Evan Symons • De Villiers Smit • Kellie Muir • Catherine Smith

ESSENTIALS

1 Family violence encompasses physical, sexual, financial and psychological abuse.

2 All forms of family violence are inter-related in a complex way. Victims of violence may suffer many forms of abuse over their lives.

3 Between 30% and 50% of women and approximately 15% of men experience family violence over their lifetimes.

4 Family violence occurs across all socioeconomic, religious and cultural groups.

5 There is a range of barriers to disclosure and reporting to authorities.

6 Effectively responding to family violence requires a multidisciplinary and co-ordinated approach involving health practitioners, social services and justice agencies.

Definition

Family violence involves all types of violence within intimate or family relationships. It includes physical and sexual abuse, threats and intimidation, psychological, emotional and social abuse and financial deprivation; it can occur across the life span.

Physical violence is defined as intentionally inflicted harm using bodily force or a weapon. It encompasses sexual violence—such as non-consensual or coercive sexual activity using physical force—sexual harassment, stalking, forced or deceptive sexual exploitation, threats or intimidation and non-personal violence, such as intentional property damage. Psychological abuse, which frequently precedes physical abuse, may take the form of threats, verbal harassment, ridicule or behaviours designed to intimidate, humiliate, control and isolate the victim.

Family violence most often occurs within current or former intimate relationships and is described as a gendered phenomenon, as it is largely perpetrated by men against women. However, although women account for the larger proportion of victims, males can also be affected, and this form of violence may also occur in same-sex relationships. Family violence may involve any family member related by blood or law. Children may be directly victimized or suffer harmful consequences when they see, hear, witness or are otherwise exposed to the effects of family violence.

The subjective experience and definition of family violence are strongly influenced by cultural beliefs and previous life experiences; the individual's perceptions of his or her experience may vary greatly depending on these differences.

Family violence is also referred to as *domestic violence* or *intimate partner violence*. The more inclusive term of family violence accounts for violence within a range of intimate and family relationships.

Incidence

The prevalence of family violence varies according to definition (whether sexual and emotional abuse are included), timing of the abuse (current, during adult life or cumulative lifetime prevalence) and whether the violence is actual or threatened. In Australia, 1 in 6 women and 1 in 16 men from 15 years of age onwards have been reported to have been victims of physical and/or sexual violence by a current or previous cohabiting partner.[1]

Australia's National Research Organisation for Women's Safety (ANROWS) reports that one in four Australian women had experienced emotional abuse by an intimate partner since the age of 15 years.[9] In contrast, one in seven Australian men had experienced emotional abuse by an intimate partner since the age of 15 years.[9] It is reported that 61% of women who had experienced violence from an ex partner had children in their care when the violence occurred.[9] Women are at greater risk of experiencing family violence during pregnancy and the early years of motherhood. Women will often experience family violence for the first time during pregnancy or experience an increase in the type or intensity of violence.[2]

Vulnerable groups

Certain groups within the population may be more vulnerable to the effects of family violence. Among these are indigenous communities, culturally and linguistically diverse (CALD) communities, people with disabilities and the elderly. They may experience distinct forms of abuse specific to their particular group or community.

Indigenous communities

Members of indigenous communities may be exposed to heightened levels of family violence. Indigenous women are five times more likely to be the victims of family violence and homicide than non-indigenous women.[3]

Culturally and linguistically diverse communities

CALD communities experience additional complexities with respect to family violence. Although it is important to avoid generalizations and stereotypes, cultural values and beliefs can have implications for the way in which the individual experiences and responds to violence. CALD victims may encounter greater difficulty obtaining assistance and support from mainstream service providers for reasons including discrimination and marginalization, lack of awareness of their legal rights and protections, immigration issues, concerns regarding bringing dishonour to the family, fear of authority figures and communication barriers.

Disability

Women with disabilities can be disproportionally affected by family violence. Victims with cognitive and physical disabilities experience greater difficulty in accessing mainstream services due to communication barriers, lack of appropriate transport and accommodation, reliance on the perpetrator of violence and limited recognition of their victimization status.

Elderly

The elderly are at risk of abuse from people on whom they depend. Physical or cognitive impairments add to their vulnerability. Older persons can become socially isolated due to a decline in social contacts and supports, thus increasing the risk that abuse will go undetected.

Risk factor identification

The identification of risk and factors contributory to family violence within intimate relationships has allowed for improved understanding of the nature, form and degree of danger to victims as well as the conditions under which incidents of family violence are more likely to occur.

Although the growing evidence base about risk factors has informed the development of a variety of tools and measures designed to improve and detect those at risk, the presence of these factors is not an infallible predictor of violence. For example, some victims with multiple risk factors will not experience escalating or severe violence, whereas fatal family violence can occur in the absence of clearly defined risk and contributory factors.

Despite this caveat, understanding these factors is an important step toward improved identification and intervention in violent behaviour. To this end, risk factors are generally classified at the level of the individual, relationship and social environment.

Individual-level risk factors have been identified for both victims and perpetrators of violence. Individual characteristics associated with men having an increased risk of perpetrating violence are alcohol abuse, drug use, low education standards, unemployment and being a former rather than current partner. There is some association between perpetrator mental health and violence, particularly conditions such as depression and psychosis. Problem gambling is also a risk factor for both the perpetration of family violence and victimization.

For victims, pregnancy and new birth have been associated with both emerging and escalating violence. There are other risk factors for both victim and perpetrator, and family violence specialists are best placed to determine this risk.

At the level of the relationship, a history of abusive and violent behaviour is among the strongest predictors of further violence. Separation or the announcement of an intention to end an intimate relationship is associated with an increased risk of violence.

Social environment factors affecting family violence include gender inequality supported by societal norms and economic or social policies that create or sustain inequalities.

Family violence has now been identified as a health issue that affects health outcomes in a multitude of physical and psychological ways. Most presentations to health professionals and emergency departments (EDs) by victims of violence are a complex mix of indirectly related physical and psychological problems and are not trauma related.

Physical injury and illness

Physical injuries resulting from family violence may have patterns similar to those of other forms of non-accidental injury, such as a history inconsistent with the injury, injuries of varying temporal stages or unreasonable delay in presentation. Non-accidental injuries are often in central rather than peripheral areas of the body. Injuries to defensive areas of the body or to the back, legs, buttocks, back of the head and soles of the feet reflect attempts at self-protection. Injuries inflicted on females are likely to be contusions, abrasions, lacerations, fractures and dislocations. The head, face and trunk have been identified as primary targets in intimate partner violence; therefore further research into intimate partner violence and traumatic brain injury has been recommended. Women are more likely to be choked, beaten or sexually abused. Men have a greater risk of having objects thrown at them or weapons used against them. Although family violence–related injuries may follow certain patterns, injury pattern is of low positive predictive value in the identification of family violence.

Abuse before, during and after pregnancy represents a threat to the well-being of both mother and baby. Approximately 40% of women who are physically abused are forced into non-consensual sex at some stage. This results in high rates of sexually transmitted disease, unintended and adolescent pregnancy and termination of pregnancy. There is also an established complex link between family violence and preterm labour, low–birthweight babies and postnatal depression.

Prevention of access to or interference with general health care or antenatal care may occur, with up to 17% of abused women reporting partner interference with accessing health care.

In Australia, homicide among intimate partners and other family members forms a substantial proportion of annual homicide incidents. Between 2002 and 2012, approximately 41% of all homicide incidents were categorized as domestic/family homicides.[4] Many homicide victims had presented to an ED in the 2 years preceding their death. Documentation of violence and intervention are often uncommon.

Psychological impact

Family violence is an independent risk factor for mental illness. Women who have experienced family violence have an approximately 11-fold increase in dissociative disorders, 6-fold increase in somatization disorders, 5-fold higher incidence of anxiety and are three times more likely to suffer depression, phobias and drug dependence.[5,6] Exposure to family violence has also been shown to be associated with the onset of post-traumatic stress disorder. Abused women have twice the rates of hazardous alcohol consumption and dependence.[6] Abuse occurring both in childhood and adulthood causes a further significant increase in the incidence of mental illness. The experience of psychological abuse, especially ridicule and humiliation, is particularly responsible for causing low self-esteem.

Impact on children

The impact of family violence on children includes potential victimization, witnessing violence, separations from family, foster care, risks of future mental illness and an increased potential to perpetrate violence in the future.

Children living in a home where violence is perpetrated against a parent are 15 times more likely to be victims of abuse or neglect themselves. Family violence is a risk factor for becoming a perpetrator of homicide in the preteenage group.

Sustained exposure to family violence contributes to cumulative harm for children, affecting their development, behaviour and well-being. Overall, approximately one-third of the population risk for all mental illness is attributable to family violence.[5]

Social

A perpetrator's controlling behaviour towards a victim can lead to the victim's social isolation, failure to acquire paid employment and lack of contact with medical practitioners.

Financial dependence and the responsibility for children increase isolation; there is also a loss of choices and the difficulty of separating from the perpetrator. Poverty among such victims is prevalent and multifactorial. Separation from or incarceration of the perpetrator may lead to further loss of income.

Homelessness may be relative, where there is no sense of safety or security in the home, or absolute, where there is a need for interim or emergency accommodation or where families are forced to live on the streets. Children or elderly people living in violent circumstances may be institutionalized by authorities or carers.

Outcomes for male victims differ from those for female victims in several significant ways. Male victims typically express fewer feelings of fear and terror and less frequently feel trapped and controlled. Men are also generally less constrained by financial dependence. As fear, control, dependence and isolation contribute greatly to the psychological outcomes of family violence, women still suffer approximately 95% of the serious physical and psychological consequences of family violence.[6]

Economic cost

The costs of family violence are vast. Costs include pain, suffering and premature mortality, health costs (victim, perpetrator and children),

production-related costs (lost productivity), consumption-related costs (property replacement), second-generation costs (child care, child protection), administrative (legal and forensic) and transfer costs (income support, lost taxes). The cost of intimate partner violence against women in Australia is estimated to be $12.6 billion per year[7] If no further action is taken to prevent violence against women, it is estimated costs will accumulate to $323.4 billion over the 30-year period from 2014 to 2044.[7]

Barriers to the detection and reporting of family violence

Detection rates of family violence in EDs are low. Only 10% of those who present with acute family violence–related injuries or issues will be asked by the attending nurse or physician to volunteer information about the violence issue. Documentation of violence in the medical record is rare. Barriers to detection may include system factors, such as inadequate privacy; cultural, social and gender issues; and/or the health practitioner's lack of time and education as well as his or her personal attitudes. The Victorian Royal Commission into Family Violence identified health professionals as being in a unique position to identify and respond to family violence and recommended that they receive targeted training to improve their awareness and responses.

Crime statistics in Australia show a general increase in the reporting of family violence. A range of barriers can inhibit victims' disclosures, including feelings of fear and shame, concerns about not being believed or about further victimization, anxiety about possible medical or legal processes, as well as familial, cultural or religious pressures. In some cases, individuals do not recognize themselves as victims of violence or may not yet have considered seeking assistance in respect to their violent partners.

Indigenous women in Australia rarely report violence. Historical interactions with police, such as forcible removal of children and high rates of Aboriginal death in custody, contribute to indigenous women fearing for the safety of themselves and their families when police or social services are involved. Moreover, the lack of accessible and culturally appropriate legal processes creates further barriers to reporting. The elderly may be prevented from reporting by fear of further abuse, neglect or the threat of institutionalization.

The Royal Commission into Family Violence highlighted that the following groups; indigenous, CALD, disabled, elderly, Lesbian, Gay, Bisexual, Transgender, Intersex, Queer/Questioning and Allied (LGBTIQA), rural, faith community, male victims, women in prison, women in the sex industry. These individuals face unique barriers to reporting their experiences of family violence and to accessing appropriate services.

Screening

The high prevalence of family violence, low positive predictive values of demographic factors and clinical presentations, low detection rates and high incidence of subsequent physical and psychological illness have supported the argument for universal screening. Opportunistic screening may increase detection rates of family violence. The use of a single screening question may be as effective as asking several questions. The use of sensitive inquiry is recommended.[8] Screening questions should be simple and direct, such as 'Do you feel safe at home?' or 'Are you afraid of your partner?' Explanation that these questions are routine may improve patient comfort. Such questions must always be asked in a safe environment (with no family member present aged over 2 years).[8]

Screening may indicate to the victim that channels of communication are open and that help will be available. It educates women about violence, its nature and prevalence. Screening may also be important in detection of perpetrators.

Most women find screening an acceptable practice; however, most medical practitioners and nurses are not in favour of it. Reported barriers include a lack of education on how to ask questions about abuse, language barriers, a personal or family history of abuse and time constraints.

Screening may improve detection rates and referral rates to external agencies. However, no evidence currently exists to show that screening leads to improved health outcomes for victims.

Management

The management of family violence is complex. Leaving a violent relationship is no guarantee of safety and may precipitate increased levels of violence. Leaving a violent relationship is a process rather than an event and requires support through all phases. Help may best be offered by a collaborative team approach; validating the disclosure, expressing concern, listening, providing support, ensuring safety and offering a bridge to services.

Understanding

Interviews with survivors of family violence provide a framework for understanding the stages through which a victim must work before leaving a violent relationship. The pre-contemplative phase is where the victim is not consciously aware of or is in denial about the abuse. A contemplation phase follows, where the abuse is acknowledged but the victim is unable to decide to leave. A preparatory stage follows, where steps are taken in preparation for leaving and taking action. The action phase involves leaving the relationship but is typically characterized by episodes of return to the relationship. A maintenance phase occurs when a period of 6 months without return to the relationship has occurred. However this is not a sequential process.

Listening and understanding where the victim is in terms of progress through these phases assists in assessing readiness for change and guides intervention. The aim is to validate the person's experience, emphasize that they did not deserve or cause the abuse and empower the making of independent decisions that lead to improvements in safety and well-being.

Referral

There are multiple services to assist victims of family violence. If available, consult internal specialists for more information and advice (e.g. social work, mental health). Relevant external services to consult include a family violence crisis line, family violence outreach and men's referral service.

Safety

Safety is paramount and emergency accommodation or hospital admission may be required to ensure immediate safety. Safety is an ongoing issue as the greatest risk of injury occurs while leaving the relationship and for the 6 to 12 months after separation. Most cases of family violence homicides occur as the woman is leaving or has left the home. Continued contact with the perpetrator due to custody issues makes the risk of abuse a continuing one. Internal and external specialist services can assist with safety planning for the victim/survivor.

Reporting

Most Australian states and territories have not implemented mandatory reporting of family violence for adults. The exception is the Northern Territory, where mandatory reporting provisions were introduced in 2009. In contrast to adult victims of family violence, all Australian states and territories have some type of mandatory reporting of suspected cases of child abuse and neglect. Variations exist regarding which professionals are legally required to report; however, these generally include doctors, nurses and midwives. Most jurisdictions protect the identity of persons making a notification whether mandated or not.

Documentation

Documentation in the medical record may provide vital evidence and should be objective and accurate. Direct quotes and descriptions of behaviours and appearances increase objectivity. Body maps and photographs assist documentation of physical injury. Sexual assault examinations ideally should be performed by specially trained staff to ensure legal admissibility of evidence.

Careful consideration must be given to ensure the security/safety of patient information so as to avoid placing the victim at further risk of violence.

The management of family violence requires a co-ordinated response from all practitioners and service providers involved from when the victim first discloses the violence. This may include the health system, social services and the police and judicial system. At all times, the victim's wishes must be paramount and the service providers should do their utmost to support these wishes.

Conclusion

Family violence is a pervasive social problem that does not discriminate across age, cultural background, religion or socioeconomic status. The implications of family violence are substantial, including physical injury, mental illness, economic and social costs and fatal outcomes. Despite the high prevalence of family violence, it frequently remains undetected and unreported. Identification of risk factors for violence and interventions aimed at increased identification and referral can be considered in the ED environment. When violence is disclosed, the expression of concern and a willingness to listen, risk assessment, safety planning, support and stage-appropriate referral are the mainstays of management.

CONTROVERSIES AND FUTURE DIRECTIONS

- Although there has been considerable research on screening for family violence in emergency departments, further research regarding the outcomes after screening interventions is required to ensure the efficacy and safety of screening.
- Mandatory reporting of violence among adults remains controversial.
- Management strategies should not be aimed at encouraging a woman immediately to leave the violent relationship. Risk assessment, safety planning, support and stage-appropriate referral are the mainstays of management.

21.4 Alcohol-related illness

Ioana Vlad

ESSENTIALS

1 **Acute alcohol intoxication and withdrawal are responsible for many emergency department attendances and carry significant morbidity and mortality.**

2 **Chronic gastrointestinal and hepatic disease, mental illness, central nervous system disease and immunosuppression are common in alcohol-dependent persons, with complications that increase the morbidity and mortality further.**

3 **Wernicke encephalopathy is an uncommon but serious illness related to vitamin B1 deficiency. Treatment requires high-dose parenteral thiamine.**

4 **Many serious illnesses mimic alcohol intoxication or are masked by it. Maintain a high index of suspicion in the intoxicated patient with an altered state of consciousness.**

5 **Emergency physicians are uniquely placed to screen for high-risk drinking and other drug use as well as to offer brief advice or intervention to this group to reduce the burden of recurrent alcohol abuse.**

Introduction

Alcohol use disorders, which include alcohol abuse and alcohol dependence, are common across the world and have a high prevalence in emergency department (ED) presentations. Alcohol misuse not only places the individual at risk of acute intoxication and injury but also poses significant long-term health issues.

Acute alcohol intoxication causes much morbidity and mortality from all forms of trauma, including falls, motor vehicle and other accidents, interpersonal violence and self-harm. Chronic alcohol use contributes to many hospitalizations and deaths due to alcohol-related medical conditions and injuries, resulting in both physical and psychosocial impairment.

Many acutely intoxicated patients have significant co-morbidities masked by alcohol.

Patient with alcohol use disorders may present in states of acute alcohol intoxication or withdrawal. Emergency physicians should not only recognize and treat alcohol-related emergencies but also intervene in patients at high risk from their alcohol intake who present with other conditions. Early opportunistic screening using recognized alcohol screening tools and standardized brief interventions reduce 'at-risk' drinking and the morbidity and mortality from alcohol-related illness.

Epidemiology

Australia was ranked second of 34 Organisation for Economic Co-operation and Development (OECD) countries in alcohol consumption per capita in 2015. Australian alcohol consumption per capita is estimated at 11.2 L of pure ethanol per person per annum.[1] A study in five rural EDs

in New South Wales found that the percentage of patients engaging in risky drinking ranged from 4% to 32%.[2] A point prevalence survey of ED patients showed that 1 in 5 Australians and New Zealanders drank at levels that increased their lifetime risk of alcohol-related disease or injury and also that 17% to 35% of injury presentations to EDs involved alcohol consumption.[3] One in seven of all patients presented for reasons related to alcohol consumption, and in certain departments the prevalence was as high as one in three. There are more alcohol-related presentations due to injury during weekends, but patients with alcohol-related conditions present to ED at all times throughout the week. The patients tend to be younger (age groups 18 to 29 and 30 to 39 years), male and brought to the ED either by ambulance or police.[3,4]

Six percent of young persons (aged 12 to 19 years) attending city hospital EDs are there for alcohol-related reasons, with injury significantly more likely among alcohol users than among illicit drug users.[5] Among young people attending the ED, nearly 38% may be drinking harmfully, 18% may have consumed alcohol in the previous 6 hours and 15% consider their attendance to be alcohol-related. Up to 45% of injured patients attending EDs may have consumed alcohol within the previous 24 hours and almost 30% in the previous 6 hours.[6]

The natural history of alcohol dependence is to remit and relapse, with a relentless progression to early death. Risk factors for alcoholism include a family history of alcohol dependence or total abstention, parental divorce, youngest child, other substance misuse, availability of alcohol and extremes of income.

Pharmacology

Pharmacokinetics

Ethanol is passively absorbed from the entire gastrointestinal tract (GIT), with about 25% from the stomach. Absorption is rapid, within 60 to 120 minutes of intake, and may be slowed by food. Ethanol is distributed throughout the body water; females and obese people with lower ratios of body water to fat reach higher blood alcohol concentrations (BACs) sooner than their leaner counterparts. Hepatic oxidative metabolism occurs via alcohol dehydrogenase. Alcohol-tolerant people also utilize the hepatic microsomal ethanol oxidizing system, which is upregulated with increasing drinking. First-order elimination kinetics becomes saturated as the BAC increases, changing to zero-order kinetics and slower sobering at higher BACs.

Pharmacodynamics

Alcohol is thought to act on γ-aminobutyric acid A ($GABA_A$) inhibitory neuroreceptors in the brain, causing central nervous system (CNS) depression. The characteristic euphoria is thought to be related to the release of endogenous opioids (endorphins). A rapidly rising BAC causes quicker and more pronounced behavioural changes than the same level achieved over hours. A steady state of absorption to metabolism and excretion can be achieved at about one standard drink per hour. A standard drink is defined as containing 10 g or 12.5 mL of pure alcohol. Acute intoxication depends on factors such as habituation, food co-ingestion, body habitus and the concentration of alcohol in the drink.

Measurement of blood alcohol concentration

The blood alcohol concentration may be estimated using a Breathalyser that estimates BAC after measuring alcohol concentration in alveolar air. This is a useful non-invasive screening tool but relies on a cooperative and awake patient being able to exhale adequately for the reading. There is an approximate difference of 15% to 20% between breath alcohol readings and serum BAC. Readings are influenced by many factors, including temperature, hyper- or hypoventilation prior to exhalation, haematocrit level, other substances such as ketones, time since ingestion and machine error. A directly measured serum blood alcohol concentration is more reliable. The Australian legal limit for driving is 0.05%; in New Zealand it is 0.04%, whereas in the United States and the United Kingdom it is 0.08%.

Chronic alcohol-related illness

Gastrointestinal

Chronic alcohol use results in disease of the GIT, liver and pancreas. Morbidity most frequently arises from GIT bleeding, liver disease and pancreatopathy.

Gastrointestinal bleeding

The most common causes of alcohol-related GIT haemorrhage are peptic ulcer disease (PUD) and the consequences of portal hypertension, such as oesophagogastric varices or subepithelial gastropathy. Mallory-Weiss tears, oesophagitis and alcoholic gastropathy are less frequent causes of alcohol-related GIT haemorrhage. Heavy alcohol use may be a risk factor for the development of PUD, although the exact pathogenesis is poorly understood and the role of alcohol may be additive to the effects of *Helicobacter pylori*, non-steroidal anti-inflammatory drugs (NSAIDs) and tobacco.

Although Mallory-Weiss tears are less common, up to 44% are associated with alcohol use and may account for significant morbidity due to blood loss.

Alcoholic liver disease

Alcoholic liver disease (ALD) comprises a spectrum of disorders from alcoholic fatty liver (steatosis) and inflammation (hepatitis) to progressive fibrosis (cirrhosis) and hepatoma. These occur from chronic insult to the liver due to oxidative stress, damage from free radicals and the immunogenicity of alcohol metabolites. Many factors are involved in the aetiology of ALD, including genetic predisposition, gender, ethnicity, nutrition, ingestion of other hepatotoxic agents (i.e. drugs of abuse, weight-loss supplements, paracetamol), obesity and co-existent chronic viral hepatitis, non-alcoholic fatty liver and other liver diseases, such as autoimmune conditions.

The duration and amount of alcohol consumed play important roles; drinking at levels above the National Health & Medical Research Council (NHMRC), Australia recommendations (more than two standard drinks a day, both in men and women) is a defined risk for the development of alcohol-related injuries, ALD and eventual cirrhosis. The NHMRC also recommend drinking less than four standard drinks per occasion so as to reduce the short-term adverse effects of alcohol use, in particular alcohol-related injuries. Alcohol dependence does not inevitably lead to cirrhosis, which occurs in only 10% to 20% of heavy drinkers.[7] Alcoholic fatty liver is a common finding among alcohol-dependent patients but is not a frequent cause for presentation to an ED.

Alcoholic hepatitis and cirrhosis Alcoholic hepatitis may present as acute anorexia, nausea, vomiting, right-upper-quadrant pain and jaundice. Treatment is supportive and abstinence from alcohol is essential (see Chapter 9.6).

