree of amnesia for the event (Mahowald, Bornemann, and Schenck, 2004). Episodes tend to occur in the first third of the night when SWS is more prominent. Electroencephalograms (EEGs) recorded during such episodes demonstrate a mixture of theta, delta, and alpha frequencies ([Fig. 87-1](#)). These disorders are thought to result from a faulty switch that prevents normal sleep-cycle progression. Episodes may be brought on by sleep deprivation, medications, noisy or stimulating environments, stress, and fever. Sleep fragmentation as a result of obstructive sleep apnea (OSA) or periodic limb movements of sleep (PLMS) may also be a precipitating factor. In one study, an association with another sleep disorder was found in 61% of children with parasomnias. In this study, the children who were successfully treated for an associated sleep disorder had resolution of the parasomnia events, whereas untreated children continued to have events (Guilleminault, Palombini, Pelayo, and Chervin, 2003). Additionally, patients with one type of parasomnia may also have other types. Based on a recent study, 41% of children with sleepwalking may also have sleep terrors, and 92% of children with persistent sleep terrors at age 6 years may also have somniloquy. At a later age, sleep terrors may progress to sleepwalking. Bruxism, hypnagogic hallucinations, and nightmares may also be associated conditions. Moreover, several studies suggest a genetic predisposition to some of the arousal parasomnias. In one study, a remarkable 96% of the patients with sleepwalking or night

terrors had a positive family history in first- to third-degree relatives.

The clinical history in a child with any parasomnia should include a complete description of the events, time of night when the events happen, frequency of episodes, recollection of the events by the child, and presence of the events during daytime naps. Information regarding whether the movements are rhythmic and stereotypical, associated with eye deviation, and associated with focal tonic-clonic activity may support an epileptic origin to the events. A home video often proves useful for identifying and classifying parasomnias and differentiating them from seizures (Mason and Pack, 2007). Examination should focus on looking for evidence of upper airway obstruction, such as adenotonsillar hypertrophy, midfacial hypoplasia, and retrognathia (Sheldon, 2004). In appropriate cases, a video EEG concurrent with sleep may be indicated to rule out seizures (Fusco and Specchio, 2005). Overnight polysomnography is indicated when there is concern for an intrinsic sleep disorder, such as OSA or PLMS, rather than to document the parasomnia per se.

Management usually includes reassuring parents that parasomnias are common in childhood and that they are benign and self-remitting. Parents should be counseled when appropriate on instituting important safety measures, including securing windows, staircases, and doors, to prevent injuries. They should be educated about appropriate pediatric sleep hygiene, such as avoiding sleep deprivation, maintaining regular sleeping hours, avoiding caffeinated drinks, and avoiding any attempts to restrain or awaken the child during an episode, which may actually be counterproductive. Scheduled or anticipatory awakenings several minutes beforehand have been attempted to abort such events when they happen consistently at particular times, but in general this approach has not been well accepted by families. Treatment of the underlying intrinsic sleep disorder such as OSA with tonsillectomy and adenoidectomy has been shown to result in disappearance of the parasomnia events. Oral iron supplementation for PLMS also has been shown to lead to improvement of parasomnia. Iron is an essential cofactor for synthesis of dopamine via tyrosine hydroxylase. Iron deficiency causes lower dopaminergic activity, which, along with complex interactions with other neurotransmitter systems, may lead to restless leg syndrome (RLS) or PLMS. A ferritin level above 50 ng/mL is the target for treatment of PLMS. Thus iron and ferritin levels should be checked in children with suspected RLS or PLMS. Medications for treatment of parasomnia itself should be reserved for those rare, protracted cases with no associated sleep disorders, with frequent parasomnias, or with a real threat for self-injury. Low-dose clonazepam or tricyclic antidepressants for a short duration have been used with good success in such cases.

### Sleepwalking

Sleepwalking occurs in up to 17% of children, is most common in children 12 to 13 years of age, and has no gender

**TABLE 87-1** Classification of Parasomnias

NREM	REM	Other Parasomnias	Normal Variants	Other Disorders
Sleepwalking	REM sleep behavior disorders	Nocturnal enuresis	Sleep talking	Catathrenia (classified as a sleep-related breathing disorder)
Confusional arousal	Recurrent isolated sleep paralysis	Exploding head syndrome	Sleep starts	Hypnic headaches
Sleep terrors	Nightmare disorder	Sleep-related hallucinations		Head banging
Sleep-related eating disorder				
NREM, nonrapid eye movement; REM = rapid eye movement.				

**TABLE 87-2** Differential Diagnosis of Parasomnia

Neurologic/Psychiatric	Cardiopulmonary	Gastrointestinal	Miscellaneous
Headache	Arrhythmias	Gastroesophageal reflux	Muscle cramp
Seizures	Angina pectoris		Tongue bite
Panic attacks	Hiccough		Pruritus
PTSD	Coughing		Night sweats
Dissociative disorders	Choking Asthma		Alternating hemiplegia of childhood in sleep
PTSD, posttraumatic stress disorder.			

**Figure 87-1.** EEG showing a parasomnia event from N3. Arrow points to the onset of the event.

predilection. Most of the patients with onset before 10 years of age outgrow the condition, but up to 25% continue to be affected by sleepwalking into adulthood. Teenagers who continue to have sleepwalking episodes often have comorbid psychiatric disorders, including panic disorder, anxiety disorder, alcohol or cigarette use, suicidal ideation, and simple phobia. Sleepwalking episodes are characterized by behaviors such as sitting up in bed and displaying complex motor movements, including changing of body position, turning, playing with sheets, and eventually getting out of the bed. Some children walk around the house, going into different rooms, downstairs, or even outside the house. Sleepwalking can be further classified into calm or agitated subtypes, with the former more common in children. Although children may get agitated if awakened in the middle of an episode, they do not have any recollection of the event in the morning. Because there is

altered awareness, the major concern during these benign behaviors is the risk for self-injury from, for example, falling down the stairs, going out of the house, or running into closed doors (Avidan and Kaplish, 2010).

### Confusional Arousals

Confusional arousals occur in up to 17.3% of the population, mainly in infants and toddlers. A typical event begins with moaning, evolving to confused and agitated behavior lasting from 5 to 15 minutes. Attempts to fully wake up the child are unsuccessful. Sleep-sex disorder (sexsomnia) is a subtype of this disorder that has been reported in adults, with onset around adolescence in some individuals. Sexsomnia involves inappropriate sexual behavior that occurs during sleep, without the conscious awareness of the individual.

## Sleep Terrors

Episodes of sleep terror occur in 1% to 6% of children, with a peak frequency between 4 and 8 years of age; gender differences have not been observed. The child may sit up suddenly and scream with a blood-curdling "battle-cry." There is an expression of intense fear on the child's face, and this is accompanied by apparent autonomic activation, including mydriasis, tachycardia, and diaphoresis. The child may be unresponsive to consoling, and if awakened, confusion and disorientation may occur. Some children may report indistinct recollections of a threat, such as monsters, spiders, or snakes, from which they have to defend themselves. In most cases however, there is no recollection of the event. The event may last from a few minutes up to 20 minutes, but a longer duration may also be seen. Because the amount of time spent in slow-wave sleep decreases with age, most cases go into natural remission by adolescence. In two studies, only 0.9% to 1.2% of affected children continued to have episodes at 7 to 13 years of age.

## Sleep-Related Eating Disorder

Usually seen accompanying sleep walking and daytime eating disorder, sleep-related eating disorder is characterized by out-of-control eating binges, predominantly of carbohydrate-containing foods, 2 to 3 hours after sleep onset, with no subsequent recall of the event. Episodes can begin in childhood, but onset is more common in the teenage years and adulthood. These behaviors have recently been described in association with the use of hypnotics such as zolpidem.

## Diagnosis

Clinicians must differentiate parasomnias classified as disorders of arousal from NREM sleep from nocturnal seizures. Frontal lobe seizures are especially important to consider, because they occur predominantly in sleep, sometimes many times per night, and are characterized by stereotypical movements, thrashing of the entire body, vocalizations, and dystonic posturing lasting 20 seconds to a few minutes, with minimal postictal drowsiness or confusion. Paroxysmal nocturnal dystonia, which is now considered to be a frontal lobe seizure, is characterized by an arousal from NREM sleep accompanied by dystonic posturing, bizarre movements of the extremities, and vocalizations, with minimal evident EEG correlation as a result of the deep-seated focus of seizure onset in the mesial frontal region. In-patient video EEG monitoring is useful in confirming the diagnosis and differentiating such events from nocturnal panic attacks, fugue states, conversion reactions, and parasomnias such as night terrors, confusional arousals, and sleepwalking.

## II. Parasomnias Associated with REM Sleep

### Nightmares

Nightmares are a form of parasomnia associated with REM sleep and are characterized by vivid dreams in the second half of the night accompanied by an intense feeling of terror or dread that typically awakens the child from sleep. The child can be easily aroused and has good recollection of the event. Nightmares are frequently seen in children between 3 and 6 years of age. Prevalence ranges from 30% to 90% for occasional episodes and 5% to 30% for frequent episodes. In children, psychiatric disorders are seen more often in those experiencing nightmares than in those without nightmares. Nightmares may also occasionally be a marker for a history of trauma or sexual abuse in children and adolescents.

## REM Sleep Behavior Disorder

REM sleep behavior disorder is characterized by the behavioral enactment of unpleasant and combative dreams with complex movements that can be vigorous and violent because of the lack of atonia during REM sleep. This disorder typically occurs in the 60s or 70s in males and may precede the onset of Parkinson disease or a progressive supranuclear palsy (PSP). The disorder is uncommon in children but may be seen in association with the use of selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine, or accompanying narcolepsy and Tourette syndrome. These episodes respond very well to small doses of clonazepam given at bedtime.

## Recurrent Isolated Sleep Paralysis

Recurrent isolated sleep paralysis is characterized by a generalized inability to speak or to move the trunk, head, and limbs that occurs during the transitional period between sleep and wakefulness. The episodes are brief and transient but may be accompanied by vivid hallucinations, which often make them very distressing. Although the condition is usually seen with narcolepsy, it may also be seen in isolated form in otherwise healthy individuals and in those with a strong family history.

## III. Other Parasomnias

### Nocturnal Enuresis

Nocturnal enuresis (bedwetting) refers to the involuntary passage of urine while asleep. It occurs in approximately 15% to 25% of children at 5 years of age, more often in boys, and in 1% to 3% of adolescents. It may be classified as primary (when present from birth) or secondary (with periods of at least 6 months of dryness before the recurrence of enuresis), and as nocturnal (occurring at night) and/or diurnal (occurring during the day). Three major pathologic factors have been considered as possible etiologies: group 1, volume dependent, with polyuria; group 2, detrusor dependent, with involuntary detrusor contractions and a small urinary bladder; group 3, with decreased arousability. There are strong associations of enuresis with genetic and familial factors, and a high prevalence of secondary enuresis in children with OSA. Treatment involves the removal of inciting factors, reassurance, behavioral programs, and the use of nasal desmopressin or oral tricyclic antidepressants such as imipramine.

### Exploding Head Syndrome

Exploding head syndrome is a harmless but potentially terrifying situation, usually occurring while a patient is falling asleep, characterized by a terrifying loud noise accompanied by myoclonic jerks or the perception of a flash of light. These episodes are very brief but lead to intense anxiety. There is no headache or pain accompanying these episodes, and they can begin in childhood. No treatment is needed aside from accurate diagnosis and reassurance.

### Sleep-Related Hallucinations

Sleep-related hallucinations are characterized as vivid dreams, or perceptions not based in reality, that occur either at sleep onset (hypnagogic hallucinations) or upon awakening (hypnopompic hallucinations). They can occur in otherwise healthy individuals, but are frequently seen as part of the symptoms of narcolepsy. The hallucinations may be visual, tactile, auditory, or kinetic in nature. They are thought to result from the brief intrusion of REM sleep into NREM sleep or wakefulness.

## IV. Normal Variants

### Sleep Talking

Sleep talking is very common in the general population and has a strong familial and genetic propensity. It can occur in REM or NREM sleep, and the main feature is talking during sleep, with or without comprehension. Arousal from sleep rarely occurs. The individual is rarely aware of it, but the talking disturbs others sharing the room. Sleep talking may be associated with other parasomnias.

### Sleep Starts

Also called hypnic jerks, sleep starts are common and involve sudden whole-body jerks experienced during the sleep-wake transition. Variations include sensory, auditory (e.g., exploding tinnitus), and visual sensations, which may occur without motor jerks. No treatment other than reassurance is necessary.

## V. Other Disorders

### Catathrenia

Also called nocturnal groaning, catathrenia can occur in REM or NREM sleep during expiration in clusters of 2 minutes to an hour. Episodes end with a snort and are accompanied by changes in heart rate. Onset may occur during childhood or adolescence. The exact etiology is unknown, and no specific therapy has been found to be effective.

### Hypnic Headaches

Hypnic headaches are characterized by diffuse headaches occurring at a consistent time, usually 4 to 6 hours after sleep onset, lasting 30 to 60 minutes. This condition is most commonly seen in older adults, and is often accompanied with nausea but no other autonomic features. Hypnic headaches are rare in children, but reported cases also show lack of autonomic symptoms; response to melatonin is seen in 40% of affected children.

### Head Banging

Also called *jactatio capitis nocturna*, head banging is now classified as a rhythmic movement disorder of sleep, and is characterized by rhythmic movements of the head and body at sleep onset in infants and toddlers. It is seen more often in children with developmental disabilities and autism, but may be seen in normal children. No specific treatment other than reassurance is indicated.

## B. NOCTURNAL PANIC ATTACKS

Nocturnal panic attacks are events in which the individual wakes from sleep in a state of panic, with panic defined as an abrupt and discrete period of intense fear or discomfort that is accompanied by cognitive and physical symptoms of arousal. These symptoms include tachycardia, sweating, shortness of breath, chest pressure, choking sensations, dizziness or lightheadedness, depersonalization or derealization, stomach discomfort, and intense fears of dying or going crazy (Table 87-3). A full panic attack (in contrast to a limited symptom attack) is defined by observation of four or more of these symptoms. The symptom profile of nocturnal panic attacks does not differ significantly from that of panic attacks that occur during wakeful states, although breathlessness and choking are more prominent. A nocturnal panic attack is an abrupt waking from sleep in a state of panic without an

**TABLE 87-3** Criteria for Nocturnal Panic Attacks

An abrupt and discrete period of intense fear or discomfort, in which four or more of the following symptoms develop out of sleep:

1. Sensation of shortness of breath\*
2. Feeling of severe choking\*
3. Fear of losing control of breathing\*
4. Fear of dying
5. Tachycardia
6. Sweating
7. Chest pain and discomfort
8. Stomach discomfort such as nausea
9. Dizziness or lightheadedness
10. Depersonalization or derealization
11. Hot or cold flashes
12. Trembling or shaking
13. Paresthesias

\*Respiratory symptoms are the predominant features in nocturnal panic attacks compared with daytime panic attacks.

obvious trigger. Nocturnal panic attacks are most often experienced by individuals with a daytime panic disorder, an anxiety disorder characterized by unexpected panic attacks, and persistent apprehension regarding the recurrence of panic attacks or changes in lifestyle as a result of their occurrence. Thus most patients with nocturnal panic attacks experience panic attacks during wakeful states as well, although a small subset predominantly or exclusively experiences nocturnal panic attacks (Nakamura, Sugiura, Komada, and Inoue, 2013). The only other anxiety disorder in which nocturnal panic attacks have been documented is posttraumatic stress disorder. Most patients report that nocturnal panic attacks occur between 1 and 3 hours after sleep onset, and only occasionally occur more than once per night. Nocturnal panic attacks typically last from 2 to 8 minutes, and return to sleep is usually difficult. Patients are able to vividly recall their nocturnal panic attacks.

Although epidemiologic studies have not been conducted, surveys of select clinical groups suggest that nocturnal panic attacks are relatively common among patients with a panic disorder, with 44% to 71% reporting having experienced nocturnal panic attacks at least once. In the largest survey to date, 58% of 1166 individuals with definite or probable panic disorder reported having experienced nocturnal panic attacks at least once, and 30% to 45% reported repeated nocturnal panic attacks. Many patients who suffer nocturnal panic attacks frequently become fearful of sleep and attempt to delay sleep onset. Avoidance of sleep may thus result in chronic sleep deprivation, in turn precipitating more nocturnal panic attacks.

Nocturnal panic attacks are an NREM event, usually occurring in late stage II or early stage III of sleep and in the absence of any associated EEG abnormalities. Nocturnal panic attacks are distinct from sleep terrors, which occur mostly during stage IV sleep and are followed by a quick return to sleep, without later recall of the event. The absence of EEG abnormalities distinguishes these attacks from nocturnal seizures. Nocturnal choking episodes may be a predominant symptom of both nocturnal panic attacks and epileptic seizures. Choking is often seen in nocturnal seizures arising from the insula, the mesial frontal cortex, and the supplementary motor area. The major distinction between nightmares and nocturnal panic attacks is the stages of sleep during which they occur; nocturnal panic attacks are an NREM event, whereas nightmares are a REM event. Also, according to EEG data, patients with panic disorder are accurate in their discrimination between dream-induced anxiety and nocturnal panic attacks, even though both are associated with autonomic activation.

Assessment of nocturnal panic attacks focuses on ruling out alternative explanations for these episodes (e.g., seizures, apnea, other emotional disorder). Differential diagnosis is made on the basis of interviews, sleep polysomnography in a sleep laboratory, and ambulatory recordings of sleep in the natural environment.

Psychological treatment for these attacks is based on recent work demonstrating that cognitive factors, such as expectations about arousal during sleep, predict increased distress and panic attacks arising out of sleep. Nocturnal panic attack is thus conceptualized as triggered by interoceptive conditioning, whereby fluctuations in normal bodily sensations that are not consciously recognized because of the sleep state elicit a conditional fear as a result of prior associative pairings with panic. Cognitive behavioral therapy (CBT) targets both daytime and nocturnal panic attacks and the accompanying chronic apprehension over their recurrence, with emphasis on the benign nature of normal physiologic fluctuations during sleep. Breathing retraining is taught as a coping technique, especially for symptoms associated with overbreathing, and patients practice interoceptive inductions tailored to these attacks (e.g., deep relaxation, “buzzer arousal inductions” from a sleeping state). Maladaptive behaviors specific to nocturnal panic attacks (e.g., television watching to facilitate sleep induction) are targeted, as are poor sleep habits, because sleep-onset insomnia often accompanies these attacks and may contribute to its augmented recurrence. Recent evidence suggests that relative to precipitant desensitization, CBT for these attacks led to substantial reductions in the frequency and severity of daytime and nocturnal panic attacks, and these gains persisted at 9-month follow up.

Pharmacologic treatment has not yet been subject to rigorous empirical testing (Craske and Tsao, 2005), although uncontrolled trials suggest that agents typically used to treat daytime panic attacks (e.g., benzodiazepines, antidepressants) can ameliorate nocturnal panic attacks, suggesting the need for future double-blind, placebo-controlled trials to establish the efficacy of these agents. Additional work is also needed to compare treatment outcomes for nocturnal parasomnias treated with CBT in combination with pharmacologic agents versus use of these agents alone.

### C. SANDIFER SYNDROME

Gastroesophageal reflux (GER) involves the retrograde movement of gastric contents across the lower esophageal sphincter into the esophagus. Although episodes of GER are often physiologic in nature, the condition can become pathologic in children when episodes are more frequent and persistent. Consequences of GER include esophagitis, esophageal symptoms, and respiratory sequelae (Lehwald et al., 2007). GER afflicts approximately 7% of infants and children. It is seen more commonly in children with neurologic impairment. Named after the neurologist Paul Sandifer, Sandifer syndrome was first reported by Kinsbourne in 1962. It is characterized

by gastroesophageal reflux disease (GERD), presenting with spastic torticollis and paroxysmal dystonic head and neck movements, head/eye version, irritability, crying, vomiting, and abdominal pain, with or without hiatus hernia. It is a rare but important symptom complex seen in 1% of children with GER; it usually appears in early infancy or childhood but has been reported to have onset even in adults. It is postulated that the abnormal movements during the reflux are the result of a mechanism to protect the airway passages from reflux or to relieve the pain caused by acid reflux. Sandifer syndrome is often mistaken for seizures, including infantile spasms. A normal EEG, especially during the event, rules out seizures. It is important to be cognizant of this condition because delay in diagnosis can lead to significant morbidity, including aspiration of the stomach acid into the lungs, anemia, and esophageal ulcers. The diagnosis is confirmed with a 24-hour pH probe study, and if necessary an upper gastrointestinal endoscopy. The symptoms of Sandifer syndrome respond very well to medical management with use of a proton pump inhibitor, although rare cases need surgical intervention, especially those involving hiatus hernia.

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

Excessive daytime sleepiness (EDS) is not uncommon in children and adolescents, with a prevalence of 4% in preadolescents and almost 20% in high school seniors. EDS is associated with changes in mood, attention, and behavior, as well as poor performance in school and on cognitive tests. Hence, it is important to accurately diagnose and treat disorders of excessive sleepiness.

Etiologies of EDS can be divided into three broad categories—insufficient sleep, fragmented sleep, and an increased need for sleep—that are detailed in [Table 88-1](#). Insufficient sleep could be due to sleep disorders such as primary insomnia or behavioral insomnia in younger children. In adolescents, insufficient sleep is typically multifactorial. In studies, the sleep duration reduced from 9.9 hours to 8 hours in 10- to 16-year-olds. Almost 40% of adolescents showed more than a 2-hour sleep difference between school days and weekends. Additionally, there is physiologic delay in sleep onset in teenagers. This delay in sleep onset combined with the increased use of various electronic media causes sleep disturbances. When combined with earlier school start times, these problems result in EDS.

Fragmented nocturnal sleep can be due to a variety of causes. These include behavioral causes, such as nighttime electronic media exposure, and behaviorally induced insufficient sleep. In younger children fragmented sleep can be caused by behavioral insomnia-sleep-onset association type. Medical disorders also can fragment sleep.

Finally, increased sleep drive or increased sleep need is the most important cause of EDS, which can be temporary or permanent. The temporary causes are physical or emotional trauma, infections, acute illnesses, or other factors. Primary permanent and recurrent hypersomnia are considered central hypersomnias and are discussed in detail in this chapter.

The International Classification of Sleep Disorders-3 (ICSD-3) classifies central hypersomnia as: 1) narcolepsy type 1 (previously narcolepsy with cataplexy); 2) narcolepsy type 2 (previously narcolepsy without cataplexy); 3) idiopathic hypersomnia; 4) Kleine-Levin syndrome (KLS); 5) hypersomnia due to a medical disorder; 6) hypersomnia due to medication or substance abuse; 7) hypersomnia due to a psychiatric disorder; and 8) insufficient sleep syndrome ([American Academy of Sleep Medicine, 2014](#)).

## ASSESSMENT OF SLEEPINESS

The assessment of EDS is important to differentiate the previously described disorders and central hypersomnias as well as to specify the type of hypersomnia ([Kothare and Kaleyias, 2008](#); [Kotagal, 2012](#)). [Figure 88-1](#) shows an algorithm that can be used for the evaluation of EDS.

### Clinical Assessment

#### History

A detailed history is crucial to identify if excessive sleepiness is truly present and assess total sleep time, as well as associated

disorders which could cause symptoms of sleepiness, and to determine whether other sleep disorders are present. The history should focus on sleep-wake patterns, including bedtime, rise time, arousals, sleep-onset latency, and the ability to wake up refreshed in the morning. Obtaining additional history pertaining to the duration and timing of naps, planned versus spontaneous naps, factors precipitating spontaneous naps, and feeling refreshed after naps is important. Associated features such as cataplexy, hallucinations, sleep attacks, and sleep paralysis also should be evaluated. To determine whether other sleep disorders are present, questioning should focus on snoring, witnessed apnea, “restless leg” symptoms in the evening and movements of the legs during sleep. A history pertaining to whether or not there is coexistent or underlying neurologic disorders such as epilepsy, migraine, genetic conditions, and head injuries also should be evaluated.