Cirrhosis typically presents late, with subtle malaise, anorexia, weight loss, weakness and fatigue along with a combination of liver cell failure and the development of portal hypertension. Acute decompensation usually manifests as symptomatic ascites, jaundice, pruritus, spontaneous bacterial peritonitis (SBP), hepatic encephalopathy, variceal bleeding and/or coagulopathy.

Ascites Ascites due to hypoalbuminaemia, secondary hyperaldosteronism and portal hypertension is usually recurrent. Sudden exacerbations may be caused by SBP, portal vein thrombosis, a hepatoma or medication non-compliance. Symptoms include abdominal discomfort, girth increase and anorexia. Fever, chills and abdominal pain occur with SBP or, conversely, signs of sepsis may be minimal but there is a sudden worsening of jaundice or encephalopathy.

Coagulopathy and encephalopathy Coagulopathy results from the failure of hepatic synthesis of coagulation factors, thus parenteral

administration of vitamin K and factor concentrate or fresh frozen plasma is required in the bleeding cirrhotic patient. GIT bleeding may also precipitate hepatic encephalopathy, with confusion and characteristic asterixis. This potentially reversible decrease in neuropsychiatric function must be distinguished from other causes of an altered level of consciousness in the cirrhotic patient.

Hepatic encephalopathy is associated with an increased nitrogenous GIT load (as from a gastrointestinal bleed), dehydration, sepsis, certain drugs, hyponatraemia or hypokalaemia, worsening liver function and increasing jaundice.[7]

Thrombocytopaenia Thrombocytopaenia is a common finding in. The aetiology is multifactorial: direct toxicity of the alcohol on the bone marrow, portal hypertension and platelet sequestration in the enlarged spleen, decreased thrombopoietin (TPO) synthesis in the liver, with a subsequent reduction in the proliferation and differentiation of megakaryocytes and platelet formation.

Alcoholic pancreatopathy

The term *alcoholic pancreatopathy* describes a group of pancreatic diseases caused by chronic heavy alcohol intake. It includes acute alcoholic pancreatitis, recurrent abdominal pain or GIT symptoms induced by alcohol, high serum levels of pancreatic enzymes or an abnormal pancreatic ultrasound. Recurrent bouts of acute alcoholic pancreatitis precede the development of pancreatic pseudocysts, chronic pancreatitis and pancreatic malignancies.

Alcohol is the most common aetiology of chronic pancreatitis (70% to 80%), although as few as 10% of heavy drinkers will develop it. Like cirrhosis, its aetiology is multifactorial; other risk factors include tobacco smoking and hyperlipidaemia, which should be addressed if early signs of pancreatopathy are recognized. Alcoholic pancreatitis, both acute and chronic, is managed conservatively with abstinence from alcohol as well as the administration of intravenous fluids, parenteral analgesia and, if pancreatic necrosis or an abscess is suspected, antibiotics (see Chapter 7.9).

Chronic pancreatitis can be debilitating, with recurrent cycles of pain and admissions to hospital. Progressive pancreatic calcification, failure of exocrine and endocrine function and chronic pain can all be mitigated if alcohol is avoided. Recurrent pancreatic insults and chronic pancreatitis increase the risk of pancreatic carcinoma by up to 16 times.

Mental health and mental state issues

Depression and suicidal intent

Alcohol is a recognized risk factor for suicide. Mood expression and intent of self-harm are often underestimated when intoxicated patients are seen in the ED. A Scandinavian study showed that 62% of 1207 'parasuicides' who presented to an ED involved alcohol use, with even higher rates in young males. Psychiatric referral was less likely if alcohol was involved; yet, after 5.6 years, 3.3% of these individuals had completed suicide. This represented a 51-fold increased risk compared with the general population, with the risk of completed suicide being greatest in the first year.[8]

Alcoholic hallucinosis

Alcohol misuse causes psychotic symptoms by several mechanisms, including direct intoxication, alcohol withdrawal, delirium tremens (DTs), Wernicke encephalopathy, Korsakoff psychosis and alcoholic dementia. Alcohol dependence doubles the risk of psychotic symptoms.

Alcoholic hallucinosis is a schizophrenia-like syndrome that differs from the other causes in that it occurs at a younger age, in a setting of clear consciousness and unrelated to acute withdrawal. There are no associated physical symptoms of autonomic dysfunction, as in the DTs, and its duration is longer, with predominantly auditory hallucinations as opposed to visual ones. Its chronicity and the derogatory auditory hallucinations are similar to those occurring in schizophrenia, but thought disorder is not a feature.

Alcohol withdrawal states

The alcohol withdrawal syndrome follows prior alcohol dependence. Its clinical importance lies in the potential severity of the symptoms and signs, the need to consider alternative or concomitant pathology and the likelihood of seizures occurring. The principal symptoms are tremor, agitation, nausea and vomiting, sweating, anxiety and autonomic nervous system overactivity with tachycardia, tachypnoea and fever. Sleep disturbance, hallucinations and generalized tonic-clonic seizures often begin within 10 hours of reduced alcohol intake, with peak intensity by day 2; it may last up to 5 days.

Alcohol withdrawal scales A number of scales measure alcohol withdrawal. One simple one is to rate symptoms as mild (tremulousness), moderate (agitation) and severe (confusion). Most EDs use an alcohol withdrawal scale (AWS) to measure symptoms, predict the likelihood of seizure and direct preventative management. The most commonly used AWS is the Clinical Institute Withdrawal Assessment—Alcohol, Revised (CIWA-R) scale. This scale measures 10 items and was primarily developed for planned detoxification or for use on general medical and psychiatric wards. Surprisingly, blood pressure and pulse, although often abnormal, are not included in the scale. A modified version that includes seizures in the AWS is also used.[9] Patients with high scores have an increased risk of seizure if they remain untreated. The higher the score, the greater the relative risk.

Pharmacological therapy Benzodiazepine (BZD) therapy reduces signs and symptoms of alcohol withdrawal and prevents complications.[10] All BZDs appear to have similar efficacy, but diazepam, lorazepam and chlordiazepoxide have been studied most. Longer-acting agents, such as diazepam used with symptom-triggered dosing (as opposed to regular), decrease the total of drugs given and both shorten and smooth the clinical course. Early treatment is preferred to waiting for advanced withdrawal.

Published data on ideal doses are lacking. High-dose oral diazepam 20 mg q1–2h may be needed for symptom control and up to 160 mg/day may be required to allow for BZD tolerance, which is common in alcohol-dependent patients. Under-dosing for fear of over-sedation is common.

Antipsychotics such as droperidol, haloperidol and olanzapine are commonly used to manage the agitation and other behavioural disturbances induced by severe alcohol withdrawal. However, they lower the seizure threshold and can cause anticholinergic syndrome if given in excessive doses. They can also cause prolongation of the QT interval and increase the risk of torsade de pointes in alcoholic patients, who are often hypokalaemic, hypocalcaemic and hypomagnesaemic. Ethanol, of course, would 'treat' the symptoms of withdrawal; however, it has been shown to be inferior to BZDs.[11]

Baclofen, a $GABA_B$ agonist, is increasingly used in the management of alcohol withdrawal, with various studies showing efficacy in decreasing withdrawal symptoms.[11]

Alcohol withdrawal seizures Around 3% to 5% of those with severe alcohol use disorder experience withdrawal seizures within 48 hours of stopping drinking, and 15% will have a seizure within their lifetimes. Previous withdrawal seizure is the strongest predictor of recurrent seizure. Most alcohol withdrawal seizures are short-lived and self-terminating. They occur early (usually 7 to 24 hours after the last drink), are grand mal in type (i.e. generalised, not focal); they usually (though not always) occur as a single episode. Localizing signs or prolonged seizures should prompt a search for alternate pathology. Intravenous BZD are the first line treatment for seizures secondary to alcohol withdrawal using the same doses as for seizures of any other cause (see Chapter 8.5). Phenytoin is not recommended for alcohol withdrawal seizures unless there is a coexistent epileptic disorder.

Delirium tremens 'DTs' are characterized by confusion, altered conscious state and autonomic hyperactivity. They usually develop 2 to 5 days after stopping or significantly reducing alcohol consumption. It usually lasts between 1 and 3 days, but in severe cases it can last up to 14 days. The incidence of DTs is reduced by effective early management of withdrawal and the exclusion of intercurrent illness. DTs occur in less than 1% of cases during any single withdrawal episode. The diagnosis is important, as the mortality from DTs approaches 15% if left untreated. As symptoms usually manifest within 48 hours, DTs may be encountered in EDs experiencing access block or in short-stay observation units.[12]

Risk factors associated with the development of DTs are older age, intercurrent illnesses, tachycardia greater than 120 beats/min, signs of alcohol withdrawal at BAC of more than 0.1%, seizure history and history of delirious episodes.[11] DTs are rare in the absence of these factors. The treatment includes management in an intensive care unit (ICU) with regular intravenous BZD, such as midazolam 0.1 to 0.2 mg/kg, and treatment of any underlying conditions, such as sepsis.[13,14] If treatment is required for hallucinations, the drug of first choice is diazepam. If hallucinations do not respond to diazepam alone or the patient has an underlying thought disorder, an antipsychotic such as olanzapine, haloperidol or droperidol may be added.

Wernicke encephalopathy

The classic features of Wernicke encephalopathy are ataxia, confusion and ophthalmoplegia, usually lateral rectus palsy. This is caused by thiamine deficiency, but severe deficiency may be present without these signs.[15] In alcohol-dependent persons, oral thiamine absorption is poor. Malabsorption, reduced storage and impaired utilization of thiamine increase the risk of Wernicke encephalopathy.

Post-mortem studies suggest that thiamine deficiency sufficient to cause irreversible brain damage remains undiagnosed ante-mortem in 80% to 90% of alcohol-dependent persons. Wernicke encephalopathy should be considered in all patients in coma, as replacement of depleted brain thiamine is necessary. The mortality from this condition approaches 20% if it is left untreated.

Treatment of Wernicke's encephalopathy is parenteral thiamine 500 mg IV tds for at least 5 days. The recommended prophylactic thiamine dosage has been increased to 200 mg parenterally tds. Ophthalmoplegia is the first sign to respond, with complete recovery after a few hours except for a residual fine horizontal nystagmus in 60% of patients. Recovery from ataxia takes a few days and can be incomplete, with persistent ataxia over the medium and long-term. Improvement in mental status may take several weeks. It is important to correct any magnesium deficiency simultaneously, because magnesium is a cofactor required for normal functioning of several thiamine-dependent enzymes. Supplementation of other water-soluble vitamins, especially niacin and pyridoxine, is advised, because patients suffering from Wernicke encephalopathy are often deficient in these vitamins. Unless the patient is acutely symptomatic from hypoglycaemia, glucose-containing intravenous fluids should be avoided before administering thiamine so as to avoid precipitating Wernicke encephalopathy.

Other alcohol-related neurological problems

Alcohol is a neurotoxin; its chronic heavy use causes CNS damage, peripheral neuropathy, myopathy and movement disorders such as tremor, parkinsonism, dyskinesias, cerebellar ataxia and asterixis.

Peripheral neuropathy

Peripheral neuropathy is common in alcohol misuse and has multiple aetiologies, including direct toxic effect of ethanol and malnutrition with thiamine deficiency. The prevalence among chronic drinkers is unclear but is estimated at between 9% and 50%. Other contributing factors are increased age, total lifetime dose of alcohol, nutritional status (malnutrition and thiamine deficiency) and family history of alcohol misuse. Alcoholic peripheral neuropathy is most commonly sensory in the lower limbs.

Alcoholic autonomic neuropathy

Alcoholic autonomic neuropathy is uncommon. It is often asymptomatic or causes erectile dysfunction in males, postural hypotension and/or diarrhoea. It is related to different pathological processes than sensory peripheral neuropathy.

Ataxia

Ataxia is a common presenting symptom and sign and may be due to peripheral neuropathy affecting proprioception, cerebellar degeneration or a combination of both. Cerebellar ataxia is possibly an extension of the insult from thiamine deficiency, as in Wernicke encephalopathy. Full recovery is rare and permanent damage occurs, affecting the superior cerebellar vermis, contrary to what occurs in Wernicke encephalopathy, where the ataxia may be reversible by thiamine administration.

Syncope

Neuronal failure resulting in syncope and amnesia is due to the direct toxic effect of alcohol on the CNS. This is especially common in binge drinkers. Orthostatic hypotension from autonomic failure is differentiated on the clear relationship to posture.

Respiratory illness in alcohol-dependent persons

Alcohol dependence increases the risk of community-acquired pneumonia owing to immunosuppression as well as general lifestyle factors, such as hygiene and smoking. Typical organisms include *Streptococcus pneumoniae* and *Haemophilus influenzae*. There is also a higher frequency of cavitating disease, empyema and unusual pathogens. Anaerobic and gram-negative organisms are frequent colonizers of the oropharynx and GIT, and aspiration pneumonia is common. Opportunistic disease, such as tuberculosis, *Pneumocystis* jirovecii pneumonia and Legionnaires' disease are also more frequent in alcohol-dependent persons.

Metabolic problems with alcohol use

Acute alcohol intoxication and chronic alcohol abuse can be associated with a variety of metabolic and electrolyte disturbances.

Alcoholic ketoacidosis

There is contention about the existence and frequency of alcoholic ketoacidosis. This refers to high-anion-gap metabolic acidosis associated with the acute cessation of alcohol on a background of chronic alcohol abuse and relative starvation. Clinical features include nausea, vomiting, abdominal pain, tachycardia, tachypnoea and hypotension, all of which may occur in other alcohol-related emergency presentations.

Chronic alcohol intake can lead to depletion of the body's carbohydrate and protein stores due to relative starvation. Reduced hepatic gluconeogenesis from substrates—such as lactic acid, glycerol and amino acids—can cause hypoglycaemia. In dehydrated states, the combination of hypotension and hypoglycaemia results in reduced insulin production and raised catecholamines, cortisol, glucagon and growth hormone. These hormones promote the utilization of fatty acids for energy, resulting in ketogenesis.

Alcoholic ketoacidosis has been described as 'a common reason for investigation and admission of alcohol-dependent patients', although research data appear limited. There may be an increased frequency of sudden death among patients who present in this fashion.[16]

Diabetic ketoacidosis

Acute alcohol intoxication can precipitate ketoacidosis in persons with known insulin-dependent diabetes.

Acute alcohol ingestion can cause a state of acute insulin resistance. Alcohol-induced postprandial hyperinsulinaemia occurs without a significant decrease in blood glucose levels, consistent with impaired insulin sensitivity. Relative starvation may result in hypoglycaemia and reduced insulin release. Alcohol-induced insulin resistance is important in these patients to recover from hypoglycaemia.

Light or moderate ethanol drinkers have a decreased risk of diabetes mellitus, while this risk is increased in heavy drinkers.[17]

Other metabolic acidosis

Metabolic acidosis in alcohol intoxication can be due to lactic acidosis, acetic acidosis or ketoacidosis.[18] One study of 60 ED patients with BAC greater than 0.1% described 7 with a raised serum lactate, all of whom had alternative reasons for this, such as seizure, hypoxia and sepsis. The treatment of an alcohol-dependent patient with metabolic acidosis is symptomatic, with intravenous crystalloid fluid resuscitation and rehydration, parenteral thiamine, 5% or 10% dextrose for hypoglycaemia, electrolyte replacement and a search for and treatment of another underlying cause, such as sepsis.

Electrolyte disturbance

Chronic alcohol abuse is often associated with various electrolyte disturbances, such as hypokalaemia, hyponatraemia, hypomagnesaemia, hypophosphataemia and hypocalcaemia. The causes include poor intake, malabsorption, excessive losses from vomiting, reduced renal tubular reabsorption and dilutional changes due to polydipsia.

Electrolyte imbalances result in the disturbance of other endocrine systems. Thus hypomagnesaemia suppresses parathyroid hormone release, resulting in hypocalcaemia. Electrolyte disturbances are also related to alcohol-induced illness, such as pancreatitis or pneumonia.

Hypoglycaemia There is little evidence that hypoglycaemia occurs in adults with simple alcohol intoxication alone; one large study of ED patients screened for alcohol use and serum blood glucose found no linear relation between blood alcohol and glucose levels. The incidence of hypoglycaemia is not increased in alcohol-related ED attendees compared with sober patients. Intravenous glucose administration has not been shown to be useful in changing rates of alcohol elimination or decreasing periods of intoxication. However, it is essential in each patient with an altered mental state to measure the blood glucose and treat if it is low.

Children and malnourished chronic alcoholics have limited hepatic glycogen stores, so glucagon is not effective in treating hypoglycaemia, as it cannot initiate gluconeogenesis. In the intoxicated or alcohol-dependent adult patient, an alternative cause for hypoglycaemia should still be sought.

Cardiovascular

Coronary heart disease

There is a reduced mortality from coronary heart disease in diabetic moderate drinkers. However, alcohol use in diabetes increases the risk of retinopathy, peripheral neuropathy and foot ulcers. Coronary protective effects of alcohol are due to influences on increased high-density lipoprotein (HDL) cholesterol, platelet function and fibrinogen.

Hypertension

Acute alcohol intake is a vasodilator, whereas drinking alcohol over the longer term causes systolic hypertension and increased aortic stiffness. An assessment by the World Health Organization Global Burden of Disease 2000 Comparative Risk Analysis attributed 16% of all hypertensive disease to alcohol intake. These findings may be confounded by other lifestyle factors, and there are many contrasting effects of alcohol at various intakes, depending on gender and body mass index (BMI). Thus raising HDL cholesterol is cardioprotective, but developing central obesity, or a 'beer gut,' is not. Overall, any benefits of moderate alcohol consumption on coronary disease are likely to be outweighed by harmful effects.

Cardiac arrhythmias

Heavy alcohol use is associated with an increased risk of sudden cardiac death, most commonly due to ventricular arrhythmias. Atrial arrhythmias including atrial fibrillation, or 'holiday heart', occur commonly after heavy binge drinking in both acute and chronic drinkers. They are not necessarily associated with cardiomyopathy. The risk of a cardiac arrhythmia is increased by electrolyte abnormalities, such as hypokalaemia, hypomagnesaemia and hypocalcaemia.

The treatment of arrhythmias is as recommended by the current Advanced Cardiovascular Life Support guidelines.

Cardiomyopathy

Concentric left ventricular hypertrophy is common in chronic alcohol users. Dilated cardiomyopathy may ensue, with progressive dilatation and fibrosis leading to congestive cardiac failure. This myotoxic process has a worse prognosis than idiopathic dilated cardiomyopathy, particularly if drinking continues. Myocyte function can improve with total abstention.

Aggressive anti-failure therapy should be implemented with dietary measures, such as reduced sodium intake, an angiotensin converting-enzyme inhibitor and other pharmacotherapy, even if total abstention cannot be achieved.

'Wet beri-beri' cardiomyopathy is caused by severe thiamine deficiency, which leads to myocardial dysfunction and peripheral vasodilation. Thiamine absorption is impaired by alcohol, and long-term use of furosemide depletes the body of water-soluble vitamins, including thiamine. Changes in myocardial function occur within 1 hour of starting parenteral thiamine therapy and function is back to normal within 1 week of treatment.[19]

Malignancy

Alcohol has been causally linked with many types of neoplasia, most commonly those of the GIT. Oropharyngeal and other head and neck cancers have a direct link to alcohol. Drinking more than 1.5 bottles of wine daily elevates the risk of oesophageal cancer 100 times. Hepatocellular carcinoma (HCC) is usually preceded by alcoholic cirrhosis in the Western world, although other causes include hepatitis B and C viruses. Progression of cirrhosis to HCC is more rapid if drinking continues. Chronic alcohol consumption is also related to laryngeal, breast, pancreatic and colorectal carcinomas.

Important illnesses to be excluded that mimic alcohol intoxication

It is hard to know when to look for another cause for altered conscious state in the habitual drinker or intoxicated person, as many alternative conditions must be considered that mimic apparent alcohol intoxication (Box 21.4.1). Close observation looking for trends in autonomic responses and neurological signs and detailed

examination looking for other pathology are more appropriate than waiting for, or intervening after, a certain period of time. Occult head injuries, unusual cerebral infection—such as cryptococcal meningitis, cerebral abscess or herpes encephalitis—are potential diagnoses that may require exclusion. Bias against treating an inebriated patient who is uncooperative and disruptive may lead to flawed early disposition in order to free up time for more 'deserving' patients, and significant injuries or other associated complications may be missed.

Alcohol-related trauma

In 2015, approximately 22% of road deaths involved young people aged 18 to 25 years despite the fact that these accounted for only 13% of licensed drivers. Of individuals, 67% were killed during times of high alcohol exposure. Alcohol users increase their risk in two ways: likelihood of injury and seriousness of injury. Alcohol abusers are more likely than sober persons to be involved in a trauma event; in addition, heavy drinkers have a higher risk for injury incidents than non-drinkers. Given similar traumatic circumstances, a drinker is likely to be hurt more seriously than a non-drinker. Although there are some exceptions, most research findings support this positive relationship between alcohol use and severity of injury. The exact mechanisms of the alcohol-severity relationship are not known, but it could be related to its disinhibitory effects as well as altered perception of risk. In addition, alcohol can complicate the initial assessment and management of the injured patient, masking physiological signs of serious injury and posing as a risk for regurgitation and aspiration of the stomach contents.

Other toxicological states in the alcohol-dependent patient

Multiple drug ingestion

Multiple drug ingestion, whether prescription or illicit, is common in regular drinkers for recreational reasons, due to dependence, to 'come down' from other drug effects, accidentally or in deliberate self-harm. The most common and important ingested drugs to consider include BZDs, opiates and paracetamol, antidepressants including tricyclics and selective serotonin reuptake inhibitors, γ-hydroxybutyrate, ecstasy and other sympathomimetics, such as cocaine and ketamine. Baclofen is increasingly prescribed to treat alcohol dependence and can cause altered mental state in deliberate overdose or if a high treatment dose is restarted after a period of non-compliance.

Other alcohols

Other alcohols—such as methanol, ethylene glycol and isopropyl alcohol—although rare, should be considered in the significantly intoxicated, self-harm patient. 'Methylated spirits' bought over the counter in Australia contains only 95% ethanol v/w with no methanol at all and, in New Zealand, the methanol content has been reduced to 2% or less, due to deaths attributed to chronic misuse and methanol poisoning there.

Serum drug levels

The only clinically useful screening serum drug levels are paracetamol and ethanol. Other drug levels take hours to days to perform (institution-dependent); thus they are not of use at the time and should be requested only if there are specific indications. The only safe antidotes to consider are naloxone, thiamine and glucose. Flumazenil is not recommended owing to the risk of inducing seizures secondary to BZD withdrawal and then not being able to manage them effectively.

Sepsis

Sepsis must be considered in any person with an altered conscious state potentially masked by alcohol intoxication; a directed septic workup should be carried out.

Treatment of alcohol-related illness

Alcohol intoxication

Intoxication starts with a feeling of well-being and an increasing sense of relaxation, followed by impairment of judgement and incoordination. At a BAC of 0.1%, dysarthria, ataxia and disinhibition are common. At a BAC of 0.2%, confusion occurs and new memories are not formed. At a BAC of 0.25%, cortical depression is seen, with the onset of stupor. At a BAC of 0.4%, most patients are unconscious and at risk of respiratory depression and death. The mean BAC found in fatal alcohol intoxication is 0.45%.

'Pathological intoxication'

Some people have idiosyncratic responses to alcohol, the 'pathological intoxication', which is more common among certain ethnic groups. A clear indicator of alcohol tolerance and neuroadaptation is the recording of high BAC in a person functioning at an otherwise reasonable level—for example the patient capable of normal conversation and gait with a BAC 0.3%. This may follow a continuous prolonged drinking binge.

Treatment of the acutely intoxicated person

The treatment of an acutely intoxicated person is supportive, protecting the at-risk airway and placing the individual in the semi-prone position to reduce the risk of gastric aspiration. Gastric emptying procedures are not recommended under any circumstances. Intravenous fluids in simple alcohol intoxication do not increase the elimination or decrease the BAC. Likewise, intravenous administration of 5% dextrose has not been shown to be useful in changing the rates of alcohol elimination or decreasing periods of intoxication.

There remains no antidote to alcohol intoxication. As alcohol affects endogenous opiate GABA receptors, both naloxone and flumazenil have been tried with no effect. Flumazenil use in the alcohol-intoxicated patient is dangerous, as it renders BZDs ineffective in the treatment of seizures for about 45 minutes after its use. It can also precipitate seizures if the patient is a chronic BZD user. Various substances have been tried in animals, but none so far is safe and/or effective. There has been interest in pyridoxine and, more recently, its analogue metadoxine in hastening alcohol metabolism and reversing both the biochemical and clinical symptoms of intoxication, but studies are small.

'Hangover'

In the United Kingdom in 2003, it was estimated that £2 billion in lost work value was due to post–alcohol-related headache and malaise 'hangover', making this a greater economic problem than habitual intoxication. Paradoxically, light or binge drinkers' hangovers cause the most lost work time, as the hangover is more common and the sufferer is more commonly in regular employment than the heavy drinker.

Hangover is distinguished from the alcohol withdrawal syndrome as it follows a defined single episode of intoxication. Symptoms include headache, feeling generally unwell, diarrhoea, anorexia, nausea, tremulousness and fatigue. The presence of two or more of these symptoms following alcohol intake has been used to define a hangover. Acetaldehyde, the dehydrogenated metabolite of alcohol, has been implicated. Alcohol alters cytokine production and thromboxane B2 is increased, an effect blocked by prostaglandin inhibitors. This may explain why prostaglandin inhibitors, such as NSAIDs, including aspirin, may have some limited prophylactic effect on hangover development.

Hangover is not solely dose-related. Hangovers are worse with dehydration, poor food intake, decreased sleep, increased physical activity while intoxicated and poor general physical condition. Congener by-products of some alcohols including aldehydes, esters, histamine, phenols, tannins, iron, lead and cobalt are found, especially in darker liquors, which are associated with an increased severity and incidence of hangover. The ingestion of clear liquors, such as gin, vodka and rum, may be associated with fewer hangovers. The evidence for hangover treatment and prevention is minimal.[20]

The habitual alcohol-dependent emergency attendee

Most EDs, particularly in metropolitan areas, have a group of recurrent ED attendees who keep presenting with alcohol intoxication and chronic alcohol-related disease. Such people are usually male, aged 30 to 40 years and often have no fixed place of abode. They are usually well known to neighbouring EDs, community services and police. They tend to attend in cycles, and an absence of attendance may indicate a prison term, a medical illness and/or hospital admission, an attempt at sobriety, use of an adjacent ED or sudden death. Over a year they may accumulate multiple investigations, especially computed tomography (CT) scans of the head. This group has an increased mortality over time from assault and other trauma as well as alcohol-related illness associated with neglect.

The emergency department as a temporary refuge

For the alcoholic individual, the ED provides a temporary refuge in an otherwise chaotic lifestyle and an opportunity for a health assessment and intervention. It is important to realize that providing care for this group of people is core business for every ED, despite any frustrations felt. Interventions to alter lifestyle and prevent recurrent attendances can be successful. ED-initiated case management involving community linkages, and assistance with accommodation improves health outcomes but may increase ED utilization. Serial inebriate programmes may target this group, often commencing with socialization skills, such as personal hygiene and nutrition management. Acceptance to such programmes is often precipitated by the threat of imprisonment. Such programmes have been demonstrated to be cost-effective.

Assessment of alcohol misuse

Alcohol screening tools

Emergency physicians witness daily the effects of lifestyle abuse on ED presentations and thus may find many opportunities to intervene opportunistically to affect the long-term health of the patient as well as treating the immediate presentation. This is particularly valuable for patients with irregular contact with other medical services, such as the itinerant and the homeless.

Screening for chronic alcohol abuse or dependence

Any screening tool to be of value must have adequate sensitivity and specificity for detecting the illness involved, and there should be an effective, cost-effective intervention available.

Box 21.4.2 CAGE screening questionnaire for alcohol abuse

C = 'Have you ever felt you should Cut down on your drinking?'
A = 'Have people Annoyed you by criticizing your drinking?'
G = 'Have you ever felt bad or Guilty about your drinking?'
E = 'Have you ever had a drink as an Eye-opener first thing in the morning to steady your nerves or help get rid of a hangover?'

Yes to two or more indicates probable chronic alcohol abuse or dependence.

Many screening tools for chronic alcohol abuse or dependence have been developed for primary care, with the best known being the CAGE questionnaire (Box 21.4.2).[21] This poses four questions on behaviour and a positive answer to two or more indicates probable chronic alcohol abuse.

Paddington alcohol test

An effective and quick alternative in the time-pressured setting of an ED is the Paddington alcohol test (PAT), which includes 'routine' focused selective screening combined with education, audit and feedback.[15] PAT has reduced screening time to 1 minute by simply quantifying the amount of alcohol consumed, how often and whether in the opinion of the patient the reason for ED attendance is excessive alcohol consumption.

Opportunistic screening and brief intervention

Brief intervention, usually consisting of a counselling session lasting 10 to 15 minutes and a pamphlet on safe levels of regular alcohol consumption, can reduce the frequency of dangerous drinking by 30%. After ED-initiated PAT screening and trained alcohol health worker follow-up, it can also reduce recurrent ED attendances by as much as 50%.

Focused PAT screening of high-risk patients (Box 21.4.3) followed by brief advice and referral for trained alcohol health worker intervention appear to be the most time- and cost-effective methods of reducing alcohol-related harm and ED attendances.[22] Brief advice consists of informing the patient during the ED 'teachable moment' that he or she has a drinking problem. This advice increases compliance to attend brief intervention later by 20%. Using PAT to screen all ED attendances as opposed to only those presentations considered at 'high risk' may increase the incidental pick-up of at-risk drinkers but may also decrease the enthusiasm of ED staff to provide screening because of the time required and the many negative

screens. Although it has been demonstrated that ED doctors and nurses with empathy and volition can be trained to provide ED-based brief intervention on the spot, the long-term benefit of this type of brief intervention is uncertain.

Pharmacotherapy for alcohol use disorder

A variety of pharmacological agents are available for the treatment of alcohol use disorders. These are rarely started in the ED, as patients need ongoing monitoring and support, and they must be referred for counselling and/or rehabilitation by their general practitioners. Agents that can be considered for use during treatment include acamprosate, naltrexone, disulfiram, topiramate or baclofen.

Acamprosate acts on GABA receptors in the CNS to reduce the craving for alcohol after detoxification. It is safe and well tolerated, suitable for use in the treatment of alcohol-use disorder and aimed at maintaining abstinence. Mild gastrointestinal side effects may occur and therapeutic levels take 5 to 7 days to become established.

Naltrexone is a partial opioid agonist that is useful in reducing the effects of endogenous opioids. It has had success in opioid addiction treatment as well as in alcohol-use disorder.

Disulfiram is an acetaldehyde dehydrogenase inhibitor. If alcohol is consumed while the patient is on disulfiram treatment, even in small amounts, unpleasant effects (flushing, throbbing headache, shortness of breath, nausea, vomiting, palpitations, hypotension, syncope) are felt immediately. It is contraindicated in patients with known ischaemic heart disease or history of psychotic episodes and in pregnancy.

Topiramate has been shown in several randomised controlled trials to be beneficial

in increasing the percentage days abstinent, decreasing the number of drinks per day, and improving levels of plasma gamma glutamyl transferase. Unfortunately it is associated with many significant adverse effects (cognitive impairment, paresthesias, weight loss, headache, fatigue, dizziness, depression), thus limiting its use. Baclofen is a GABA agonist that is increasingly prescribed to treat alcohol dependence. There are still only limited data regarding its benefits. Tolerance develops with therapeutic use, and if patients restart a high treatment dose after a period of abstinence, they can develop significant CNS and respiratory depression. Sudden cessation of chronic baclofen treatment can also be associated with a withdrawal syndrome characterized by hallucinations, delirium, seizures and fever.[23]

These agents may be used safely in combination, although this has not been shown to have a superior effect. Pharmacotherapy produces better results when used in combination with cognitive behavioural therapy and motivational sessions.

CONTROVERSIES

- The true prevalence and incidence of alcoholic ketoacidosis is uncertain.
- The dose of parenteral thiamine to prevent Wernicke encephalopathy is somewhat controversial.
- There is a question about whom to target for brief intervention by emergency clinicians: high-risk attendances or unselected patients.

21.5 The challenging patient

Georgina Phillips • Kirsten Cassidy

ESSENTIALS

1 **Many patients characterized as 'challenging' share common characteristics, including complex and chronic medical disease, mental illness, marginalization, poverty, high levels of drug and alcohol use and lack of social supports, safety and security.**

2 **An understanding of the issues that contribute to the challenging nature of some patients may help the practitioner to develop a management approach characterized by sound knowledge, clear and achievable goals and compassion.**

3 **Management strategies and practiced communication techniques may help to alleviate the dissatisfaction and frustration frequently experienced by the clinician.**

4 **Allied health and psychiatric services in the emergency department facilitate multidisciplinary and holistic care for the patient with complex needs.**

5 **Safety and security for all patients and staff must be assured. Physician self-awareness and self-care will help guard against burn-out in these situations.**

Introduction

The emergency department (ED) may be the only easily accessible health care for patients with multiple and challenging needs. For those impaired due to chronic illness, drugs and alcohol, mental illness or social circumstances, the ED is an environment where services are available 24 hours a day or during crisis. The challenges posed by complex patients are compounded by system factors, such as decreased after-hours services, ED overcrowding and access block. Some patients require urgent management for reasons other than medical issues—for example, a behaviourally disturbed patient who causes disruption and threatens violence within the ED, a very important person (VIP) who may distract the attention of staff or someone who poses a security risk. This chapter describes and discusses several types of patients with the aim of understanding the circumstances that contribute to these presentations and helping the practitioner to develop an approach to management.

The management of a complex patient in a difficult environment represents a common challenge for emergency physicians. As approximately 1 in 20 patient interactions are likely to be challenging, clinicians can accept, train and prepare for these situations as they should for any complex resuscitation. All emergency staff may find dealing with challenging patients tiring and frustrating and experience feelings of dissatisfaction. Physician characteristics such as younger age, longer working hours, depression and anxiety can contribute to increased feelings of frustration.[1] Self-awareness and the maintenance of physician well-being is an essential platform for the successful and satisfying management of these complex situations.

THE HOMELESS PATIENT

ESSENTIALS

1 **Multidisciplinary management of the homeless person is required.**

2 **Discharge planning is difficult and short-stay admission is frequently required.**

Definition and epidemiology

Definitions of homelessness vary. A homeless person is often considered to be someone living on the streets without shelter. A broader definition includes any person without a conventional home who lacks most of the economic and social supports that a home normally affords. These persons are often cut off from the support of relatives and friends, have few independent resources and often no immediate means; in some cases they have little prospect of self-support.

The most widely accepted definition in Australia, and the one used by government and other specialist agencies to gather data, describes three kinds of homelessness:

- Primary homelessness, such as sleeping rough or living in an improvised dwelling.
- Secondary homelessness, including staying with friends or relatives and with no other usual address, including people in specialist homelessness services.
- Tertiary homelessness, including people living in boarding houses or caravan parks, over both the short and long term, with no secure lease and no private facilities.[2]

Concepts of homelessness vary with culture. People from Aboriginal and Torres Strait Islander

cultures may experience homelessness when they are separated from their spiritual home, despite adequate shelter; conversely, they may feel a spiritual connection to the land on which they live independent of the presence of shelter. Three broad categories of indigenous homelessness are identified in Australia: those living in public places, those at risk of losing their house and those who are spiritually homeless.[3]

Estimates of the prevalence of homelessness are difficult to arrive at owing to variations in definition and methodologies of identification. Every night in Australia, around 105,000 people are homeless.[4] More than 160,000 Australians experience homelessness each year, one-third of them children, and resources allocated in response to homelessness are grossly inadequate. Homelessness is more prevalent among women and is closely related to the experience of domestic violence and inequity in general. Homelessness among children, families and older people is increasing. The Australian indigenous population comprises 3.3% of the Australian population but accounts for 25% of those accessing homeless services, primarily as a result of domestic and family violence, overcrowded dwellings and evictions.[5] Ex-prisoners, war veterans, the mentally and physically ill, people leaving health care facilities and protective services, youths and people in rural communities experience an increased incidence of homelessness.

Clinical features

Homeless patients presenting to the ED exhibit high rates of complex physical and mental illness and substance dependence. Due to poverty and social isolation, access to health care is impeded, with a subsequent cycle of deterioration in health. Lack of housing stability, social supports and points of reference within the local community lead to a high rate of utilization and re-presentation to the ED despite the development of outreach programmes and case management strategies.[6] Homeless patients may present to the ED up to 10 times more frequently than the rest of the population.[7]

Re-presentation rates within 28 days of discharge are high and may account for up to 48% of all re-presentation episodes and 23% of all patients who re-present to the ED.[7] Certain features, such as sociodemographics (age <65 years, receiving government pension), service utilization history (case management and discharge at own risk) and clinical features (primary psychiatric presentation, complex medical history and high numbers of prescribed medications) are highly predictive of re-presentation.[7,8] Presentations by homeless people are often of low acuity. Triage categories are non-urgent in up to 91% of attendances.[7]

Presentations with infectious diseases (e.g. TB and HIV), penetrating trauma, depression, schizophrenia and ethanol and drug abuse are common. Deliberate self-harm presentations are more frequent and are followed by a higher rate of re-presentation with recurrent self-harm and approximately double the rate of death from successful completion of suicide than in the domiciled population.[9] Homeless patients presenting with deliberate self-harm are more likely to be recent victims or perpetrators of violence or to have criminal records or a personality disorder, thus highlighting the complex links between these variables.

Management

The management of the homeless patient requires a multidisciplinary approach and an understanding of the social and financial constraints the patient faces. Allied health services may be able to provide background information or links to established community services, assist with discharge planning or with emergency accommodation or other social services. Discharge planning may be especially difficult and short-stay admission for the management of simple conditions normally treatable at home or admission to low-acuity facilities may assist with improvements in health and other social parameters. A compassionate approach to the homeless patient, where patients were assigned a volunteer who offered food and conversation, was found to decrease significantly rates of re-presentation, dispelling the myth that increasing patient satisfaction encourages homeless patients to re-attend.[10]

THE PRISONER

ESSENTIALS

1 **The prison population is disadvantaged and vulnerable.**

2 **Prisoners' health needs differ from those of the general public.**

3 **Presentations are often injury-related and are generally of high acuity.**

4 **Security events are uncommon.**

Definition and epidemiology

In all states and territories except Queensland, prisoners are defined as persons greater than 18 years of age remanded or sentenced to adult custody (age 17 in Queensland).[11] The patient brought to the ED by police from the community under arrest differs from the patient who is residing in prison. Both types of patients may pose security issues, but their health needs and demographics differ.

Table 21.5.1 Challenges involving the prisoner in the emergency department

Security issues	*Patient care issues*
Perceived threat to safety of staff and other patients	Clinical management of complex illness
Potential for violent incidents	Medical, psychiatric and addiction co-morbidities
Presence of non-hospital security staff	Maintenance of confidentiality
Weapons in the emergency department	Discharge planning

The prisoner poses several challenges when seen in the ED (Table 21.5.1).

The prison population in general has low educational achievements, poor records of employment, high reliance on social welfare, poor nutrition and more complex physical and mental health needs when compared with the general population; from a health perspective, these represent a cohort of patients distinct from the wider community.[12]

Prisoners have a high rate of pre-existing mental and physical illness, substance use and dependence and high rates of hospitalization. They also have a high rate of risk-taking behaviours that increase the likelihood of poor health, such as tattooing and heavy alcohol and substance use. They display behaviours with addictive or compulsive orientations and low impulse control. These factors contribute to the illnesses experienced, modes of presentation and responses to the health staff and treatments offered.

Clinical features

Prisoners are commonly younger men and frequently indigenous (Australian, Maori and Pacific Islander). Presentations are most commonly injury related and are overall more severe as compared with those in the general male population, with a higher frequency of fractures, blunt head injuries, greater rates of hospital admission and death.[13]

Mental health issues and high suicide risk are common among prisoners and incarceration is more common in those with mental illness. Risk factors for incarceration for those with mental illness include prior incarcerations, substance-related diagnoses, homelessness, schizophrenia, bipolar or other psychotic disorder diagnoses and male gender.[14]

Substance withdrawal is implicated in approximately 9% of presentations and 6% of admissions.[15] Due to the increased risk of overdose following periods of abstinence, recently

released inmates who use opiates are at particularly high risk of overdose, and overdose deaths are eight times more likely in the 2 weeks following release than in a comparable non-incarcerated group of men.[16]

Prisoners have a high rate of admission to hospital (range 36% to 49%), which may be due to a higher acuity of illness, with approximately 80% of prisoners triaged as category 3 or above, thus exacerbating the practical and logistical difficulties encountered in managing unwell people in custody. Prisoners have a decreased length of stay in the ED compared with the non-prisoner population.[15]

Violence and security issues

Episodes of violence are uncommon. The rate of security incidents may be lower than for the non-prisoner population.[15] Perceived threat and the accompanying stress caused to staff are yet to be quantified.

The presence of weapons provides the potential for serious injury to the patient if escape is attempted or to staff if the patient removes a weapon from security staff. Fatalities have been documented.[15]

Management

The urgency with which a prisoner is assessed depends on a combination of medical issues and security considerations; prioritization, in order to expedite management and decrease length of stay in the ED, is reasonable.

Prisoners may perceive the ED as a threatening, embarrassing environment that lacks privacy, where they can be seen by members of the public to be under guard and restrained. Most express feelings of distress when removed from their familiar environment. Prisoners are unable to have the normal reassurance and support of family while in hospital. The presence of guards during medical assessment raises confidentiality concerns for the patient. These concerns need to be weighed against security issues. Guidance from custodial staff as to whether it is safe for them leave the cubicle or remove restraints may be helpful. If the clinician feels insecure, custodial staff should remain within the room. The history obtained in the presence of guards may be inaccurate. Patients may be fearful of disclosing the mechanism of injuries due to fears of reprisal or prison guards in attendance overhearing the circumstances of injury.

In many Australian states, psychiatric services are not resourced or mandated to care for prisoners, and mental health acts do not cover those incarcerated under separate forensic laws. This may render the ED care of the mentally unwell prisoner even more difficult, as psychiatric illness may be undiagnosed or undertreated and access to normal mental health clinicians to aid in assessment and treatment may not be available.

Opportunities for following up of medical conditions are limited. There may be little possibility for observation of the person's condition upon return to detention. Outpatient follow-up is time- and resource-intensive and logistically difficult for the prison staff. There is therefore often a need for more extensive investigation while the prisoner is in the ED. A low threshold for ruling out potential illnesses and for admission to hospital is generally required.

If the patient is returning to prison, clear written discharge instructions should be formally communicated and discharge medication with dispensing instructions provided. Liaison with the prison nurse or forensic medical officer should establish whether their facilities and staffing can provide the expected management.

THE BEHAVIOURALLY DISTURBED AND VIOLENT PATIENT

ESSENTIALS

1 **Complex co-morbidities of organic illness, psychosocial issues and substance misuse can manifest as acute behavioural disturbance.**

2 **An understanding of legal and ethical considerations can inform rapid decisions and humane treatment in behavioural emergencies.**

3 **A safe environment and team approach can maximize containment of disturbed and violent behaviour while respecting the privacy and dignity of patients.**

4 **A strategic approach to understanding and managing violence in the ED may minimize the harmful effects of violence to staff, patients and carers.**

Aetiology and epidemiology

A behavioural emergency can be defined as an unarmed threat by a patient or others characterized by agitation, aggression, violence and irrational or altered behaviour. Violent and unarmed threats involving patients in the ED have been described with an incidence of between 0.3%[17] and 2%.[18] Accurate information on the incidence and subsequent management of acute behavioural disturbance is limited by the lack of clarity around what constitutes a behavioural emergency and significant differences in treatment response both within and between EDs. Heavy recreational drug use and alcohol binge drinking in the community have contributed to the public perception that behavioural disturbance requiring urgent medical care has increased. It has also been argued that psychiatric deinstitutionalization and limited community supports have led to an influx of unstable, mentally ill patients to the ED.

The aetiology of acute behavioural disturbance in the ED is largely mental illness or substance intoxication and often a combination of the two.[17] A smaller number have an organic illness, including dementia, manifesting as a behavioural emergency.[19] Most patients are male (approximately 65%) and under the age of 40,[17,20] and around 20% are brought to the ED in police custody.[17,21] The majority of unarmed threats occur in the late afternoon, evening and overnight, with a weekly peak on Saturdays.[17] Between 58% and 80% of these require some form of chemical or physical restraint as part of management.[17,18,20]

Prevention

Experienced clinicians are able to recognize environmental and individual factors that can lead to unstable and dangerous behaviour. Crowded, noisy and brightly lit departments are the antithesis of the calm and stable surrounds that promote controlled behaviour and de-escalate aggression. Fear, confusion and inadequate communication can trigger anger and aggressive behaviour in both patients and carers; also, long waiting times and negative waiting room environmental factors have been suggested as contributors to violence in the ED.

In order to prevent anger or illness from escalating to a behavioural emergency, recognition of verbal and non-verbal cues is required, as well as an ability to utilize environmental and clinical resources to ensure a calm, controlled situation. EDs are now incorporating separate rooms or areas that are quiet, private and secure as sites for the assessment and containment of behavioural disturbance.[22] This model has become the recommended standard in Australia for assessing and containing aggressive and agitated patients both at a national[23] and state level.[24] Physical separation from the main ED and the removal of stimulation may be enough to reverse the trend to increased aggression. Respectful and clear communication with lowered voice level, eye contact and non-threatening body language may establish a rapport that enhances a therapeutic bond between clinician and patient. Explanation of

treatment decisions and the reasons for them may alleviate confusion, while bargaining and rewarding compliance can diffuse tension. It is recommended that, while also setting clear behavioural limits, the patient should be allowed a semblance of autonomy and control.

A 'security response' is utilized in the ED to contain behaviour when disturbance and aggression can be anticipated.[25] This is aided by prior police and ambulance notification of the imminent arrival of a patient who represents a behavioural emergency. A team comprising hospital security service, nursing and medical staff can in itself be a disincentive for increased aggression when an aroused patient is being confronted. In the event of violence, the team response carried out in a separate area of the ED can quickly control behaviour safely and thus prevent further episodes or prolongation of aggression.

Clinical features

Clinical assessment comprises three components: diagnosis, evaluation of risk and assessment of arousal (Table 21.5.2).

Signs of acute intoxication or withdrawal may follow recognized patterns or drug toxidromes, whereas psychiatric instability may manifest with features of psychosis. Differentiating between organic illness, delirium and substance intoxication or psychosis can be extremely difficult in the initial assessment and may be clarified only after immediate management and behavioural containment. A breath alcohol determination is useful, and intravenous puncture sites may suggest substance misuse. In an agitated and aroused patient, the act of taking a blood pressure or putting a stethoscope on the chest may be recognized as a familiar and non-threatening action and thus be better tolerated than attempting to get a detailed history or expecting a rational response to verbal requests.

The role of investigations in the behaviourally disturbed patient is dictated by the clinical presentation. Routine laboratory blood testing is of low yield. Urine drug screens have no role in the acute assessment or management. Cognitive abilities should guide the readiness for psychiatric assessment, rather than the suspected presence of drugs or alcohol. A positive breath alcohol should not preclude mental health assessment in the patient who is alert and orientated.[26]

Table 21.5.2 Aims of clinical assessment in the face of acute behavioural issues

Diagnosis	What is the aetiology of the behaviour: psychiatric, substance related, organic, personality?
Risk assessment	Can the patient's autonomy be over-ridden? Can he or she be kept in the emergency department against his or her will?
Arousal assessment	Does the patient require containment or sedation, and how rapidly?