### Physical Examination

Obesity, assessed by an elevated age-appropriate body mass index, craniofacial anomalies (micrognathia, midfacial hypoplasia), tonsillar hypertrophy, enlarged tongue base, deviated nasal septum, swollen inferior turbinates, high arched palate, and mouth breathing may all be associated with obstructive sleep apnea (OSA) and should be evaluated. Additionally, the presence of lineae nigricans, reflecting insulin resistance, should be assessed. Signs suggestive of other neurologic disorders such as a head injury also should be identified.

### Subjective Evaluation Tools

Subjective evaluation tools include questionnaires and sleep logs/diaries. Sleep logs give an estimate of the number, duration, and timing of daily episodes of nocturnal sleep, daytime naps, and wake periods. These can be used to evaluate sleep-wake habits. These may reveal the evidence of chronically insufficient sleep.

To assess sleepiness, questionnaires such as the Stanford Sleepiness Scale (SSS), the Epworth Sleepiness Scale (ESS), and the Pediatric Daytime Sleepiness Scale (PDSS) can be used. SSS and ESS are mainly used in adults, whereas the PDSS was specifically developed to assess sleepiness in school-age children.

### Objective Evaluation Tools

Objective evaluation tools are discussed in detail in the online  chapter.

#### Actigraphy

Actigraphs are miniature computerized wristwatch-like devices that measure limb activity, based on which sleep and wake periods can be indirectly calculated. Actigraphs help to determine whether sleep is insufficient and to confirm sleepiness.

## Nocturnal Polysomnography

Polysomnography (PSG) is the gold standard for evaluating sleep disorders. As the name suggests, it is an electrophysiological recording of multiple parameters, including an electroencephalogram (EEG), a chin electromyogram (EMG), and an

**TABLE 88-1** Etiologies of Excessive Sleepiness in Children

Insufficient Sleep	Increased Sleep Drive	Fragmented Nocturnal Sleep
Paradoxical insomnia	Central hypersomnias	Primary sleep disorder
Behaviorally induced insufficient sleep syndrome	Traumatic brain injury	GERD
Behavioral insomnia of children—sleep onset association type	Medications	Allergy, eczema
Behavioral insomnia of children—limit setting type	Infections	Asthma
Circadian rhythm sleep disorders	Metabolic disorders	Other medical disorders
Psychophysiological insomnia		Medications
Idiopathic insomnia		Illicit drugs, alcohol

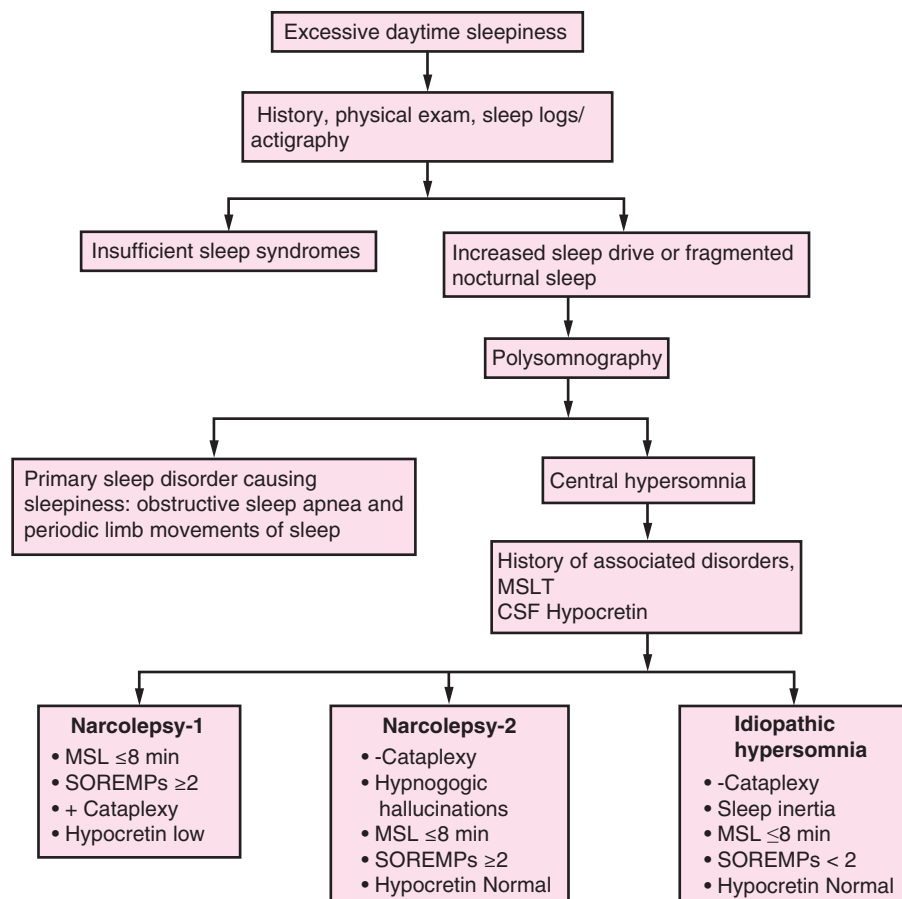

electrooculogram which help to score various sleep stages. Respiratory effort is detected using chest and abdominal belts. Oronasal flow is detected using nasal thermistors and nasal flow pressure transducers. Extremity movements are monitored by EMG leads placed on the legs and sometimes on the arms. Gas exchange is assessed by monitoring oxygen and CO<sub>2</sub> via pulse oximetry and end-tidal/transcutaneous CO<sub>2</sub>. Simultaneously, video monitoring is performed.

## Multiple Sleep Latency Test (MSLT)

The MSLT is a validated measure of the ability or tendency to fall asleep. The MSLT is performed to assess the degree of sleepiness and the timing of rapid eye movement (REM) sleep onset. The MSLT is performed by allowing five nap opportunities, lasting 20 minutes each, at 2-hour intervals. For each nap opportunity, sleep latency is defined as the time from lights out to N1. Sleep-onset REM periods (SOREMPs) are characterized by onset within 15 minutes of sleep onset. The mean sleep latency (MSL; arithmetical mean of sleep latency of all naps) is an index of the severity of sleepiness. The combination of MSL and the number of SOREMPs help to differentiate various central hypersomnias as seen in [Figure 88-1](#) and discussed later in this chapter.

## The Maintenance of Wakefulness Test (MWT)

The MWT is a validated objective measure of the ability to stay awake for a defined time. The MWT assesses the efficacy of treatment for safety issues regarding driving.

**Figure 88-1.** Algorithm showing the approach in evaluation of children with excessive daytime sleepiness.

## Cerebrospinal Fluid Hypocretin-1 Levels

The levels of CSF hypocretin are diagnostic in narcolepsy type 1 and are a part of the new diagnostic criteria for this disorder. The CSF hypocretin level also helps in the diagnosis of narcolepsy type 2. Hypocretin-1 is measured from CSF by radioimmunoassay (RIA), using a polyclonal antibody.

## Histocompatibility Antigen (HLA) Subtypes

HLA subtypes are helpful in the differential diagnosis of hypersomnias. HLA DQ1\*0602 is positive in 76% to 90% with narcolepsy type 1, 40% to 57% narcolepsy type 2, and 12% to 38% in the normal population.

## NARCOLEPSY TYPE 1 (NARCOLEPSY WITH CATAPLEXY)

The ICD-3 definition of narcolepsy type 1 is: a) daily periods of an irrepresible need to sleep or daytime lapses into sleep occurring over for at least 3 months; b) cataplexy and a MSL of 8 minutes or less and two or more SOREMPs on MSLT (SOREMP within 15 min of sleep onset in nocturnal polysomnography may replace one of the SOREMPs on MSLT); or c) CSF hypocretin level of 110pg/mL or less.

Chronic daytime sleepiness, hypnagogic hallucinations (vivid dreams at sleep onset), sleep-onset paralysis, cataplexy, and fragmented night sleep are the characteristic symptoms of narcolepsy. The incidence of narcolepsy in the United States is 1.37 per 100,000 persons per year (men: 1.72; women: 1.05), which is highest in the second decade, followed by a gradual decline. The prevalence is approximately 56 per 100,000 persons. Recently there was an increase in the incidence after H1N1 infection or after receiving a specific adjuvanted H1N1 vaccine, mostly affecting prepubertal children and adolescents. The onset of narcolepsy type 1 is commonly in childhood, and 34% of all narcolepsy subjects experienced symptoms before the age of 15 years, 16% before the age of 10 years, and 4.5% before age 5 years (Fig. 88-2). Rare cases with the onset during infancy also have been reported. The patients with H1N1 vaccine-related narcolepsy have the onset at a younger age than nonvaccinated cases.

EDS is the most common presenting symptom of narcolepsy type 1 and is seen in over 90% of patients. However, sleepiness may be unrecognized, leading to a delay in the diagnosis. The lack of recognition may be due to parents considering children as “lazy,” or unaware that sleepiness in children presents as mood swings, inattentiveness, or hyperactive

**Figure 88-2.** Graph depicting the age of onset of narcolepsy. (Data derived from Challamel, M.J., et al., 1994. *Narcolepsy in children.* *Sleep* 17S:17.)

behavior. Additionally, children may have a chronic waxing and waning of drowsiness with superimposed excessive sleep periods and long, unrefreshing naps (Nevsimalova, 2014). Over time, the sleepiness may improve to a limited degree.

Cataplexy consists of episodes of sudden muscle weakness in all skeletal muscles except the extraocular and respiratory muscles in response to an emotional stimulus—most commonly laughter. It is the most specific symptom of narcolepsy type 1. It may not be present at onset. In large case series, 83% to 100% of patients had cataplexy. Other triggers are emotions such as anger, surprise, or others. The resulting muscle weakness generally lasts for a few seconds to minutes and is associated with muscle atonia, the absence of muscle stretch reflexes, the absence of H- and F-waves on nerve conduction studies, and the full preservation of consciousness. Moreover, at the onset, one third of children may have “cataplectic facies”: semipermanent facial weakness leading to droopy eyelids, open mouth, and/or tongue protrusion. Emotion-triggered cataplectic attacks may occur on top of this weakness. Cataplectic facies may later be replaced by typical cataplexy. Additionally, hypotonia and complex motor movements also occur closer to the onset of narcolepsy, more commonly in younger children. Complex motor movements also may resolve later in the disease. Moreover, the children with H1N1 vaccine-related narcolepsy more commonly have cataplexy, hypotonia, and tongue protrusion than the children with sporadically occurring cases.

Hypnagogic hallucinations also are present in children with narcolepsy representing REM dysfunction. In large case series, 32% to 57% of children had such hallucination (Wu, et al., 2014). Contrasting with cataplexy, hallucination is not very specific to narcolepsy. Unlike adults, hallucinations may be in the form of simple visual forms. These occur in relation to sleep and are multisensory as opposed to auditory hallucinations seen in schizophrenia. The hallucinations are frequently associated with sleep paralysis, which also is a phenomenon of REM dysfunction. Sleep paralysis occurs in 19% to 41% of children with narcolepsy, lasts seconds to minutes, and may end spontaneously or by verbal or tactile stimuli.

Fragmented nocturnal sleep also is common in narcolepsy. Fragmentation may be related to the lack of orexin, influencing the on-off sleep/wake switch. Patients with narcolepsy exhibit less circadian clock-dependent alertness during the daytime and sleepiness at night. Moreover, obesity and precocious puberty are seen in up to 74% and 17% respectively of such children, especially in the younger patients. Children with obesity and narcolepsy have an earlier onset of sleepiness and cataplexy and have poorer nocturnal sleep and higher sleep-disordered breathing. The suggested mechanisms for obesity are reduced hypocretin and leptin levels and decreased basal metabolic rate. In addition, obesity could be related to eating disorders. Moreover, weight gain is significantly more common in children with H1N1 vaccine-related narcolepsy than in sporadic cases.

## Pathophysiology

The key pathophysiologic event in human narcolepsy-cataplexy is hypocretin ligand deficiency caused by targeted loss of hypocretin-secreting neurons in the hypothalamus. The most likely mechanism of loss is autoimmune (Partinen, et al., 2014), which is discussed in detail in the online version.

## Diagnosis

The diagnosis of narcolepsy in children remains challenging with the delay in diagnosis ranging 8 to 22 years. The presence

of cataplexy and younger age at onset were associated with earlier diagnosis. With better technologies and improved health professional awareness, the gap between the onset and diagnosis is closing. A careful history examination, relevant questionnaires, and sleep logs/actigraphy are important in excluding other disorders. On actigraphy, increased sleep fragmentation and daytime naps are seen. Nocturnal polysomnography is performed to evaluate for other sleep disorders that fragment sleep and cause daytime sleepiness. Nocturnal polysomnography followed by MSLT remains the gold standard in the diagnosis. The MSLT and nocturnal polysomnography diagnostic criteria are discussed earlier in this chapter. A recent study identified that the specificity of SOREMP in nocturnal polysomnography for detection of narcolepsy with cataplexy was 97%, whereas the sensitivity was 88.5%.

HLA testing also is useful. There is a strong association between narcolepsy and HLA DQ antigens, specifically DQB1\*0602, which are present in up to 95% of patients with narcolepsy type 1. HLA DQB1\*0602 positive subjects are at a 251-fold increase risk of narcolepsy. Additionally, all subjects with H1N1 vaccine-related narcolepsy have a positive HLA DQB1\*0602.

Low CSF hypocretin levels can confirm the diagnosis of narcolepsy type 1. CSF hypocretin levels of less than 110 pg/mL have a greater than 95% specificity in diagnosing narcolepsy type 1. Positive DQB1\*0602 and low CSF hypocretin-1 are found in 87.4% of cases of narcolepsy type 1. The hypocretin assay may be most useful when an HLA DQB1\*0602-positive patient with suspected narcolepsy-cataplexy is already receiving psychostimulants and in whom discontinuation of these medications is inconvenient or impractical. Additionally, CSF hypocretin levels also may help in the differential diagnosis of hypersomnia as narcolepsy type 1 have low levels, whereas subjects with narcolepsy type 2 and idiopathic hypersomnia patients exhibit normal levels (Fig. 88-3). Furthermore, ASO and anti-DNAse B titers also may assist in establishing the diagnosis.

## Treatment

Currently, narcolepsy is an incurable, lifelong disease. Available treatments focus on improving symptoms, which include reducing daytime sleepiness, controlling cataplexy, and correcting nocturnal sleep fragmentation. The management of narcolepsy is difficult in the pediatric population due to lack of data from randomized studies and no FDA-approved

**Figure 88-3.** Cerebrospinal fluid levels of hypocretin-1 in patients with narcolepsy-cataplexy, narcolepsy without cataplexy, and idiopathic hypersomnia. (Data derived from Kanbayashi, T., et al., 2002. CSF hypocretin-1 [orexin-A] concentrations in narcolepsy with and without cataplexy and idiopathic hypersomnia. *J Sleep Res* 11, 91.)

medical treatments. Lifestyle changes also are a mainstay of management, especially in children. These include increasing nighttime sleep, having a scheduled 20- to 30-minute nap, and a daily exercise regimen. Teenagers should be counseled against driving and avoiding endangering work and social situations if daytime sleepiness is uncontrolled.

## TREATMENT OF DAYTIME SLEEPINESS

### Wake-Promoting Agents

Modafinil and its biologically active r-isomer, armodafinil, are approved for treatment of excessive sleepiness in narcolepsy in adults. These agents are believed to be dopamine reuptake inhibitors and affect alpha-adrenergic, serotonergic, and GABA pathways (Dauvilliers, et al., 2007; Mignot, 2012; Lecendreux, 2014). Modafinil is metabolized through cytochrome P450 with a half-life of 13 hours. Armodafinil has a longer half-life than modafinil. In various case series in children and adolescents, modafinil has been efficacious in up to 85% of subjects. Daily doses ranging from 50 to 600 mg have been reported. However, additional benefit is not seen beyond 400 mg daily dosing. The typical starting dose in children is 50 to 100 mg, which should be titrated to achieve the desired control of sleepiness. Common side effects are headache, irritability, and a loss of appetite. It also may cause hepatic dysfunction and severe skin reactions such as Stevens-Johnson syndrome.

### Stimulants

Amphetamines and related compounds are simple derivatives of catecholamine and affect the dopaminergic and noradrenergic pathways and possibly the serotonergic systems. Dextroamphetamine and the newer lisdexamfetamine dimesylate, which is a prodrug with a long half-life, may be useful in pediatric narcolepsy. The side effects are tachycardia, hypertension, palpitations, anxiety, irritability, and psychotic reactions. Development of tolerance and dependence also are possible. Due to the effects on the metabolism and endocrine and cardiac function, close monitoring is recommended. Typical starting doses are 2.5 to 5 mg and 20 mg daily for dextroamphetamine and lisdexamfetamine, respectively, with gradual increases based on the patient's response.

Methylphenidate and related compounds are similar to amphetamines but do not completely substitute the catecholamine mechanism of action which is through dopamine reuptake inhibition and dopamine release. Methylphenidate is short acting and hence has a high potential for dependence and tolerance. Various longer acting formulations are available with varying half-life, onset of action, and reduced addiction potential. The side effects are similar to amphetamines, and similar precautions and monitoring are recommended. Methylphenidate preparations also have been used to treat sleepiness in narcolepsy.

### Treatment of Cataplexy

Antidepressants have been used in the treatment of cataplexy. The use is off label even in adults. Selective serotonergic reuptake inhibitors (SSRI) such as fluoxetine and dual serotonergic and noradrenergic reuptake inhibitors (SNRI) such as venlafaxine are the most commonly used agents with venlafaxine apparently being the most efficacious. Tricyclic antidepressants such as clomipramine and protriptyline also have been used but are less effective. Common side effects are headache, nausea, agitation, abdominal pain, and diarrhea. A few series describe successful treatment with SSRI/SNRIs for pediatric

cataplexy. In one study, venlafaxine was the third most commonly used medication in pediatric narcolepsy. The maximum daily doses ranged from 63 to 95 mg with high continuation rates. The most common side effect was irritability. It did not improve sleepiness, sleep paralysis, and hypnagogic hallucinations significantly.

## TREATMENT OF NOCTURNAL SLEEP FRAGMENTATION

The successful treatment of nocturnal sleep fragmentation can improve the daytime sleepiness. Although not specifically studied, longer acting melatonin and other hypnotics may be used to improve fragmentation.

### Sodium Oxybate

Sodium oxybate was initially developed as an anesthetic agent but was found to increase N3 and REM and thus was studied in detail in adults with narcolepsy and cataplexy. It is now approved for the treatment of cataplexy and excessive sleepiness in adults with narcolepsy. It was also found to improve nocturnal sleep fragmentation, thus becoming the only drug that treats all symptoms of narcolepsy. The mechanism of action is unclear, but it is believed to activate the GABA-B receptor. The half-life is 30 minutes and the total duration of effect is only 2 to 4 hours. Therefore two doses given 4 hours apart in older children and three divided doses for very young children are required. However, it may take weeks or months to see a clinically meaningful effect on sleepiness and cataplexy. Several case series have reported the use of sodium oxybate in children. Murali and Kotagal reported that 88% showed symptom improvement, including the reduced frequency and severity of cataplexy in a small study in pediatric narcolepsy. Aran and associates reported using doses of 6800 to 7600 mg with side effects of irritability, weight loss, and nausea. These side effects were more common in prepubertal than postpubertal children. Mansukhani and Kotagal reported improved symptoms in 86% of the children in combination with other medications. Increased nightmares, nocturnal awakenings, tremors, and blurred vision were reported as side effects. The doses used ranged from 3 to 7 grams. In another study, efficacy of 85% for daytime sleepiness, 82% for cataplexy, and 95% for nocturnal fragmentation symptom relief have been reported. Headache, nausea, weight loss, irritability, and parasomnias were reported side effects.

Apart from the limited data in children, one of the biggest limiting factors is the safety concern. The street form of sodium oxybate has been used recreationally and as a "date rape" drug. It also can cause respiratory depression at high doses, especially with concomitant use of alcohol, and can precipitate withdrawal symptoms in certain situations. Due to this concern, the availability of the prescription drug is limited through a central pharmacy and training is required. Nevertheless, most studies suggest that it is safe when used at nighttime in patients with narcolepsy. However, psychiatric comorbidity and the need for extensive parental involvement also may be limiting factors for its increased use in children.

### Future Treatments

Immunosuppressive agents such as immunoglobulin and natalizumab have been used for the treatment of narcolepsy. Additionally, mazindol, pitolisant (an H3 receptor inverse agonist), and hypocretin replacement therapies also have been used. However, currently there are limited data to recommend their use in children.

## NARCOLEPSY TYPE 2

The ICSD-3 definition of narcolepsy type 2 differs from narcolepsy type 1 in that it is not associated with cataplexy and if the CSF hypocretin test is performed, levels greater than 110pg/mL are seen. The definition also requires ruling out other disorders that present with daytime sleepiness. The diagnosis of narcolepsy type 2 is more challenging as cataplexy is absent. The main presenting feature of narcolepsy type 2 is sleepiness, which may be similar to that seen in narcolepsy type 1. Hypnagogic hallucinations, with or without sleep paralysis, can occur in up to 28% of patients. On average, the frequency of hallucination is three episodes per month. These occur with less frequency in the general population, but hallucinations commonly occur in various psychiatric disorders. Hence, frequent sleep paralysis and hallucinations in the absence of psychiatric symptoms may help to diagnose narcolepsy type 2. There is a poorer association with HLA DQB1\*0602, which is positive in 40% of subjects. CSF hypocretin levels are low in 24%, borderline in 8%, and normal in 68% of patients. Low CSF hypocretin levels in a narcoleptic child may be predictive of the future development of cataplexy. Additionally, the first SOREMPs in nocturnal polysomnography in narcolepsy type 2 may arise out of N1 or wakefulness and from N1 on MSLT in many subjects, which may help to differentiate this entity from nonnarcoleptic disorders. However, MSLT may be falsely negative. In a study, after the second MSLT, the diagnosis changed in 53% of the subjects with sleepiness. Hence, a second MSLT is often recommended (Baumann, et al., 2014).

## KLEINE-LEVIN SYNDROME (KLS)

Kleine-Levin syndrome (KLS) is a rare neuropsychiatric disorder of relapsing-remitting episodes of hypersomnia and behavioral, psychiatric, and cognitive disturbances. The ICSD defines it as at least two recurrent episodes of excessive sleepiness and sleep duration, lasting 2 days to 5 weeks, recurring at least once every 18 months with normal alertness, cognitive function, behavior, and mood between the observed episodes and cognitive dysfunction, altered perception eating disorder, or disinhibited behavior during the episodes that is not better explained by another disorder(s). The onset is in adolescence, with a male predominance. Hypersomnolence is characterized by sleeping 18 to 20 hours per day. Incomplete forms of the syndrome also have been recognized. Hyperphagia may be in the form of binge eating, leading to a 2 to 5 kg increase in body weight. In a recent large study, 45% had birth and developmental abnormalities. In patients with prolonged episodes, the durations of the first episode was on an average of 32 days with longer subsequent episodes and an average 9 years for the disease-course. During the episodes, affected individuals had shorter sleep time, higher levels of anxiety, increased agitation, and more feelings of disembodiment and amnesia than subjects with shorter episodes. Between episodes, individuals with KLS were more tired, needed more naps, fell asleep more rapidly, and had higher anxiety/depression scores. Nocturnal polysomnography during the sleepy period exhibits decreased sleep efficiency (SE), latency to REM, and N3. The MSLT reveals moderately shortened mean sleep latency in the 5- to 10-minute range but lacks the two or more SOREMPs that are typically seen in narcolepsy. The episodic hypersomnia gradually diminishes or evolves into classic depression. A disturbance of hypothalamic function has been hypothesized but not yet definitively established. The association of Kleine-Levin syndrome with HLA DQB1\*0201 and the occasional precipitation after systemic infections, as well as the relapsing and remitting nature, are suspicious for an autoimmune

etiology. There is no satisfactory treatment, although lithium is somewhat effective. Modafinil may reduce the duration of the symptomatic episodes.