Risk assessments are often made rapidly and intuitively in the highly agitated and aggressive patient. The decision to contain and restrain an aroused patient with extreme behaviour is primarily based around the perceived threat of harm to self or others. If patient competence cannot be assessed, then the assumption of risk of harm and the doctor's duty of care override patient autonomy. Clinical features that are suggestive of high risk include threats or actual self-harm, suicidal behaviour or ideation, threats or actual violence to others, altered conscious state due to illness, injury or substance intoxication and incompetence. Risk assessments and restraint can be made only within an acute framework (i.e. pertaining to hours rather than weeks or months), as this is the length of time a person can humanely be contained within an ED setting. Patients with longer-term high-risk behaviours are not suitable for physical or chemical restraint in the ED and may be managed more appropriately in a mental health or forensic setting.

Assessment of arousal requires utilization of collaborative and clinical tools and informs decisions about urgency and methods of restraint. Information about behaviour immediately prior to ED presentation can be gathered from police and ambulance officers. Physical struggle and violence requiring restraint during transport to the ED is an indication of the need for ongoing restraint. Physical intimidation, threats or acts of violence to self, people or property, attempts to escape, uncontrollable verbal abuse and aggressive acts such as spitting, all indicate extreme arousal and the need for immediate containment and restraint. Signs that a patient is increasingly aroused and that violence may be imminent, include physical agitation and restlessness, pacing, sweating, loss of rational thinking, increased voice tone, swearing or foul language, eye widening and pupil dilation. Early recognition of these prodromal features may prevent the escalation of aggression and ensure the safety of both staff and patient.

Legal and ethical considerations

Sedation and restraint for behaviour containment represent significant deprivations of personal liberty. Australasian law strongly upholds the fundamental principle of individual autonomy and mental health legislation mandates a 'least restrictive' approach to involuntary care. Emergency physicians must also respect patient autonomy and be mindful of employing the least restrictive practices in making decisions to restrain aroused and aggressive patients (see Chapter 28.1).

The ability to detain and treat people without their consent is lawfully recognized in emergency situations, committal under legislation (e.g. mental health acts), suicide prevention, to protect others from harm, self-defence, 'necessity' or 'in best interests' and for incompetent patients.[27] Thus ED staff are comprehensively protected under the law if they act in good faith and with integrity when managing acute behavioural disturbance. Doctors are also legally required to maintain confidentiality, to take reasonable care, not to take advantage of a patient and to meet professional standards. Containment and restraint often take place in highly visible sites within the ED, where the patient is exposed to the scrutiny of other staff, patients and visitors, which can undermine personal privacy and confidentiality. Similarly, abusive and aggressive patients may provoke anger and frustration in ED staff. Competent patients are responsible for their actions and are expected to behave within a reasonable and legal framework. Damage to property and assault to person are crimes that are subject to prosecution if they occur in an ED and toward ED staff. There are occupational health and safety requirements that mandate a safe working environment and can inform structural changes and clinical practices in the management of violence in the ED.

Medical ethics and the law complement each other in recognizing personal autonomy and human rights. A compassionate approach that respects the human dignity of all patients and recognizes the medical duty to provide care is likely to result in both a lawful and an ethical framework for managing patients with behavioural emergencies.

Management

Once the decision to contain and restrain a patient with behavioural disturbance has been made and preventative de-escalation measures have been unsuccessful, it is worth determining the desired end point of management. Containment methods differ significantly according to the desired outcome, which may range from a calmed, awake patient through to one who is fully tranquillized and physically restrained. In an ED setting, containing and restraining a patient is not therapeutic and should be viewed as a transient departure from the normal physician-patient collaboration.

Containing a highly aroused and aggressive patient requires a team of trained staff: a minimum of six people comprising hospital security staff and orderlies, with medical and nursing staff to assist with team leadership, documentation, drug administration and subsequent monitoring.[28] Smaller hospitals may have to utilize police in their initial team response, but this is not recommended,

given the differing training and aims of hospital- and police-based restraint practices. Police should be involved when a weapon is present or the violent person is not a patient receiving treatment. The importance of prior planning, regular aggression management training and good communication cannot be overemphasized.

Chemical restraint

The pharmacological management of the acutely aroused patient is discussed in detail elsewhere (see Chapter 20.6), but the principles should be emphasized. The least traumatic measures are advocated, depending on the desired end point of chemical restraint and the risks to staff and patient in administration.

Oral benzodiazepines are preferred where possible and may allow patients a small sense of control if they are able to choose this option ahead of parenteral sedation. Choice between intramuscular or intravenous administration of sedation depends on perceived risks to staff, ease of obtaining intravenous access, need for blood tests or other intravenous therapy and desired rapidity of sedative effect. A standardized intramuscular sedation protocol can be effective and safe.[29] Where rapid tranquillization is desired, the intravenous route of administration is required, as the onset of action is within the first 5 minutes rather than the approximate 15 to 20 minutes of intramuscular drugs.[30] Commonly used drugs for rapid tranquillization include benzodiazepines (diazepam and midazolam), neuroleptics (droperidol and haloperidol) and antipsychotics (olanzapine). Increasingly, ketamine is used in patients who are difficult to sedate and in transport situations.[31] A combination of intravenous midazolam with droperidol or olanzapine has been shown to be more effective than midazolam alone or than high-dose droperidol or olanzapine alone with respect to time to adequate sedation and need for re-sedation.[32,33] Intravenous midazolam alone may cause more adverse events relating to airway obstruction and over-sedation and is more likely to require re-sedation within an hour. High-dose parenteral midazolam is not supported due to concerns about effect and safety.[34] Careful monitoring in a high-acuity area of the ED is required when parenteral chemical restraint is used.

Physical restraint

Physical restraint can initially proceed on the floor and move to a trolley as soon as practical. A five-point hold is recommended, involving securing the head as well as the upper and lower limbs in firm grasp. Personal protective gear of gown, safety goggles and gloves should be worn by all involved and an oxygen mask or loosely applied towel over the face can be used if the patient is spitting. Although it is paramount not to inflict harm on the patient, the safety of staff is also a priority and may justify the use of moderate physical force. Using staff physically to restrain a patient is a temporary measure only and should be followed by more definitive restraint in the form of sedating drugs, physical shackles or both.

Physical restraint with shackles provokes emotional distaste in many clinicians, but it can be used safely and humanely in an ED setting. There have been reported deaths in restrained, agitated patients, described largely in the United States, where 'hobble' restraints including prone positioning with hands and feet secured together behind the back are used.[35] Where supine positioning is used, physical shackles have been shown to be safe.[36] Soft-edged, strong, fabric shackles securing the wrists and ankles of a supine patient to the trolley are recommended. Concomitant chemical sedation is advised, with appropriate monitoring. Prolonged shackling is inhumane and carries risks of musculoskeletal injury, respiratory compromise and psychological trauma. All Australian states have laws that mandate careful and close observation of physically restrained patients as well as regular review of the need for such ongoing, extreme restraint.

Although few EDs have appropriate resources, it may be possible to contain patients with behavioural disturbance in a less restrictive manner by using seclusion rooms. Such areas must be visible to ED staff, be easily accessible to a security response team and have no dangerous furniture or fittings with which patients could potentially harm themselves or others.

Patient perspective

Emergency clinicians rarely consider patient preferences when faced with the need urgently to control aggressive or threatening behaviour, and there is limited evidence to inform this issue. The majority of patients prefer chemical restraint rather than physical for interventions, and seclusion is preferred over physical shackles. Benzodiazepines are the preferred drug for chemical sedation rather than neuroleptics.[37]

Disposition

Behaviourally disturbed patients commonly spend many hours in the ED, both for accurate assessment and for diagnostic purposes. Increasingly, the lack of access to general medical, psychiatric and detoxification inpatient beds means that timely transfer for definitive care is delayed. The result is prolonged, inhumane containment of behaviourally disturbed patients, which is likely to lead to worse therapeutic outcomes. For this reason, ED doctors must be strong advocates on behalf of their patients as well as maintaining vigilant clinical review of the patients' physical and mental state and the need for ongoing restraint. Patients who are transferred to inpatient wards for ongoing care must be alert, have stable vital signs, not require further monitoring and be declared safe for transfer by the most senior available ED clinician. Respiratory depression and death have occurred in patients transferred to psychiatric wards after receiving chemical sedation from the ED; therefore the time, nature and route of drug administration must be taken into account in considering safety for transfer.

The decision to admit a patient depends on the result of clinical and investigative findings, ongoing mental health and risk assessment and the progress of the patient over time. It may be appropriate to keep behaviourally disturbed patients under ED observation for up to 24 hours in order to clarify the aetiology of the altered behaviour and determine a safe disposition. Patients with aggression and arousal due to substance intoxication often wake up several hours later with normal behaviour and no recollection of their earlier violence. This presents a preventive health opportunity to counsel, educate and refer the patient for ongoing drug and alcohol review. Patients should be informed that their substance misuse has resulted in dangerous behaviour both for themselves and others, but many will already be socially marginalized and vulnerable as a result of homelessness, substance addiction and psychosocial stressors. A multidisciplinary care-coordination approach optimizes a safe discharge for these patients.

Normal clinical and investigative findings, the absence of substance intoxication and exclusion of acute mental illness mean that the patients do not require further ED care. Such patients may still present a behavioural challenge and, if ongoing risk to self or others exists, they should be discharged to the care of the police. Collaborative decision making with mental health clinicians is often required in such situations, as these patients often suffer antisocial or other personality disorders that are difficult to manage in both forensic and health settings. For those discharged to the community, mental health and social work follow-up is recommended.

At all stages in the assessment, containment, restraint and disposition of patients with acute behavioural disturbance, clear documentation is mandatory. The importance of recording management events and the reasons behind containment or discharge decisions protects staff from clinical and legal criticism as well as aiding care in potential future ED presentations.

Violence

The impact of occupational violence and aggression is under-recognized in Australasian EDs, although it has been increasingly documented.[38] Violence severity appears to

have increased, with some recent fatal consequences.[39] Aggression and violence most often stem from acutely disturbed patients, although violence in the ED can also come from visitors and carers as well as hospital staff. Internationally recognized as a growing problem, ED violence is also generally poorly documented and under-reported, with limited formal hospital support for those exposed and rare conviction for the perpetrators.[40,41] Although conventional definitions of violence centre around the act of intent to cause physical or psychological harm, in an ED setting, aggression and violence are commonly manifestations of underlying illness or substance intoxication. The absence of a malicious intent to cause harm may be a reason why violence has been under-recognized in the hospital environment and has led to an alternative workplace definition: any episode in which staff experience either implicit or explicit challenges to their personal safety, health or sense of well-being.[42]

Other reasons for under-reporting of ED violence stem from hospital systems that act as barriers by burdening staff with excessive and time-consuming paperwork, confusing policies, inadequate confidentiality and lack of peer support. Although most episodes of violence in the ED do not result in serious physical injury, staff who experience violence may be traumatized, which can lead to feelings of stress and anger. The cumulative effect of violence may result in clinician 'burnout' and staff attrition.

The concept of 'zero tolerance', which has been adopted from the justice system in some hospitals, is unworkable in the health care setting, where clinical aggression is conjoined with a duty of care between the clinician and the patient. As a principle, zero tolerance fails to recognize that aggression and violence may be manifestations of a clinical illness that requires remediation and care. Three core components comprise a strategic approach to managing violence in the ED: environment (appropriateness, safety); staff (education, training, teamwork); and systems (reporting, follow up, peer support, policies).[43] Prevention and early intervention within a safety and patient-care framework is emphasized. Principles of training should be applied to all health care providers and include training programs tailored to staff groups, stratified risk levels within the organization and included within a culture of continuous quality improvement underlies prevention of occupational violence and aggression training and responses.

Generally a comfortable environment with clear visibility that facilitates good communication will have a greater effect on behaviour modification than the increasing fortification of waiting rooms, triage and clinical areas in the ED. Violence minimization is assisted by security cameras and televisions at triage so potential aggressors can see that they are being monitored, the visible proximity of security staff, high visibility within the clinical work space, restricted access areas, minimizing access to potential weapons as well as widely dispersed and simple-to-use duress alarm devices. Introducing armed security personnel into EDs increases risk to staff and patients and is not recommended.[24] Staff training and support are paramount in managing ED violence. Physician can learn and practice communication techniques to de-escalate aggressive interactions.[44] Interdisciplinary programmes that involve role play and real scenario discussions can enhance cooperation between all ED staff while also clarifying roles and responsibilities during actual security responses. Peer education sessions can serve to change culture towards a preventative and proactive approach, based on good communication skills and sound knowledge about behavioural emergencies. Hospital security staff are experts in the containment of aggressive and violent patients within a healthcare framework and can lead team-based prevention and safety training for ED staff.

In general, ED doctors are required to take a leadership role when managing a violent episode, although collaboration with experienced nursing colleagues improves care. Awareness of personal factors that may affect the escalation of violence and the subsequent outcomes is therefore essential. Anger, fear and personal insult can lead to interactions with aroused patients that may escalate aggression rather than diffuse tension. The role of peer support and follow up in such situations is vital. Similarly, issues of gender, language and culture are often under-recognized as factors influencing the escalation and management of a behavioural emergency. Male staff may experience higher levels of physical violence than women. Self-awareness and consideration of these issues can optimize management of the violent episode, as well as minimize the potential negative outcomes for staff and others.

The final component of the structured approach to ED violence management is ensuring adequate documentation and follow-up systems, which include debriefing and support. Reporting should be incorporated into the standard documentation of any security incident within the ED, rather than the onus of staff who have been victims of violence. As the issue of workplace violence is one of occupational health and safety, follow-up of violent incidents should fall within this framework, thus depersonalizing the impact of aggression and owning violence as an organizational responsibility rather than one belonging to the individual.

THE FREQUENT ATTENDER

ESSENTIALS

1 **Frequent attenders to the ED have increased morbidity and mortality.**

2 **Assumptions about inappropriate use of the ED have been shown to be false.**

3 **ED-based multidisciplinary care coordination can lead to improved psychosocial status for frequent attenders.**

Definition and epidemiology

Patients who present to hospital EDs more than three times a year can be defined as 'frequent attenders'[45] and represent a particularly vulnerable population.[46] Both internationally and within Australasia, the frequent attender population has consistent characteristics that include poverty, homelessness, chronic and complex medical illness, psychiatric illness and drug and alcohol abuse.[47–49] Frequent attenders also suffer a high mortality, with an increased risk of death from violent causes such as suicide and substance misuse.[50] They are known to use health services in a frequent, chaotic and episodic way; they often attend multiple EDs and are difficult to engage in any long-term care. Importantly, availability and engagement with primary health care providers does not alter ED use by frequent attenders.[51]

Although they represent only a small number of people, frequent attenders can be responsible for up to 8% or more of annual ED attendances.[52] Demographic details vary according to how the frequent attender population is defined and analysed in the literature; however, they are consistently more likely to be male, older and socially isolated.[6,46] A range of 27% to 55% have chronic and complex medical illnesses as the key reason underlying their frequent ED use, whereas the remainder suffer primarily psychiatric, social or drug- and alcohol-related illness.[6,53] Commonly, heavy ED users display a combination of all of these co-morbidities. Patterns of attendance generally fall into two categories, with those suffering primarily psychosocial illness or substance abuse sustaining consistently frequent ED use over many years, whereas those with primarily chronic medical illness showing peak ED attendance over 1 to 2 years.[53] Recent research from New Zealand demonstrates the natural attrition of frequent ED attenders over time[54]; however, the principal finding in studies around the world is the high mortality rates in this population.

Clinical features

There is great variability in the clinical presentation of frequent attenders. Acute exacerbations of underlying chronic medical illness are common as are traumatic injuries or injuries and illness sustained through violence or substance misuse, including acute substance intoxication. Infections in the respiratory, gastrointestinal and dermatological systems are frequent. Deterioration in mental state or self-harm and suicide attempts are also common reasons for ED attendance.[52] Compared with the whole population, frequent attenders are more likely to present out of hours,[55] have more serious and urgent illness and more often require inpatient services.[46] Frequent attenders are more likely to discharge themselves from the ED prior to completing their ED care or to self-discharge before assessment after the initial triage process.[52]

There is a pervasive assumption that frequent attenders present to the ED excessively and unnecessarily and are therefore suitable for diversion to general practitioners. Evidence suggests that this belief is false and that the majority of patients presenting frequently for ED care do so appropriately and are unsuitable for diversion to primary care providers.[52] Patients may be adversely affected if their symptoms are belittled and their attendance classified as 'inappropriate'.[56]

Management

Understanding the vulnerability of frequent attenders and their complex co-morbidities while adopting a humane approach is fundamental. Medical care follows standard procedures. Access to past history and information from all health care and community services involved in the care of the frequent attender provides an essential context enabling timely, focused and relevant care, without unnecessary duplication of services and investigations. The development and wide dissemination of individualized acute care plans can assist in streamlining assessment and management when frequent attenders re-present to the ED after hours. Utilization of ED-based multidisciplinary services for care coordination has been shown to be of benefit when caring for the frequent attender.[6]

Attempts to reduce perceived unnecessary ED attendance have met with varying results. Neither the education of patients nor management care plans has reduced the frequency of their ED attendance. The most successful international diversion strategies have adopted multidisciplinary approaches, including social worker support.[57,58] ED-based multidisciplinary case management has been shown to increase ED utilization but also to lead to improvement in psychosocial factors, such as housing status and engagement with primary and community care providers.[6] If psychosocial improvements are desired, ED use may have to increase for frequent attenders. Frequent attenders are a complex, unwell and chaotic population. Diversion away from the ED has no proven patient benefit; therefore it may be that the ED is the best site of care for such vulnerable patients and can have a role in improving their overall well-being.

THE PATIENT WITH DRUG-SEEKING BEHAVIOUR

ESSENTIALS

1 **Drug addiction can be viewed as a chronic, organic disease.**

2 **Drug-seeking behaviour is problematic for the patient and the clinician.**

3 **Physicians managing these patients may experience dissatisfaction, frustration and feelings of manipulation.**

Definition and aetiology

Drug abuse is defined as a maladaptive pattern of drug use indicated by continued use despite knowledge of its being a social, occupational, psychological or physical problem that is caused or exacerbated by the use.[59] Addiction is defined as a primary, chronic neurobiological disease that develops as a result of genetic, psychosocial and environmental factors and manifests as use of a substance to the extent that the user is periodically or chronically intoxicated, exhibits compulsive use, has great difficulty in voluntarily ceasing or modifying his or her substance use and exhibits determination to obtain psychoactive substances by almost any means. Typically, tolerance is prominent and a withdrawal syndrome frequently occurs when substance use is interrupted.[59] Drug-seeking behaviour can be defined as behaviour aimed at obtaining controlled substance prescriptions for reasons of dependence, abuse or illicit use in a manner that is problematic to the prescriber.[60] Patients may have a range of underlying disorders, such as psychiatric illness, substance misuse, chronic pain and complex medical conditions, which have resulted in drug dependence and institutionalized behaviour on many levels.

The concept of addiction as a disease is useful in modifying the clinician's approach to patients with addiction issues. The illness model has countered the widely held view of addiction as a wilful behaviour with moral implications. Likening addiction to other chronic illnesses, such as hypertension and diabetes, helps to understand the chronicity of the problem and the vulnerability to relapse. The rehabilitation of patients with substance-abuse problems has, however, been handled largely by non-physicians who work closely with their patients, therefore rendering effective intervention in the ED challenging.

Clinical features

Identification of the patient seeking drugs may be difficult. Features raising suspicion of drug seeking include previously documented drug-seeking behaviours, inconsistent history or examination findings, requests for specific narcotic or other drugs of dependence, unwillingness to try simple analgesia, higher than expected analgesia requirements and demanding or aggressive behaviour. Other features that may raise suspicion include complaints of lost or stolen prescriptions or medications, letters from remote medical practices supporting the provision of medications and presentations that are possible to feign, such as migraine or ureteric calculus. Drug-seeking patients commonly have a past history of mental illness, drug dependence and self-harm.[61]

The possibility of missing organic illness is considerable in patients suspected of drug seeking, as nearly 20% require hospital admission and 17% self-discharge against medical advice. Missed, too, is the opportunity to acknowledge drug dependence and refer appropriately. Of drug-seeking patients seen in the ED, only 11% have a documented discussion around this issue in the medical record and only 23% are referred to addiction, psychiatric or chronic pain services.[61]

Management

There is considerable individual variation in the management of patients who are drug seeking. Clinicians often find these interactions frustrating and unsatisfying and may feel abused or manipulated. The development of a general approach may assist (Box 21.5.1).

Limit setting requires confidence, experience and familiarity with local laws that limit the

Box 21.5.1 General approach to the drug-seeking patient

Attempt to develop rapport with the patient.
Ensure that new organic pathology does not exist.
Determine that genuine pain has been adequately treated.
Once you have some degree of certainty that problematic drug-seeking behaviour exists, set clear limits regarding medications requested.
Consider the possibility of open discussion with the patient regarding the behaviour.
Consider referral to appropriate services for ongoing care.
Develop management protocols for particular patients if frequent attendance or threatening behaviours develop.

prescribing of controlled drugs. A departmental policy regarding the drugs within the ED that are available for dispensing after hours and may be prescribed on an outpatient basis can give guidance. Approaches vary, but a factual and dispassionate explanation about the inability to prescribe controlled substances due to departmental policy or legal requirements may be of assistance.

The physician must determine the appropriateness and utility of an open discussion surrounding the perceived problem behaviour. If open discussion is possible, referral for assistance may be more successful. Opportunities for interdisciplinary discussion of particular patients and an approach to their management with the development of an easily accessible electronically available protocol may assist those in front-line management.

THE VERY IMPORTANT PERSON

ESSENTIALS

1 **Management of the VIP should be based on the maintenance of standard clinical procedures.**

2 **Management may be aided by the establishment of a plan resembling a disaster plan aimed at co-ordination of clinical and administrative issues.**

3 **Specific issues include security, confidentiality and management of the media.**

Definition

A VIP in the ED can be defined as anyone whose presence in the ED may, by virtue of fame or public position, disrupt normal ED functioning.[62] The VIP may be a person of worldwide repute or may also be someone of local fame or importance, such as a prominent staff member. A 'VIP syndrome' can occur where the treating staff become so overwhelmed by the person's presence that they cease to operate in their normal way and the patient's care is compromised. Disaster plans are formulated in hospitals to deal with situations that overwhelm normal ED operations. In a similar manner, the formulation of a plan to deal with VIPs to ensure optimal management of the patient may help to prevent poor outcomes.

Management

Medical issues

The key goals of management should be the maintenance of standard clinical procedures. The clinician should perform a standard clinical evaluation without omitting questioning, examinations or procedures that would normally occur due to other considerations, such as embarrassment. Consultation with inpatient specialists should proceed as appropriate and the frequency and timing should reflect standard practice. Deviation from normal procedures—whether in assessment, referral or disposition, invites errors and lack of clarity in management decisions. Health care providers function most efficiently in performing their normal roles; nursing staff, junior medical staff and allied health should be involved as appropriate.

Access to the ED should be restricted after the arrival of the patient. Heads of state may be accompanied by their own teams of physicians. The treating clinician should liaise and consult with these physicians when immediate concerns, such as resuscitation, have been addressed.

EDs are accustomed to managing multiple complex patients at once. However, the presence of a VIP may consume the attention of many staff. The senior medical and nursing clinicians must ensure that adequate staff is assigned to the management of other patients in the ED and that other patients do not suffer adverse outcomes due to the presence of the VIP.

Different issues arise in treating medical colleagues or their families, other staff members or friends and relatives who are 'relative' VIPs. In aiming to expedite the management and ensure the comfort of someone who is known to the treating clinician, as with the VIP, the safest pathway for the patients is not to deviate from standard medical care.

Administrative issues

The essential administrative issues are security for the VIP and the hospital staff, protection of privacy and confidentiality, containment of the press, timely release of appropriate information and a co-ordinated response to the VIP's needs. If the patient is of national importance, the response may resemble a disaster response and require the appointment of a central co-ordinator to manage the initial crisis, security control and media liaison.[62]

Liaison with hospital security is essential to minimize entry of unnecessary people to the ED and to ensure the safety of the VIP. Assistance from clinical staff may be required to identify those required to enter the ED. Internal security may need to liaise and cooperate with external security teams. The VIP's security team must not impede medical management.

Confidentiality should be respected and consent to release information should be obtained as with any other patient. Release of information to the media should occur in a graded and accurate manner. Disclosure should occur on two levels: the first is the acknowledgement that the VIP is present and seeking medical attention and the second level involves the graded release of medical information.[62] One senior clinician should be appointed to convey this information. Ideally, a centre for the media should be set up on a site remote from the ED.

Although the presence of a VIP in the ED may not overwhelm services in the same way as a disaster, a similar approach with a pre-formulated plan of management may assist with the management of these rare and unexpected events and assist in attaining positive outcomes for the VIP and all other patients in the ED.

CONTROVERSIES AND FUTURE DIRECTIONS

- Refugees and asylum seekers held in detention facilities are increasingly requiring emergency care. They differ substantially to the standard prisoner population, are extremely vulnerable and have complex health needs that require a well-informed and deeply compassionate approach.
- The development of acute behavioural centres similar to trauma centres may assist in streamlining the management of acute behavioural disturbance.
- Given the significant deprivations of rights and liberty that are applied in containing those with behavioural disturbance, there is a need to learn more from patients about their experiences.
- The increasing prominence of violence as a critical issue in EDs requires careful policies and practices that protect staff safety and well-being without compromising effective emergency care.
- The perception of inappropriate ED use by frequent attenders remains controversial; some health care workers and health policy makers continue to assume that frequent attenders can and should be diverted to primary care providers.
- Understanding of drug dependence as a chronic, organic brain disease may reduce stigma and lead to the development of better medical models of treatment that can enhance the behavioural and social therapies currently practised.

21.6 End-of-life decision making and palliative care

William Lukin • Ben White • Carol Douglas

ESSENTIALS

1 An emergency department attendance represents an opportunity to set goals for care during the attendance and beyond.

2 End-of-life discussions and advance care planning assist early decision making about treatment goals and end-of-life care.

3 Knowledge of the law assists decision making at the end of life.

4 Not all dying patients require the skill set of a palliative care specialist, but every dying patient will benefit from a palliative approach.

5 Palliative care does not preclude active treatment where the intent is understood by patient and family.

6 Failure to diagnose dying can compromise patient care.

7 The emergency department should foster close relationships with local specialist palliative care providers to improve and ensure timely access for patients and families and also to ensure that emergency staff have access to the knowledge and skills available.

Introduction

Improved socioeconomic conditions and advances in medicine, including improved management of chronic disease, have resulted in extended life expectancy. Prior to death, many people now experience a period of progressive deterioration in health and loss of independence due to complex multi-system disease and possible cognitive impairment. It is estimated that up to 40,000 adult deaths occur in Australia annually in the setting of a medical decision to withhold, limit or withdraw treatment.[1] End-of-life decision making, such as decisions not to provide, to limit or to discontinue life-sustaining treatments and the decision to transition care to a palliative approach are now a common part of the practice of emergency medicine.

End-of-life discussions and decision making can be challenging owing to the complexity of balancing family wishes with the best interests of the patient and dealing with families in times of great stress. End-of-life decisions require an understanding of the law and ethical positions of peak medical bodies and are greatly assisted by patients and their families having considered, discussed and documented their wishes. These discussions and decisions may be communicated informally or formally in advance care plans and directives supported by common law and legislation.

Palliative care is the provision of care to those facing life-limiting or life-threatening illness and focuses on the needs of the patient as a whole across various domains, not just the physical. In addition, it looks at the family as a unit also requiring care. For patients for whom the palliative approach should be adopted, palliative care skills enable the emergency physician to engage patients on a dying trajectory and allow them to take control of this process and plan for the time they have remaining, be it hours, days or months. This enables planning for the non-physical aspects of the dying process and reduces time lost to futile medical endeavours.

The most important aims of end-of-life discussions and palliative care are the identification of what the patient sees as an acceptable outcome from any proposed treatment, enabling early and wise decisions about the appropriateness of treatment and improving communication with patients and families to facilitate the provision of patient-centred care.[2]

Definitions

Definitions are given in Table 21.6.1.

General legal principles in end-of-life decision making

Patients have the right to decide whether to accept or refuse medical treatment. This right is underpinned by Western liberal concepts of self-determination and individual autonomy.[3] Although the state has an interest in preserving the life and health of citizens, this interest is subject to an individual's right to self-determination.

Therefore a patient's informed consent must be obtained before treatment commences. To perform a medical procedure against the wishes of a patient can amount to trespass and battery in common law and can also contravene guardianship and medical treatment legislation.[4] A legitimate refusal of treatment must be respected, even if it is contrary to medical opinion. Where a person lacks capacity and so cannot give consent, he or she may have an advance directive (AD), or consent should be obtained from a legally authorized decision maker, such as a substitute decision maker or parent if the patient is a child.

There are exceptions to the need for consent to treat. One is cases of emergency where both the common law and various types of legislation (including guardianship legislation) permit the provision of lifesaving or other urgent treatment. Another exception is where mental health legislation authorizes treatment.[5]

A patient generally has no legally enforceable right to demand a particular treatment. Medical practitioners are not obliged to offer treatment that is not in a patient's best interests, such as treatments that are futile and where the burdens exceed the benefits of treatment. In Australia, an exception exists under Queensland's guardianship legislation for adults who lack decision-making capacity; in such cases consent *is required* to withhold or withdraw life-sustaining treatment.[6]

Although the vast majority of disagreements about end-of-life care are resolved informally, recourse may also be had to the courts and, for adults who lack capacity, to guardianship tribunals and the statutory office of public advocate or guardian.

Expected legal knowledge of medical practitioners

Despite attempts to harmonize the law regulating end-of-life decision making, it varies across Australian states and territories[7] and the rest of the world. Medical practitioners play significant legal roles at the end of life, including assessing a patient's capacity to understand and make decisions, determining the scope of any consent or refusal and whether it applies to current circumstances and understanding the operation of guardianship laws to find a patient's substitute decision maker when the individual is not competent.[1,8]

Table 21.6.1 Definitions of terms

Term	*Definition*
Advance care planning (ACP)	A process that allows competent individuals to express their views regarding future health care decisions if the capacity to express those views is lost.
Advance directive (AD)	A statement that allows competent individuals to state in advance how they wish to be treated if they lack decision-making capacity in the future. Making an AD can be part of ACP. Different terms are used for ADs in different jurisdictions.
Futile treatment	The definition of futile treatment is contested, but treatment may be considered futile when it is no longer providing a benefit to a patient or the burdens of providing the treatment outweigh the benefits.
Good medical practice	Practice that is consistent with currently recognized medical standards, practices and procedures and currently recognized ethical standards of the medical profession.
Life-limiting illness	An illness where it is expected that death will be a direct consequence of the specified illness.
Life-sustaining treatment	Medical treatment that supplants or maintains the operation of vital bodily functions that are temporarily or permanently incapable of independent operation. This includes assisted ventilation, artificial nutrition and hydration and cardiopulmonary resuscitation but excludes measures of palliative care.
Palliative care	An approach that improves the quality of life for patients and their families facing life-threatening illness through the prevention and relief of suffering by means of early identification and rigorous assessment and treatment of pain and other problems, physical, psychosocial and spiritual.
Substitute (surrogate) decision maker ('person responsible' in some jurisdictions)	The person legally responsible for making decisions about health care, including its limitations, on behalf of an adult patient who lacks decision-making capacity. State guardianship or medical treatment legislation determines a patient's substitute decision maker.
Enduring guardian, attorney or medical treatment decision maker (terms vary depending on jurisdiction)	A substitute decision maker who is given authority by a patient to make health care decisions on behalf of that patient if capacity is lost.

Medical practitioners (including emergency physicians) have significant knowledge gaps regarding the law about end-of-life decision making.[9] Because doctors play important *legal* roles in these decisions, training on the law in this area across all stages of medical education (including continuing professional development) would support doctors in improving their legal knowledge while also avoiding possible risks to them and harms to patients.[9]

Advance care planning and advance directives

Advance care planning (ACP) is planning and expressing wishes for future health and personal care for a time in the future when the individual cannot make or communicate decisions. ACP provides a means for people to ensure that their wishes and preferences are known. Most doctors, nurses and members of the community support ACP, but rates of formal planning are low despite evidence that ACP leads to improvement in end-of-life care, patient and family satisfaction and reduction of anxiety and depression in surviving relatives.[10]

ADs are generally a form of written advance care plan made by a competent person recognized by common law and/or legislation depending on the jurisdiction. An AD can be written at any time of life and may relate to periods of temporary or permanent incapacity. Content may vary from an expression of personal values and wishes to specific medical directions by a person with a life-limiting illness.

ADs are recognized in many parts of the world, including all Australian jurisdictions; six Australian states and territories now have specific legislation relating to ADs. All jurisdictions also have legislative provisions that allow patients to appoint a substitute decision maker, designated variously as an *enduring guardian*, *enduring attorney* or *medical treatment decision maker*, depending on the jurisdiction. The guardianship legislation of all states and territories allows for the appointment of a guardian by a court or tribunal, but this occurs only where less formal mechanisms are inadequate.[6]

A National Framework for Advance Care Directives authored by the Clinical, Technical and Ethical Principal Committee of the Australian Health Minister's Advisory Council aims to provide a practical and ethical basis to the development of a national framework for advanced directives.[7]

Limitation or withdrawal of treatment

Emergency medicine practitioners may be confronted with circumstances where the patient and family have not considered the desired outcomes of their ongoing treatment or that death may be a possible outcome of their current condition. Up to 35% of deaths in EDs involve patients in the terminal phases of existing chronic illness who attend the ED for conditions that represent the natural evolution of the illness.[11] The ED has become a place where terminally ill patients frequently die and where decisions regarding the limitation or withdrawal of care are often made.

Although doctors generally must not cause or hasten a patient's death, there are circumstances where limiting or withdrawing treatment is lawful. These include when a competent adult refuses treatment, when another person (such as a substitute decision maker or parent) has lawfully refused treatment on behalf of the patient and when the treatment is not in the patient's best interests, either because it is considered futile or the burdens are not justified by the potential benefits.[4]

The Australian Medical Association states that if a medical practitioner acts in accordance with good medical practice, the following forms of management at the end of life do not constitute euthanasia or physician-assisted suicide: (1) not initiating life-prolonging measures and (2) not continuing life-prolonging measures and the administration of treatment or other action intended to relieve symptoms that may have a secondary consequence of hastening death.[12,13]

Despite growing community interest in ADs and an increasing burden of chronic disease, the majority of patients presenting to EDs have not discussed their end-of-life wishes with family or expressed their wishes in an AD.[14] In these situations, discussions should focus on the desired outcomes of treatment and the delivery of treatments consistent with those desires that offer some comfort and assistance to the patient.

Resuscitation and not-for-resuscitation orders

When first described in the 1960s, cardiopulmonary resuscitation (CPR) involved simple resuscitative measures to reverse physiological instability. Although CPR can 'stay' death on occasion, it is frequently applied in circumstances that will not result in a return to previous health and is applied in patients who are actually dying.[15] American health care culture has been described as one of medical optimism, characterized by an unwillingness to give up hope for a miracle, which has led patients to choose distressing and

burdensome treatment options that eventually end in death, whether or not these treatments had been instituted.[16] Unrealistic expectations of outcomes from CPR are common.[17]

The combination of knowledge deficits, unrealistic expectations of outcomes and medical optimism have left patients and doctors with a sense that there is a presumed consent to CPR unless otherwise indicated.[15] Not-for-resuscitation (NFR) orders have developed in response to CPR being universally applied and the presumed consent to its use. The absence of an NFR order has come to be considered as an order to perform CPR unless otherwise instructed.[15] CPR is no longer seen as a medical intervention with specific indications but one of many patient choices.

The American Heart Association defines the goals of resuscitation as follows: to preserve life, restore health, relieve suffering, limit disability and respect the individual's decisions, rights and privacy.[18] Decisions to commence, continue or terminate resuscitation are based on the difficult balance between the benefits, risks and cost these interventions to the patient, family members and health care system.[19] Ethical reasons for withholding attempted resuscitation include respecting the patient's autonomy and choices, weighing maleficence against beneficence (avoiding treatment that may cause more harm than benefit), trying to provide a good 'quality of death' and the consideration of resources.[19]

Some peak medical bodies provide ethical guidance on these issues.[18,20–22] The United Kingdom's General Medical Council (GMC) advises that 'in cases where you assess that such treatment is unlikely to be clinically appropriate, you may conclude that CPR should not be attempted'.[23] The Medical Board of Australia recognizes that 'doctors have a vital role in assisting the community to deal with the reality of death and its consequences', and good medical practice involves both 'understanding the limits of medicine in prolonging life and recognizing when efforts to prolong life may not benefit the patient'. The medical board also states that there is no duty to prolong life at all costs but that there *is* a duty exists to know when not to initiate and when to cease attempts at prolonging life.[24]

The ability to 'refuse' an NFR order perpetuates the paradigm that CPR is solely a patient choice and that all deaths can potentially be prevented. The performance of CPR, under the guidance of the bodies such as the GMC and the Medical Board of Australia, is a medical decision that the patient can refuse but on which the patient cannot insist (although the situation under Queensland's guardianship legislation discussed earlier should be noted).

Palliative care

The World Health Organization defines palliative care as an approach that improves the quality of life of patients who are living with a life-limiting illness and their families through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems—physical, psychosocial and spiritual.[25]

Palliative care is an emerging area in emergency medicine, with international evidence suggesting that the care of the patient who is imminently dying is not done well in EDs. In addition, the care of the patient who is on a dying trajectory and presents to the ED needs further research. Palliative care focuses on the needs of the patient as a whole across various domains, not just the physical. In addition, it looks at the family as a unit also requiring care. Emergency physicians should adhere to the principles of a good death for all of the patients who die in EDs.[26] For patients for whom the palliative approach should be adopted, skills in palliative care enable the emergency physician to engage patients on a dying trajectory and support them in taking control of this process and putting in place a plan for the end of life. This allows for choice of place of death outside of the acute setting, which requires appropriate social and clinical supports. The discussions surrounding such planning include the non-physical aspects of the dying process and may reduce time lost to futile medical endeavours that are likely to ensue in the acute setting.

Specialist palliative care versus a palliative approach

Not all dying patients need the skill set of a specialist palliative care provider. However, all patients living with a life-limiting disease and those dying in the ED can benefit from a palliative approach to care. This approach focuses on the quality of life remaining for those with life-limiting disease. This approach can be adopted by all clinicians who deal with dying patients. The complexity (in respect to palliation) of a patient fluctuates as the patient approaches the end of life. For patients whose needs are complex, timely referral to specialist palliative care providers may be helpful.

Palliative care skills for the emergency physician

Communication skills in the palliative domains (physical, spiritual and psychosocial)

Appropriate discussion around these domains enables patients to regain some control of the dying process and improves the experience for patients and families. Although there is often no time for in-depth exploration of all these themes in a given patient encounter, simple acknowledgement of their existence by the clinician can help shape priorities for the presentation. Conversations that begin in the ED can be a stimulus for further discussions with treating teams and can also encourage and prompt families to have these discussions. While traditionally viewed as difficult, such discussions are generally welcomed by patients and families. To walk away from a dying patient without this engagement is a failure of care and a loss of opportunity for the patient.

Impeccable assessment skills

The needs of these patients for comprehensive evaluation are the same as those for any other patient coming into the ED. To deal with physical symptoms appropriately, a diagnosis is required and appropriate investigations may be undertaken if there is likely to be a benefit. For example, delirium in an older person may be relatively simply resolved through appropriate investigation and treatment of the underlying cause and should not be ignored or generically treated with sedation.

Pain relief and symptom control

Uncontrolled pain or other distressing symptoms may prevent engagement in appropriate end-of-life discussions and planning. It is imperative that these needs be met promptly in the ED. Where these needs are complex, early referral to specialist palliative care providers may assist. No patient should have uncontrolled pain in an ED and processes should address this with pain score assessments, protocol-driven analgesia and the fostering of a culture where patients and families can speak up and voice concern. For patients using opioids other than morphine relative potencies must be taken into account. This is crucial when providing rescue analgesia and for titration of adequate pain relief. If there is doubt seek specialist advice.

Management of common symptoms including nausea and dyspnoea is required to minimize the suffering experienced at the end of life. Patients who are distressed by dyspnoea may require palliation with an opioid. There is an evidence base for this approach to care, and concerns by clinicians in palliating dyspnoea with an opioid are unwarranted.[27]

Developing a local protocol for managing pain and other symptoms in the ED is recommended.

Anticipating the end of life and diagnosing the dying

The concept of identifying patients who are at the end of life implies a recognition of the fact that they will not recover from a their illness. The need for this emphasis stems from a societal view that denies death and an acute care system that views death as the enemy. Failure to diagnose dying in

a timely manner can result in over-investigation, initiation of inappropriate treatments and false perceptions of hope for the patient and family. Such lack of recognition results in patients and families being denied the opportunity to plan for what is to come and to make choices. The well-recognized 'surprise question'[28] is 'Would you be surprised if your patient were to die in the next 12 months?' A response of 'no' indicates a sensitive measure for commencing ACP and having the 'difficult conversation' around poor prognosis and life-limiting illness.

For emergency clinicians the question could be posed as 'Would you be surprised if this patient died during this admission?' If the answer is no, there is an opportunity to engage the patient and family in discussions about the goals of this admission. Referral to palliative care providers from the ED can shorten the length of stay in hospital by facilitating transfer home with support; this will increase the likelihood that goals of care around the end of life are established and reduces the burden on the medical emergency response teams within the hospital.

The dying

For patients whose death is imminent (hours), it may not be appropriate to transfer them out of the ED. In this case, compassionate comfort-based care is necessary and has been shown to be supported by the use of a clinical framework such as that developed by the International Collaborative for Best Care of the Dying.[29] Such an approach enables hospice-level care to be delivered in all care settings, such as a short-stay unit. Best care of the dying is supported by the application of clear communication of the dying process, seeking to deal with the spiritual and cultural needs of the patient and family, ensuring anticipatory prescribing and de-prescribing of non-essential medicines and the rationalization of inappropriate interventions. Medications to control symptoms are provided by the subcutaneous route and via a continuous infusion mechanism where warranted.

The provision of high-quality end-of-life care requires early discussions and planning with the patient and family so that all concerned with the patient's care are clear about the goals of treatment. Silvester identifies three opportunities to ensure that patient-centred care is delivered at the end of life.[30] First, a competent person may consider and express his or her wishes via ACP. Second, when a person is no longer competent, health care professionals should determine whether ADs exist and have discussions with substitute decision makers about what outcome the patient would have wished. Third, the delivery of care at the end of life should provide a 'good death': avoiding suffering and the prolongation of dying, achieving a sense of control, relieving burdens placed on the family and strengthening relationships with loved ones.

CONTROVERSIES AND FUTURE DIRECTIONS

- Close partnering between emergency providers and palliative care providers will provide timely intervention in emergency departments so that opportunities to establish goals of care are not lost.
- Short-stay units should be able to provide hospice-level care to the dying with support as required from specialist palliative care services or the use of locally tailored care plans for the dying person.
- End-of-life and palliative care may become subspecialty areas for emergency physicians.
- Assisted dying legislation is in place in Victoria and more states may follow. Patients seeking access to physician-assisted dying will come to emergency departments. Clinicians will need to know how to respond to these patients.[19]

21.7 Organ and tissue donation

Martin J. Dutch • David Pilcher

ESSENTIALS

1 **Organ donation should be considered for all patients where death is expected. Suitability for donation should be discussed with an organ donation specialist.**

2 **A substantial numbers of missed potential organ and tissue donors can be identified in emergency departments (EDs) and intensive care units (ICUs).**

3 **Clinical triggers have been introduced in Australian EDs to assist with the early identification of potential donors.**

4 **Knowledge of pathways to donation and the skills required to commence donation discussions may decrease the numbers of missed potential donors and improve the numbers of organ and tissue donors.**

5 **Admission to an ICU should be considered for any intubated patient in the ED in whom end-of-life care is considered. This can facilitate early family discussions, timely prognostication and consideration of organ and tissue donation if appropriate.**

Introduction

Transplantation has become the therapy of choice for patients with end-stage organ failure. However, worldwide, there are not enough organs available to meet the demand for those on transplantation waiting lists. In Australia at any one time, there are approximately 1400 people awaiting organ transplantation. In 2017, there were 519 deceased organ donors in Australia and 1675 transplant recipients.[1] Between 2007 and 2016, over 1000 patients were admitted to Australian and New Zealand intensive care units (ICUs) primarily to assess their suitability for organ donation; of these, almost two-thirds came directly from the emergency department (ED).[2]

In Australia there is a relatively small pool of potential donors, as less than 2% of patients who die in hospital are eligible to donate their organs.[1,3] Despite this scarcity there is potential to increase the number of organ donors through higher consent rates, improved identification, increased resources for education, coordination, surgical retrieval and transplantation services. Despite high rates of community support for donation, consent rates for donation (approximately 60%) have changed little.[4] Identification of missed opportunities for organ donation may have the greatest impact on donor numbers. Missed opportunities include situations where life-sustaining therapies are withdrawn in patients

with imminent or potential brain death, particularly in the ED; patients who may be suitable but with whom donation is never raised owing to clinicians' unwillingness to discuss donation; resource pressures; and an incorrect perception that a patient may not be medically suitable.[5]

Although the donation of solid organs is a rare opportunity, eye and tissue (e.g. skin, bone, heart valves and connective tissues) donation can occur up to 24 hours after death and may be applicable to a larger population of patients, especially those in the ED. Few absolute contraindications to donation exist. Liver donation has occurred from patients over 80 years of age. HIV is no longer an absolute contraindication and organs are commonly donated from patients with a history of hepatitis C. Corneal donation may even be possible in patients with metastatic and hematological malignancies in whom the donation of other organs and tissue is not possible.

Emergency practitioners play an important role in the donation process. Within Australia, there is strong support for organ donation amongst ED staff, particularly amongst those who have had specific training and experience with organ donation. Lack of education, resources and time are commonly identified by ED staff as barriers to donation.[6] However, donors identified in the ED have a greater rate of proceeding to successful donation than those referred from other inpatient critical care settings.[7] Emergency clinicians are ideally placed to exhibit positive attitudes toward donation, support donation, identify and support potential donors and help families to make informed decisions about donation.

Donation pathways

The initial critical step in making organ donation a reality is to recognize the potential donor. These are usually ventilated patients in the ED or ICU who are expected to die often of neurological injuries but also potentially from non-neurological conditions.

Donation after brain death

The majority of deceased organ donations in Australia (70%) occur following brain death. Criteria to diagnose brain death vary slightly in different countries[8,9] but essentially depend on the loss of capacity for consciousness and the ability to breathe. If preconditions are met (e.g. no effects of sedating drugs and a diagnosis consistent with producing severe brain injury), brain death may be diagnosed clinically by demonstrating loss of all brain-stem reflexes. A clinical diagnosis of brain death cannot be made until a period of observation has elapsed (minimum 4 hours in Australia). Thus brain death is rarely diagnosed in the ED, but patients who might become brain dead are commonly identified there.[2] When clinical testing is not possible, imaging tests (e.g. cerebral angiogram, nuclear medicine scan and computed tomography [CT] angiography) may be performed. The donation of heart, lungs, liver, pancreas, bowel and kidneys from one brain-dead donor can lead to up to eight organ transplants.

Donation after circulatory death

Although donation after brain death has remained the most common route for organ donation, the 2000s saw renewed interest in donation from patients in whom death was diagnosed after cessation of circulation. Unlike brain-dead donation, the practices and processes for donation after circulatory death (DCD) vary widely across countries and reflect differing social, medical and legal environments. Patients considered for DCD in Spain and France are commonly those who present following cardiac arrest (with or without failed attempts at resuscitation)—so-called uncontrolled DCD. In contrast, in Australia, the United Kingdom and the United States, DCD is usually performed in patients who undergo elective withdrawal of cardiorespiratory support in the ICU after determining that he or she will not recover—so-called controlled DCD.[10] DCD currently accounts for 30% of donations throughout Australia but has the capacity to increase overall donor numbers even further with improved recognition of potential donors.[1,11] Kidney, lung and liver donations commonly occur through the DCD route. Although possible, heart, pancreas and bowel donations are less common.