Menstrual-related Kleine-Levin Syndrome (previously menstrual-related hypersomnia), idiopathic hypersomnia (IH) and hypersomnia due to medical disorders, medications, or substance abuse are discussed in detail in the online chapter.

### INSUFFICIENT SLEEP SYNDROME (ISS)

The ICSD-3 defines insufficient sleep syndrome as: a) daily periods of irrepensible need to sleep or daytime lapses into sleep or behavioral disturbances in prepubertal children for most days for at least 3 months; b) shorter sleep times on history, sleep logs, or actigraphy; c) longer sleep duration on weekends or vacations; and d) sleepiness not better explained by other disorders. These individuals may have short MSL on MSLT and one in six subjects has multiple SOREMPs. However, most of the SOREMPs in ISS occur after N2 as opposed to N1 in narcolepsy. The additional differentiation from narcolepsy is that longer sleep duration is noted on weekends or holidays compared with weekdays.

In conclusion, EDS in children may be caused by a variety of disorders, which may be difficult to accurately diagnose. As EDS significantly affects overall functioning, these disorders should be assessed and managed appropriately so as to improve overall quality of life.

## INTRODUCTION

Restless legs syndrome (RLS) is a common neurologic sensorimotor disorder characterized by the complaint of a strong or irresistible urge to move the legs (Simakajornboon et al., 2009). Also known as Willis–Ekbom disease (WED), RLS was first described by Thomas Willis in 1685. However, Swedish neurologist Karl-Axel Ekbom formally described the traits of this disorder in a monograph titled *Restless Legs* written in 1945 (Allen et al., 2014). Later, in his 1960 publication in *Neurology*, Ekbom defined all clinical features, provided diagnostic criteria, and coined the term “restless legs syndrome” (Mitchell, 2011).

Much of the medical literature since the initial descriptions of RLS has focused on adult populations, and it was not until the mid-1990s that detailed reports of RLS affecting children started to appear (Picchiatti and Stevens, 2008). Then, in 2003, consensus criteria for the diagnosis of RLS in children and adolescents were published after a workshop meeting by the International Restless Legs Syndrome Study Group (IRLSSG) at the National Institutes of Health (Picchiatti and Stevens, 2008). Because of updates being made to the adult RLS diagnostic criteria and the numerous publications regarding pediatric RLS since 2003, the pediatric RLS diagnostic criteria were revised and updated in 2013 (Picchiatti et al., 2013).

## PREVALENCE

In the United States and Western Europe, RLS is found to occur in 5% to 10% of adults (Picchiatti et al., 2007) with about one third affected to a moderate or severe degree (Picchiatti and Picchiatti, 2008). However, histories obtained from adults who meet criteria for RLS reveal that 40% had initial onset of symptoms before the age of 20 years (Simakajornboon et al., 2009). In 2007 the Peds RLS Epidemiology, Symptoms and Treatment (REST) Study found that criteria for definite RLS were met by 1.9% of 8- to 11-year-olds and 2.0% of 12- to 17-year-olds (Picchiatti et al., 2007). These findings suggest that approximately 984,000 school-aged children in the United States are affected by RLS (Picchiatti and Picchiatti, 2008). One quarter to one half of the affected 8- to 17-year-olds in this population were reported to have moderate to severe symptoms (Picchiatti et al., 2009). Unlike adult RLS, in which there is a 2:1 female-to-male ratio, there is no gender bias in pediatric RLS (Picchiatti and Picchiatti, 2008).

## SYMPTOMS

In his 1960 publication providing diagnostic guidelines, Ekbom wrote that “the sensations appear only when the patient is at rest, most often in the evening and early part of the night, and produce an irresistible need to keep the legs moving. Furthermore, the sensations are not felt in the skin

but deep down inside the legs” (Ekbom, 1960). Over the years, the diagnostic criteria that evolved placed more emphasis on the urge to move, or akathisia, and less on the uncomfortable sensations, or dysesthesias (Allen et al., 2014). The 2003 consensus statement published by the IRLSSG again included “unpleasant sensations” as part of the diagnostic criteria for RLS (Allen et al., 2014). This allowed the use of leg discomfort as one of the criteria for making the diagnosis of definite RLS in children. Children undergoing evaluation for RLS are encouraged to use terms in their own words, when able, to describe the unpleasant sensations. Terms and phrases such as “oowies,” “boo-boo,” “tickle,” “bugs,” “spiders,” “ants,” “want to run,” and “a lot of energy in my legs” have been used by children (Picchiatti et al., 2007; Simakajornboon et al., 2009). These symptoms or unpleasant sensations are worse at rest, relieved by movement, and most severe at night (Picchiatti and Stevens, 2008). Because of difficulties that children may have in describing their symptoms, the time that elapses between initial sleep consultation and diagnosis of definite RLS is 4.4 years (Simakajornboon et al., 2009). The time between onset of clinical sleep disturbance and diagnosis is even longer at 11.6 years (Simakajornboon et al., 2009).

## PRESENTATION

RLS is an underrecognized disorder among children and adolescents. The fact that it is underrecognized, combined with the difficulties young children have in providing a description of their symptoms, makes RLS an underdiagnosed disorder in children (Simakajornboon et al., 2009). Children often present to specialty clinics when family members seek medical advice for moderate to severe symptoms that often result in sleep disturbances (Picchiatti et al., 2007). Children and adolescents in the Peds REST Study who met criteria for the diagnosis of definite RLS were more likely to have a history of difficulty falling asleep or staying asleep at night compared with those who did not meet criteria for definite or probable RLS (69.4% vs. 39.6%) (Picchiatti et al., 2007). As a consequence, many of these children also present with a history of daytime sleepiness. Other complaints and problems at the time of initial presentation include “growing pains,” “school problems,” “short attention,” and hyperactivity (Picchiatti and Stevens, 2008).

## DIAGNOSIS

In 2003, the NIH/IRLSSG published diagnostic criteria for RLS that included separate criteria for children and defined definite, probable, and possible pediatric RLS (Allen et al., 2014). Information from new research led to the simplification of the pediatric diagnostic criteria and integration with the newly revised adult RLS criteria in 2013 (Box 89-1) (Allen et al., 2014). Special considerations for the diagnosis of RLS in children were also outlined (Box 89-2), and research criteria for

**BOX 89-1** International Restless Legs Syndrome Study Group (IRLSSG) Consensus Diagnostic Criteria for Restless Legs Syndrome/Willis–Ekbom Disease (RLS/WED)

RLS/WED, a neurologic sensorimotor disease often profoundly disturbing sleep and quality of life, has variable expression influenced by genetic, environmental, and medical factors. The symptoms vary considerably in frequency from less than once a month or year to daily, and severity from mildly annoying to disabling. Symptoms may also remit for various periods of time. RLS/WED is diagnosed by ascertaining symptom patterns that meet the following five essential criteria, adding clinical specifiers where appropriate.

Essential diagnostic criteria (all must be met):

1. An urge to move the legs usually but not always accompanied by, or felt to be caused by, uncomfortable and unpleasant sensations in the legs.<sup>a,b</sup>
2. The urge to move the legs and any accompanying unpleasant sensations begin or worsen during periods of rest or inactivity such as lying down or sitting.
3. The urge to move the legs and any accompanying unpleasant sensations are partially or totally relieved by movement, such as walking or stretching, at least as long as the activity continues.<sup>c</sup>

4. The urge to move the legs and any accompanying unpleasant sensations during rest or inactivity only occur or are worse in the evening or night than during the day.<sup>d</sup>
5. The occurrence of the above features is not solely accounted for as symptoms primary to another medical or a behavioral condition (e.g., myalgia, venous stasis, leg edema, arthritis, leg cramps, positional discomfort, habitual foot tapping).<sup>e</sup>

Specifiers for clinical course of RLS/WED:

1. Chronic-persistent RLS/WED: symptoms when not treated would occur on average at least twice weekly for the past year.
2. Intermittent RLS/WED: symptoms when not treated would occur on average <2/week for the past year, with at least 5 lifetime events.

Specifier for clinical significance of RLS/WED:

The symptoms of RLS/WED cause significant distress or impairment in social, occupational, educational, or other important areas of functioning by their impact on sleep, energy/vitality, daily activities, behavior, cognition, or mood.

<sup>a</sup>Sometimes the urge to move the legs is present without the uncomfortable sensations, and sometimes the arms or other parts of the body are involved in addition to the legs.

<sup>b</sup>For children, the description of these symptoms should be in the child's own words.

<sup>c</sup>When symptoms are very severe, relief by activity may not be noticeable but must have been previously present.

<sup>d</sup>When symptoms are very severe, the worsening in the evening or night may not be noticeable but must have been previously present.

<sup>e</sup>These conditions, often referred to as "RLS/WED mimics," have been commonly confused with RLS/WED particularly in surveys because they produce symptoms that meet or at least come very close to meeting criteria 1–4. The list here gives some examples that have been noted as particularly significant in epidemiologic studies and clinical practice. RLS/WED may also occur with any of these conditions, but the RLS/WED symptoms will then be more in degree, conditions of expression, or character than those usually occurring as part of the other condition.

<sup>f</sup>The clinical course criteria do not apply for pediatric cases or for some special cases of provoked RLS/WED such as pregnancy or drug-induced RLS/WED, where the frequency may be high but limited to duration of the provocative condition.

(Allen RP, Picchiatti DL, Garcia-Borreguero D, et al. Restless legs syndrome/Willis-Ekbom disease diagnostic criteria: updated International Restless Legs Syndrome Study Group (IRLSSG) consensus criteria-history, rationale, description, and significance. *Sleep Med* 2014;15:860–73.)

**BOX 89-2** Special Considerations for the Diagnosis of Pediatric Restless Legs Syndrome

- The child must describe the RLS symptoms in his or her own words.
- The diagnostician should be aware of the typical words children and adolescents use to describe RLS.
- Language and cognitive development determine the applicability of the RLS diagnostic criteria, rather than age.
- It is not known if the adult specifiers for clinical course apply to pediatric RLS.
- As in adults, a significant impact on sleep, mood, cognition, and function is found. However, impairment is manifest more often in behavioral and educational domains.
- Simplified and updated research criteria for probable and possible pediatric RLS are available (Box 89-3).
- Periodic limb movement disorder may precede the diagnosis of RLS in some cases.

(Picchiatti DL, Bruni O, de Weerd A, et al. Pediatric restless legs syndrome diagnostic criteria: an update by the International Restless Legs Syndrome Study Group. *Sleep Med*. 2013;14:1253–9.)

probable and possible pediatric RLS were updated (Box 89-3) (Picchiatti et al., 2013). Other conditions that may mimic RLS (Box 89-4) should be ruled out (Picchiatti et al., 2013). The common mimics of RLS are often described as pain without the need to move (Picchiatti and Picchiatti, 2010).

**BOX 89-3** Research Diagnostic Criteria for Probable and Possible Pediatric Restless Legs Syndrome**PROBABLE RLS**

The child meets all five essential criteria for RLS, except criterion 4 (occurrence only or worsening in the evening or night).

**POSSIBLE RLS**

The child is observed to have behavior manifestations of lower extremity discomfort when sitting or lying, accompanied by motor movement of the affected limbs. The discomfort is characterized by RLS criteria 2–5 (is worse during rest and inactivity, relieved by movement, worse in the evening or night, and is not solely accounted for as primary to another medical or a behavioral condition).

(Picchiatti DL, Bruni O, de Weerd A, et al. Pediatric restless legs syndrome diagnostic criteria: an update by the International Restless Legs Syndrome Study Group. *Sleep Med* 2013;14:1253–9.)

In order to diagnose RLS in children and adolescents, a description of the RLS sensations should be obtained from the patients in their own words. In addition, the presence and nature of any sleep disturbances and a detailed family history should be obtained from the parents, and an investigation of any suspected contributing factors or differential diagnoses should be completed. A physical and neurologic examination

**BOX 89-4** Differential Diagnosis of Pediatric Restless Legs Syndrome**COMMON MIMICS**

- Positional discomfort
- Sore leg muscles
- Ligament sprain/tendon strain
- Positional ischemia (numbness)
- Dermatitis
- Bruises
- Growing pains

**LESS COMMON MIMICS**

- Leg cramps
- Arthritis
- Other orthopedic disorders
- Peripheral neuropathy
- Radiculopathy
- Myelopathy
- Myopathy
- Fibromyalgia
- Complex regional pain syndrome
- Drug-induced akathisia
- Sickle cell disease

(Picchiatti DL, Bruni O, de Weerd A, et al. Pediatric restless legs syndrome diagnostic criteria: an update by the International Restless Legs Syndrome Study Group. *Sleep Med* 2013;14:1253–9.)

should be performed, and in some cases, polysomnography may be needed for those children who are unable to provide a description of the unpleasant sensations they may be experiencing because of RLS and in whom periodic limb movement disorder (PLMD) is suspected (Picchiatti and Picchiatti, 2008; Picchiatti and Picchiatti, 2010).

One diagnosis that many children and adolescents are given before being diagnosed with RLS is growing pains. In the Peds REST Study, 29.6% of children and 36.8% of adolescents in the study were previously diagnosed with this condition (Picchiatti et al., 2007). Growing pains is a common pediatric diagnosis with a conservative estimated prevalence of 4.7%, but unlike RLS, there is no unified definition or diagnostic criteria. There is overlap between the diagnostic criteria for RLS and the accepted or adopted diagnostic criteria for growing pains, but two features or criteria do distinguish the two disorders. The first is that growing pains are thought to be strictly bilateral, whereas RLS can be unilateral or bilateral; the second is that growing pains are strictly painful, whereas RLS can be associated with a variety of discomforts or unpleasant sensations.

## Iron Deficiency

Iron plays a role in brain dopamine production and synaptic density, myelin synthesis, energy production, and probably in norepinephrine and serotonin neurotransmitter systems (Picchiatti and Picchiatti, 2010). Serum ferritin, a measure of body iron stores, has been found to be low in adults and children with RLS, and adult studies have shown that a serum ferritin level below 50 mcg/L is associated with increased severity of RLS (Picchiatti and Picchiatti, 2008). Low ferritin has been shown to correlate with the occurrence of RLS augmentation. Studies also have shown an increased prevalence of RLS in individuals with iron-deficiency anemia and in blood donors (Picchiatti and Picchiatti, 2008). Serum ferritin levels have been found to be below 50 mcg/L in 83% to 89% of pediatric cases of RLS and less than median normative

values for age and sex in up to 75% of cases (Picchiatti and Picchiatti, 2008; Picchiatti and Picchiatti, 2010). In addition, serum ferritin levels of <12 mcg/L were found in children with RLS and attention deficit hyperactivity disorder (ADHD) compared with children with ADHD alone. Caution should be used when interpreting the results of serum ferritin levels as ferritin is an acute-phase reactant and can be elevated for up to 4 weeks after a febrile illness.

## Iron and Neuroimaging

Studies revealing decreased concentrations of iron and ferritin in cerebrospinal fluid (CSF) suggest that RLS is also associated with a low brain iron content. These findings have prompted investigations of iron concentrations in the brain using other diagnostic modalities, including magnetic resonance imaging (MRI). One of the first studies using a 1.5T MRI found decreased iron concentration in the substantia nigra (SN). A subsequent study using a 3T MRI found decreased iron concentration in the SN of RLS patients who had symptom onset before age 45 years. Non-MRI assessments of brain iron concentrations have supported these findings. Postmortem analyses of the brains of RLS patients have shown lower concentrations of iron in the dopaminergic neurons of the SN. B-mode ultrasound imaging of the midbrain also has shown decreased iron in the SN of RLS patients.

## Family History and Genetics

In the Peds REST Study, 71.4% of children with definite RLS and 80% of adolescents with definite RLS had at least 1 parent respond who had symptoms suggestive of RLS (Picchiatti et al., 2007). A positive history in both parents was found in 17.1% of children and in 16% of adolescents with definite RLS (Picchiatti et al., 2007). In both groups, mothers were more likely to have symptoms with a parental female-to-male ratio of 2.4:1 in children and 2.2:1 in adolescents (Picchiatti et al., 2007). In a later study, one or both biological parents had a positive family history of RLS in 77% of individuals, and when both parents were available for interview, 85% of cases had a parent with RLS (Picchiatti and Stevens, 2008). Early onset of RLS with symptoms occurring before the age of 35 to 40 years is now recognized as highly familial (Picchiatti and Picchiatti, 2008), and adult studies of early-onset RLS have shown a 40% to 92% family prevalence (Picchiatti and Picchiatti, 2010).

In adults, genome-wide studies reported that RLS is associated with gene variants of BTBD9 (on chromosome 6p21.1), MEIS1, and MAP2K5/LBXCOR and possibly associated with PTPRD and A2BP1 (Simakajornboon et al., 2009; Picchiatti and Picchiatti, 2010). BTBD9 also is associated with periodic limb movements in sleep (PLMS) (Picchiatti and Picchiatti, 2010). One study of gene variants in pediatric RLS showed that 87% of children in the study had a positive family history of RLS and association with MEIS1 and MAP2K/LBXCOR variants but not BTBD9.

## Coexistent Conditions

In addition to sleep disturbances and daytime sleepiness, children with RLS may also experience other problems that are often recognized and diagnosed before the diagnosis of definite RLS is made. These include ADHD, depression, and anxiety (Picchiatti et al., 2013). Two earlier studies found a high incidence of PLMS in children diagnosed with ADHD (26% of 69 children in the first study and 64% of 14 children in the second study). More recent findings suggest that approximately 25% of those with RLS have problems with attention,

and 13% to 35% of those with the diagnosis of ADHD meet criteria for RLS (Picchietti et al., 2013). In addition to causing difficulties with attention, poor sleep can also affect memory and emotional regulation in childhood and adolescence (Picchietti and Picchietti, 2008). Poor sleep can lead to negative effect and emotional lability, easy frustration, and difficulty controlling impulses (Picchietti and Picchietti, 2008). In adolescents with sleep disturbance, those with RLS symptoms were found to have a lower grade point average. In a recent study, adolescents and young adults between age 12 to 20 years with the diagnosis of RLS and associated difficulty falling asleep were also found to have worse psychosocial health scores and lower health-related quality of life.

Children may also present with a history of frequent parasomnias such as sleepwalking, sleep terrors, and nightmares (Picchietti and Stevens, 2008). In one study, some children were reported to have sleep-related rhythmic movement disorder such as head rolling and body rocking in addition to the parasomnias (Picchietti and Stevens, 2008). The parasomnias resolve after treatment of RLS and PLMD, suggesting that sleep disruption associated with RLS and PLMD may trigger the occurrence of parasomnias.

Sleep-related rhythmic movement disorder should not be confused with PLMS, a common feature in those with RLS. PLMS are brief extremity jerks during sleep lasting 0.5 to 5.0 seconds, occur at 20- to 40-second intervals, are more common in the lower extremities (legs, feet, and toes) than in the upper extremities, and may be accompanied by transient arousals from sleep, cardiac accelerations, spikes in blood pressure, and sleep disruption (Picchietti and Picchietti, 2008; Picchietti and Stevens, 2008). Often, patients with PLMS are unaware of the movements and the associated arousals from sleep (Picchietti and Picchietti, 2008). Up to 26% of children referred for sleep studies were found to have >5/hour PLMS, and in some children and adolescents, sleep disturbance and PLMS may predominate over complaints of leg discomfort leading to a delay in the diagnosis of RLS for up to 11 years after the onset of clinical sleep disturbance (Picchietti and Picchietti, 2008). One study found that PLMS occur more commonly in Caucasian children than in African American children. Approximately 80% to 90% of adults with RLS also have PLMS, which should not be confused with PLMD (Picchietti and Stevens, 2008). The diagnosis of PLMD is made in the absence of other primary sleep disorders, including RLS (Box 89-5) (Picchietti and Picchietti, 2008). In other words, an individual can have RLS with PLMS but not RLS and PLMD (Picchietti and Picchietti, 2010). In young children, a diagnosis of PLMD can precede a diagnosis of RLS because these children are unable to provide a description of the sensory symptoms associated with RLS (Picchietti and Picchietti, 2010).

With an estimated prevalence of 3% to 15%, enuresis is another common pediatric problem that can occur with PLMS and fragmented sleep. One study found that children with nocturnal enuresis (NE) had a significantly higher periodic limb movement index, a higher arousal index, and a higher awakening index on polysomnography compared with controls.

## TREATMENT

RLS can be managed with pharmacologic and nonpharmacologic treatments. First, it is important to identify and avoid any exacerbating factors (Box 89-6) (Picchietti and Picchietti, 2010). Two exacerbating factors are related to sleep habits, and establishment of healthy and consistent sleep habits is important in children as these changes alone can eliminate symptoms of RLS in mild cases (Picchietti and Picchietti, 2010). The number of hours of sleep recommended for children between

### BOX 89-5 Diagnostic Criteria for PLMD

- A. Polysomnography shows repetitive, highly stereotyped limb movements that are
  - 0.5 to 10 seconds in duration
  - minimum amplitude of 8  $\mu$ V above resting EMG
  - in a sequence of 4 or more movements
  - separated by an interval of more than 5 seconds (from limb-movement onset to limb-movement onset) and less than 90 seconds (typically there is an interval of 20 to 40 seconds)
- B. The PLMS index exceeds 5/hour in pediatric cases and 15/hour in most adult cases.
- C. There is clinical sleep disturbance or a complaint of daytime fatigue.
- D. The PLMS are not better explained by another current sleep disorder, medical or neurologic disorder, mental disorder, medication use, or substance use disorder (e.g., PLMS at the termination of cyclically occurring apneas should not be counted as true PLMS or PLMD).

(Picchietti MA, Picchietti DL. Restless legs syndrome and periodic limb movement disorder in children and adolescents. *Semin Pediatr Neurol* 2008;15:91–9.)

### BOX 89-6 RLS Exacerbating Factors

- Insufficient sleep for age
- Irregular sleep schedule
- Low body iron stores
- Pain
- Caffeine
- Nicotine
- Alcohol
- Medications

(Picchietti MA, Picchietti DL. Advances in pediatric restless legs syndrome: iron, genetics, diagnosis and treatment. *Sleep Med* 2010;11:643–51.)

age 2 and 10 years is 12 to 10 hours, respectively, and adolescents should get 9 hours of sleep (Picchietti and Picchietti, 2010). Additional nonpharmacologic remedies that have been suggested include mental activity, such as reading, card games or computer work, and physical activity, such as aerobic and lower-body resistance training for 3 days per week (Mitchell, 2011).

Because low serum ferritin levels have been found in a higher percentage of children with RLS and is associated with increased severity of symptoms, iron replacement is recommended when the serum ferritin level is 50 mcg/L or less. Two pediatric trials with oral iron supplementation found improvement with a rise in mean serum ferritin levels from 40.8 to 74.1 mcg/L and from 29.1 to 55.7 mcg/L (Picchietti and Picchietti, 2010). The typical dose of iron recommended for children 6 years of age and older is 50 to 65 mg of elemental iron once or twice daily (Picchietti and Picchietti, 2010). Vitamin C can enhance iron absorption and can be given with the oral iron supplement in the form of fruit juice. However, iron absorption can be reduced when taken with calcium, and so the iron supplement should be given 1 to 2 hours before or after the consumption of dairy products (Picchietti and Picchietti, 2008). Iron studies, including serum ferritin level, should be rechecked 2 to 4 months after initiation of iron supplementation.

For those children who are unable to tolerate oral iron supplementation because of intolerable gastrointestinal side effects or when there is a need for rapid replenishment of iron stores, intravenous infusion of iron formulations (iron dextran, low-molecular-weight iron dextran, ferric carboxymaltose, and iron sucrose) can be provided. One study found improvement in symptoms associated with RLS and PLMD in children when given a one-time infusion of iron sucrose with an average dose of 3.6 mg/kg (range 1.21 to 6.6 mg/kg), and serum ferritin levels were found to increase from a mean pre-treatment level of 15.3 mcg/L to a mean postinfusion level of 45.7 mcg/L.

Because studies have shown improvement in RLS after supplementation with iron, therapy with iron is often the first choice for treatment. However, for those who do not respond to iron replacement therapy, other medication options should be considered. Although there are no FDA-approved medications for pediatric sleep disorders, several medications have been used clinically based on efficacy in adults with RLS. In adults, dopaminergic medications are widely used and considered first-line treatment for RLS (Simakajornboon et al., 2009). Carbidopa/levodopa and dopamine agonists (pramipexole and ropinirole) are commonly used, and ropinirole was the first FDA-approved medication for treatment of moderate to severe primary RLS in 2005 followed by pramipexole in 2006 (Simakajornboon et al., 2009). The use of dopaminergic medications is associated with improvement in RLS symptoms and reduction of PLMS and associated arousals from sleep (Simakajornboon et al., 2009). Common side effects of dopaminergic medications include nausea, vomiting, insomnia, daytime drowsiness, hallucinations, obsessive-compulsive behavior, nasal congestion, and fluid retention (Simakajornboon et al., 2009).

Another medication not FDA-approved for the treatment of RLS in children but used clinically is clonidine, an alpha-2 adrenergic receptor agonist used to treat hypertension. Clonidine, given at a dose of 0.2 to 0.4 mg at bedtime, can be helpful for children who have sleep onset problems and also can help manage symptoms of ADHD (Picchiatti and Picchiatti, 2010). Clonazepam, a benzodiazepine, can be used to reduce the unpleasant sensations associated with RLS and improve quality of sleep (Picchiatti and Picchiatti, 2008). Gabapentin, which is an anticonvulsant approved by the FDA for treatment of epilepsy in children that blocks voltage-dependent calcium channels and modulates excitatory neurotransmitter release, can also reduce the sensory and motor symptoms of RLS and improve sleep quality (Picchiatti and Picchiatti, 2010). Temazepam, a benzodiazepine, and zolpidem, which interacts with GABA-benzodiazepine receptor complexes, are used in adults with RLS and may be considered for older children and adolescents with RLS who have severely disturbed sleep (Picchiatti and Picchiatti, 2010). Intrathecal baclofen has not been shown to be effective in relieving RLS symptoms.

## CONCLUSIONS

Studies over the last 20 years have shown that RLS is a common disorder in pediatric populations and should be considered when evaluating a child for sleep difficulties and sleep disturbances. RLS should especially be considered when a child presents with these complaints and has been diagnosed with ADHD or has signs and symptoms of mood disorders such as anxiety and depression. RLS is not a diagnosis that should be overlooked as untreated symptoms can lead to poor school performance and lower quality of life in older children and adolescents.

## APPARENT LIFE-THREATENING EVENTS

### Introduction

An apparent life-threatening event (ALTE) is an acute, unexpected episode in an infant that is witnessed by and is frightening to a caregiver because of some combination of apnea, color change, change in muscle tone, choking, or gagging. The term may be applied to any of a heterogeneous group of events, and therefore the list of possible underlying etiologies is broad, ranging from benign to severe. Although previous terminology such as “near-miss SIDS” (sudden infant death syndrome) or “aborted crib death” was occasionally applied to such events, research has not borne out the assumption that ALTE may represent a precursor to SIDS. Therefore the relationship between ALTE and SIDS has been rejected. However, in many infants such events represent a manifestation of serious underlying disease. Distinguishing which infants have medically significant events from those that do not poses a significant challenge to the clinician.

### Definition

The widely accepted definition of ALTE was established at a consensus conference of the National Institutes of Health in 1986, which defined ALTE as “an episode that is frightening to the observer and that is characterized by some combination of apnea (central or occasionally obstructive), color change (usually cyanotic or pallid but occasionally erythematous or plethoric), marked change in muscle tone (usually marked limpness), choking, or gagging. In some cases, the observer fears the infant has died” ([National Institutes of Health, 1987](#)). The term is usually applied only to children younger than 1 year of age. Although in many cases such episodes are aborted through stimulation or resuscitation, note that contrary to the belief of some this is not a requirement to meet the definition, as some ALTEs may self-resolve.

### Epidemiology

The incidence of ALTEs ranged from 0.58 to 2.46 per 1000 live births in recent population-based studies in the Netherlands and Austria, respectively, and ALTEs were estimated to account for 0.6% to 0.8% of all emergency department visits by infants in two British studies. The average age of infants with ALTE is 8 weeks, and ALTEs occur in roughly equal frequency between males and females.

### Risk Factors

Risk factors for ALTE include a history of prematurity, likely because of immature respiratory center and arousal mechanisms; history of prior ALTE or of episodes of pallor, cyanosis, apnea, or feeding difficulties; common cold or symptoms of upper respiratory infection; and age less than 10 weeks.

### Etiology/Differential Diagnosis

The differential diagnosis of ALTE is extremely broad ([Box 90-1](#)) and ranges from normal phenomena in infants such as periodic breathing or transient choking and gagging during a feeding to true medical or surgical emergencies. Often the infant appears perfectly healthy by the time he or she presents to medical attention, and in many cases—ranging from roughly 10% to nearly 50% in some studies—no underlying cause of the event is ever identified despite appropriate evaluation. Alternatively, some infants receive more than one diagnosis.

In cases for which a cause is assigned to the event, the three most common diagnoses are gastroesophageal reflux (GER), seizure, and lower respiratory tract infection. Of these, gastroesophageal reflux is the most common diagnosis, accounting for roughly 30% of diagnoses in many case series. However, whether GER is the true etiology of the event is highly uncertain because GER is common in healthy infants and a causal relationship between GER and ALTE is difficult to establish. GER may more likely be the true cause of the ALTE if the event was characterized by choking or gagging during or immediately after a feeding, if it was characterized by obstructive apnea rather than a lack of respiratory effort, or if gastric contents were noted in the infant’s mouth or nose during the episode. Furthermore, the clinician should distinguish between GER symptoms and feeding difficulties (poor suck, poor swallowing coordination).

The second most common diagnosis assigned after evaluation for ALTE in many case series is seizure, accounting for approximately 15% to 30% of all cases when febrile seizures are included. Seizures are more commonly the etiology in patients who exhibited a change in muscle tone and no history of choking or gagging during the event. The EEG is often normal immediately after the ALTE. In one cohort of infants with ALTEs who were diagnosed with seizures, only 47% were diagnosed within 1 week of their ALTE presentation and 71% were diagnosed within 1 month ([Bonkowsky et al., 2008](#)). Abnormal brain MRI and developmental delay were found only in those patients who went on to develop chronic epilepsy ([Bonkowsky et al., 2009](#)).

Lower respiratory tract infections are the third most common diagnosis for ALTE in many studies, accounting for approximately 10% to 20% of all patients. Pertussis was diagnosed in 6% to 9% of patients presenting to the ER with ALTE and RSV in up to 15% in some study series.

Any number of other gastrointestinal, neurologic, respiratory, and infectious conditions as well as pathology of nearly every bodily system can also present as ALTE. ALTE may be the initial presentation of metabolic disorders, including inborn errors of metabolism (2% to 5% of cases), many of which are treatable if recognized in a timely manner. Specific inborn errors of metabolism such as organic acidurias, urea cycle disorders, maple syrup urine disease, and fatty acid oxidation disorders may present with acute life-threatening illness.

**BOX 90-1** Differential Diagnosis of an Apparent Life-Threatening Event**Cardiac**

Congenital heart disease  
Arrhythmia (long QT syndrome, WPW)  
Myocarditis  
Cardiomyopathy

**Child abuse**

Munchausen syndrome by proxy (suffocation, intentional salt poisoning, medication overdose, physical abuse, head injury)  
Smothering (unintentional or intentional)

**Gastrointestinal**

Gastroesophageal reflux  
Volvulus  
Intussusception  
Laryngeal chemoreflex  
Gastroenteritis  
Incarcerated hernia

**Infectious**

Sepsis  
Urinary tract infection  
Upper respiratory tract infection  
Encephalitis/meningitis  
Pneumonia

**Metabolic**

Inborn errors of metabolism  
Reye's syndrome  
Nesidioblastosis  
Hypocalcemia  
Hypomagnesemia  
Hypoglycemia

**Neurologic**

Malignancy  
Seizure disorder

Caregivers  
Medications in the home

**Medication**

Prescriptions  
Over-the-counter medications  
Herbs, herbal teas, or supplements

(Adapted from Hall KL, Zalman B. Evaluation and management of apparent life-threatening events in children. *American Family Physician*; published by the American Academy of Family Physicians; 2005.)

Nonaccidental trauma has been shown to be a frequently missed cause of ALTE, and is another important consideration as mortality rates in these patients are extremely high.

**EVALUATION**

The evaluation of an infant presenting with ALTE consists primarily of a focused history and physical examination with diagnostic testing as indicated based on the results of this assessment.

**History**

The history should elicit a detailed description of the event. If apnea was present the history should attempt to determine whether it was central or obstructive and the length of the apneic period. Shallow breathing, episodes of central apnea less than 30 seconds, and periodic breathing of the newborn

may be normal events if not associated with cardiac instability. If color change was observed, the history should attempt to distinguish central cyanosis, which is more concerning, from acrocyanosis or flushing, which are common in normal infants. The history should assess whether the event was self-resolving, required stimulation for resolution, or required resuscitation. Further elements of patient history relevant to the evaluation of ALTE are shown in [Box 90-2](#).

**Physical Examination**

The physical examination should begin with a general assessment of appearance and complete vital signs, including blood pressure and blood oxygenation measurements. Height, weight, and head circumference should also be measured and compared with norms. Particular attention should be paid to the neurologic, cardiac, and respiratory systems as well as possible signs of abuse such as bruising or a bulging anterior fontanel.

## Diagnostic Testing

There is no widely accepted consensus or algorithm for diagnostic testing in infants presenting with ALTE; instead, it is largely dependent on the individual patient's history and physical examination. In 2009 the Dutch Academy of Pediatrics recommended a minimum initial diagnostic panel for ALTE that includes complete blood count with differential, C-reactive protein, serum glucose level, arterial blood gas determinations, urinalysis, electrocardiography, and assessments for *Bordetella pertussis* and respiratory syncytial virus in season. Some experts believe that serum electrolytes, ammonia, pyruvate and lactate, and urine toxicology screen should also be included in the minimum diagnostic evaluation. Further testing including, but not limited to, chest x-ray, EEG, full septic workup, evaluation for nonaccidental trauma (such as neuroimaging, retinal examination, and skeletal survey), investigations for GER, and polysomnography may be appropriate as dictated by the individual clinical picture. Several excellent reviews discuss the circumstances under which such tests may be merited in further detail (Fu et al., 2012; Tieder et al., 2013).

## INPATIENT VERSUS OUTPATIENT MANAGEMENT

Most experts agree that admission for at least 24 hours of in-hospital observation is warranted in most cases of ALTE. In a retrospective study of 625 infants admitted for ALTE, 46 (7.4%) had a subsequent extreme cardiorespiratory event (central apnea >30 seconds, bradycardia >10 seconds, or desaturation >10 seconds with pulse oximetry <80%), usually within 24 hours of admission. Risk factors that increased the likelihood of having subsequent extreme events were postconceptional age less than 43 weeks (5.2-fold increase), premature birth (6.3-fold), and URTI symptoms (11.2-fold) (Al-Kindy et al., 2009). Infants with a history of multiple ALTEs also have been shown to be at especially high risk (approximately four-fold) of requiring significant subsequent medical intervention because of a serious underlying diagnosis. Infants without a previous history of ALTE, who were not born prematurely, who have a normal physical examination, who are greater than 30 days old, and who had a brief self-resolving episode may be reasonable to discharge without admission for observation. In all cases, however, caretakers should be given resources for prompt medical follow up and for basic life support courses. They should also be instructed not to shake their infants as a method of stimulation during an ALTE, a practice that has been found to occur in up to one third of ALTE cases.

## HOME MONITORING

The use of home cardiorespiratory monitors that alert caregivers to bradycardia or absence of chest wall movement (and in some cases to blood oxygen desaturation) is controversial. There is no evidence that home monitors prevent SIDS or provide therapeutic benefit after ALTE. However, some experts agree that on a case-by-case basis such monitors may be appropriate for infants with a high risk of apnea, bradycardia, or desaturations because of prematurity or for infants with unstable airways, dysregulated breathing, or chronic lung disease.

## RISK OF SIDS

The American Academy of Pediatrics Task Force on SIDS has stated that there is no evidence that ALTE is a precursor to

SIDS (Moon, 2011). Although longitudinal studies tracking outcomes of infants who experience ALTE have found elevated death rates in these infants from some etiologies as described below, SIDS has not been found to be one of them. Bolstering the argument that SIDS and ALTE do not lie on the same pathophysiologic continuum is the finding that risk factors for SIDS and ALTE appear to be largely distinct; that ALTEs tend to occur during the day and SIDS at night; that ALTEs peak in the first 2 months of life compared with SIDS between 2 and 4 months of age; and that while SIDS is more common in boys, ALTE occurs equally among genders. Even though SIDS has several modifiable risk factors, particularly the placement of an infant in the prone sleeping position, the same has not been found for ALTEs. In fact, though the 1994 recommendation from the AAP that infants be placed supine for sleep led to a dramatic reduction in SIDS rates (see SIDS section), no reduction in ALTE rates was noted.

## RISK OF DEATH

The risk of death in infants presenting with ALTE ranges from roughly 0.5% to 1.1% in 12-month to 5-year follow-up periods in studies that tracked the outcomes of patients presenting with first ALTE. Causes of death included pneumonia, underlying neurologic disorder, child abuse, and SIDS. Risk factors for a serious underlying diagnosis include a history of multiple ALTEs and suspected child maltreatment. Infants with a history of prematurity are at increased risk for subsequent severe events likely because of immature respiratory control, and possibly at increased risk of death, although in some studies this risk appears to return to baseline once the infant reaches between 43 and 48 weeks of postconceptional age.

## SUDDEN INFANT DEATH SYNDROME

### Introduction

SIDS is characterized by the sudden unexpected death of an infant during sleep. Despite a dramatic decline in recent decades, SIDS remains the leading cause of death in children between 1 month and 1 year of age. Although SIDS has long been enigmatic—perhaps because it likely represents the common result of a heterogeneous set of processes—insight into its pathogenesis continues to evolve. Below are reviewed selected hypotheses regarding the biological basis of SIDS as well as key risk factors—and some protective factors—that appear to make some infants more or less vulnerable to this devastating and still largely mysterious occurrence.

### Definition

SIDS is defined as the sudden death of an infant less than 1 year of age that remains unexplained after a thorough case investigation, including a death scene investigation, autopsy, and review of the clinical history. SIDS is a subset of sudden unexpected infant deaths and comprises roughly 80% of such deaths. Approximately 20% of sudden unexpected infant deaths have a clear cause such as unequivocal suffocation or entrapment, infection, ingestions, metabolic diseases, or trauma (accidental or nonaccidental). However, in many cases distinguishing between SIDS and other causes of sudden unexpected infant death, particularly those that seemingly occur during a sleep period, is challenging. Some cases initially classified as SIDS are subsequently found to be attributable to entities such as metabolic disorders or cardiac channelopathies after further investigation.

## Pathogenesis

### The Triple-Risk Model

The biological basis of SIDS remains an area of active research. However, the improved understanding of risk factors for SIDS, along with the distribution of most deaths between 1 month and 4 months of age, helped lead to the creation of the widely cited triple-risk model for SIDS proposed by Filiano and Kinney in 1994. This model suggests that SIDS occurs in infants when (1) an external stressor or trigger event is encountered, (2) by an infant with an intrinsic vulnerability, and (3) during a critical period of development. External risk factors include prone or side sleeping, airway covering from soft or loose bedding, bed-sharing, overheating, and infections, as discussed below. These represent homeostatic stressors for the infant that may lead to airway obstruction, rebreathing of exhaled gasses, altered cardiorespiratory regulation in response to heat stress, or impaired arousal.

Although an infant would normally be able to overcome such stressors with a compensatory or protective response, in some vulnerable infants these responses fail, particularly when the stressor converges on the infant between 1 and 4 months of age. It is hypothesized that this convergence leads to a failure of homeostatic protective mechanisms such as arousal and head turning or head-up tilt—a failure that is likely potentiated by sleep—resulting in progressively worsening respiratory effort and/or gas exchange, hypoxia, bradycardia, acidosis, hypotension, and death (Fig. 90-1).

### The 5-Hydroxytryptamine System

Investigation of what contributes to the intrinsic vulnerability of some infants to SIDS has focused on the brainstem because

of its role in arousal and homeostatic functions. The most well-studied brainstem system in relation to SIDS is the medullary 5-hydroxytryptamine (serotonergic) system, which is important for arousal and autonomic control, including responses to hypercarbia and hypoxia. There is evidence that there is decreased 5-HT(1A) receptor binding density in areas of the medulla important for autonomic control in SIDS victims compared with controls as well as in male infants compared with female infants, which could potentially account for the gender discrepancy observed in SIDS rates. Recent studies have also shown decreased levels of serotonin itself and of tryptophan hydroxylase, an enzyme that synthesizes serotonin, in relevant areas of the medulla. Perhaps also supporting the serotonin hypothesis is evidence of decreased medullary 5-HT(1A) receptor immunoreactivity in infants exposed to nicotine in utero, which could potentially contribute to the higher rate of SIDS observed in such infants.

### EPIDEMIOLOGY

SIDS is the leading cause of death of infants between 1 month and 1 year of age in the United States, with a rate of 42.6 deaths per 100,000 live births in 2012, accounting for 1679 cases (U.S. Department of Health and Human Services, 2014). Fortunately, SIDS rates have declined dramatically since the discovery in the early 1990s that the prone sleep position dramatically increases the risk of SIDS, which led the American Academy of Pediatrics to issue a recommendation that infants be placed in the nonprone sleep position (the “Back to Sleep” campaign) as a strategy for reducing SIDS rates. Despite minimal change in the years preceding the recommendation, SIDS rates declined by over 50% in the United States in the subsequent decade, with a decrease from 120

**Figure 90-1.** Hypothesized five stages in death from SIDS. (Adapted from Kinney HC, Thach BT. The sudden infant death syndrome. *N Engl J Med* 2009;361:795–805.)

deaths per 100,000 live births in 1992 to 58.1 per 100,000 live births in 2002 as the prevalence of infants placed to sleep in the supine position increased from 13% to 72% (Moon, 2011). The rate of SIDS remains highest in American Indian/Alaska Native (90.4 per 100,000 live births in 2012) and non-Hispanic black (85.1) infants compared with non-Hispanic white (41.8), Hispanic (22.1), and Asian or Pacific Islander (14.8) infants. This may be because of differences in risk factors for SIDS, most notably prone positioning during sleep, which may differ between racial and ethnic groups. According to the National Infant Sleep Position Study, the rate of supine positioning for black infants was 53%, Hispanic infants 73%, white infants 75%, and Asian infants 80% (National Infant Sleep Position Study, 2015).

SIDS is more common in male than in female infants in a roughly 3:2 ratio for unknown reasons.

Perhaps surprisingly, only approximately 10% of SIDS cases occur in the first month of life. Roughly two thirds of SIDS deaths occur in the second, third, or fourth month of life, with a median age of 11 weeks. Ninety percent occur before the age of 6 months and 98% occur before 9 months of age.

## Risk Factors

Hundreds of epidemiologic and case-control studies have examined the risk factors for SIDS, including both environmental and inborn risk factors, and the identification of some of these risk factors has helped lead to a dramatic decline in SIDS rates as discussed above. Below, several of the most widely studied and agreed-upon risk factors are discussed, along with proposed pathophysiologic explanations of why such factors might contribute to SIDS.

## Prone and Side Sleep Position

The prone sleep position is the most well-established risk factor for SIDS, with an excess odds ratio compared with supine positioning varying from 2.4 to as high as 13.1 across studies. Prone positioning has been shown to increase the risk of rebreathing expired gases, particularly when soft bedding is used, leading to hypercarbia and hypoxia. Moreover, the prone position is associated with decreased arousals from sleep, even in the face of apnea. Prone positioning may also increase the risk of hyperthermia and even decrease cerebral oxygenation compared with supine positioning. Other studies have found that there is altered cerebrovascular control in infants sleeping in the prone position and that compensatory responses for prone positioning are diminished between 2 and 3 months of age, corresponding to the peak age of SIDS.

Though much less well studied, side positioning of an infant for sleep is also unsafe compared with the supine position, with an elevated risk similar in magnitude to that of prone positioning. This is perhaps because of the high likelihood of rolling prone.

## Bed-Sharing

A 2012 meta-analysis of 11 studies investigating the association of bed-sharing and SIDS revealed a summary OR of 2.88 (95% confidence interval [CI]: 1.99–4.18) (Vennemann et al., 2012). The risk was highest for infants of smoking mothers (OR, 6.27; 95% CI, 3.94–9.99) and infants less than 12 weeks old (OR, 10.37; 95% CI, 4.44–24.21). Some argue that this may be confounded by infants who are brought into bed because they are ill. Moreover, deaths from an adult rolling onto an infant during sleep are more properly classified as “accidental suffocation or strangulation in bed” rather than SIDS, but this is often difficult to ascertain. The AAP

recommends that infants share a room with their parents without bed sharing.

## Soft Bedding and Bedding Accessories

Soft bedding and bedding accessories such as pillows, quilts, comforters, and sheepskins are associated with an increased risk of SIDS, as they increase the potential of airway covering and rebreathing. In one study of soft bedding there was a 5-fold increased risk regardless of sleep position, which increased to 21-fold when the infant was placed prone with soft bedding (Hauck et al., 2003). The AAP recommends that infants sleep on a firm surface without any soft or loose bedding, with infant sleep clothing used in place of blankets as necessary.

## Overheating

Several studies have suggested that thermal stress may increase the risk of SIDS. Although overheating is more likely to occur in infants placed in the prone position, both overheating and prone positioning appears to be independently associated with SIDS. It is less clear, however, if the risk associated with overheating is independent of the increased risk of asphyxia posed by additional clothes or blankets in the sleep environment.

## Maternal Smoking

Maternal smoking during pregnancy is thought to be the largest preventable risk factor for SIDS aside from sleep position, with an effect that appears to be dose dependent. The putative pathways through which prenatal nicotine exposure leads to elevated SIDS risk are numerous. Several studies have demonstrated an adverse effect of exposure to tobacco products in utero on infant arousal thresholds in both term and preterm infants; some have also demonstrated impaired responses to hypoxemic and hypercarbic challenges. These phenomena may be related to effects of nicotine exposure on the brainstem serotonergic, as discussed above. Smoke exposure also increases the risk of preterm birth and low birth weight, both of which are additional independent risk factors.

## Prematurity

Premature infants are at a roughly fourfold greater risk of SIDS than term infants. This may be because of immature autonomic control systems and the presence of fewer and shorter arousal periods in preterm compared with term infants, particularly in the prone position.

## Infection

There is postulated to be a role of infection in some cases of SIDS, as approximately half of infants who die of SIDS have a seemingly trivial infection at the time of death. Some polymorphisms that could contribute to an excessive inflammatory response in response to infection have been found to be more common in SIDS victims than in controls, and microbial isolates in victims of sudden unexpected infant death are more likely to grow some pathogens at autopsy than are those from infants dying of known noninfectious causes such as drowning or congenital heart disease. However, a causal relationship between these pathogens and SIDS is less clear.

## Genetics

Although there is no evidence of a strong heritable contribution to SIDS, several genetic polymorphisms have been

observed that may increase susceptibility to SIDS in combination with environmental risk factors. These include polymorphisms in genes affecting serotonin transport and autonomic function, which are found more often in SIDS victims than in controls. Mutations in cardiac sodium or potassium channel genes such *SCN5A*, a sodium channel gene that is related to a prolonged QT interval, may be found in 5% to 10% of cases of sudden unexpected infant deaths after molecular testing. Mutations in genes involved in energy metabolism, particularly mutations in the medium-chain acyl-coenzyme A dehydrogenase gene, may be found in approximately 1% of cases of sudden unexpected infant deaths upon metabolic evaluation. If case investigation reveals a “lethal” genetic defect, such as mutations yielding long-QT syndrome or MCAD deficiency, such cases should no longer be classified as SIDS but as explained deaths. In most cases, however, genetic polymorphisms are believed to simply provide a predisposition to SIDS, which may make SIDS more likely when combined with other triggers such as prone sleeping, maternal smoking, infection, or overheating.