Uncontrolled donation after circulatory death in the emergency department

The recognition that patients who died following out-of-hospital cardiac arrest might still be suitable donors has led to the creation of 'rapid response teams' or 'mobile donor units' to facilitate organ donation. Although these have resulted in successful donations in Spain, France, Japan and the United States, some programs have closed down due to a failure to identify more than a handful of patients.[12] In addition, concerns over the use of vascular cannulation techniques for organ perfusion—which are similar to extra-corporeal membrane oxygenation—cardiopulmonary resuscitation (ECMO–CPR), lack of consistency over an appropriate 'hands-off' observation (varying from 2 minutes in some US states to 20 minutes in Italy) and the large resources required for small numbers of suitable patients[13] have limited uptake of these techniques worldwide. Within Australia, a more socially acceptable, cost-effective and productive method is to identify intubated patients in the ED considered likely to die and to continue cardiorespiratory supports until its elective withdrawal later in the ICU (if appropriate).[11,14]

Initiatives to improve organ donation rates

There is wide variation in rates of organ donation throughout the world, with Spain's more than 30 donors per million population often highlighted as a target for others. Many factors influence these numbers, including the number of road traffic fatalities, attitudes toward ongoing treatment of patients who are going to die but in whom wishes about donation are not known, access to intensive care beds (lower in the UK than in Spain and Australia), end-of-life practices in general and public support for organ donation among others. However, countries that have successfully increased donation rates have concerted approaches towards the identification of potential donors, support for clinicians involved in donation, public promotion about the benefits of organ donation and transplantation, clear legislation, infrastructure and funding.

For many years, Australia's donation rate lagged a long way behind that of similar developed countries. In the late 2000s, building on experiences from abroad, federal funding led to the formation of the Australian Organ and Tissue Authority. A co-ordinated national approach to increasing organ donation was undertaken with increased publicity, provision of dedicated organ donation staff to hospitals, improved education (notably through 'Family Donation Conversation [FDC]' workshops) and initiatives to improve the identification of potential organ donors. This has led to a progressive increase in donor numbers to 20.7 per million population in 2017 from below 10 per million in 2000.[15]

Identification of potential organ donors

The emergency clinician has a central role in the early identification and support of potentially suitable organ donors, with the majority of all potential donors being initially admitted through an ED. Emergency clinicians are almost always involved in decisions to withdraw life-sustaining treatments in EDs, and one study showed that almost half of all missed donors have their life-sustaining treatment withdrawn within the ED.[3]

As with all high impact–low frequency events, it is important that clinicians be familiar with their typical clinical presentations and that departments implement aides and processes that enhance identification.

Most potential donors present with severe neurological insults from a limited range of primary pathologies. Severe intracranial haemorrhage is the most common pathology, with other causes including traumatic brain injury, hypoxic-ischaemic insult (e.g. from prolonged cardiac arrest), and large-territory thrombotic

Box 21.7.1 GIVE clinical trigger	
G	Glasgow Coma Scale score ≤5
I	Intubated
V	Ventilated
E	End-of-life care

stroke.[3] However, patients dying from single organ chronic disease (e.g. chronic respiratory failure) are also increasingly being recognized as potential donors via a controlled DCD pathway.[11]

Clinical triggers have been developed worldwide and aim to minimize the number of missed potential donors.[3] The Australian GIVE clinical trigger was introduced in 2010 (Box 21.7.1). Although it has performed well in identifying potential brain-dead donors, it has lower sensitivity for identifying DCD pathway patients. This has led to the promotion of routine referral for all patients in critical care environments who are undergoing end-of-life care.[16]

The identification and facilitation of organ donation is a whole-of-hospital responsibility. Many hospitals now consider routine admission from ED to ICU of

(A) patients with catastrophic brain injuries.[17,18,19]
(B) intubated patients considered for withdrawal of life-sustaining treatment.
(C) patients in whom organ donation is being considered.

The rationale for this approach includes improved prognostication,[4] an unrushed approach to end-of-life care, allowing time to have discussions with family members and the provision of care by teams with high-frequency experience of end of life in a critical care environment. In addition, admission to an ICU is a cost-effective use of health care dollars.[20]

Management of devastating brain injuries and support of the potential donor within the emergency department

Given that the majority of potential organ donors are admitted through EDs, the management of these patients in this early phase has important implications. Although for some patients there is a high degree of prognostic certainty about futility, it is increasingly appreciated that early prognostication is fraught with difficulty.[17,21,22] Many centres now routinely support these patients in the ED to facilitate admission to the ICU.

In the ED, clinicians should aim for normal physiological parameters.[23] Early urinary catheterization as well as arterial and central venous access should be achieved to facilitate these aims. Restoration of normal physiology benefits both patients with prognostic uncertainty and patients who proceed to organ donation. It is associated with higher numbers of organs transplanted per donor and a reduction in delayed graft function in recipients.[18,23]

The progression of pathophysiology that results in eventual brain death is associated with common, predictable sequelae (Table 21.7.1). The emergency clinician should both actively seek and treat these states to maintain the opportunity for donation until it can be appropriately raised with family.

Table 21.7.1 Common sequelae of devastating brain injury and treatment

Clinical signs	*Practice tips*
Hypertension and tachyarrhythmias (Autonomic storm)	Often transient, no intervention may be required. Consider short-acting agents if persistent (esmolol, glyceryl trinitrate). Anticipate hypotension and later need for central access and vasopressors.
Bradycardia	Usually resistant to atropine. Consider adrenaline, isoprenaline or pacing.
Hypotension	May be rapid in onset and can occur during autonomic storm; 90% of patients require vasopressor support (e.g. noradrenaline). If persistent, consider vasopressin infusion and intravenous corticosteroid. Consider and treat diabetes insipidus (see later). Consider myocardial dysfunction: treat with adrenaline and intravenous (Tri-iodothyronine) T3.
Polyuria (>3–4mL/kg/h)	Consider diabetes insipidus if Na is rising >145 or high plasma/low urine osmolarity exists: treat with desmopressin (DDAVP) given as an intravenous bolus of 1–4 μg (paediatric dose: 0.25–2 μg) q2–6h *or* vasopressin: intravenous infusion at a dose of 0.5–2.0 U/h (paediatric dose: 0.002–0.04 U/kg/h). Replace losses with equivalent volume of 5% dextrose. Consider other causes (e.g. mannitol).
Coagulopathy	Commonly a consequence of anticoagulants, direct brain injury or multi-trauma. Correct early with blood products.
Hypoxia	Consider neurogenic pulmonary oedema or aspiration. Treat with positive end-expiratory pressure (PEEP) and mandatory positive-pressure ventilation. Consider antibiotics and need for bronchoscopy.

(Adapted with permission from Opdam HI, Silvester W. Potential for organ donation in Victoria: an audit of hospital deaths. *Med J Aust.* 2006;185:250–254.)

Conversations with families in the emergency department

Although initial information about diagnosis and prognosis may be conveyed to family, in most practice settings FDCs rarely need to occur within the ED. At all times FDCs are best conducted by senior staff with significant experience with donation who have undergone training in specialist donation communication.[16]

In hospitals with a co-located ICU, patients with devastating brain injury should be ideally admitted to the unit. Admission allows time for improved prognostication, time for family to gather and, when appropriate, an unhurried approach to end-of-life care. A comprehensive approach to end-of-life care routinely includes determination of medical suitability for organ donation and ensuing exploration.

The aim of communication in the ED is to explain the gravity of the situation, the expected outcome and, if appropriate, to convey that the patient is dying. Admission to the ICU facilitates an unhurried approach to end-of-life care by experienced practitioners. Should a family raise the issue of donation in the ED, it can be gratefully acknowledged and the family referred to the intensive care staff to continue the conversation.

However, a number of less common scenarios can sometimes compel an earlier discussion within the ED. These include situations where there is universal agreement of futility and haemodynamic instability, thus necessitating a rapid exploration of organ donation, or where there is no co-located ICU and transfer to another hospital would be only for the purpose of exploring donation. In these scenarios, it is important that the emergency clinicians be familiar with the hallmarks of best practice in raising donation, as outlined further on.

Best practice in raising organ donation

The aim of a FDC is to assist families with making an informed and enduring decision regarding organ donation. The decision should sit comfortably with the known wishes of the patient and family. The principles listed here have a growing evidence base and they apply regardless of the location of the conversation. They have been endorsed by the Australasian College for Emergency Medicine.[1]

- Medical futility should have been established by a multidisciplinary team.
- Before they are asked to consider organ and tissue donation, the family must understand that the patient has died (if brain dead) or that death is expected following the withdrawal of treatment.

Prior to a FDC,

- The state's donation agency should be contacted and the Organ Donor Register checked.
- A clinician who is not the treating clinician and who has specific donation communication training should be recruited to attend the meeting (donation specialist).
- A pre-meeting should be held with clinicians to determine clinical facts and allocate roles.

During the FDC,

- Discuss patient care and prognosis with family.
- Confirm family understanding of death, or expected death following the withdrawal of treatment, before donation is offered to the family.
- Separate conversations about death and donation to create time and space for family.
- The opportunity for donation is offered to the family in a team-based approach, including the provision of accurate information about donation and transplantation.

Following the FDC,

- Team review occurs after each FDC process to provide an opportunity to reflect upon and improve practice.

Eye and tissue donation

Donated human tissue has the capacity to reduce morbidity and in some cases, save lives. Tissue that can be donated includes corneas, sclerae, whole eye preparations, heart valves, pericardium, bone, skin and other musculoskeletal tissues. Amongst many indications, donated tissue is used to patch ventricular septal defects, reconstruct joints, restore sight and reduce mortality in severe burns.

Every year more than 4700 patients die in Australian EDs. The potential pool of eye and tissue donors is significantly larger than that of organ donors, as eye and tissue donors do not have to die within a critical care environment. Within hospitals, EDs are an important source of potential donors. A recent study showed that one in three ED deaths were medically suitable to be eye donors and one in seven were medically suitable to be tissue donors.[24,25]

The most common contraindications to donation include maximal age (which varies by jurisdiction and tissue type), neuro-degenerative conditions (e.g. Alzheimer or Parkinson disease), risk factors for blood-borne virus transmission, non-haematological malignancies (for eye donation), and any malignancy (for non-ophthalmic tissue donation).

Most eye and tissue procurement organizations have collaborative relationships with coronial services that facilitate eye and tissue donation, even in coronial cases. Eye donation can frequently occur on the hospital premises. Tissue retrieval must often occur in a controlled environment within 24 hours of death, so the identification of potential donors, discussion with families, and notification of eye and tissue donation agencies must occur in a timely fashion but can occur after the death of the donor.

Studies of bereaved families report comfort with either a direct approach by treating clinicians or a delayed telephone approach.[26] Despite having a high level of professional and community support, the opportunity of eye or tissue donation is rarely offered to bereaved families.

Despite the total number of patients who die within EDs each year, managing the death of a patient within the ED is a rare event for the individual clinician. Timely identification of a potential eye or tissue donor is complicated by the rarity of death as well as the complexity of age, medical and social exclusion criteria.

The routine consideration of eye and tissue donation as part of a comprehensive approach to bereavement is best facilitated by integration into a specific process or pathway. In some international jurisdictions, this is mandated by law.[27] The implementation of an eye and tissue donation pathway within ED can promote a broader awareness of donation.

CONTROVERSIES AND FUTURE DIRECTIONS

- With the increasing frequency of DCD, clinical triggers for the identification of potential donors may have to be extended to include all those in whom withdrawal of life-sustaining therapies is being considered.
- Although the number of donors from patients presenting to EDs in cardiac arrest is low, the growing use of extracorporeal membrane oxygenation (ECMO) may potentially result in more donations from patients who subsequently die despite initial successful resuscitation.
- Rates of eye and tissue donation could be increased by the identification of potential tissue donors in the ED.

SECTION 22

PAIN RELIEF

Edited by *Conor Deasy*

22.1 General pain management

Adrian Murphy

ESSENTIALS

1 **Acute pain is the most common symptom in the emergency setting.**

2 **Pain is a complex, multidimensional, subjective phenomenon.**

3 **Effective pain management involves both accurate assessment and timely treatment.**

4 **Patient self-reporting is the most reliable indicator of the presence and intensity of pain.**

5 **Both pharmacological and non-pharmacological techniques should be employed for the treatment of acute pain. Effective pain relief should always be achievable.**

6 **In acute abdominal pain, titrated opioid analgesia should *never* be withheld, pending surgical review; the effect of analgesia on physical signs should not be used as a diagnostic test.**[1–3]

Introduction

Pain is defined by the International Association for the Study of Pain as: 'An unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage'.[4] Acute pain is defined as: 'Pain of recent onset and probable limited duration. It usually has an identifiable temporal and causal relationship to injury or disease'.[5] Whereas in some conditions the nature and progression of the pain may be helpful in making the diagnosis of the underlying pathology, too great a reliance has been placed upon this feature, thereby allowing the patient to suffer needlessly for prolonged periods. For example, the notion that analgesia masks clinical signs in the context of abdominal pain is a fallacy; provision of pain relief often enhances a clinician's diagnostic ability.[5,6]

It is recognized that failure to adequately treat acute severe pain, in the emergency setting, is associated with adverse biochemical, physiological, metabolic, and psychological sequelae, and in some patients may alter responses to future painful episodes.[7] Thus the timely management of acute pain is a fundamental pillar of good emergency medicine practice to reduce the avoidable suffering to our patients.

Physiology

Pain is one of the most complex aspects of an already intricate nervous system.[5] A number of theories have been developed to explain the physiology of pain, but none is proven or complete.

'Gate Control Theory'

In 1965, the Melzack–Wall 'Gate Control Theory' emphasized mechanisms in the central nervous system that control the perception of a noxious stimulus and thus integrated afferent, upstream processes with downstream modulation from the brain.[8] However, this theory did not incorporate long-term changes in the central nervous system to the noxious input and to other external factors that impinge upon the individual.[8]

Nociceptor function

Most pain originates when specific nerve endings (nociceptors) are stimulated, producing nerve impulses that are transmitted to the brain. Nociception is the detection of tissue damage by specialized transducers.[8] It is now recognized that nociceptor function is altered by the 'inflammatory soup' that characterizes a region of tissue injury.[8] The final pain experience is subject to a complex series of facilitatory and inhibitory events that precedes pain awareness, such as past experience, anxiety or expectation.[9] There are two types of nociceptors[10]:

I. Mechanoreceptors, which are present mainly in the skin (also muscle, joints, viscera, meninges) and respond rapidly to pinprick or heat via Aδ, myelinated afferent neurons.

II. Polymodal, which are widely distributed throughout most tissues and are the nerve endings of unmyelinated C-type afferent neurons. These respond to tissue damage caused by mechanical, thermal or chemical insults and are responsible for the slow onset, prolonged, poorly localized, aching pain following an injury.

Once transduced into electrical stimuli, conduction of neuronal action potentials is dependent on voltage-gated sodium channels.[5] A number of chemicals are involved in the transmission of pain to the ascending pathways in the spinothalamic tract. These include substance P and calcitonin gene-related peptide, but many others have been identified.[5,11,12] Opioid receptors are present in the dorsal horn and it is

thought that encephalins (endogenous opioid peptides) are neurotransmitters in the inhibitory interneurons.[10]

Phospholipids released from damaged cell membranes trigger a cascade of reactions, culminating in the production of prostaglandins that sensitize nociceptors to other inflammatory mediators, such as histamine, serotonin and bradykinin.[10]

The threshold for the perception of a painful stimulus is similar in everyone and may be lowered by certain chemicals, such as the mediators of inflammation. The discrete cognitive processes and pathways involved in the interpretation of painful stimuli remain a mystery. The cognitive and emotional reactions to a given painful stimulus are variable among individuals and may be affected by culture, personality, past experiences and underlying emotional state.[5,8,13] In addition, intense and ongoing stimuli further increase the excitability of dorsal horn neurons, leading to central sensitization.[5] With increased excitability of central nociceptive neurons, the threshold for activation is reduced and pain can occur in response to low intensity, previously non-painful stimuli known as allodynia.[5] Pain is therefore a complex, multidimensional, subjective phenomenon.[13]

Assessment of pain and pain scales

Pain intensity may be assessed subjectively (i.e. as reported by the patient) or by some objective measures. In daily clinical practice, health care providers employ a combination of tools to estimate the degree of physical patient distress including subjective assessment, for example, not only by asking the patient to rate the intensity of their pain, but also by the nature of the illness or injury, the patient's appearance, behaviour and physiological concomitants. No single method has proved to be 100% reliable.

Pain scales have been developed because there are no reliable physiological or clinical signs to measure pain objectively. Ultimately the perception of pain is an individual experience. Three scales have become popular tools to quantify pain intensity[14,15] as follows:
Visual analogue scale (VAS),
Numeric rating scale and
Verbal rating scale.

Visual analogue scale

The VAS usually consists of a 100-mm line with one end indicating 'no pain' and the other end indicating the 'worst pain imaginable'. The patient simply indicates a point on the line that best indicates the amount of pain experienced. The minimum clinically significant change in patient pain severity measured with a 100-mm VAS is 13 mm.[16] Studies of pain experience suggest that less than a 13 mm change in pain severity, although statistically significant, is not clinically significant.[16]

Numeric rating scale

The patient is asked in the numeric rating scale to choose a number from a range (usually 0 to 10) that best describes the amount of pain experienced, with zero being 'no pain' and 10 being the 'worst pain imaginable'.

Verbal rating scale

The verbal rating scale simply asks a patient to choose a phrase that best describes the pain, usually 'mild', 'moderate' or 'severe'.

Pain intensity is generally accepted to fall into one of three categories, as follows: mild pain (1–3/10), moderate pain (4–6/10), and severe pain (7 or greater/10).

In the clinical setting, anxiety, sleep disruption and illness burden also contribute to the burden of pain.[12] It is difficult to use a unidimensional pain scale to measure a multidimensional process. Using pain intensity alone will often fail to capture the many other qualities of pain and the overall pain experience. The best illustration of this problem is that the same pain stimulus can be applied to two different people with dramatically different pain scores and analgesic requirements.[17] At best, the use of pain scales is an indirect reflection of 'real' pain, with patient self-reporting still being the most reliable indicator of the existence and intensity of pain.[18] Indeed some authorities have suggested that simply asking the patient 'Do you require medication to relieve your pain?' may be all that is required to trigger initiation of analgesic therapy.

Nevertheless, pain scales are simple and easy to use. They are now routine in many emergency departments (EDs), often being a standard part of the triage process, which leads to substantially faster provision of initial analgesia.[7]

General principles

Patients in pain should receive timely, effective and appropriate analgesia, titrated according to response.[5] The following points should be stressed:

- The correct analgesic dose is 'enough'; that is, whatever amount is needed to achieve appropriate pain relief.
- A patient's analgesic requirements should be reviewed frequently. Do not wait for pain to return to its previous level before re-dosing with analgesia. Larger early doses and more frequent doses of analgesia are associated with lower total doses and shorter duration of analgesic use. Some patients have been misled into believing that pain medicine is dangerous, so it is important to explain the safety and efficacy of this approach.
- EDs should have specific policies relating to pain and analgesia.
- Senior clinicians should lead by example.

Routes of administration

Analgesic agents may be administered by many routes including oral, intranasal, subcutaneous, intramuscularly, intravenous, epidural, nebulized, intra-pleural, intra-articular and transdermal. All may have a role in a specific clinical situation.[7] There is a good rationale for the use of the intravenous route in moderate-to-severe pain[7] and titration of intravenous opioids remains the standard of care for acute severe pain. However, in the presence of severe pain, and in patients where immediate vascular access is problematic, the intramuscular (e.g. morphine or ketamine), oral transmucosal (e.g. fentanyl citrate), or intranasal routes may provide a useful alternative in delivering timely and effective analgesia (e.g. intranasal diamorphine/fentanyl/ketamine).

Specific agents

Opioids

The term 'opioid' refers to all naturally occurring and synthetic drugs producing morphine-like effects. Morphine is the standard opioid agonist against which others are judged.[19] These drugs are the most powerful agents available in the treatment of acute pain. Unfortunately, many health care providers are responsible for oligoanalgesia, citing concerns regarding the risks of respiratory depression and inducing iatrogenic addiction. Less than 1% of patients who receive opioids for pain develop respiratory depression.[20] Tolerance to this side effect develops simultaneously with tolerance to the analgesic effect.[21]

Opioid receptor effects

Opioids are responsible for a variety of effects via a number of receptors including analgesia, euphoria, respiratory depression and meiosis (μ receptor); cough suppression and sedation (κ receptor); dysphoria and hallucinations (σ receptor); nausea and vomiting, and pruritus (δ receptor).[10] Opioids act on injured tissue to reduce inflammation in the dorsal horn to impede transmission of nociception and supraspinally to activate inhibitory pathways that descend to the spinal segment.[12]

Use of intravenous opioids

From a clinical practice point of view, many patients who require intravenous opioid may also require admission to hospital, as there will be ongoing opioid requirements that can only be administered in hospital. There have been occasions where patients have received opioid

analgesia that has relieved their pain and they have then been discharged without a final diagnosis. This is an unacceptable practice. A patient may present with abdominal pain with vomiting and, for instance, a provisional diagnosis of gastroenteritis is made. After opioid analgesia is given the patient may feel better and be discharged. A diagnosis, such as appendicitis or bowel obstruction, may not have been excluded. It is therefore necessary for patients to have an appropriate diagnostic evaluation to confirm a benign cause and to reassess the patient after the opioid effects have waned. For patients in whom the final diagnosis is certain, such as in anterior shoulder dislocation for example, discharge is appropriate after a suitable period of observation until the patient is deemed clinically fit for discharge. This is a different scenario from that described previously, as it is a single system problem in which there is no doubt about the diagnosis. In summary, pain that is considered severe enough to warrant intravenous opioid analgesia requires a high index of suspicion for significant pathology.

Side effects

All potent opioid analgesics have the potential to depress the level of consciousness, protective reflexes and vital functions. It is mandatory that these are closely monitored during and after administration.[10] Specific side effects include:

- respiratory depression: rare <1%
- nausea and vomiting: nausea occurs in approximately 40% and vomiting in 15%[10]
- hypotension: opioids may provoke histamine release
- constipation
- spasm of the sphincter of Oddi; therefore patients with biliary colic may initially experience more pain. There is no good evidence to suggest that pethidine has any clinically significant advantage at equi-analgesic doses over other opioids for biliary or renal colic[19]
- meiosis.

Morphine

The standard intravenous morphine dose is 0.1 to 0.2 mg/kg or more, and a duration of action of 2 to 3 hours. This should be initiated as a loading dose of opioid to provide rapid initial pain relief aiming for an optimal balance between effective pain relief and minimal side effects. This means tailoring the approach to each individual patient. Thus a young fit healthy man with renal colic may require an initial bolus of 0.1 mg/kg morphine, followed by further increments of 0.05 mg/kg. Conversely, a frail elderly patient may only tolerate 1.0 to 2.5 mg morphine total to begin with. There may also be considerable inter-individual variation in response to analgesia. Procedural pain may require higher-dose opioid analgesia, which has been found to be well tolerated and safe.[22] Appropriate monitoring and resuscitation equipment should be available to maximize safety. Rapid pain relief and titration to effect are obvious advantages. Intramuscular administration is unreliable with variable absorption and older routine practices, such as prescribing '5 to 10 mg morphine IM', take no account of an individual's requirements.[10]

Fentanyl

Allergic reactions are extremely rare with opioids. Fentanyl does not release histamine, making it ideal for treating patients with reactive airways disease. There are advantages in using fentanyl for brief procedures in the ED because of its short half-life. The intravenous dose of fentanyl is 1 to 2 μg/kg or more, with a duration of action of 30 to 60 minutes. High doses of fentanyl may produce muscular rigidity, which may be so severe as to make ventilation difficult, but which responds to naloxone or muscle relaxants. Intranasal fentanyl is an effective analgesic in the ED and in the pre-hospital setting.[5] The intranasal route of drug delivery is fast and painless, and confers an onset of action time similar to the intravenous route given it avoids first-pass metabolism and crosses the blood-brain barrier.