## PREVENTION

As discussed above, evidence suggests that the risk of SIDS is minimized with supine sleep position, firm sleep surface without loose bedding, avoidance of overheating, and avoidance of tobacco product exposure, among other measures. Additionally, several studies, including a 2011 meta-analysis, have concluded that breastfeeding has a protective effect against SIDS even when accounting for potential confounding factors, with an approximate halving of the risk (Hauck et al., 2011). In addition to providing immune benefits and reducing the rates of infectious illnesses, which are a risk factor for SIDS, breastfed infants have been found to have a lower arousal threshold during sleep, which may contribute to the protective effect.

Pacifier use also appears to have a protective effect against SIDS, reducing risk by twofold or even greater in several studies, including a meta-analysis. Pacifiers may be protective because of alterations in jaw/airway positioning during sleep or through favorable alterations in autonomic tone that persist even after loss of the pacifier during sleep.

There is no evidence that home cardiorespiratory monitors are protective against SIDS, and the AAP recommends against their use for this purpose.

## The Cerebellum and the Hereditary Ataxias

Paymaan Jafar-Nejad, Stephen M. Maricich, and Huda Y. Zoghbi

An expanded version of this chapter is available on [www.expertconsult.com](http://www.expertconsult.com). See inside cover for registration details.

The cerebellum governs complex motor movements. Disruptions of its inputs or basic structure secondary to developmental anomalies, degenerative diseases, vascular insults, or trauma result in a characteristic spectrum of motor symptoms and signs (Ito, 2002). We will begin by considering these signs and their relation to cerebellar structure; we will then consider the prominent causes of ataxia, with a primary emphasis on the hereditary ataxias. Other conditions associated with cerebellar dysfunction are discussed thoroughly in other sections of this volume.

### THE LANGUAGE AND LOGIC OF CEREBELLAR DYSFUNCTION

Cerebellar lesions or dysfunction disturb regulation of muscle tone, motor control, and coordination of movement. A number of studies have also linked the cerebellum to various higher order cognitive processes subserved by the cerebellar hemispheres and the dentate nuclei, such as sensory discrimination, attention, working memory, semantic association, verbal learning and memory, and complex problem solving. The specific constellation of symptoms is sometimes useful for localizing the cerebellar lesion, but often there is considerable overlap (Manni and Petrosini, 2004).

*Ataxia* is a broad term that refers to a disturbance in the smooth performance of voluntary motor acts. It can be manifested as *abasia* (inability to walk due to spasticity, chorea, or tremor), *asynergia* (lack of coordination between parts that normally act in unison), *dysmetria* (inaccuracy in judging distance or scale, resulting in undershoot or overshoot of intended position of limb or eye), *dysdiadochokinesia* (inability to perform rapid alternating movements, such as pronation and supination of the hand or screwing in a light bulb), and impaired check/excessive rebound responses. Vermal lesions result in truncal ataxia and *titubation* (a faltering, staggering gait when walking and bobbing or swaying of the head and trunk when in a sitting position), whereas hemispheric lesions cause limb ataxia.

*Cerebellar (ataxic) dysarthria* produces abnormalities in articulation (slurring and inaccuracy in range, force and timing; patients sound as if they are inebriated), phonation (vocal quality can be harsh or uneven), resonance (a nasal quality is common), and prosody (patients tend to place equal and excessive emphasis on each syllable). Other kinds of dysarthria exist: there is, for example, the hypokinetic dysarthria seen in Parkinson disease, in which bradykinesia due to loss of dopaminergic neurons in the substantia nigra tends to produce low volume of speech or hoarseness, reduced pitch variability, palilalia (repetition of syllables), and very slow

speech. There is evidence that left cerebellar lesions interfere with speech prosody because of disruptions of interconnections with the right cerebral hemisphere, which mediates this process. *Cerebellar mutism* is sometimes seen after removal of vermian tumors and may result from bilateral involvement of the dentatorubrothalamic tracts.

*Hypotonia* is a decrease in muscle tone in response to stretch. It is typically seen with acute hemispheric lesions and is often accompanied by hyporeflexia. Hypotonia likely results from decreased fusimotor activity resulting in decreased muscle spindle afferent response. It is usually a transient phenomenon after an acute lesion but can be seen in chronic lesions as well.

*Intention tremor* can occur after lesions of the dentate nuclei and is manifest only when the individual attempts to make a directed movement. Postural tremor is a rare manifestation of cerebellar damage.

Eye movement abnormalities are also a manifestation of cerebellar disease, predominantly in the form of pathologic nystagmus (smooth pursuit in one direction alternating with saccadic pursuit in the other). They usually occur when the vermis or flocculonodular lobe are affected. *Ocular dysmetria* (conjugate overshoot or undershoot of a visual target accompanied by voluntary saccades) can result from midline or hemispheric lesions.

Nonmotor manifestations of cerebellar disease can also occur. A cerebellar cognitive affective syndrome has been described in patients with isolated cerebellar lesions of a number of different etiologies; executive functions, spatial cognition, personality changes, and language deficits are all present. The postulated neural substrate involves circuits that link prefrontal, posterior parietal, superior temporal, and limbic cortices to the cerebellum.

Disorders that specifically affect different cerebellar subdivisions lead to a characteristic spectrum of motor abnormalities. *Midline cerebellar disease* causes disorders of stance and gait, truncal titubation, rotated postures of the head, and disturbances in eye movements. These can be subdivided into *rostral vermal lesions* that result in abasia or gait ataxia and *caudal vermal lesions* that cause nystagmus in addition. Lesions of the *fastigial nuclei*, which receive their input from the vermis, result in abasia. *Intermediate hemisphere disease* or lesions of the interposed nuclei cause delayed check (rebound) responses, truncal titubation, dysdiadochokinesia, action tremor, oscillation of outstretched extremities, and incoordination on finger-nose-finger and heel-shin maneuvers. Disruption of the *cerebellar hemispheres and dentate nuclei* result in dysarthria, limb ataxia, hypotonia, terminal and intention tremor, and abnormal eye movements.

## NONHEREDITARY CAUSES OF ATAXIA

Cerebellar disease can result from a number of underlying conditions, many of which are listed in [Box 91-1](#). The most prevalent causes of acute cerebellar ataxia are viruses (e.g., coxsackievirus, rubeola, varicella), traumatic insults, and toxins (e.g., alcohol, barbiturates, antiepileptic drugs) (see [Chapter 92](#)).

Congenital abnormalities of the nervous system, such as Chiari malformation, Dandy-Walker malformation, and basilar impression, can be associated with ataxia. Hemorrhage, infarction, and embolism are unusual causes of selective cerebellar damage. Tumors of the cerebellum (vermal and hemispheric) or the adjacent brainstem, particularly pontine gliomas, are relatively common, but angioblastomas of the cerebellum are rare; von Hippel-Lindau disease, a neurocutaneous condition, is associated with vascular lesions of the cerebellum, as is the PHACE syndrome (posterior fossa malformations, hemangiomas, arterial anomalies, coarctation of aorta and cardiac defects, and eye abnormalities).

Numerous metabolic conditions affecting the central and peripheral nervous systems lead to ataxia. Endocrinologic abnormalities, particularly hypothyroidism, may present with ataxia as the predominant manifestation. Autoimmune disorders can cause ataxia, although this is rare in children; detection of antiigliadin and antiendomysial antibodies indicates gluten sensitivity, a treatable cerebellar syndrome that can appear even in the absence of gastrointestinal symptoms or malabsorption.

## THE HEREDITARY ATAXIAS

The hereditary ataxias can be conceptually divided into two main classes. The first group is ataxias that are caused by enzymatic defects, which are usually inherited in an autosomal recessive manner and typically present in childhood; fortunately, many of these are now treatable. Their basic features and treatments are presented in [Table 91-1](#). The second group, consisting of the progressive degenerative ataxias, can be further categorized based on their mode of inheritance: the

autosomal recessive ataxias, of which Friedreich ataxia is by far the most common; the autosomal dominant inherited ataxias (spinocerebellar ataxias, episodic ataxias, and dentatorubropallidoluysian atrophy [DRPLA]); and the very rare X-linked ataxias. The spastic ataxias can be either autosomal recessive or autosomal dominant, and will be considered as their own group. Given the space constraints and clinical focus of this volume, we will devote the greater part of our discussion to the ataxias that are more likely to be encountered in the clinic, particularly those that present in childhood, along with any distinctive features, treatments, and differential diagnoses that should be considered. We refer readers interested in detailed molecular genetics to the online version of this chapter and to the burgeoning literature that each year sheds greater light on pathophysiology.

## Autosomal Recessive Inherited Syndromes

The recessive ataxias tend to present earlier than the autosomal dominant syndromes, usually in childhood. Because of the inheritance pattern, many cases will present without a clear family history of progressive ataxia; the clinician must maintain genetic causes high on the list of differential diagnoses. We begin here with Friedreich ataxia and ataxia-telangiectasia, the two most common of this relatively uncommon class of diseases. Other recessive ataxias are considered in light of differential diagnosis.

### Friedreich Ataxia (Spinocerebellar Ataxia—MIM 229300)

Friedreich ataxia (FRDA) is the most common autosomal recessive spinocerebellar ataxia, with a prevalence rate of 1 to 2 per 100,000. FRDA shares one notable feature with many of the autosomal dominant ataxias discussed later in this chapter: it is caused by a dynamic mutation—in this case, the expansion of an intronic GAA repeat in the *Frxataxin* (FXN) gene ([Brigatti et al., 2012](#)). Dynamic mutations are notable for causing clinical variability because shorter expansions produce milder phenotypes whereas longer expansions produce more severe, earlier onset disease. For this reason, although FRDA is

**TABLE 91-1** Treatable Causes of Inherited Ataxia

Disorder	Metabolic Abnormality	Distinguishing Clinical Features	Treatment
Ataxia with vitamin E deficiency	Mutation in alpha-tocopherol transfer protein	Ataxia, areflexia, retinopathy	Vitamin E
Bassen-Kornzweig syndrome	Abetalipoproteinemia	Acanthocytosis, retinitis pigmentosa, fat malabsorption	Vitamin E
Hartnup disease	Tryptophan malabsorption	Pellagra rash, intermittent ataxia	Niacin
Familial episodic ataxia type 1 and type 2	Mutations in potassium channel (KCNA1) and $\alpha_{1A}$ voltage-gated calcium channel, respectively	Episodic attacks, worse with pregnancy or birth control pills	Acetazolamide
Mitochondrial complex defects	Complexes I, III, IV	Encephalomyelopathy	Possibly riboflavin, CoQ <sub>10</sub> , dichloroacetate
Multiple carboxylase deficiency	Biotinidase deficiency	Alopecia, recurrent infections, variable organic aciduria	Biotin
Pyruvate dehydrogenase deficiency	Block in E-M and Krebs cycle interface	Lactic acidosis, ataxia	Ketogenic diet, possibly dichloroacetate
Refsum disease	Phytanic acid, alpha-hydroxylase	Retinitis pigmentosa, cardiomyopathy, hypertrophic neuropathy, ichthyosis	Dietary restriction of phytanic acid
Urea cycle defects	Urea cycle enzymes	Hyperammonemia	Protein restriction, arginine, benzoate, alpha-ketoacids

 Vasculitis  
 von Hippel-Lindau disease

typically thought of as manifesting during the early school years, its onset can sometimes be detected as early as 2 years of age or as late as the beginning of the third decade of life. (Dynamic repeats will be discussed in greater detail in the section on autosomal dominant ataxias.)

The first sign of FRDA is usually a progressive gait ataxia, although occasionally electrocardiogram (ECG) abnormalities reveal cardiomyopathy before the ataxia manifests with widening of the base and wavering, which seems to be caused by a loss of proprioception. The poor balance is accentuated when visual input is removed, as in the Romberg test. The gait can be grossly disorganized, with such a marked reeling or lurching quality that it appears contrived. The upper extremities soon become uncoordinated, distal muscles begin to waste, and tremor or choreiform movements may develop in the face and arms. Irregular ocular pursuit is often prominent; dysmetric saccades, square wave jerks, and failure of fixation suppression of the vestibuloocular reflex are common. Cataracts, retinitis pigmentosa, and optic atrophy can also occur. Dysarthria typically develops early in the disease course and the slurring and staccato volume changes are severe enough to quickly render speech ineffectual. Auditory dysfunction is common and may be accompanied by vertigo. Within several years kyphoscoliosis shifts the patient's center of gravity, making walking nearly impossible.

Deep tendon reflexes are lost early on in the disease course, unless the patient had adult onset (usually after age 25). Position and vibration sense are grossly impaired, and pain and temperature sensations are lost in the distal extremities. Club-foot and pes cavus are nearly always present. Cardiomyopathy occurs in two-thirds of FRDA patients and is progressive. In advanced stages of the disease, patients may experience exertional dyspnea, palpitations, and anginal pain; later in the disease course, arrhythmias (especially atrial fibrillation) and congestive heart failure are frequent. (Cardiac dysfunction is the leading cause of death in FRDA.) Twenty percent of patients show an abnormal glucose tolerance curve due to insulin resistance, which may also affect relatives; another 10% develop diabetes mellitus. Thermal dysregulation, intermittent emesis, and respiratory dysfunction have been reported. The mean age of death is in the middle thirties.

In the minority of patients with shorter GAA expansions (less than 500), the age of onset is between 26 and over 40 years, with the smaller repeats producing later onset and milder symptoms. Disease progression is slower in these patients and they have a lower incidence of secondary skeletal abnormalities. Very rarely, patients homozygous for GAA expansions may present with spastic paraparesis and hyperreflexia but not ataxia.

**Differential diagnosis.** Children with FRDA who have not yet developed dysarthria or extensor plantar responses may be difficult to distinguish on clinical criteria alone; because one-fourth of FRDA patients display atypical clinical signs, DNA testing is the only means to a definitive diagnosis. FRDA is most frequently confused with *demyelinating hereditary motor and sensory neuropathy type I (HMSN1 or CMT1)*, which can present in childhood with clumsiness, areflexia, and minimal distal muscle weakness. Another consideration is *ARSACS (Autosomal Recessive Spastic Ataxia of Charlevoix-Saguenay; Table 91-2)*, in which patients are characterized by spasticity, dysarthria, distal muscle wasting, foot deformities, truncal ataxia, absence of sensory potentials in the lower limbs, retinal striations similar to those in Leber optic atrophy, and frequent mitral valve prolapse. *Vitamin E deficiency* causes ataxia with areflexia but is usually distinguishable from FRDA by the greater likelihood of hyperkinesia and titubation, less severe peripheral neuropathy, and the lack of cardiomyopathy. It is obviously important to test for both abetalipoproteinemia

and alpha-tocopherol deficiency, because these ataxias can be cured by large doses of Vitamin E. *Friedreich Ataxia 2 (MIM 601992)* has been reported in families with a FRDA phenotype but without point mutations or GAA expansions in the X25 gene; the biological basis for the phenocopy is not known, but it has been proposed that mutations in genes that lie in the iron metabolism pathway may be responsible.

**Treatment.** Frataxin is thought to be active in iron/sulfur cluster biosynthesis; the repeat expansion diminishes frataxin levels and leads to increased oxidative stress, which can be mitigated by certain antioxidant treatments. Notably, a high proportion of FRDA patients have decreased serum CoQ10 levels; as CoQ10 deficiency causes mitochondrial dysfunction, low- and high-dose CoQ10/vitamin E therapies have proven effective in improving International Cooperative Ataxia Rating Scale scores. A0001 ( $\alpha$ -tocopheryl quinone; EPI-A0001), a potent antioxidant, causes a dose-dependent improvement in neurologic function, as measured by the Friedreich Ataxia Rating Scale (FARS). Therapy with other antioxidants, iron chelators, and/or glutathione peroxidase mimetics has been suggested but not thoroughly tested. Idebenone, a short-chain analog of coenzyme Q10, has been able to improve cardiac function and decreased ventricular mass. In low dose trials, idebenone treatment has no effect on the progression of ataxia, but higher doses (up to 60 mg/kg/day) are well tolerated, provide neurologic benefit, and improve activity of daily life in FRDA patients who are still ambulatory. Symptomatic treatment in the form of antispasticity agents can be helpful to relieve painful muscle spasms, and surgical correction of scoliosis is palliative (Di Prospero et al., 2007).

### Ataxia-Telangiectasia (Louis-Bar Syndrome—MIM 208900)

Several ataxia syndromes are caused by defects in DNA repair mechanisms; why the cerebellum is particularly vulnerable to such defects is unknown. Ataxia-telangiectasia (AT), caused by mutations in the DNA repair factor *ataxia-telangiectasia mutated (ATM)*, is one of the most common inherited causes of early childhood-onset ataxia in most countries, with a prevalence of one in 40,000 to 100,000 live births in the United States. Its core neurologic features are ataxia, oculomotor apraxia, and choreoathetosis, but neoplasia and sinopulmonary disease are equally prominent concerns and usually the cause of death by the fourth or fifth decades of life.

Early motor development appears to be normal until around the time that the child starts walking, when ataxia is noted. The ataxia progresses until ambulation is impossible, by the beginning of the second decade. Choreoathetosis and dystonia occur in up to 90% of patients, and these motor findings become more prominent with increasing age. Facial weakness leads to the characteristic impassive faces, as well as drooling and dysarthria. Although strength is initially normal, many patients in their 20s and 30s develop progressive spinal muscular atrophy predominantly affecting the hands and feet. Peripheral neuropathy in the form of diminished deep tendon reflexes and loss of large fiber sensation is also seen. Mental function is well-preserved, although deficits in short-term memory can occur in the third and fourth decades.

Oculomotor apraxia is a distinguishing feature of the disease. The apraxia commonly presents before the appearance of conjunctival telangiectasias and is characterized by defects of initiating voluntary saccades, hypometric voluntary saccades accompanied by compensatory eye-blinking and/or head-thrusting movements, and disrupted smooth pursuit movements. Involuntary saccade initiation and optokinetic nystagmus can be impaired as well, and vestibuloocular reflexes can be increased.

**TABLE 91-2** Autosomal Recessive Cerebellar Ataxias

Ataxia	Chromosome	Gene	Gene Product	Mechanism	Age of Onset (Years)
Friedreich ataxia	9q13	X25	Frxataxin	GAA repeat	2–51

ARSACS	13q12	SACS	Sacsin	Frameshift and nonsense mutations	1–20

**Figure 91-5.** Characteristic conjunctival telangiectasis observed in a 12-year-old with ataxia-telangiectasia.

Telangiectasias are usually first observed in patients between the ages of 2 and 4 years, although they can occur as early as birth and as late as 14 years of age (Figure 91-5). In addition to the conjunctivae, they appear on exposed areas of the skin, particularly areas of friction and trauma such as the auricle, nasal bridge, antecubital, and popliteal spaces. Sun exposure enhances their appearance. Premature aging of hair and skin is common, as are skin infections, including chronic blepharitis. Vitiligo and café-au-lait spots can be seen. Rarely, scleroderma-like lesions occur.

Recurrent sinopulmonary infections are common, affecting 90% of patients, and usually result in chronic bronchitis, bronchiectasis, or both. The impairment of cellular immunity is also manifest by abnormally developed or absent adenoids, tonsils, lymphoid tissue, and thymus gland. Patients have impaired delayed hypersensitivity response to skin-sensitizing antigens and a delayed homograft-rejection response. The DNA repair defect puts patients at greater risk than the general population for Hodgkin disease, leukemia, lymphoma, and lymphosarcoma. Other commonly associated neoplasms are brain tumors, gastric adenocarcinomas, ovarian dysgerminomas, gonadoblastomas, cystic adenofibromas, uterine leiomyomas, and thyroid adenomas. Hypogonadism is frequent in both genders, and growth retardation is notable despite normal levels of growth hormone. Insulin-resistant diabetes is also occasionally seen as part of the clinical constellation.

**Differential diagnosis.** The core triad of ataxia, oculomotor apraxia, and choreoathetosis occurs in several related diseases, usually without the extraneurologic features of AT. One nonclassic presentation of AT includes early onset dystonia. Patients with mild variant forms of classic AT may lack immunodeficiency, telangiectasias, cancer or sinopulmonary infections; these individuals have a later onset and slower progression of neurologic signs, longer lifespans, and somewhat less chromosomal instability and cellular radiosensitivity. Interestingly, atypical AT can be misdiagnosed as FRDA until the natural progression of the disease reveals a greater spectrum of symptoms. *Ataxia-telangiectasia-like disorder 1 (ATLD1; MIM 604391)* patients are almost identical to those with AT except they lack telangiectasias. They do, however, show increased susceptibility to DNA damage because of the

underlying defect in DNA repair (the mutated gene, *MRE11*, is part of a complex that senses DNA double-strand breaks and recruits ATM to repair the damage). Approximately 6% of ataxia-telangiectasia patients may in fact have ATLD1. *ATLD2 (MIM 615919)* has been described in several patients from an extended Ohio Amish family with developmental delay, ataxia, and sensorineural hearing loss. Other features include short stature, cutaneous and ocular telangiectasia, and photosensitivity with evidence of predisposition to sun-induced malignancy in one patient. None of the patients had evidence of immunodeficiency. *Early onset ataxia with ocular motor apraxia and hypoalbuminemia (EAOH; also known as ataxia-oculomotor apraxia 1/ AOA1; MIM 208920)* is also clinically similar to AT but without extraneurologic features (see separate entry). *Xeroderma pigmentosum (XP)* and *Cockayne syndrome (MIM 278760)*, caused by mutations in the DNA repair factor ERCC4, can also present neurologically, with ataxia, tremor, weakness, nystagmus, and sensorineural hearing loss, though the cutaneous manifestations such as sun sensitivity appear earliest and are very prominent. Interestingly, some XP patients do not develop neurologic signs until midlife.

**Laboratory findings.** Serum alpha-fetoprotein (AFP) is elevated about 10 ng/mL in greater than 90% of classic AT (but note that serum AFP can remain higher than normal in unaffected children up to around 24 months of age). Carcinoembryonic antigen (CEA) levels are also typically elevated in affected individuals. Most patients have decreased concentrations or absence of immunoglobulin (Ig) A and E; IgM, G1, and G3 concentrations are normal or elevated, and immunoglobulin G2 and G4 concentrations are generally decreased. Although the diagnosis can be made clinically, genetic testing for mutations in the *ATM* gene is recommended, as *ATM* heterozygotes are at an increased risk of cancer.

**Treatment.** Patients with severe recurrent infections and low IgG levels can receive intravenous Ig; those with chronic bronchiectasis need aggressive pulmonary hygiene. Early and continued physical therapy can minimize contractures and scoliosis. Children must be monitored for early signs of malignancy (bruising, localized pain or swelling, weight loss), but treatment of neoplasms is a delicate proposition because patients are extremely sensitive to radiation and chemotherapy and demonstrate resultant ulcerative dermatitis, severe esophagitis, dysphagia, and deep-tissue necrosis. Conventional doses of cancer therapies are fatal in AT. In fact, patients should avoid exposure to ionizing radiation, such as CT scans. L-DOPA derivatives and anticholinergics may improve basal ganglia dysfunction; amantadine, fluoxetine, or buspirone may help with the loss of balance and impaired speech; tremors can often be controlled by gabapentin, clonazepam, or propranolol (Lavin et al., 2007).

### Early Onset Ataxia with Ocular Motor Apraxia and Hypoalbuminemia (Ataxia-Oculomotor Apraxia 1, AOA1—MIM 208920)

EAOH/AOA1 is the most frequent cause of autosomal recessive cerebellar ataxia in Japan, and the second most common cause in Portugal; it accounts for up to 10% of autosomal recessive cerebellar ataxias. Caused by mutations in *aprataxin (APTX)*, which is involved in single-strand DNA repair, the disease is clinically similar to AT (see previous section) and should be considered in early onset ataxia when both FRDA and AT have been excluded. A slowly progressive ataxia (mean age of onset 4 years of age; range 2 to 10 years) is followed by dysarthria, upper-limb dysmetria, mild intention tremor, choreoathetosis, and upper limb dystonia. Ocular apraxia

typically occurs a few years after symptom onset, progressing to ophthalmoplegia. Areflexia, sensory and motor neuropathy, and retinal/macular lesions seen on funduscopy are common. Different degrees of cognitive impairment can be observed, but intellect can also be normal. Lifespan is not affected.

Laboratory studies reveal hypoalbuminemia and hypercholesterolemia in the majority of cases as a later manifestation of the disease. An EMG invariably reveals axonal neuropathy. Genetic testing to rule out AT and locate mutations in the gene *APTX* is useful.

**Differential diagnosis.** A second ataxia-telangiectasia–like disease has been described in families of several different ethnic backgrounds. *Ataxia with Oculomotor Apraxia 2 (AOA2)*, also known as *Spinocerebellar ataxia autosomal recessive 1 (SCAR1)* (MIM 606002), is caused by mutations in the *SETX* gene, which produce gait ataxia, sensory motor neuropathy, and ocular apraxia, the latter occurring about 50% of the time. Although overall cognitive function is normal, subtle changes in executive function can be seen on neuropsychological testing. AOA2 is distinguished from AOA1 by its slightly later age of onset (ages 10 to 22 years), less common ocular apraxia, high levels of serum alpha-fetoprotein (AFP), and normal serum albumin. The functional prognosis is also better in AOA2. Half of the Portuguese families diagnosed with AOA, however, have no mutations in either *APTX* or *SETX* identifiable by mutation scanning; they may have mutations in other genes or mutations not detectable by this method, such as large deletions. Interestingly, other mutations in *SETX* are transmitted in an autosomal dominant manner and cause juvenile amyotrophic lateral sclerosis (ALS4). Some mutations in *APTX* produce an adult-onset ataxia with oculomotor apraxia. Other SCARs (SCAR2 through SCAR17) have each been described in only a handful of individuals in geographically distinct populations (listed in [Table 91-2](#); see online chapter for more information).

**Treatment.** Muscle coenzyme Q10 (CoQ10) is often low in patients with AOA1, but this deficiency responds to supplementation. Also recommended is a high protein diet to restore serum albumin concentration and prevent edema. It is interesting to note that SCAR9, also known as Coenzyme Q10 Deficiency Primary 4 (COQ10D4—MIM 612016), and SCAR10 also show some clinical improvement with CoQ10 supplementation, suggesting these ataxias involve respiratory chain dysfunction.

### Mitochondrial DNA Depletion Syndrome 7 (Hepatocerebral Type) (MTDPS7—MIM 271245); Infantile Onset Spinocerebellar Ataxia

MTDPS7, previously known as infantile onset spinocerebellar ataxia (IOSCA) is the second most common inherited ataxia in Finland, with a population carrier frequency of more than 1 in every 230. That said, it has been described only in Finland, and only a few dozen cases have been thoroughly reported. It is characterized by hypotonia, ophthalmoplegia, sudden onset hearing loss, seizures, and sensory axonal neuropathy. Dysfunction starts usually within the first 2 years of life with clumsiness and difficulty walking or loss of the ability to walk; athetosis, ataxia, ophthalmoplegia, and hearing loss appear by school age, with sensory axonal neuropathy appearing by adolescence. Refractory epilepsy can occur early or late and is the predominant cause of death.

**Differential diagnosis.** IOSCA disease results from a recessive mutation in C10Orf2 encoding Twinkle (Y508C), a mitochondrial deoxyribonucleic acid (mtDNA)-specific helicase. Different mutations in this same gene cause *autosomal dominant progressive external ophthalmoplegia (adPEO)* with multiple mtDNA deletions (MIM 606075), a neuromuscular disorder

sharing a spectrum of symptoms with MTDPS7. *Progressive myoclonic epilepsy* (MIM 254800) was first described in families from Estonia and eastern Sweden, but Finland has a greater number of affected individuals. The disease typically presents with generalized tonic-clonic seizures and myoclonus, with ataxia seen later in the course. *Ramsay Hunt syndrome* is actually a heterogeneous group of disorders whose clinical hallmarks are progressive ataxia and myoclonus. The presentation, age of onset, and severity are variable, and the differential diagnoses includes *myoclonic epilepsy associated with ragged red fibers (MERFF)* (MIM 545000) and *sialidosis* (MIM 256550), which are described elsewhere in this text.

Other early onset ataxias that affect the eyes and ears include *Behr syndrome* (MIM 210000), which is an optic atrophy beginning in childhood, in conjunction with ataxia, spasticity, and mental retardation. *Marinesco-Sjögren syndrome* (MIM 248800) is characterized by cataracts, ataxia, myopathy, varying degrees of mental retardation, and short stature.

### Autosomal Dominant Inherited Ataxias (Spinocerebellar Ataxias)

The dominantly inherited spinocerebellar ataxias ([Table 91-3](#)) are a group of conditions characterized by premature cerebellar neuronal loss, with some types involving additional structures such as the optic nerve, basal ganglia, brainstem, and spinal cord. When the onset is in adulthood, as is typical, the patient may first notice difficulty turning corners or decrements in acquired fine motor control skills, such as those used in sport. Despite the rather circumscribed pathology, these disorders are surprisingly heterogeneous: patients with SCA display various clinical features of progressive ataxia, motor impairment, extrapyramidal symptoms, retinal degeneration, deafness, ophthalmoplegia, dorsal column dysfunction, and peripheral neuropathy. The overall incidence of SCA is 1 to 5 in every 100,000, with an average age of onset in the fourth decade of life.

We should note that the SCAs were earlier designated the *olivopontocerebellar atrophies (OPCAs)* because of the frequent presence of atrophy involving the cerebellum and the pontine and olivary nuclei. They have also been known as autosomal dominant cerebellar ataxias (ADCAs), primarily because of the Harding classification system, which attempted to categorize these disorders by constellation of clinical signs. Type I ADCAs have a cerebellar syndrome plus pyramidal signs, supranuclear ophthalmoplegia, extrapyramidal signs, and dementia. Type II ADCAs show a cerebellar syndrome plus pigmentary maculopathy. Type III ADCAs are “pure” cerebellar syndromes that have mild, if any, pyramidal symptoms ([Harding, 1993](#)). Some authors have attempted to keep these clinical categories and assign genetically defined SCAs to them, but the clinical findings are so variable that they are unreliable for precise diagnosis.

Genetic studies over the last 25 years have confirmed that genetic heterogeneity underlies the complex clinical picture ([Table 91-3](#)). It is worth noting that a number of these ataxias appear to result from a common mutational mechanism: expansion of a repeat tract, usually a trinucleotide repeat, within the disease-causing gene. The expanded repeats, whether in the coding or noncoding region of the disease gene, are known as *dynamic mutations* because they show repeat instability, with a tendency to expand in germline transmission. Repeat expansions that occur in the noncoding region of the gene underlie Friedreich ataxia (discussed previously) and spinocerebellar ataxias 8 and 12 ([Dick et al., 2006](#)). Interestingly, two diseases that share this mutational mechanism, fragile X syndrome and myotonic dystrophy, are not characterized by ataxia—but fragile X syndrome is related

**TABLE 91-3** Molecular Genetics and Salient Features of Autosomal Dominant Cerebellar Ataxias

Ataxia	Chromosome	Gene	Gene Product	Mechanism	Age of Onset (Years)	Normal Repeat	Expanded Repeat	Core Features in Addition to Ataxia
<b>POLYQ EXPANSION</b>								
SCA1	6p23	SCA1	Ataxin-1	CAG repeat	6–60	6–44*	39–82*	Ophthalmoparesis, pyramidal and extrapyramidal signs
SCA2	12q24	SCA2	Ataxin-2	CAG repeat	2–65	15–24	35–59	Slow saccades, peripheral neuropathy
SCA3/MJD	14q32.12	ATXN3	Ataxin-3	CAG repeat	11–70	13–47*	45–84*	ophthalmoparesis, pyramidal, extrapyramidal, and amyotrophic signs
SCA6	19q13	CACNA1A	Cav2.1	CAG repeat	16–73	4–20	21–33	Dysarthria, nystagmus, occasional mild proprioceptive deficit
SCA7	3p14.1	SCA7	Ataxin-7	CAG repeat	Birth-53	4–35	37–460	Ophthalmoparesis, retinopathy, pyramidal signs, dementia
SCA17	6q27	SCA17	TBP	CAG repeat	3–48	25–42	45–66	Gait ataxia, extrapyramidal signs, dementia
DRPLA	12p13.31	DRPLA	Atrophin-1	CAG repeat	4–55	7–34	53–93	Choreoathetosis, dystonia, seizures, myoclonus, dementia
<b>NONCODING EXPANSION</b>								
SCA8	13q21	SCA8	SCA8 RNA	CTG repeat in 3' UTR	18–72	2–91*	110–1300*	Gait ataxia, dysarthria, nystagmus, spasticity
SCA10	22q13	SCA10	Ataxin-10	ATTCT repeat in intron 9	14–45	10–29	750–4500	Gait ataxia, dysarthria, nystagmus, spasticity, seizures, neuropathy
SCA12	5q32	SCA12	P2R2B	CAG repeat in 5' UTR	8–55	7–32	51–78	Tremor, dysarthria, hyperreflexia, sometimes dystonia, late dementia
SCA31	16q22.1	BEAN/TK2	BEAN/TK2	TGGAA repeat insertion in intron of BEAN and TK	45–72	Rarely (0.23%) 1.5–2.0 kb	2.5–3.8 kb	Decreased muscle tone, horizontal nystagmus
SCA36	20p13	NOP56	NOP56	GGCCTG repeat in intron 1	>50	4–14	650–2500, rarely short repeats of 25–31	Slowly progressive gait ataxia, ocular abnormalities, upper motor neuron signs, some develop hearing loss
<b>OTHER MUTATIONS</b>								
SCA5	11q13.2	SPTBN2	β-3 spectrin	Deletion, missense mutations	10–68			Pure, slowly progressive cerebellar syndrome (ataxia, dysarthria)
SCA11	15q15.2	TTBK2	TTBK2	Truncation mutation	15–43			Mild, slowly progressive gait and limb ataxia
SCA13	19q13.33	KCNC3	KCNC3	Missense mutations	<1–60			Early onset: motor delay, mental retardation, hyperreflexia
SCA14	19q13.4	PKC-γ	PKC-γ	Missense mutation	0–69			Facial myokymia, hyperreflexia, dystonia, myoclonus; late-onset cases are more pure cerebellar ataxia
SCA15	3p26.1	ITPR1	ITPR1	Deletion, missense mutation	Child-Adult			Slowly progressive pure cerebellar syndrome
SCA16	-	-	-	-				Early reports now merged with SCA15; SCA16 considered “vacant”

**TABLE 91-3** Molecular Genetics and Salient Features of Autosomal Dominant Cerebellar Ataxias (*Continued*)

Ataxia	Chromosome	Gene	Gene Product	Mechanism	Age of Onset (Years)	Normal Repeat	Expanded Repeat	Core Features in Addition to Ataxia
SCA19/22	1p13.2	KCND3	KCND3	Missense mutations	10–45			Cognitive impairment, postural tremor, myoclonus in Dutch family; pure cerebellar syndrome in Chinese kindred
SCA20	11q12	260kb duplication	Multiple genes	Duplication	19–64			Palatal tremor, dysphonia; dentate calcification on computed tomography
SCA21	1p36.33	TMEM240	TMEM240	Truncation, missense mutations	6–30			Extrapyramidal signs, severe cognitive impairment
SCA23	20p13	PDYN	PDYN	Missense mutations	43–56			Slowly progressive gait and limb ataxia, hyperreflexia
SCA26	19p13.3	EEF2	EEF2	Missense mutation	26–60			Slowly progressive pure cerebellar syndrome
SCA27	13q34	FGF14	FGF14	Fibroblast growth factor deficiency	5–20			Early onset hand tremor, dyskinesia, slowly progressive ataxia; psychiatric symptoms, cognitive deficits
SCA28	18p11.21	AFG3L2	AFG3L2	Missense mutations	12–36			Slowly progressive; dysarthria, lower limb hyperreflexia
SCA29	3p26.1	ITPR1	ITPR1	Missense mutation	Infant			Motor and mild cognitive delay; very slowly progressive or nonprogressive gait ataxia
SCA34	6q14.1	ELOVL4	ELOVL4	Missense mutation	Early skin lesions, late ataxia			Skin lesions appear after birth, disappear by age 25, then reappear in middle age along with ataxia and decreased tendon reflexes
SCA35	20p13	TGM6	TGM6	Missense mutations	40–48			Gait affected first; upper limbs later; hyperreflexia, tremor, torticollis, ocular dysmetria
SCA38	6p12.1	ELOVL5	ELOVL5	Missense mutations	34–51			Nystagmus, slow saccades
SCA40	14q32.11	CCDC88C	CCDC88C	Missense mutations	42–43			Ocular dysmetria, intention tremor, dysdiadochokinesia, hyper-reflexia
<b>MUTATION UNKNOWN</b>								
SCA4	16q22	Unknown	Unknown	Unknown	19–59			Sensory axonal neuropathy and pyramidal signs
SCA18/SMNA	7q31-q32	Unknown	Unknown	Unknown	12–25			Peripheral neuropathy
SCA25	2p	Unknown	Unknown	Unknown	1.5–39			Severe sensory neuropathy, gastrointestinal symptoms
SCA30	4q34.3-q35.1	Unknown	Unknown	Unknown	45–76			Slowly progressive pure cerebellar syndrome
SCA32	7q32-q33	Unknown	Unknown	Unknown	Broad range of age at onset			Cognitive impairment, infertility
SCA37	1p32	Unknown	Unknown	Unknown	38–64			Dysmetric vertical saccades, some nystagmus

to an ataxia. Whereas the full-blown CGG expansion in the *FMR1* gene that causes fragile X silences the gene, subtle “pre-mutation” expansions cause a late-onset, progressive ataxia with tremor (and sometimes cognitive impairment) known as *Fragile X-associated Tremor/Ataxia Syndrome (FXTAS; MIM 309550)* that occurs in older relatives of children with fragile X. Interestingly, the small expansions characteristic of pre-mutations do not silence the *FMR1* gene, but rather cause a dominant toxic effect at the RNA level. FXTAS could easily be mistaken for a late-onset SCA, though it is usually misdiagnosed either as essential tremor, Parkinson disease, or as Alzheimer disease when it involves dementia. Regardless, different repeat expansions in the same gene can produce dramatically different phenotypes.

There is a particular subclass of repeat diseases caused by a CAG repeat expansion in the coding region of the respective disease genes, where it produces an expanded polyglutamine tract in the resultant protein that encodes for the amino acid glutamine (Zoghbi and Orr, 2000). These “polyglutamine diseases” consist of dentatorubropallidoluysian atrophy (DRPLA), spinocerebellar ataxias (SCAs) 1, 2, 3, 6 and 7, Huntington disease (HD), and spinobulbar muscular atrophy (SBMA). SBMA and HD are not spinocerebellar syndromes, although some patients with HD can present with ataxia. The polyglutamine expansion is usually a few repeats, but this is enough to cause earlier onset (“anticipation”) and a progressively more severe phenotype in each subsequent generation. Here, then, is the reason this group of diseases is so clinically heterogeneous. The longer the polyglutamine protein, the greater the neural toxicity, and the greater the number of brain regions that succumb to it (Riess et al., 2008). It is not clear why the threshold for vulnerability to toxicity differs across brain regions, but the cerebellum seems to be especially sensitive in this regard.

One consequence of the dynamic nature of these mutations is that family history can be deceiving. An older relative might develop a slight ataxia at the same time a grandchild is developing changes in mood or behavior and losing vision. Often, older relatives have died before developing clear phe-

notypes or are misdiagnosed with conditions related to advanced age. The difficulty is most extreme with infantile onset cases, which often look nothing like the adult-onset disease. Adult SCA2, for example, begins with ataxia, but one case of infantile onset SCA2 has been reported to cause apneic episodes and frequent vomiting in the perinatal period progressing to hypotonia, severe developmental delay, blindness, and death by 2 years of age. As mentioned previously, juvenile cases often show pathology in neural tissues quite distinct from those affected by the adult-onset disorders; the retina is neural tissue that appears to have a higher threshold for damage from polyglutamine toxicity than many other brain tissues. In this regard, it is interesting to note that in SCA7 patients with more than 59 repeats, visual impairment is the most common presenting symptom; in individuals with pathologic repeats of less than 59, the presenting symptom is ataxia. This supports the notion that larger expansions are required to elicit ocular symptoms, although there is yet no mechanistic explanation.

In short, the clinical phenotypes of the SCAs are so variable that one cannot reliably diagnose a particular case on clinical grounds alone. This holds even for the SCAs that are caused by nonrepeat mutations, such as SCA5, 13, 14, and 27. Genetic testing has simplified matters in many cases, and Table 91-3 provides a snapshot of the various SCAs and DRPLA according to genotype. These features should help the clinician prioritize gene testing, which is commercially available for the most common SCAs (in fact, screening for SCAs 1, 2, 3, and 6 should identify 50% of familial cases). The curious reader is encouraged to consult the online version of this chapter and other references for a more thorough account.

## Episodic Ataxias

There are currently eight episodic ataxias, all of which are rare dominant disorders (see online chapter). They tend to have early onset; the frequency and duration of attacks varies widely, as do the features (Jen et al., 2007). The episodic ataxias (EAs) are summarized in Table 91-4.

**TABLE 91-4** The Episodic Ataxias

Episodic Ataxia	Chromosome	Gene	Gene Product	Mechanism	Age of Onset (Years)	Duration of Episodes, Frequency	Features
EA1	12p13	EA1	KCNA1	Channelopathy	Early childhood	Seconds to minutes can be several per day	Ataxia, triggered by exercise, fever, stress, sudden motion
EA2/FHM	19p13	CACNA1A	Cav2.1	Channelopathy: missense and nonsense mutations, deletion	4–30	Minutes to days	Ataxia, migraine, ocular features; interictal nystagmus, ataxia, epilepsy Responds to acetazolamide
EA3	1q42	Unknown	Unknown	Unknown	1–42	1 min to 6 hours	Vertigo, imbalance, tinnitus, diplopia Responds to acetazolamide
EA4	Unknown	Unknown	Unknown	Unknown	23–42	Short, can evolve to constant	Vertigo, nausea, tinnitus, horizontal nystagmus, oscillopsia; triggered by sense of visual motion
EA5	2q22-q23	CACNB4	CACNB4	Channelopathy: missense and nonsense mutations	Juvenile	Hours	Ataxia; same mutation in German kindred-produced general epilepsy without ataxia

**TABLE 91-4** The Episodic Ataxias (*Continued*)

Episodic Ataxia	Chromosome	Gene	Gene Product	Mechanism	Age of Onset (Years)	Duration of Episodes, Frequency	Features
EA6	5p13	SLC1A3	EAAT1	Missense mutation	5	Hours to days	Progressive ataxia, seizures, hemiplegia
EA7	19q13	Unknown	Unknown	Unknown	<20	Hours to days; once a month to once a year	Weakness, dysarthria
EA8	1p36-p34	Unknown	Unknown	Unknown	2	Minutes to hours; twice a day to twice a month	Ataxia, weakness, dysarthria, persistent intention tremor

**TABLE 91-5** The Hereditary Spastic Ataxias

Spastic Ataxia (MIM#)	Gene	Mode of Inheritance	Age of Onset (Years)	Features
SPAX1 (108600)	VAMP1		10–20 yrs	Progressive leg spasticity, dysarthria, ocular movement abnormalities
SPAX2 (611302)	KIF1C		1–16 yrs	Frequent falls, ataxia, head tremor, hyperreflexia, fasciculations
SPAX3/ARSAL (611390)	MARS2	AR	2–59 yrs; mean 15 yrs	Ataxia and spasticity
SPAX4 (613672)	MTPAP	AR	Early childhood	Ataxia, spastic paraparesis, dysarthria, optic atrophy, upper limb hypertonía
SPAX5 (614487)	AFG3L2	AR	Childhood	Spasticity, ataxia, oculomotor apraxia, dystonia, myoclonic epilepsy
SPAX6/SACS/ARCSACS (270660)	SACS	AR	Childhood	Spasticity and ataxia, very slow course, stops progressing after age 20
SPAX7	Unknown	AD	Infancy–20	Symmetric ataxia, dysarthria, pyramidal signs, optic atrophy
SPAR (607565)	Unknown	-	15–35	Later onset: spastic paraplegia early onset: + ataxia, mental retardation

## Hereditary Spastic Ataxias

The hereditary spastic ataxias are a heterogeneous group of disorders that combine the features of hereditary spastic paralysis and spinocerebellar ataxia (see online chapter). They typically present first with lower limb spasticity followed by ataxia, dysarthria, impaired ocular movements, and gait disturbance (Table 91-5).

### X-LINKED SPINOCEREBELLAR ATAXIAS

Besides Fragile X-associated ataxia syndrome (FXTAS, noted previously), several very rare X-linked ataxias have been described based on the pattern of inheritance in specific kindreds. No genetic localization has yet been established for any of them. The reader is referred to the online version of this chapter for brief descriptions and relevant references.

### MANAGEMENT OF CEREBELLAR DYSFUNCTION AND ATAXIA

When ataxia is the result of certain metabolic disorders or toxins, trauma, or neoplasia, specific therapies for the underlying condition can be curative (Table 91-1). Direct neurologic causes of ataxia, however, such as inherited diseases, are for the most part not yet amenable to treatment. The only therapies at present that have proven beneficial to patients, though far from curative, are acetazolamide for certain episodic ataxias (Table 91-4), vitamin E, and coenzyme CoQ10 for the respective deficiencies. The array of genes involved makes the notion

of developing specific therapies for each of these very rare diseases rather daunting, yet ongoing research has turned up promising avenues for therapeutic development, especially for the polyglutamine diseases. The advent of high-throughput screening approaches in cellular and invertebrate models of these diseases is facilitating the search for compounds that reduce polyglutamine toxicity.

In the meantime, it is important to remember that patients benefit from physical and occupational therapy and all the supportive forces that promote health and happiness in any of us; though these approaches will not restore mobility in advanced disease, they nonetheless alleviate other symptoms such as spasticity and greatly improve quality of life.

The term “cerebellum” is from Latin, meaning “the little brain.” It is a part of the hindbrain situated in the posterior cranial fossa. The cerebellum is organized into different regions with specialized functions. The cerebellum integrates massive sensory information from many regions of the brain and spinal cord. This information is used by the cerebellum to smoothly coordinate ongoing movements and to participate in motor planning. Detailed anatomy and physiology of the cerebellum and its pathways are discussed in Chapter 91.

Acute cerebellar ataxia refers to a group of acquired disorders that result in acute dysfunction of the cerebellum. These conditions are usually associated with either intoxication or inflammation of the cerebellum from infectious, postinfectious, or paraneoplastic processes. The cerebellum regulates the coordination of movement, muscle tone, and motor control. The word “ataxia” is derived from the Greek word *ataktos*, which means “lack of order.” Acute ataxia is defined as an unsteadiness of walking, coordination, or fine motor movement with duration greater than 72 hours. Acute cerebellar ataxia is the most common cause of childhood ataxia, accounting for about 30% to 50% of all cases, in children less than 6 years of age.

### CLINICAL EVALUATION OF ACUTE ATAXIA

Acute cerebellar ataxia typically presents with rapidly progressive symptoms evolving over a few hours but at most over 1 to 2 days. In cases associated with a prodromal illness, the onset of ataxia is usually within 1 to 3 weeks after the onset of the prodromal illness. Although a gait disturbance is the primary or only symptom in most patients, in other patients, a wide range of clinical signs of cerebellar dysfunction could be observed (Box 92-1).