Pethidine

Pethidine use in the emergency setting has largely been superseded by other, more attractive, analgesic alternatives.[19,23]

Oral opioids

Oral opioids tend to be underused in the ED, but are effective for all levels of pain and are associated with improved patient satisfaction. Their side effect profile may be better than paracetamol/codeine combinations. Oxycodone (immediate release) reaches peak levels at 45 minutes to 1 hour but the dose should be reduced and dosing interval increased in the elderly and in those with hepatic or renal dysfunction. The main contraindication is acute respiratory depression. The initial dose is 5 to 10 mg. However, it is important to be aware that global opiate-related deaths have soared both for men and women, across the entire socioeconomic spectrum. The increased prescribing of oral opioids has been implicated with increased deaths. Acute health care providers should ideally initiate analgesic therapy using simple analgesia (i.e. paracetamol, non-steroidal anti-inflammatory drugs [NSAIDs] etc.), in the first instance. Failure to adequately treat pain intensity following this invariably requires a step-wise approach, escalating to opiate analgesia.

Codeine Codeine is the most commonly used oral opioid prodrug. Unfortunately, up to 6% to 10% of the Caucasian population, 2% of Asians and 1% of Arabs have poorly functional cytochrome P450 2D6 (CYP2D6), which may render codeine largely ineffective for analgesia in these patients, although some analgesic efficacy may occur via alternate cytochrome P450 pathways.

Prescribed alone in doses as high as 120 mg, codeine has been demonstrated to be no more effective than placebo in both the adult and geriatric populations, while causing increasing gastrointestinal side effects, such as nausea, vomiting and constipation, with increasing doses.[7] It is frequently given in combination with paracetamol or aspirin.

Tramadol Tramadol is a new opioid, with novel non-opioid properties.[24] Its efficacy lies between codeine and morphine. It has a relative lack of serious side effects, such as respiratory depression, and the potential for abuse and psychological dependence is low.[24] However, other side effects, such as nausea, vomiting, dizziness and somnolence, may be troublesome and there is a risk of seizures.[24,25] Thus it should be avoided or used with caution in patients who are taking drugs that reduce the seizure threshold, such as tricyclic antidepressants and Selective serotonin re-uptake inhibitor (SSRIs). Also, the concomitant administration of tramadol with monoamine oxidase inhibitors, or within 2 weeks of their withdrawal, is contraindicated.[24] The role of tramadol in emergency medicine is ill defined. One review concluded that tramadol does not offer any particular benefits over existing analgesics for the majority of emergency pain relief situations,[25] with oral doses having equivalent analgesic effects in mild-to-moderate severity acute pain compared with currently available analgesics.[25] Intravenous tramadol is less effective than intravenous morphine.[25]

However, tramadol may be useful in certain situations[25]:

- for patients in whom codeine is not effective
- where NSAIDs are contraindicated
- for the treatment of chronic pain.

Tapentadol Tapentadol is a centrally acting **opioid analgesic** with a dual mode of action as an **agonist** of the **μ-opioid receptor** and as a **norepinephrine reuptake inhibitor**. Analgesia occurs within 32 minutes of oral administration, and lasts for 4 to 6 hours.

It is similar to **tramadol** in its dual mechanism of action in terms of its ability to activate the mu opioid receptor and inhibit the reuptake of norepinephrine. The general potency of tapentadol is considered to be somewhere between that of tramadol and **morphine**, with an analgesic efficacy comparable to that of **oxycodone** despite a lower incidence of side effects. It is generally considered a weak–moderate strength opioid, similar in efficacy to the better-known opioids

such as **hydrocodone** and **pethidine**. The initial dose is 50 to 100 mg orally administered every 4 to 6 hours, and titrated to response. The maximum dose over 24 hours is 600 mg.

Non-opioid analgesics

Simple analgesics

Non-steroidal anti-inflammatory drugs NSAIDs are either non-selective cyclo-oxygenase (COX) inhibitors or selective inhibitors of COX-2 (COX-2 inhibitors). NSAIDs are effective analgesic agents for moderate pain, specifically when there is associated inflammation.[7] As with opioids, there are multiple routes of administration available. Unfortunately, their use in acute severe pain is limited by the length of onset time of 20 to 30 minutes. There is no clear superiority of one agent over another. There is up to a 30% incidence of upper gastrointestinal bleeding when NSAIDs are used for over 1 to 2 weeks. The risk of bleeding in the elderly for short (3 to 5 days) acute therapy appears to be minimal.[7] NSAID use in pregnancy (especially late) is not recommended. Ibuprofen is considered the NSAID of choice in lactation.

NSAIDs have a spectrum of analgesic, anti-inflammatory and antipyretic effects and are effective analgesics in a variety of pain states.[5] Unfortunately, significant contraindications and adverse effects limit the use of NSAIDs, many of these being regulated by COX-1.[5] NSAIDs are useful analgesic adjuncts and hence NSAIDs are therefore integral components of multimodal analgesia.[5] NSAID side effects are more common with long-term use. The main concerns are renal impairment, interference with platelet function, peptic ulceration and bronchospasm in individuals who have aspirin-exacerbated respiratory disease.[5] In general, the risk and severity of NSAID-associated side effects is increased in elderly people.[5]

Caution is therefore needed in the elderly and in patients with renal disease, hypertension and heart failure, or with asthma. NSAIDs reduce renal cortical blood flow and may induce renal impairment, especially when used in patients already on diuretics. In patients with asthma, 2% to 20% are aspirin sensitive and there is a 50% to 100% cross-sensitivity with NSAIDs.

Ketorolac is a parenteral NSAID that is equipotent to opioids, with ketorolac and morphine equivalent in reducing pain. There is a benefit favouring ketorolac in terms of side effects when ketorolac is titrated intravenously for isolated limb injuries.[26,27] However, the utility of ketorolac in acute pain is limited due to a prolonged onset of action and a significant number of patients (25%) who exhibit little or no response.[28] There is also benefit to using ketorolac for acute renal colic.[26,29] A combination of morphine and ketorolac offered pain relief superior to either drug alone and was associated with a decreased requirement for rescue analgesia in patients with renal colic.[30] Rectal NSAIDs (e.g. indomethacin 100 mg) are an effective alternative to parenteral NSAIDs in the treatment of renal colic.

Paracetamol Paracetamol is an effective analgesic for acute pain[5] and has useful antipyretic activity.[31] The addition of an NSAID further improves efficacy.[5] Paracetamol inhibits prostaglandin synthetase in the hypothalamus, prevents release of spinal prostaglandin and inhibits inducible nitric oxide synthesis in macrophages.[31] Indications for paracetamol include mild pain, particularly of soft tissue and musculoskeletal origin, mild procedural pain, supplementation of opioids in the management of more severe pain allowing a reduction in opioid dosage and as an alternative to aspirin.[31] Paracetamol has no gastrointestinal side effects of note and may be prescribed safely in patients with peptic ulcer disease or gastritis.[7] Aspirin has the risk of gastrointestinal side effects, such as ulceration and bleeding. It also has an antiplatelet effect, which lasts for the life of the platelet.

Paracetamol is rapidly absorbed with a peak concentration reached in 30 to 90 minutes.[31] The recommended adult dose is 1 g every 4 to 6 hours to a generally accepted maximum of 4 g/day.[31] Paracetamol has a low adverse event profile and is an excellent analgesic, especially when used in adequate doses. Parenteral paracetamol is now available and may have additional utility (e.g. in the vomiting patient). Chronic use of paracetamol alone does not seem to cause analgesic nephropathy.[31] It can be used safely in alcoholics and patients with liver metastases.[31,32]

Combination drugs Non-opioid agents (e.g. paracetamol, NSAIDs and paracetamol/codeine combinations) are all useful analgesics for mild-to-moderate pain. A systematic review found that paracetamol–codeine combinations in single dose studies produce a slightly increased analgesic effect (5%) compared with paracetamol alone.[33] However, none of the studies reviewed were based in the ED. In multidosage, paracetamol–codeine preparations have significantly increased side effects.[33] However, other reports state that the combination of paracetamol 1000 mg plus codeine 60 mg has a number needed to treat of 2.2.[5] NSAIDs have a higher rate of serious adverse effects.

Other analgesic agents

Nitrous oxide

Nitrous oxide is an inhalational analgesic and sedative which, in a 50% mixture with oxygen (Entonox), has equivalent potency to 10 mg morphine in an adult.[10] The Entonox delivery system uses a preferential inhalational demand arrangement for self-administration, which requires an airtight fit between the mask/mouthpiece and face. As the patient holds the mask/mouthpiece, their grip will relax if drowsiness occurs, the airtight seal will be lost and the gas flow stops, thereby avoiding overdosage.

This system requires a degree of patient involvement and cooperation and is useful for patients who have difficult intravenous access or are needle-phobic. Patients who are elderly, young, confused or uncooperative will not find the technique effective. Nitrous oxide increases the volume of a pneumothorax or any other gas-filled cavity, so is contraindicated in patients with pneumothorax or pneumoperitoneum.

Ketamine

Ketamine is an *N*-methyl-D-aspartate (NMDA) antagonist. It may be employed in anaesthetic, analgesic, or procedural sedation doses. It is a unique anaesthetic that induces a state of dissociation between the cortical and limbic systems to produce a state of dissociative anaesthesia, with analgesia, amnesia, mild sedation and immobilization. It does not impair protective airway reflexes, and random or purposeful movements are frequently observed in patients after administration. Side effects include hypersalivation, vomiting, emergence reactions, nightmares, laryngospasm, hypertension, tachycardia and increased intracranial pressure.[34,35]

There are many potential contraindications to ketamine use including upper or lower respiratory infection, procedures involving the posterior pharynx, cystic fibrosis, age younger than 3 months, acute glaucoma or globe penetration, uncontrolled hypertension, congestive cardiac failure, arterial aneurysm, acute intermittent porphyria and thyrotoxicosis.[35] Despite this, ketamine is used increasingly in the EDs as part of the procedural sedation (see Chapter 22.3). It is also an effective analgesic at sub-dissociative doses especially for opioid resistant pain (e.g. 0.2 to 0.3 mg/kg bolus plus infusion at 0.2 mg/kg/h).

Pain relief in pregnancy

Non-pharmacological treatment options should be considered where possible for pain management in pregnancy, because most drugs cross the placenta.[5] Use of medications for pain in pregnancy should be guided by published recommendations.[5] Paracetamol is regarded as the analgesic of choice.[5] NSAIDs are used with caution in the last trimester of pregnancy and should be avoided after the 32nd week.[5] The use of NSAIDs is associated with increased risk of miscarriage.[5] Overall, the use of opioids to treat pain in pregnancy appears safe.[5]

Non-pharmacological therapies

Although pain perception involves neuroanatomical processes, the other interrelated component of pain reaction is psychophysiological. The use of non-pharmacological techniques is therefore important. These include empathy, a compassionate approach, a calm manner, patient distraction and verbal reassurance. Immobilization of fractures with splinting is effective, as is the application of ice to a wound. Other techniques, such as hypnosis, transcutaneous nerve stimulation, acupuncture and manipulation, have not been widely studied in the ED setting.

Special pain situations and non-analgesic agents

This chapter has focused on specific analgesic agents, but there are many miscellaneous agents that are effective in providing disease-specific analgesia.

Examples of these include:

- triptans for migraine
- glyceryl trinitrate and β-blockers for acute cardiac ischaemia pain
- antiviral agents for herpes zoster
- antidepressants (e.g. nortriptyline), anticonvulsants (e.g. carbamazepine) or gabapentin for neuropathic pain
- oxygen therapy for cluster headache
- calcium gluconate for hydrofluoric acid burns
- hot water (43°C) for venomous marine stings.

In addition, adjuvant therapy with anxiolytics, such as midazolam, contributes to pain relief. Obtaining a definitive diagnosis allows directed therapy that contributes to pain relief. If specific treatments appear to be ineffective, then the diagnosis should be reconsidered.

Acute neuropathic pain

Acute neuropathic pain is an important issue in the ED. This may be due to conditions such as sciatica and cervical radiculopathy. In addition to agents such as the antidepressants (e.g. nortriptylline) or anticonvulsants (e.g. carbamazepine), another option includes the use of antihyperalgesic drugs, such as gabapentin 100 to 300 mg/dose, repeated as necessary, titrating up to a maximum of 3600 mg/day over time. The main side effects are dizziness, somnolence and ataxia. However, there have been no ED studies of gabapentin or pregabalin and there is wide variability of response.

Chronic pain

Chronic pain 'commonly persists beyond the time of healing of an injury and frequently there may not be any clearly identifiable cause'.[5] Patients with chronic pain attend the ED with exacerbations of their chronic pain and are often taking multimodal therapies prescribed by a pain specialist. The main difference between acute and chronic pain is that, in chronic pain, central sensitization is the main underlying pathophysiology.[36] It is important to avoid a judgemental attitude to these patients as there is a risk of overlooking serious pathology.

Antihyperalgesic drugs in the setting of chronic pain, especially ketamine, are of particular value in those with poor opioid responsiveness.[5] Other antihyperalgesics may be useful for neuropathic pain, such as gabapentin and pregabalin.

Another issue with chronic pain is to be aware of adjuvant therapies for decreasing the likelihood of chronic pain developing. For example, early management of acute zoster infection may reduce the incidence of post-herpetic neuralgia.[5] Aciclovir given within 72 hours of onset of the rash accelerates the resolution of pain and reduces the risk of post-herpetic neuralgia.[5] Amitriptyline 25 mg daily in patients over 60 years for 90 days, started at the onset of acute zoster, reduces pain prevalence at 6 months post-zoster infection.[37]

Likely developments over the next 5 to 10 years

- Further study on the role and utility of various oral analgesics for commonly treated conditions in the ED, including new agents or formulations
- Use of patient-controlled analgesia
- Alternative administration techniques, including needleless systems and microneedle technology
- Use of non-pharmacological techniques, such as acupuncture[38]
- Better understanding of the pathophysiology of pain.

CONTROVERSIES

- Development of a uniform approach to pain research in order to make meaningful comparisons between studies
- Development of an objective measure of pain
- The effectiveness of codeine combinations in ED patients.

22.2 Local anaesthesia

Anthony F.T. Brown

ESSENTIALS

1 **Local anaesthetic infiltration and nerve blocks may be used as a supplement to oral, inhaled or parenteral analgesia.**

2 **Also, they may be the primary method of achieving analgesia, particularly where pain is localized to a digit or within a peripheral nerve distribution region.**

3 **Local anaesthetic toxicity may occur with inadvertent bolus intravenous injection or by exceeding the recommended maximum safe dose. Neurological and cardiovascular effects predominate and may be fatal.**

4 **Resuscitation equipment should always be available when using these agents. Refractory local anaesthetic systemic toxicity with cardiovascular collapse or arrest may respond to 20% lipid emulsion therapy.**

5 **Intravenous regional anaesthesia with prilocaine for a Bier block is a simple, safe technique commonly used for reduction of forearm fractures, but requires two medical practitioners and specialized equipment.**

6 **Formal training and accreditation should occur prior to independent practice, particularly with more complex blocks, such as Bier and the femoral nerve.**

Local anaesthesia

Local anaesthetic infiltration and nerve blocks should be used for patients presenting to the emergency department (ED) with pain, either to supplement other analgesia or for definitive pain relief. Nerve blocks are most appropriate when the pain is localized, as in certain fractures and wounds to a digit, or within a peripheral nerve distribution region. Local anaesthesia may also be used topically, particularly in children, and prior to arterial blood gas puncture and insertion of large intravenous cannulae where, contrary to popular perception, it does not increase the likelihood of failure.[1,2]

Pharmacology

Local anaesthetic agents are all weak organic bases that inactivate plasma membrane voltage-gated fast sodium channels, temporarily blocking membrane depolarization and preventing nerve impulse transmission. All are vasodilators, with the exception of ropivacaine and cocaine, hence the use of adrenaline to prolong their duration of activity and to improve safety by delaying absorption and/or by administering lower effective doses.

Amino ester and amino amide local anaesthetics

Amino esters

Local anaesthetic agents that contain an ester bond between the intermediate chain and lipophilic aromatic end (amino esters) include cocaine, procaine and amethocaine. They are poorly protein bound and undergo hydrolysis by plasma pseudocholinesterase to para-amino benzoic acid.

Amino amides

Amide-type agents that contain an amide bond between the intermediate chain and aromatic end (amino amides) include lignocaine, prilocaine, bupivacaine and ropivacaine. They are highly protein bound, much more stable and undergo hepatic metabolism.

Local anaesthetics are available in single or multidose vials, with or without dilute adrenaline at 1:200,000 (containing 5 μg adrenaline per millilitre) to prolong their duration of action.

Local anaesthetic reactions

Antioxidants, such as sodium bisulphite or metabisulphite, are added to adrenaline-containing solutions and preservative, such as methylparaben, to multidose vials and are implicated in some apparent 'allergic' reactions to the local anaesthetic. Other reaction mimics include vasovagal episodes, adrenergic sympathetic stimulation and anxiety-related responses.

True allergy to local anaesthetics is extremely rare at <1.0% reactions, when verified by progressive challenge testing, and is usually to the amino amides.[3] More common are contact dermatitis or delayed local swelling (discussed later).

Duration of action

The duration of action of local anaesthetics is related to the degree of protein binding, vasoactivity, concentration and possibly pH, although the addition of adrenaline is the most practical way to prolong their effect. Table 22.2.1 gives standard maximum safe doses and duration of action of commonly used agents. Solutions containing adrenaline should not be injected near end arteries, such as in the fingers, toes, nose or penis, even though surprisingly this well-established dogma is not supported by the literature. Normal blood flow is restored to the digit within 60 to 90 minutes of inadvertent injection of local anaesthesia with adrenaline (epinephrine) at standard commercial dilutions, without any evidence of harm.[4]

Adverse effects

Systemic toxicity

Systemic toxicity occurs after unrecognized rapid intravenous or intra-arterial injection or by exceeding the recommended safe maximum dose. Symptoms and signs of toxicity are related to plasma drug levels and progress from circumoral tingling, dizziness, tinnitus and visual disturbance to muscular twitching, confusion, convulsions, coma and apnoea. Cardiovascular effects are also seen with high plasma levels, including bradycardia, hypotension and cardiovascular collapse ultimately with ventricular fibrillation or asystole, which are all exacerbated by associated hypoxia. See Box 22.2.1 for the features of local anaesthetic toxicity related to increasing plasma levels.

Management of systemic toxicity

The management of systemic toxicity includes immediate cessation of the drug, summoning

Box 22.2.1 Features of systemic local anaesthetic toxicity (in order of increasing plasma levels)

Circumoral tingling
Dizziness
Tinnitus
Visual disturbance
Muscular twitching
Confusion
Convulsions
Coma
Apnoea
Cardiovascular collapse (highest plasma levels)

help, airway maintenance, supplemental oxygen and incremental doses of an intravenous benzodiazepine, such as midazolam 0.05 to 0.1 mg/kg, for seizures. Major reactions may require endotracheal intubation, fluids and cautious use of vasopressors and inotropes, as high doses can impede resuscitation in toxic cardiomyopathy. Refractory arrhythmias with cardiovascular collapse from local anaesthetic systemic toxicity (LAST) may respond best to intravenous 20% lipid emulsion 1.5 mL/kg bolus followed by 0.25 mL/kg/min for roughly 10 minutes following the recovery of vital signs.[5]

As adverse reactions occur immediately or within minutes after local anaesthetic use, medical expertise, resuscitation equipment and monitoring facilities must always be readily available.

Other reactions

Other adverse reactions to local anaesthetics involve allergy, including contact dermatitis, and rarely anaphylaxis predominantly to the amino amides, catecholamine effects from added adrenaline, vasovagal reactions when the patient is upright (such as during a dental procedure), cytotoxic delayed wound healing, malignant hyperthermia from amino amide use and methaemoglobinaemia due to prilocaine or benzocaine (Box 22.2.2).

Topical anaesthesia

Some agents such as EMLA (eutectic mixture of local anaesthetics including 2.5% lignocaine and 2.5% prilocaine) are used topically, particularly to decrease the pain of insertion of cannulae or for lumbar puncture and suprapubic catheter insertion in children. EMLA takes up to 1 hour for maximal effect and, paradoxically, is a venoconstrictor making vessel puncture harder. A potentially superior alternative for cannula insertion is 4% amethocaine (AnGel), as this has a quicker onset and is a vasodilator, although operator experience in cannulation is likely to be of more relevance.[6]

Box 22.2.2 Adverse reactions to local anaesthetics (other than systemic toxicity)

Allergy:
- Amides >> esters
- Additives, such as methylparaben, sodium metabisulphite

Catecholamine effects from added adrenaline
Vasovagal
Delayed wound healing
Malignant hyperthermia
Methaemoglobinaemia—prilocaine, benzocaine

Likewise, a mixture of 1:1000 adrenaline, 4% lignocaine and 0.5% amethocaine, with the acronym ALA (or known as LET in North America standing for lidocaine, epinephrine and tetracaine) up to 0.1 mL/kg, may be used inside small wounds instead of, or to reduce the pain of, injecting local anaesthetic prior to closure, again in children or adolescents.

Specific nerve blocks

The following nerve blocks are contraindicated in uncooperative patients, those with local sepsis in the injection zone and in the rare patient with true local anaesthetic allergy. Care must be taken not to exceed the recommended maximum local anaesthetic doses (see Table 22.2.1), and monitoring facilities, resuscitation equipment and medical expertise must be available at all times.

Formal training and accreditation should occur prior to independent practice, particularly with the more complex blocks, such as Bier and femoral nerve.

Table 22.2.1 Maximum recommended safe dose and duration of action of common local anaesthetics

Drug	*Dose (mg/kg)*[a]	*Duration (h)*
Lignocaine	3	0.5–1
Lignocaine with adrenaline	7	2–5
Bupivacaine	2	2–4
Prilocaine	6	0.5–1.5

[a]A 1% solution contains 10 mg/mL.

Digital nerve block ('ring block')

Indications

Wound debridement, suturing, drainage of infection, fracture or dislocation reduction around the nail, fingertip and distal finger or toe.

Contraindications

Local sepsis, Raynaud phenomenon and peripheral vascular disease.

Technique

Use 2% plain lignocaine. Inject 1 to 1.5 mL using a 25-gauge needle into the palmar aspect of the base of the finger or toe, approaching vertically from the dorsum. Withdraw the needle until subcutaneous and rotate slightly until pointing to the extensor surface of the digit and inject a further 0.5 mL (Fig. 22.2.1). Perform the same procedure on the other side of the digit. Allow at least 5 minutes for the block to work.

Complications

Avoid intravascular injection by aspirating prior to injection. Do not use a tourniquet or more than 4 mL total volume, to avoid impairing the circulation due to high local tissue pressures.

Nerve blocks at the wrist

These provide anaesthesia to the hand, particularly for diffuse lesions hard to infiltrate directly, such as 'gravel rash', or when the hand is swollen or burned.

Ulnar nerve wrist block (lateral approach)

Indications Procedures on the medial border of the hand and medial 1.5 digits or combined

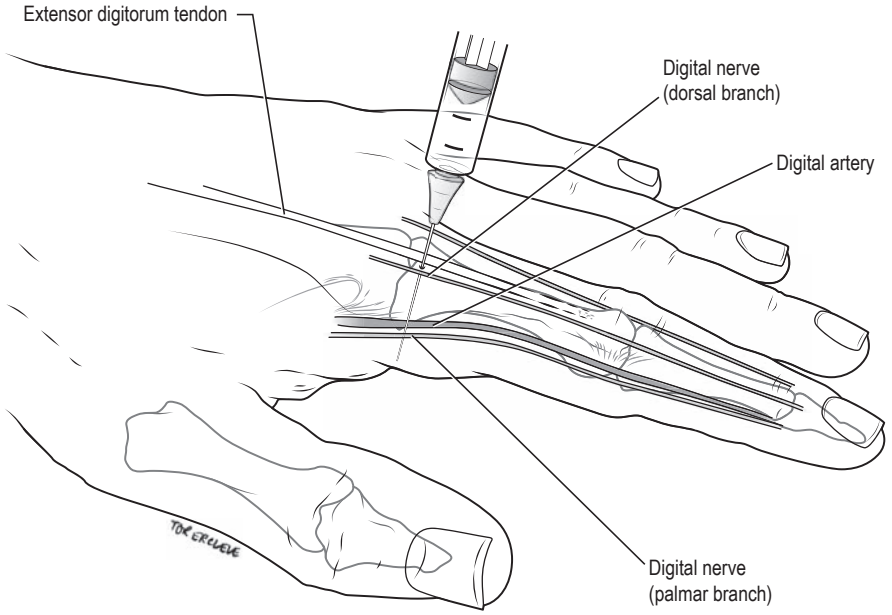

FIG. 22.2.1 Digital nerve block.