Evaluating a pediatric patient presenting with acute ataxia begins with obtaining a detailed history of the presenting illness, including the onset, timing, and progression of symptoms. This process could be a key component for excluding serious etiologies (Ryan and Engle, 2003). The most commonly reported causes of childhood ataxia include postinfectious, toxin ingestion, and Guillain-Barré syndrome (GBS). A history of fever, antecedent respiratory and gastrointestinal infections, and varicella and Epstein-Barr virus infections are commonly reported in postinfection-mediated cerebellar ataxia. A history of recent vaccinations or an exposure to toxins, alcohol, drugs, or household medications and chemicals commonly provides information suggesting a specific diagnosis. A family or personal history of recurrent ataxic episodes, seizures, or migraine headaches may propose a metabolic or genetic disorder. Recent head or neck trauma can present with ataxia and may be because of vertebralbasilar dissection or intracranial bleeding.

Signs of cerebellar dysfunction (see Video 92-1) could be categorized into the following groups: (1) speech deficits, (2) oculomotor disturbances, (3) limb ataxia, (4) deficits of posture and gait, and (5) cognitive disturbances (Pandolfo and Manto, 2013).

Physical examination may be challenging in significantly ataxic children, especially in cases of altered responsiveness.

Children with postinfectious cerebellar ataxia are normally alert and interactive. Abruptly altered responsiveness suggests toxic ingestion or a severe central nervous system (CNS) disturbance, such as stroke or an acute disseminated encephalomyelitis (ADEM). Therefore it is essential to differentiate poor coordination from weakness. Physical examination should focus on identifying life-threatening conditions that may require immediate intervention. Symptoms such as confusion, hallucinations, or somnolence may indicate toxin ingestion, demyelinating diseases, stroke, or meningoencephalitis (Sivaswamy, 2014). Signs of elevated intracranial pressure such as papilledema should be excluded. Motor examination should focus on eliciting weakness as younger children with hemiparesis or paraparesis may present with ataxia (i.e., “paretic ataxia”). A detailed cerebellar examination should evaluate different components of cerebellar dysfunction. Ataxia caused by pathology of the cerebellum is present even with eyes open and is not or only minimally exacerbated by eye closure; therefore, a Romberg test will be negative. Sensory examination and an examination of deep tendon reflexes should be performed to evaluate peripheral nerves or roots, dysfunction of which may result in a “sensory” ataxia.

Acute cerebellitis presents with a wide range of symptoms varying from subtle gait abnormality to more fulminant forms involving truncal instability, head titubation, intention tremor, dysmetria, and nystagmus. Physical examination may possibly reveal fever or meningismus, which can be indicative of a CNS infection. Pharyngitis, lymphadenopathy, and splenomegaly occur in Epstein-Barr virus infection. Otoroscopic and skin (viral exanthema) examination may be useful. In addition, ataxia is a common feature of acute postinfectious demyelinating encephalopathy. Brainstem encephalitis can involve the inflow and outflow tracts of the cerebellum, resulting in ataxia (Ryan and Engle, 2003).

### CAUSES OF ACUTE CEREBELLAR ATAXIA

The most common causes of acute cerebellar ataxia are inflammatory cerebellitis and toxin ingestion. Together they constitute nearly 80% of the cases of childhood ataxia (Ryan and Engle, 2003). Other common causes of childhood ataxia are listed in Box 92-2 and discussed in this section.

#### Inflammatory Cerebellitis

##### Infectious/Postinfectious

Acute cerebellar ataxia most commonly results either from postinfectious autoimmune-mediated cerebellar inflammation or as a result of direct infection of the cerebellum. This accounts for about 30% to 40% of all cases. A history of antecedent illness 1 to 3 weeks before presentation is obtained in about 70% of patients (Ryan and Engle, 2003). Numerous infectious agents have been implicated (Table 92-1), with varicella being the most common organism associated with cerebellar inflammation (Bozzola et al., 2014). Cerebellar dysfunction can occur before the eruption of the exanthem. When direct infection of cerebellar parenchyma

- Epilepsy (nonconvulsive status, minor motor status)

occurs, postinfectious cerebellitis is felt to represent the majority of cases.

**Demyelinating**

ADEM and multiple sclerosis (MS) are acquired inflammatory demyelinating diseases of the CNS white matter that can involve the cerebellum. ADEM is typically a monophasic condition that usually occurs after a preceding infection. Patients present acutely with multifocal neurologic deficits invariably including encephalopathy. The cerebellum is involved in about half of all cases. Magnetic resonance imaging (MRI) often reveals large, confluent multifocal white matter lesions of the cerebral and cerebellar hemispheres.

MS is a recurrent demyelinating disorder of the CNS that often involves the cerebellum and spinal cord. Approximately 5% of all patients with MS have their first attack before age 18. Cerebellar involvement at MS disease onset is more common in children compared with adults.

Neuromyelitis optica (NMO) is a recurrent demyelinating condition caused by antibodies to aquaporin 4 water channels on astrocytic foot processes. These channels are concentrated in the lining of the cerebrospinal fluid aqueductal system. Given the proximity of the fourth ventricle to the cerebellum, children with aquaporin 4 autoantibodies often have episodic ataxia (EA). Unlike ADEM and MS, Neuromyelitis optica (NMO) relapses are more likely to result in permanent disability.

The Miller Fisher variant of GBS is another inflammatory cause of acute ataxia consisting of ataxia, areflexia, and ophthalmoparesis. These may occur in up to 10% of all children with GBS. It is associated with antibodies to the gangliosides GQ1b, GD3, and GT1a (van Doorn et al., 2008).

\*Most commonly reported.

**Paraneoplastic**

The presence of malignancy frequently triggers a complex immunologic response in the affected individual, including activation of cell-mediated and humoral immune systems. As part of the normal humoral response to malignancy, antibodies that cross-react with normal CNS antigens can be produced. Opsoclonus-myoclonus ataxia syndrome (OMAS) is a rare paraneoplastic condition that is associated with neuroblastoma. The condition typically affects toddlers between age 1 and 3 years. It presents with acute onset of ataxia, behavioral disturbance, rapid chaotic movements of the eyes (opsoclonus), and myoclonic jerking of the limbs, leading to common description of the condition as “dancing eye, dancing feet syndrome.” This was initially described as “Kinsbourne encephalitis.” Ataxia may be the only initial symptom leading to an initial diagnosis of an acute cerebellar ataxia. With time, opsoclonus and myoclonus become prominent. Early behavioral disturbances in a child with acute ataxia should raise suspicion for OMAS. Although the condition is felt to be immune-mediated, no specific antibody has been identified. However, a number of studies have identified autoantibodies to CNS antigens in patients with OMAS. The most commonly reported target is to the cerebellar Purkinje cells. However, anti-Hu antibodies, usually associated with small-cell lung cancers in adults, have also been reported. Neuroblastoma underlies more than half of all cases of OMAS, but only 2% to 3% of patients with neuroblastoma develop OMAS. Detecting the presence of neuroblastoma requires CT or MRI, bone and metaiodobenzylguanidine (MIBG) scans, bone marrow testing, urine catecholamine measurements, and other studies. Studies report strong diagnostic yields of <sup>131</sup>I MIBG scintigraphy ranging from 70% to 92% in detecting the primary tumor. Ataxia has also been described as a paraneoplastic phenomenon in isolated pediatric cases of Hodgkin disease, Langerhans cell histiocytosis, and hepatoblastoma.

### BOX 92-3 Reported Toxicology Screening for Acute Ataxia

- Alprazolam
- Triazolam and temazepam
- Diazepam and lorazepam
- Benzodiazepine
- Phenytoin
- Phenobarbitone
- Carbamazepine
- Phenothiazine

## Intoxication

Accidental poisoning in children aged less than 6 years is the most common form of toxin ingestion. Ataxia may be seen with ingestion of lead, alcohol, anticonvulsants, benzodiazepines, antihistamines, organic chemicals, or heavy metals. A retrospective study reports that 32.5% of acute ataxia in children is caused by ingestion regardless of whether a history of toxin exposure is elicited (Gieron-Korthals et al., 1994). Agents responsible for positive screening are listed in Box 92-3 (Whelan et al., 2013). Several studies have reported benzodiazepines as a common cause of ataxia. Isopropanol (found in rubbing alcohol) ingestion has been reported to cause ataxia in 5% of 91 children younger than 6 years of age. Clinical evidence of toxicity typically develops between 0.5 and 2 hours postingestion.

## Mass Lesions

Posterior fossa tumors, including medulloblastoma, pilocytic astrocytoma, and ependymoma, account for approximately 50% of all childhood brain tumors. These usually present with a slowly progressive ataxia and symptoms of increased intracranial pressure such as headache, vision disturbances, and focal deficits on neurologic examination. Cerebellar abscess is an uncommon cause of acute ataxia as symptoms usually develop slowly over a period of days and weeks. Nevertheless, the sudden hemorrhage into a posterior fossa tumor with resultant acute ataxia may be the first evidence of malignancy.

## Trauma

Isolated acute ataxia is uncommon from blunt force trauma. Cerebellar contusion or posterior fossa bleeds can cause ataxia, which can be associated with headache. This may be caused by direct axonal injury or because of mass effect.

## Vascular

Posterior circulation strokes, although rare in children, can present with acute ataxia. This possibility should be considered especially in children predisposed to thromboembolic disease. Arteriovenous malformations with hemorrhage and traumatic vertebral artery dissection can present with acute ataxia. Cerebral angiography identifies an abnormality mostly in the V2 segment (C1 to C6) of the vertebral artery in dissection.

## Metabolic/Genetic

Many inborn errors of metabolism can present with ataxia, which can develop acutely or intermittently because of triggered decompensation (see Table 92-2). The first presentation of such disorders in childhood can mimic an acute cerebellar ataxia. Several inborn errors of metabolism can present with ataxia as an early, prominent symptom. Some examples

include glucose transporter-1 deficiency syndrome, pyruvate dehydrogenase deficiency, and biotinidase deficiency. Furthermore, disorders affecting mitochondrial function are also well known to have ataxia as an early and prominent symptom. A recent study found that specific risk factors were helpful in differentiating acquired (i.e., noninherited) from inherited etiologies of subacute or chronic childhood ataxia (Benini et al., 2012). These risk factors included (1) duration of symptoms greater than 2 weeks; (2) consanguinity; (3) a first-degree relative with similar presentation; (4) presenting symptoms of abnormal gait, rash, ichthyosis, or multiorgan abnormalities; and (5) an abnormal examination finding of motor function (gait, tone, strength), deep tendon reflexes, and clonus, dysmetria, pes cavus, or sensory deficits. The presence of these risk factors suggested a greater likelihood of a genetic or metabolic disorder that frequently could be determined by specific testing, including mitochondrial DNA testing, chromosomal microarray, serum lactate, pyruvate, carnitine, acylcarnitine, vitamin E and amino acid determinations, urine organic acid screening, and testing for fragile X syndrome. For more information on hereditary ataxias, see Chapter 91.

Recurrent genetic ataxias (EA type 1 [EA1] to EA7) may mimic acute cerebellar ataxia at first presentation. However, recurrent episodes, a favorable response to acetazolamide, and typical clinical features (see Chapter 91) distinguish these disorders from acute cerebellar ataxia. EA1 (KCN1A) and EA2 (CACNA1A) account for the majority of cases.

## Other Neurologic Disorders

Ataxia is common in basilar migraine, in which it can be associated with vertigo and focal neurologic deficits. Focal causes of cerebellar dysfunction have to be ruled out, although positive visual phenomena strongly suggest the migrainous nature of the episode.

Benign paroxysmal vertigo is thought to be a migraine equivalent and is more common than benign paroxysmal positional vertigo, which can also present as acute ataxia. Detailed event description, family history, and the Dix-Hallpike maneuver could be revealing.

Ataxia can be prominent during the ictal or postictal phases of seizures and in nonconvulsive seizures. Glutamic acid decarboxylase (GAD) antibody (GAD-ab) has been implicated in a spectrum of neurologic syndromes. However, there is insufficient presently data regarding the role of GAD-ab in childhood acute ataxia. The role of antimyelin-associated glycoprotein, glutamate receptor delta-2 autoantibody, and post-varicella anticytosomal antibodies in acute ataxia remains to be clearly delineated.

Sensory ataxia results from loss of sensory input to the cerebellum owing to lesions in the posterior column of the spinal cord or the peripheral nervous system. It is characterized by a positive Romberg sign (ataxia worse on closing eyes) and diminished deep tendon reflexes. Sensory ataxia is present in as many as 15% of pediatric cases of GBS, usually in association with neuropathic weakness and other sensory symptoms (Gieron-Korthals et al., 1994).

Optic ataxia is caused by impaired visual control of the direction of limb-reaching for a visual target. It may be associated with lesions in the superior parietal lobule, which also affects visual-guided saccades and other forms of eye-hand coordination.

## Psychogenic

A psychogenic or nonorganic cause of ataxia must be considered when the examination findings are bizarre, inconsistent, or incongruent. Further evaluation should address possible

previous psychiatric illness, secondary gain, or a precipitating event. Psychogenic ataxia is a diagnosis of exclusion.

## INVESTIGATIONS IN ACUTE ATAXIA

Acute postinfectious cerebellar ataxia is a diagnosis of exclusion. A thorough history and physical examination are far more likely to identify the etiology rather than an extensive workup. The selection of primary laboratory and radiologic investigations should be based on clinical scenario. Serious conditions that may present with ataxia should be excluded. Of all investigations performed in the diagnostic workup of acute cerebellar ataxia, the urine and/or serum drug screen are most likely to prove diagnostic, even where a source of ingestion is not immediately apparent (Gieron-Korthals et al., 1994). Neuroimaging should be obtained if there is concern of a mass lesion. CSF analysis should be done if there is concern for acute CNS infection or the diagnosis is uncertain.

### Computed Tomography and Magnetic Resonance Imaging

The diagnostic screening yield of CT and MRI is low; only 5% of children initially being evaluated for ataxia showed any telling abnormalities (Figure 92-1). CT and MRI are more commonly used to rule out a specific diagnosis such as tumor, stroke, ADEM, or the risk of herniation before lumbar puncture (Whelan et al., 2013).

In children with OMAS, MRI or CT of the chest, abdomen, and pelvis, with thin cuts through the adrenals, is recommended. Nuclear scintigraphy is also recommended if conventional imaging is nondiagnostic.

### Cerebrospinal Fluid

CSF examination is frequently performed in the evaluation of children with acute ataxia. Data from reported studies of children with acute ataxia found abnormal CSF findings in 43% of children undergoing lumbar puncture (Whelan et al., 2013). CSF studies showed mild pleocytosis and variable elevations of protein. In one study, CSF was analyzed according to the suspected etiology (e.g., viral, vaccine-related, and idiopathic) and no significant differences were noted (Connolly et al., 1994).

### Electromyography and Electroencephalography

Electromyography (EMG) and nerve conduction velocity studies should be considered in evaluation of acute-onset ataxia in cases in which clinical diagnosis of the Miller Fisher variant of GBS is suspected (Whelan et al., 2013). Very early (less than 4 days) electromyography assessment in GBS may be nondiagnostic; however, testing multiple motor and sensory nerves (greater than or equal to 3) may detect abnormal findings suggestive of disease. EMG is also useful in confirming the diagnosis of EA1, by showing continuous motor unit activity, most often in the hands.

Studies reported electroencephalographic (EEG) findings in 24 of 57 children with acute ataxia. Data on 24 children with acute ataxia showed nonspecific EEG abnormalities in 42%.

Acute ataxia may be present during the ictal or postictal phase of seizures in children (Ryan and Engle, 2003). Nonconvulsive epileptic states have also been referred to as pseudoataxia and may present as ataxia with or without alteration of consciousness. Clinicians can consider obtaining an EEG if

there is a history of epilepsy or evidence of an altered mental status or the clinical suspicion of nonconvulsive status epilepticus. Nonconvulsive seizures are usually seen with preexisting seizure disorders and cognitive impairment. This diagnosis is associated with underlying EEG abnormalities with dramatic clinical and electrographic improvement when treated appropriately (Whelan et al., 2013).

### Toxicology

Ataxia after ingestion is most frequently caused by medications but less often from exposure to organic chemicals, solvents, and heavy metals. Accidental poisoning in children less than 6 years of age is the most common form of toxin ingestion, with a second peak in adolescence, where intoxication occurs as a result of substance abuse (Gieron-Korthals et al., 1994). A high index of suspicion should always be maintained, because a history of ingestion or exposure might not be forthcoming. After ingestion, ataxia is often accompanied by mental status changes such as lethargy, confusion, inappropriate speech, or unconsciousness. Toxicology screens are therefore of value in the initial evaluation of acute ataxia in children. Other agents associated with ataxia in children include phencyclidine and other recreational drugs, antiepileptic drugs, anticholinergic agents, muscle relaxants, "magic" mushrooms, and cold remedies.

### Urinary Catecholamines/Metaiodobenzylguanidine Scintigraphy

Opsoclonus-myoclonus syndrome is a rare autoimmune disorder in which a neuroblastoma is found in at least 50% of affected individuals. Evaluation for an occult neuroblastoma should occur in all children with opsoclonus or myoclonus accompanying the ataxia as well as in children with isolated ataxia whose symptoms do not begin to resolve within 2 weeks (Figure 92-2). On the use of MIBG scintigraphy in patients suspected of having neuroblastoma, studies have reported a sensitivity for tumor detection in the range of 70% to 92% (Brunklaus et al., 2012). One study detected residual, recurrent, or metastatic neuroblastoma in 16 of 20 patients (80%). Another study showed MIBG sensitivity of 70% in detecting abdominal or pelvic neuroblastoma and 83% in detecting thoracic neuroblastoma (Brunklaus et al., 2012). In a third study, sensitivity differences between <sup>131</sup>I MIBG and <sup>123</sup>I MIBG were not observed. Neuroblastomas frequently spontaneously involute, which may account for the observation that no tumor is found in up to half of all cases of OMAS.

Neuroblastoma may be associated with elevated levels of one or more urinary catecholamine metabolites; vanillylmandelic acid (VMA) and homovanillic acid (HVA) are the most common catecholamines examined. In a reported study, only 37 of 408 (9%) patients had elevated urinary HVA or VMA levels, and neuroblastoma was subsequently diagnosed.

### Other Tests

Autoimmune disorders are believed to play an important role in acute ataxia. Testing performed to screen for autoimmune disorders includes examination for the presence of antinuclear antibodies—anti-SS-A/Ro and anti-SSB/ladanticardioplin antibody, and antiphospholipid antibodies. There are insufficient data regarding the role of GAD-ab in childhood acute ataxia (Whelan et al., 2013). There are insufficient data to draw conclusions regarding the diagnostic yield of screening testing of autoimmune disorders in children presenting with acute ataxia.

## Treatment and Prognosis

Acute postinfectious cerebellitis is usually a self-limited condition with most children showing a spontaneous recovery within the first week. Full recovery is expected within 3 months of onset in at least 50% of children, but recovery remains incomplete in a minority of cases. The typical approach to a child with inflammatory cerebellitis is to exclude a primary infectious etiology. After an active infection is ruled out, a trial of immunosuppression is usually warranted. Corticosteroids, such as solumedrol in a daily dose of 20 to 30 mg/kg up to 1000 mg a day, are usually pulsed for 3 to 5 days. If there is no improvement in symptoms, then plasmapheresis or intravenous immunoglobulin is the second-line alternative. Intravenous immunoglobulin (IVIg) is frequently given at 2 g/kg/day. Plasmapheresis is typically done with five exchanges performed every other day. In patients who do not have the resolution of symptoms, the use of rituximab 375 mg/m<sup>2</sup> weekly for 4 weeks has been reported to show benefit.

Children with OMAS frequently require prolonged treatment with IVIg and corticosteroids to prevent relapses. Typical IVIg dosing is 1 to 2 g/kg/day every month or every other month. Pranzatelli and colleagues (Tate et al., 2012) have described symptom improvement using a multimodal approach of adrenocorticotropic hormone in conjunction with IVIg or rituximab for over 1 year.

Children with the Miller Fisher variant of GBS should be admitted to the hospital for careful monitoring of respiratory and autonomic function. Corticosteroids are felt to be contraindicated for GBS, with IVIg or plasmapheresis as the first-line therapy. The recommended dose of immunoglobulin is 2 g/kg over 2 to 5 days. The decision for active treatment depends on status of ambulation and respiratory and bulbar involvement. With or without specific treatment, more than 90% of children with GBS and Miller Fisher syndrome recover completely within 6 to 12 months of disease onset.

Recovery from acute postinfectious demyelinating encephalopathy is typically somewhat slower than that from acute cerebellar ataxia and can be hastened by treatment with corticosteroids. However, a minority of patients were left with significant sequelae. Single relapses can occur in as many as 10% of affected children. Multiple relapses raise the possibility of an underlying diagnosis of MS.

Systemic infections and brainstem encephalitis should be treated with standard antibiotic/antiviral protocols, although outcome in brainstem encephalitis is uncertain.

Treatment of toxic ingestion depends on the nature and amount of the ingested substance. Monitoring the blood concentration of the drug, the liver and kidney functions, and stabilizing vitals while allowing spontaneous elimination of the ingested agent is important. Often times, no specific treatment is available. In some cases, administration of an antidote, chelation, dialysis, or other therapies is required (Ryan and Engle, 2003).

Ataxia related to postconcussion syndrome usually clears by 6 months. Tumors, stroke, and traumatic brain injury are likely to have significant sequelae with incomplete recovery. Vertebrobasilar dissection may need anticoagulation in the short-term followed by a period of antiplatelet therapy. Significant cerebellar bleeds need posterior fossa decompression. Determination of the precipitating stress is important in managing psychogenic ataxia. EA1 may respond to antiepileptic medication. Both EA1 and EA2 respond to daily acetazolamide.

Daily nicotinamide administration (50–300 mg) may reverse neurologic complication in Hartnup disease. Acute ataxia in some cases of maple syrup urine disease may respond to thiamine 1 g and ongoing supplementation (maintenance

100 mg daily). Acetazolamide has been shown to abort acute attacks of ataxia in pyruvate dehydrogenase deficiency.

Basilar artery migraine can be managed the same as other forms of migraine. Migraine prophylaxis is useful when attacks are frequent, as in benign paroxysmal vertigo.

Nonmetastatic neuroblastoma should be removed surgically. If no obvious tumor is detectable at first presentation, periodic surveillance is essential in suspected cases. Adrenocorticotropic hormone, corticosteroids, and IVIg will improve symptoms in 80% of patients with neuroblastoma. Relapses may occur during course of treatment or after discontinuing therapy. Epileptic ataxia (pseudotaxia) responds to anticonvulsant drugs.

Behavioral or learning difficulties were present in 20% of children during the recovery phase from acute cerebellar ataxia but resolved in most within 6 months (Connolly et al, 1994). Some data suggest that immunosuppression improves developmental outcome in children with OMAS.

## INTRODUCTION

Movement disorders are characterized by impaired voluntary movement, the presence of involuntary movements, or both. There may be impaired targeting and velocity of intended movements, abnormal involuntary movements, abnormal postures, or excessive movements that appear normal at inappropriate or unintended times. Movement disorders in children include athetosis, chorea, dystonia, myoclonus, parkinsonism, stereotypies, tics, and tremor (Carducci and Fernandez-Alvarez, 2007; Singer et al., 2016). Movement disorders may be accompanied by weakness, spasticity, hypotonia, ataxia, apraxia, and other motor deficits, although many authors do not include these accompanying deficits.

Movement disorders have been divided into “hyperkinetic” disorders, in which there is excessive movement, and “hypokinetic” disorders, in which there is a paucity of movement. Hyperkinetic disorders consist of abnormal, repetitive involuntary movements and include most of the childhood movement disorders, such as chorea, dystonia, athetosis, myoclonus, stereotypy, tics, and tremor. Hypokinetic movement disorders are primarily akinetic or rigid. The primary syndrome in this category is parkinsonism, occurring most commonly in adulthood as Parkinson disease or one of the many forms of secondary parkinsonism.

Movement disorder terminology has been well defined for adults, but less so for children. Therefore it is likely that movement disorders are underreported in children, and that there is inconsistent terminology. Recently there have been attempts to provide specific definitions of childhood motor disorders. According to these definitions, childhood disorders can be divided into three major categories: hypertonic disorders, hyperkinetic disorders, and negative signs (Sanger et al., 2003; Sanger et al., 2006; Sanger et al., 2010). Hypertonic disorders include spasticity, dystonia, and rigidity. Hyperkinetic disorders include chorea, dystonia, athetosis, myoclonus, tremor, stereotypies, and tics. Negative signs include weakness, reduced selective motor control, ataxia, apraxia, and developmental dyspraxia, although we will not discuss these here. Consensus definitions for these terms have been established, although the list is not intended to be exhaustive and disorders of gait, balance, speech, and eye movement are not included. The prevalence in children of different types of disorders is not known, although there have been studies investigating symptoms in certain populations, including children with cerebral palsy.

In this chapter, general features of pediatric movement disorders will be discussed followed by discussion of many specific movement disorders. Other related disorders are discussed in other chapters in this book, including hereditary ataxias (Chapter 91), acute ataxia (Chapter 92), paroxysmal dyskinesias (Chapter 94), movement disorders of infancy (Chapter 95), drug-induced movement disorders (Chapter 96), cerebral palsy (Chapter 97), and tics (Chapter 98).

## CHARACTERISTIC FEATURES OF PEDIATRIC MOVEMENT DISORDERS

Movement disorders in children differ from those in adults in several aspects. Perhaps the most important is that movement disorders in childhood occur in the context of development, and thus manifestations may vary with age and developmental stage. Diagnosis in children may be complicated by the fact that many symptoms have more than one cause, and any particular underlying pathophysiology may lead to a complex combination of symptoms. The diagnostic workup in children is guided by symptoms, but the existence of a large class of diseases that can lead to the same set of symptoms often necessitates a broad etiologic workup. There may be both specific etiologic treatments, as well as symptomatic treatments, both of which may be beneficial in an individual child. In particular, many of the causes of childhood movement disorders do not yet have any specific treatment, yet symptomatic treatment for the resulting movement disorder can be extremely helpful and lead to improvement in quality of life.

## DIAGNOSIS OF MOVEMENT DISORDERS

Classification of a movement disorder based upon the spatial and temporal pattern is essential for diagnosis. It is also important to define the context in which the movements occur. Although it is often helpful to list the characteristics of the movements (Table 93-1), the diagnosis relies on pattern recognition, and the clinician must see the movements. If the movements are not apparent during the neurologic examination, repeating the examination at another time or obtaining video recordings of the movements is important to making an accurate diagnosis. The widespread availability of video cameras has substantially improved diagnosis of movement disorders.

When approaching a patient with a movement disorder, it is helpful to address some key questions:

1. Is the number of movements excessive (hyperkinetic) or diminished (hypokinetic)?
2. If hyperkinetic, do the individual movements appear normal or abnormal?
3. Is the movement paroxysmal (sudden onset and offset), continual (repeated again and again), or continuous (without stop)?
4. What is the developmental stage of the child, and has development been normal?
5. How does voluntary movement influence the movement disorder? Are symptoms and signs present at rest (body part supported against gravity), with maintained posture, with action, with approach to a target (intention), or a combination?
6. Has the movement disorder changed over time?

**TABLE 93-1** Phenomenological Classification of Movement Disorders

Movement Disorder	Brief Description
Athetosis	Slow, continuous, writhing movements of distal body parts, especially the fingers and hands
Chorea/ballism	Chaotic, randomly triggered, repetitive, brief, purposeless movements or movement fragments of multiple body parts that may overlap in time. Rapid, but not as rapid as myoclonus. When very large in amplitude and affecting proximal joints, choreic limb movements are often called ballism
Dystonia	Repetitive, sustained, abnormal postures and/or movements, worsened by attempted movement or posture. Abnormal postures typically have a twisting quality
Myoclonus	Sudden, brief, shocklike unidirectional movements that may be repetitive or rhythmic
Parkinsonism	Hypokinetic syndrome characterized by a combination of rest tremor, slow movement (bradykinesia), rigidity, and postural instability
Stereotypy	Patterned, purposeless, episodic, rhythmic movements
Tics	Intermittent, discrete, repetitive brief movements or postures, most frequently involving face, head, or upper body
Tremor	Rhythmic oscillation about a central point or position, involving one or more body parts

7. Do environmental stimuli or emotional states precipitate, exacerbate, or alleviate the movement disorder?
8. Is the patient aware of the movements?
9. Can the movements be suppressed voluntarily?
10. Are the movements heralded by a premonitory sensation or urge? (It may be helpful to ask the patient, "Why do you do that?")
11. Does the movement disorder abate with sleep?
12. Are there other findings on the examination suggestive of focal neurologic deficit or systemic disease?
13. Is there a family history of a similar or related condition?

Obtaining a very careful history of the time course of symptoms is often extremely helpful. With careful questioning, it is often possible to distinguish between relentlessly progressive disorders, paroxysmal disorders with intervening periods of normal function, stepwise progressive disorders, or paroxysmal episodes of worsening superimposed on a background of progression. The effect of intercurrent illness should be assessed because many disorders (static or progressive) will have episodic worsening in the context of otherwise minor viral or bacterial illness.

Laboratory tests, imaging, and other diagnostic testing should be based on the specific movement disorder. There is no "movement disorder workup" because the causes are varied and some movement disorders (e.g., tics) are rarely symptomatic of an underlying disease.

Movement disorders may be difficult to characterize, unless other symptoms and behavioral context are taken into account. Chorea can resemble myoclonus. Dystonia can resemble spasticity. Paroxysmal movement disorders, such as dystonia and tics, may resemble seizures. Movements in some situations may be normal and in others may indicate underlying pathology. For example, frequent eye blinking can be perfectly

normal and appropriate in one setting (a windy day at the beach) but excessive in another (tics). Movements that raise concern about a degenerative disorder in older children (progressive myoclonus) may be completely normal in an infant (benign neonatal myoclonus). Thus it is important to view the movement disorder in the context of a complete history and neurologic examination.

## ETIOLOGY OF MOVEMENT DISORDERS IN CHILDREN

The causes of pediatric movement disorders are extensive. The most common cause of secondary disorders is likely to be cerebral palsy, with a prevalence of 2 per 1000. However, cerebral palsy itself represents a constellation of injuries and symptoms, and there is a wide range of types of injury, localization, and combinations of symptoms. Cerebral palsy can be associated with almost all forms of childhood movement disorders, and despite the lack of an ongoing destructive process, the clinical picture may change during development. The diagnosis and management of cerebral palsy is discussed in Chapter 97.

Specific types of movement disorder may represent dysfunction of particular localized regions of the central nervous system. Ataxia most likely occurs due to dysfunction of the cerebellum or its afferent and efferent pathways. Bradykinesia most likely occurs with dysfunction of the substantia nigra or striatum, leading to presynaptic or postsynaptic failure of dopaminergic transmission. Chorea typically occurs with dysfunction of the striatum or subthalamic nucleus, but it also can occur with widespread cerebral injury (e.g., after encephalitis). Dystonia most likely involves dysfunction of the striatum or globus pallidus, but thalamic, cortical, or cerebellar abnormalities cannot be excluded as contributors. Myoclonus most likely involves cortical, brainstem, or spinal injury to gray matter. Localization of tremor depends on the type, with some forms involving cerebellar or brainstem circuits. Tic disorders probably involve an abnormality of the basal ganglia, but cortical mechanisms may also contribute.

## APPROACH TO TREATMENT

Treatment of childhood movement disorders is based primarily on symptomatology, independent of the underlying cause. When a specific treatment for the underlying cause is available, this should be implemented, but in many cases such treatment is only partially effective. The goal of symptomatic treatment is to disrupt the connection between the pathophysiology and the expression of clinical impairment.

It is essential to ask both the child and the parents for the most significant cause of disability. In some cases, the impairment that is most evident to the clinician is not the primary cause of disability. Sometimes, treatment of the functional limitation or direct treatment of a disability is more effective, less time-consuming, and less risky than attempts to treat the underlying pathophysiology, and therefore it is essential to be certain that any treatment addresses the needs and goals of the child and family. In particular, it is usually neither necessary nor possible to treat all symptoms. It is most helpful to pick specific goals and to monitor progress toward those goals. In many cases, a team approach has been found to be helpful, particularly when there are multiple impairments leading to disability, and the team approach allows appropriate focusing and selection of interventions. In some cases, a supportive environment and adaptive equipment are more effective than any medical intervention.

## CLASSIFICATION OF CHILDHOOD MOVEMENT DISORDERS

The first step toward diagnosing and treating a movement disorder is to define the disorder (Table 93-1). Individual names of movement disorders can refer to neurologic signs or to neurologic syndromes or diseases, which can cause some confusion.

### CHOREA

Chorea describes an apparently random, nonrhythmic, purposeless set of movements of either distal or proximal muscles that appears to flow from one muscle or muscle group to another without any pattern. Chorea occurs at rest and with action and gives the child a “fidgety” appearance and the inability to remain still. It is associated with motor impersistence (e.g., the inability to maintain the tongue extended). Chorea may worsen or improve with voluntary movement, but even very severe chorea may not prevent accurate voluntary movement for some children. Many individuals with chorea will incorporate the involuntary movements into a

voluntary movement in order to mask the movements. However, the involuntary movements can lead to significant disability, and some children will injure themselves if they have large amplitude movements.

The causes of chorea in childhood are numerous. A list of important causes of chorea in children is presented in Box 93-1. See the online version of this chapter for a more detailed description of specific entities.

### Sydenham Chorea

Sydenham chorea is the most common cause of chorea in children. It has its onset weeks or months after an acute infection with group A beta-hemolytic streptococcus (GABHS) and is one of the major Jones criteria for the diagnosis of rheumatic fever. Symptoms may persist for weeks or months, but chorea almost always resolves spontaneously within 6 months. There have been rare reported cases of continued or recurring symptoms. The chorea typically involves the distal musculature, initially of one hand and then of both, with a “piano-playing” pattern. Other, more severe forms of chorea, including ballism, have been observed. Large, generalized

#### BOX 93-1 Causes of Chorea in Childhood

##### STATIC INJURY/STRUCTURAL DISORDERS

- Cerebral palsy
- Stroke
- Trauma
- Moyamoya disease
- Vasculitis
- Tumors
- Congenital malformations
- Joubert syndrome

##### HEREDITARY/DEGENERATIVE DISORDERS

- Ataxia-telangiectasia (A-T), and Ataxia-Telangiectasia-Like Disorder (ATLD)
- Ataxia oculomotor apraxia (AOA) (includes AOA-1, AOA-2, and early onset cerebellar ataxia and hypoalbuminemia [EOCA-HA])
- Fahr disease
- Pantothenate kinase-associated neurodegeneration (PKAN, associated with mutations in *PANK-2*, pantothenate kinase-2 gene), and other causes of Neuronal Brain Iron Accumulation (NBIA)

##### METABOLIC DISORDERS

- Acyl-coA dehydrogenase deficiencies
- Mitochondrial disorders, including Leigh’s syndrome
- GM<sub>1</sub> gangliosidosis
- Lesch-Nyhan disease
- Niemann–Pick type C
- Methylmalonic aciduria
- Nonketotic hyperglycemia
- Kernicterus
- Hypoparathyroidism
- Propionic acidemia
- Hyponatremia
- Hypomagnesemia
- Hypocalcemia
- Hypo- or hyperglycemia
- Vitamin E deficiency or malabsorption
- Bassen-Kornzweig disease
- Complications of cardiac bypass

##### INFECTIOUS/PARAINFECTIOUS DISEASE

- Encephalitis/postencephalitis

##### IMMUNE-MEDIATED/DEMYELINATING DISORDERS

- Sydenham chorea
- Lupus erythematosus
- Henoch-Schönlein purpura
- Anticardiolipin or antiphospholipid antibody syndrome
- Anti-NMDA antibody syndrome

##### DRUGS/TOXINS

- Neuroleptic medications, and neuroleptic-like antiemetics (haloperidol, chlorpromazine, pimozide, prochlorperazine, metoclopramide)
- Calcium channel blockers (flunarizine, cinnarizine)
- Antiepileptic medications (phenytoin, carbamazepine, valproate, phenobarbital)
- Anticholinergic medications (trihexyphenidyl, benztropine)
- Antihistamines
- Tricyclic antidepressants
- Clomipramine
- Stimulants (including methylphenidate, dexamphetamine, pemoline, and bronchodilators)
- Clonidine
- L-DOPA
- Cocaine
- Bismuth
- Lithium
- Manganese
- Ethanol
- Carbon monoxide
- Oral contraceptives
- General anesthesia (including propofol)—during induction or emergence

##### PAROXYSMAL DISORDERS

- Complex migraine
- Alternating hemiplegia of childhood
- Paroxysmal kinesigenic dyskinesia (PKD)
- Paroxysmal nonkinesigenic dyskinesia (PNKD)
- Paroxysmal exercise-induced dyskinesia (PED)

##### ENDOCRINE DISORDERS

- Hyperthyroidism
- Pheochromocytoma

body movements in some patients previously inspired the term “St. Vitus’ dance.”

Antibasal ganglia antibodies (ABGA) are found in some children, and it has been hypothesized that production of these antibodies is triggered due to molecular mimicry by streptococcal antigens. ABGA can be detected in the cerebrospinal fluid and antistreptolysin (ASLO) antibodies can be detected in serum. However, the high prevalence of positive ASLO titers in the general population means that both acute and convalescent ASLO titers must be measured in order to probe for an acute infection. The clinical situation often provides a strong indication for the diagnosis, but if other neurologic symptoms are present or there is doubt about the etiology, a more complete workup may be needed, including tests for thyroid function, toxins, metabolic disorders, or encephalitis.

Sydenham chorea usually does not require treatment, although acute streptococcal infection should be treated if present. All children diagnosed with Sydenham chorea, even in cases of isolated chorea, should be treated with penicillin, both acutely for treatment and long term for prophylaxis, according to the American Heart Association guidelines (Gerber et al., 2009). Valproic acid, carbamazepine, or neuroleptics may provide symptomatic benefit for Sydenham chorea. When associated obsessive-compulsive or behavioral symptoms are present, these symptoms are often managed with selective serotonin reuptake inhibitors. Treatment with immune suppressant medication, including corticosteroids or intravenous immunoglobulin preparations, has been studied, but the natural history, with spontaneous resolution of symptoms, makes interpretation of efficacy in open clinical trials difficult. A randomized, blinded, placebo-controlled study showed that a 4-week, 2-mg/kg daily oral dose of prednisone, followed by a taper, reduced duration of chorea and accelerated the reduction in symptoms. Weight gain was substantial by the end of 2 months, and long-term outcome, including recurrence rates, was not different between groups (Paz et al., 2006).

The prognosis for the movement disorder is excellent, and complete resolution occurs in most cases. Recurrence is rare and is sometimes associated with recurrence of other symptoms of rheumatic fever. There appears to be a higher risk of chorea gravidarum in women with a previous history of Sydenham chorea.

## Medication-Induced Chorea

Medication-induced chorea can be dose-related or a tardive phenomenon, so evaluation of a child with chorea requires a careful history of past and current medication exposure. Medication-induced chorea is discussed in Chapter 96. Treatment of medication-induced chorea requires elimination of the precipitating agent.

## Genetic Chorea

A large number of genetic disorders have chorea as a symptom. For some, such as benign hereditary (familial) chorea, chorea is major or sole manifestation. For others, chorea is accompanied by other neurologic or system symptoms. These disorders are listed in Box 93-1 and are discussed in detail in the online version of this chapter.

## Chorea Associated With Systemic Illness and Autoimmune Disorders

Several systemic disorders may have chorea as a major manifestation. Hyperthyroidism can be a cause of chorea,

and any child with unexplained acute or persistent chorea should have serum testing for thyroid function. Autoimmune diseases, including lupus erythematosus, and antiphospholipid antibody syndromes, can be a cause of chorea, and there is increasing recognition of the association of chorea with vasculitis and autoimmune syndromes with antibodies to neuronal membrane channels, including anti-NMDA encephalitis. Other systemic diseases associated with chorea are listed in Box 93-1. Because early treatment can be life-saving, a high level of suspicion for autoimmune disorders in children with acute onset of chorea in conjunction with encephalopathy should be maintained (Chapters 118, 119).

## Ballism

Ballism is a high-amplitude, flinging movement, usually due to involuntary movements of proximal joints. Ballism is part of the spectrum of chorea and involves similar pathophysiological mechanisms. When ballism involves one side of the body, it is called hemiballism. Hemiballism is the classical manifestation of hemorrhage or infarction affecting the subthalamic nucleus but can be associated with lesions in other parts of the basal ganglia.

## Treatment of Chorea

Chorea is often difficult to treat. Sydenham chorea responds to symptomatic treatment with dopamine D2 receptor antagonists, valproic acid, or carbamazepine. Other forms of chorea are less likely to respond to those medications. Benzodiazepines or dopamine depletors (tetrabenazine, reserpine) may be helpful in some cases. Deep brain stimulation can be considered in severe refractory cases.

## DYSTONIA

Dystonia occurs as an isolated phenomenon or in association with other neurologic signs or symptoms. Dystonia is defined as “a movement disorder in which involuntary sustained or intermittent muscle contractions cause twisting and repetitive movements, abnormal postures, or both.” Although the term seems to imply an abnormality of tone, dystonia is not primarily a disorder of tone, but rather a disorder of posture and/or movement. When individuals with dystonia are at rest, tone is often diminished, although, in severe dystonia, involuntary contractions persist during attempted rest and tone may be increased. Dystonia can manifest as either hypertonic dystonia with increased stiffness, hyperkinetic dystonia with increased movements, or a combination of the two. Due to the complexity of identifying causes of dystonia, an international classification system has been proposed (Albanese et al., 2013). This system is based on two axes: clinical characteristics and etiology.

Dystonia is commonly triggered or exacerbated by voluntary movement, and it may fluctuate in severity over minutes, weeks, or months. Dystonia can be movement-specific, so that a muscle may exhibit involuntary contraction only during certain voluntary movements and not others. Dystonic contractions resolve during sleep. Individuals with dystonia sometimes discover that touching one part of the body may relieve the dystonic spasms; this phenomenon is called a sensory trick or *geste antagoniste*. Sensory tricks are less common in patients with symptomatic dystonia. Dystonia may be generalized or focal, involving just a single body part. Causes of dystonia in childhood are summarized in Box 93-2.

**BOX 93-2** Causes of Dystonia in Childhood**STATIC INJURY/STRUCTURAL DISORDERS**

- Cerebral palsy
- Hypoxic-ischemic injury
- Kernicterus
- Head trauma
- Encephalitis
- Tumors
- Stroke in the basal ganglia (which may be due to vascular abnormalities or varicella)
- Congenital malformations affecting basal ganglia

**HEREDITARY/DEGENERATIVE DISORDERS**

- DYT1 (autosomal dominant, TorsinA)
- DYT2 (autosomal-recessive, Hippocalcin)
- DYT4 (autosomal dominant,  $\beta$ -tubulin 4a)
- DYT5 (autosomal dominant, GTP cyclohydrolase 1)
- DYT6 (autosomal dominant, THAP1)
- DYT8 (autosomal dominant, Myofibrillogenesis regulator 1)
- DYT9 (autosomal dominant, GLUT1)
- DYT10 (autosomal dominant, PRRT2)
- DYT11 (autosomal dominant [maternal imprinting],  $\epsilon$ -Sarcoglycan)
- DYT12 (autosomal dominant, Na<sup>+</sup>/K<sup>+</sup> ATPase  $\alpha$ 3 subunit)
- DYT15 (autosomal dominant, unknown)
- DYT16 (autosomal recessive, Protein kinase activator PRKRA)
- Pantothenate kinase-associated neurodegeneration (PKAN; neuronal brain iron accumulation type 1, due to mutations in *PANK2*)
- PLA2G6-associated neurodegeneration (PLAN)
- Huntington disease (Westphal variant, IT15–4p16.3)
- Spinocerebellar ataxias (SCAs, particularly SCA3/Machado–Joseph disease)
- Striatal necrosis
- Leigh syndrome
- Neuroacanthocytosis

- HARP syndrome (hypoprebetalipoproteinemia, acanthocytosis, retinitis pigmentosa, and pallidal degeneration)
- Tay-Sachs disease
- Sandhoff disease
- Niemann–Pick type C

**METABOLIC DISEASE**

- Glutaric aciduria types 1 and 2
- Acyl-CoA dehydrogenase deficiencies
- Neurotransmitter disorders
- Mitochondrial disorders
- GM<sub>1</sub> gangliosidosis
- Lesch-Nyhan disease
- Wilson disease
- Vitamin E deficiency
- Methylmalonic aciduria
- Tyrosinemia

**DRUGS/TOXINS**

- Neuroleptic and neuroleptic-like antiemetic medications (haloperidol, chlorpromazine, olanzapine, risperidone, prochlorperazine)
- Calcium channel blockers
- Stimulants (amphetamine, cocaine, ergot alkaloids)
- Anticonvulsants (carbamazepine, phenytoin)
- Thallium
- Manganese
- Carbon monoxide
- Ethylene glycol
- Cyanide
- Methanol

**PAROXYSMAL DISORDERS**

- Paroxysmal kinesigenic dyskinesia (PKD)
- Paroxysmal nonkinesigenic dyskinesia (PNKD)
- Exercise-induced dyskinesia (PED)

**Genetic Dystonias**

The tremendous advances in molecular and genetic research and diagnostic tools have led to the identification of specific etiologies of dystonias that were previously considered to be idiopathic. Many genetic forms of dystonia have assigned genetic loci identified as DYT<sub>x</sub>. The most important forms are discussed here. More detailed and extensive discussion can be found in the online version of this chapter. Paroxysmal dystonias are discussed in Chapter 94.

**DYT-1 Dystonia**

DYT-1 dystonia is also known as Oppenheim's dystonia, or dystonia musculorum deformans. The median age at onset is 10 years, with a range of 4 years to adulthood. Usually, onset is either in an upper or lower extremity. The general features include a gradually progressive dystonia that eventually involves multiple limbs and progresses to generalized dystonia, often affecting both distal and proximal musculature. However, there is great variation in the progression and severity. DYT-1 dystonia is autosomal-dominant, with reduced penetrance.

DYT-1 dystonia usually does not respond to dopaminergic medication. The mainstay of treatment is anticholinergic medication, but often very high doses are required. Other medications such as benzodiazepines, baclofen, carbamazepine, neuroleptics, or tetrabenazine have been tried with varied

success. Deep brain stimulation is especially effective in patients with DYT-1 dystonia.

**DYT-5 Dystonia (Dopa-Responsive Dystonia)**

Dopa-responsive dystonia (DYT-5) is also known as Segawa disease after its first description in 1976. The presentation is very similar to DYT-1 dystonia in many patients, although it can have onset at an earlier age. The average age at onset is 6 years, with a range of onset from 1 to 12 years. It frequently starts in a limb in children. In adolescents and adults, it is often accompanied by parkinsonism. The combination of dystonia and parkinsonism is due to decreased but not absent dopamine production. Diurnal variation is present in 77% of children, with milder symptoms in the morning and gradual worsening of symptoms as the day progresses. Untreated, DRD is a progressive disorder and this helps to distinguish it from static disorders such as cerebral palsy. Untreated cases can develop secondary orthopedic deformities, including joint contractures, muscle and tendon shortening, and scoliosis.

DRD is due to mutations in the GTP cyclohydrolase 1 gene. GTP cyclohydrolase is an enzyme that is important for the synthesis of tetrahydrobiopterin, which is a cofactor for the enzyme tyrosine hydroxylase. Tetrahydrobiopterin is also a cofactor for tryptophan hydroxylase and phenylalanine hydroxylase, although reduced function of these enzymes does not seem to be the primary cause of symptoms. Rare cases of

homozygosity for GTP cyclohydrolase mutations have been reported, with a more severe phenotype.

Dramatic improvement during a trial with l-DOPA strongly suggests the diagnosis, but a precise diagnosis can be made by quantitative evaluation of cerebrospinal fluid neurotransmitters and pterins or genetic testing (Chapter 44).

### DYT11 Dystonia (Myoclonus Dystonia Syndrome)