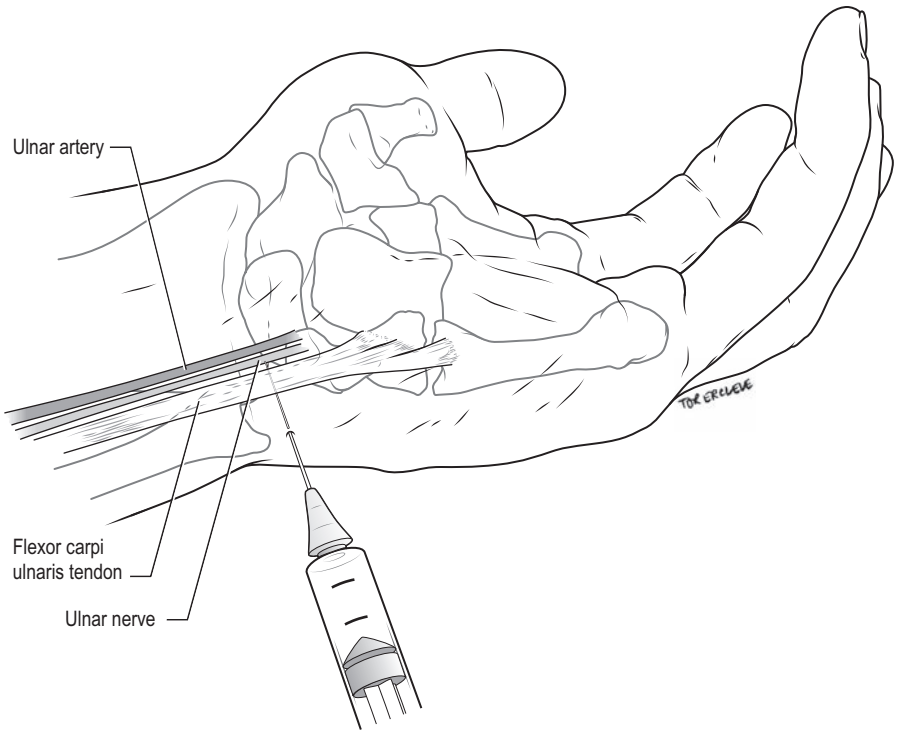

FIG. 22.2.2 Ulnar nerve wrist block (lateral approach).

with median and radial nerve blocks for hand anaesthesia.

Contraindications Local sepsis, neuritis.

Technique Identify the flexor carpi ulnaris tendon at the proximal palmar crease. Introduce a 25-gauge needle on the ulnar aspect of the tendon, directed horizontally and laterally for 1 to 1.5 cm under the tendon. Inject 4 mL of 1% lignocaine. Withdraw the needle until subcutaneous, then inject 5 mL of 1% lignocaine fanwise to the dorsal midline, to block superficial cutaneous branches (Fig. 22.2.2).

Median nerve wrist block

Indications Procedures on the lateral border of the hand in the territory supplied by the median nerve, excluding the medial 1.5 digits or combined with ulnar and radial nerve blocks for hand anaesthesia.

Contraindications Local sepsis, carpal tunnel syndrome or neuritis.

Technique Identify the tendons of the flexor carpi radialis and palmaris longus at the proximal wrist crease. Introduce a 25-gauge needle vertically 0.5 to 1 cm lateral to the palmaris longus (or 0.5 cm medial to the flexor carpi radialis in the 10% of individuals lacking a palmaris longus). Inject 5 mL of 1% lignocaine when the needle gives as it penetrates the flexor retinaculum or paraesthesiae are elicited, at a depth usually of no more than 1 cm to the skin (Fig. 22.2.3). Avoid injecting into the nerve itself, as it may lie more superficial than this.

Radial nerve wrist block

Indications Procedures on the dorsal radial aspect of the hand or combined with ulnar and median nerve blocks for hand anaesthesia.

Contraindications Local sepsis, neuritis.

Technique Identify the tendon of the extensor carpi radialis and infiltrate 5 to 10 mL of 1% lignocaine subcutaneously in a ring around the radial border of the wrist to the area overlying the radial pulse, at the level of the proximal palmar crease (Fig. 22.2.4).

Nerve blocks of the leg

Femoral nerve block

Indications Analgesia for fractured shaft of femur, especially prior to applying dynamic splintage.

Contraindications Local sepsis, bleeding tendency.

Technique Preferably use ultrasound guidance; the goal is to place the needle tip immediately adjacent to the lateral aspect of the femoral nerve, below the fascia iliaca or between the two layers of the fascia iliaca, that surround the femoral nerve. Proper deposition of local anaesthetic is confirmed either by observation of the femoral nerve being displaced by the injectate or by the spread of the local anaesthetic above or below the nerve, surrounding and separating it from the fascia iliaca layers. If ultrasound is not available, palpate the femoral artery below the midpoint of the inguinal ligament, which extends from the pubic tubercle to the anterior superior iliac spine. Insert a 21-gauge needle 1 cm lateral to this point, perpendicular to the skin. Advance until paraesthesiae are elicited down the leg and withdraw slightly, aspirate to exclude intravascular placement and inject 10 mL of 0.5% bupivacaine (50 mg). Alternatively, feel for a give as the needle punctures the fascia lata, aspirate, then inject 10 mL of 0.5% bupivacaine fanwise laterally away from the artery (Fig. 22.2.5).

Complications Puncture of femoral artery.

Foot blocks at the ankle

Indications Where local anaesthetic infiltration of the foot is awkward or difficult because of thick sole skin or pain, or when excessive amounts of anaesthetic would otherwise be required.

Contraindications Local sepsis, peripheral vascular disease.

Technique Three superficial nerves, the sural, superficial peroneal and saphenous, are blocked by subcutaneous infiltration in a band around 75% of the ankle circumference. Two deeper nerves—the posterior tibial by the posterior tibial artery and the deep peroneal (anterior tibial) nerve by the dorsalis pedis artery—are blocked, usually in combinations with the superficial ones, according to the area of anaesthesia required.

Sural nerve The sural nerve is blocked by injecting 3 to 5 mL of 1% lignocaine subcutaneously in a band between the Achilles tendon and the lateral malleolus, 1 cm above and posterior to the malleolus (Fig. 22.2.6). It anaesthetizes a small strip on the lateral dorsum of the foot at the base of the little toe to the lateral malleolus and the posterolateral aspect of the ankle and heel.

Superficial peroneal nerves Superficial peroneal nerves are blocked by injecting 4 to 6 mL of 1% lignocaine subcutaneously in a band between the extensor hallucis longus tendon and the lateral malleolus, on the anterior aspect of the ankle (see Fig. 22.2.6). This block anaesthetizes the dorsum of the foot, save for the lateral aspect (see the previous discussion of the sural nerve) and interdigital web between the hallux and second toe (see the later discussion of the deep peroneal nerve).

Saphenous nerve The saphenous nerve is blocked by injecting 3 to 5 mL of 1% lignocaine subcutaneously above the medial malleolus,

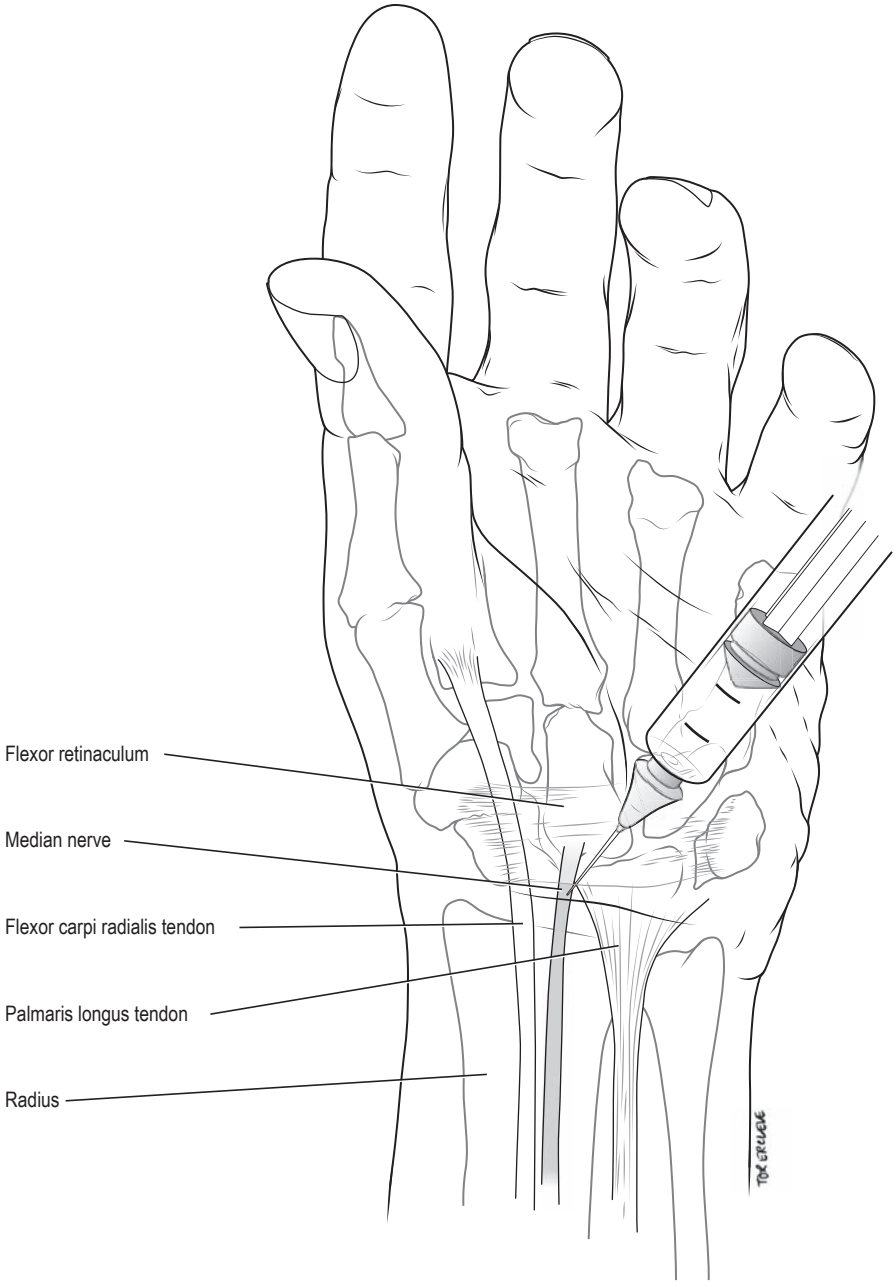

FIG. 22.2.3 Median nerve wrist block.

laterally until over the tibialis anterior tendon (Fig. 22.2.7). It anaesthetizes the area around the medial malleolus anteriorly and, to a lesser degree, posteriorly.

Posterior tibial nerve The posterior tibial nerve is blocked by infiltrating 3 to 5 mL of 1% lignocaine immediately lateral to the posterior tibial artery as it passes behind the medial malleolus, at a depth of 0.5 to 1 cm to the skin (see Fig. 22.2.7). It anaesthetizes the sole of the foot, excluding the posterolateral heel (see the previous discussion of the sural nerve), via its medial and lateral plantar branches.

Deep peroneal (anterior tibial) nerve The deep peroneal (anterior tibial) nerve is blocked by infiltrating 1 to 2 mL of 1% lignocaine just above the base of the medial malleolus, lateral and behind the extensor hallucis longus by the dorsalis pedis pulse at a depth of 0.5 cm (see Fig. 22.2.7). It anaesthetizes the interdigital web between the hallux and second toe.

Complications Exceeding a total volume of 20 mL of 1% lignocaine local anaesthetic (i.e. 3 mg/kg) risks systemic toxicity or poor peripheral perfusion due to raised tissue pressures.

Intravenous regional anaesthesia or Bier block

Indications

Operative procedures, such as debridement, tendon repair and foreign body removal in the forearm and hand. Reduction of fractures and dislocations, typically Colles fracture of the wrist.

Contraindications

Local anaesthetic sensitivity; peripheral vascular disease, including Raynaud phenomenon; sickle cell disease; cellulitis; uncooperative patients, including children; hypertension with systolic blood pressure over 200 mm Hg; severe liver disease; and unstable epilepsy.

Technique

Two doctors are required, allowing one to perform the manipulation and the other, with training in the procedure and resuscitation skills, to perform the block. Explain the procedure to the patient and obtain informed consent. Assemble and check all equipment and apply standard monitoring, including ECG, non-invasive blood pressure and pulse oximetry.

Use a specifically designed and maintained single 15 cm adult cuff, placed over cotton wool padding to the upper arm. Double-cuff tourniquets require higher inflation pressures, as they are narrower. The upper cuff is inflated first, followed by the lower cuff later, after the injection of the local anaesthetic has had time to take effect, thereby reducing tourniquet discomfort. The upper cuff is then released. The use of a double cuff does not always reduce the ischaemia pain and predisposes to accidental wrong cuff release, so this requires additional expertise and understanding.

Insert a small intravenous cannula into the dorsum of the hand of the injured limb and a second cannula in the other hand or wrist as emergency access to the central circulation. Exsanguinate the injured limb by simple elevation and direct brachial artery compression for 2 to 3 minutes, carefully supporting the limb at the site of any fracture. An Esmarch bandage may be used instead, in the absence of a painful wrist fracture.

Keep the arm elevated and inflate the cuff to 100 mm Hg above systolic blood pressure. The radial artery pulse should now be absent and the veins remain empty. If this is not the case, do not inject anaesthetic but repeat the exsanguination procedure and cuff inflation.

Lower the arm once the radial artery pulse is absent and the veins are empty, and inject 2.5 mg/kg (0.5 mL/kg) of 0.5% prilocaine slowly over 90 seconds and record the time. Alternatively, 1% plain lignocaine (1.5- to 3-mg/kg total lignocaine dose) diluted to a concentration of 0.5% can be used.

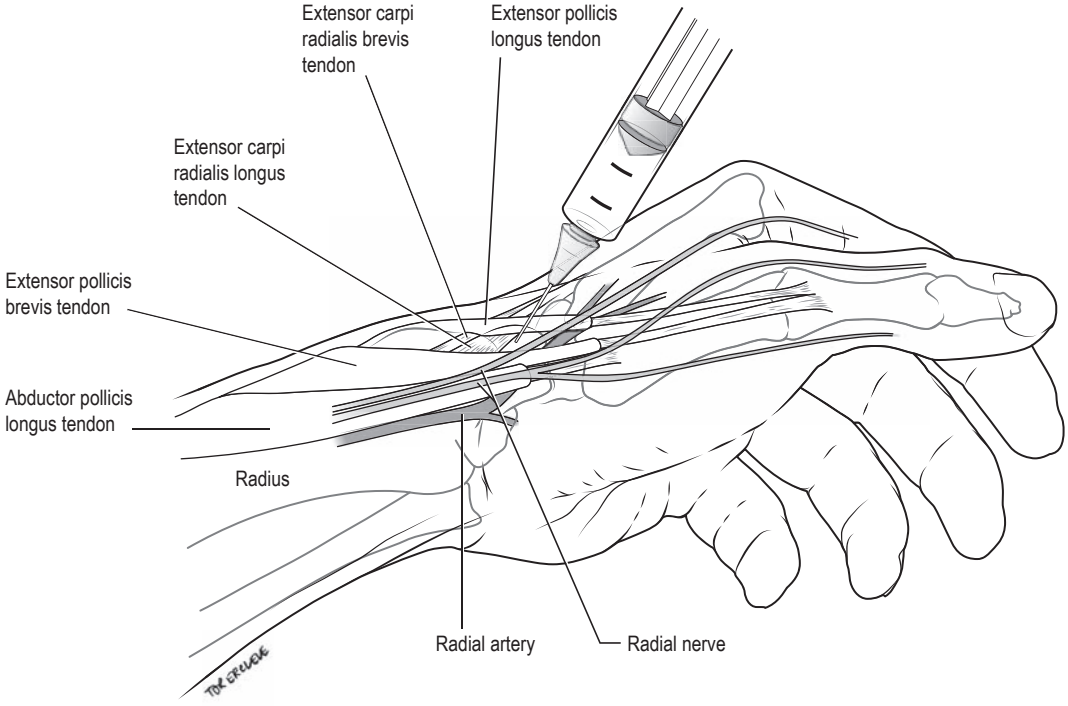

FIG. 22.2.4 Radial nerve wrist block.

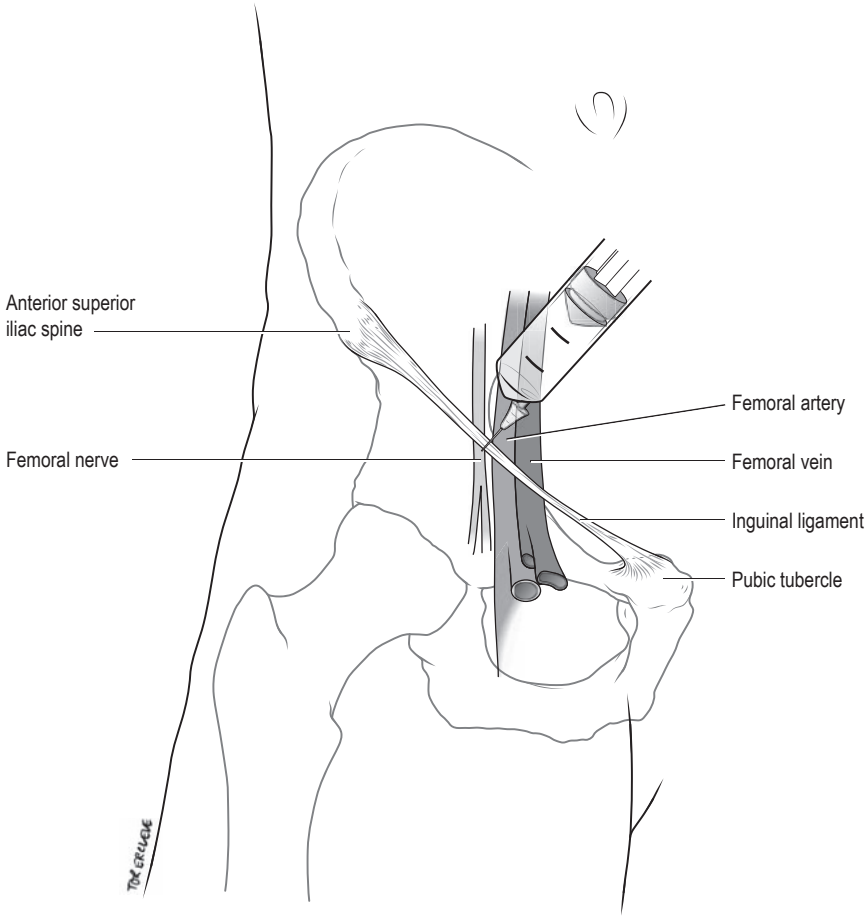

FIG. 22.2.5 Femoral nerve block.

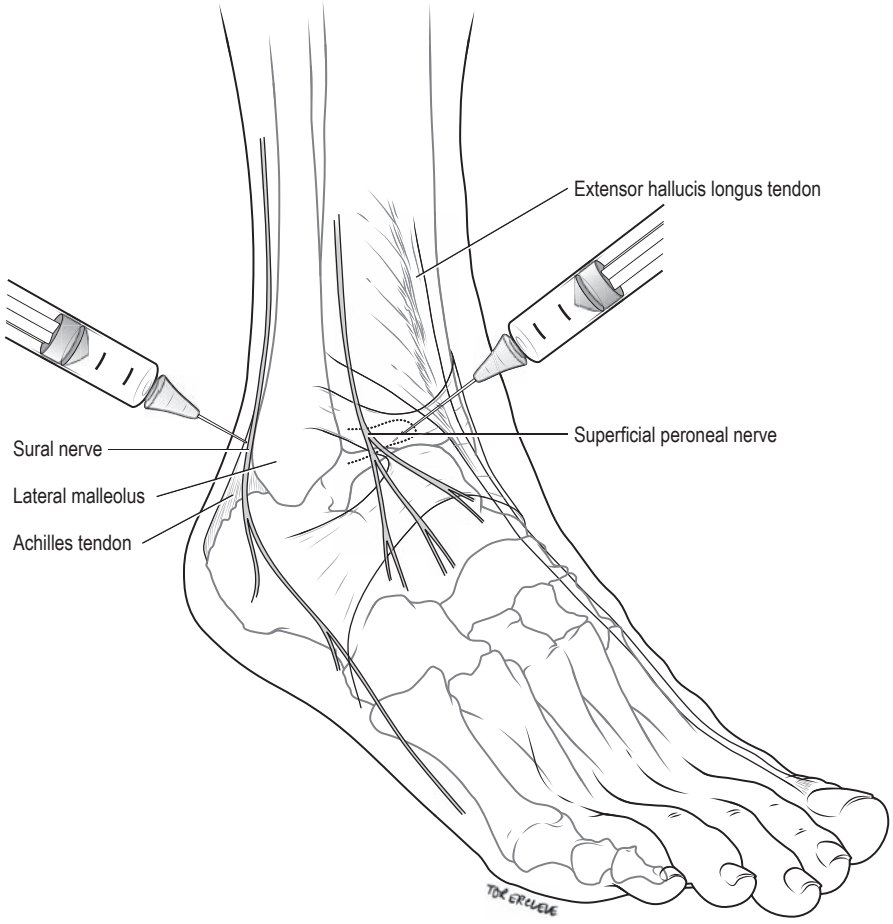

FIG. 22.2.6 Sural and superficial nerve blocks.

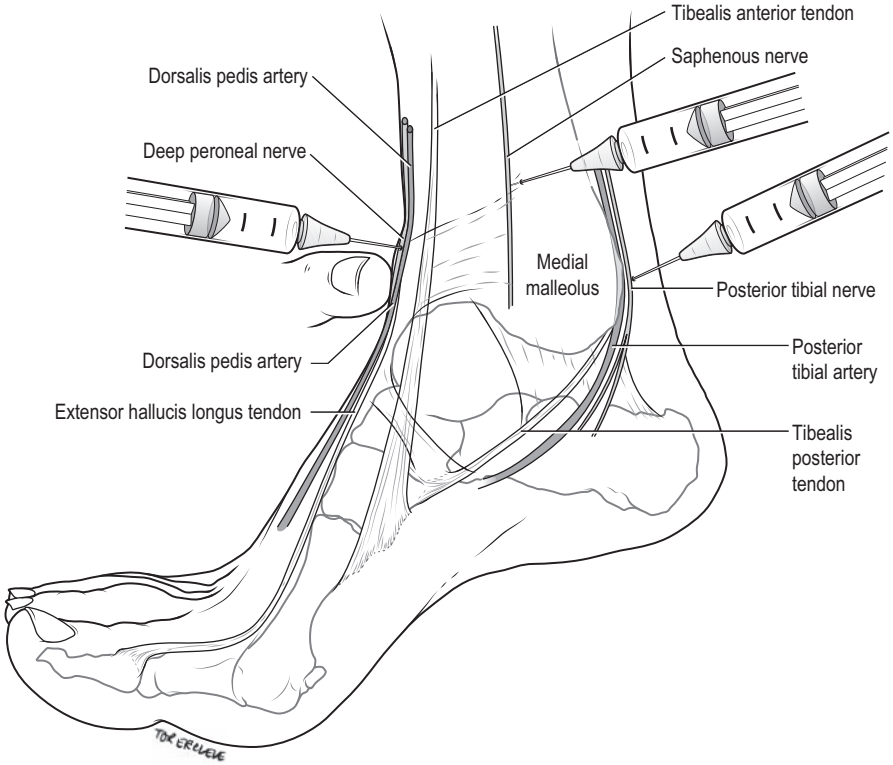

FIG. 22.2.7 Saphenous, posterior tibial and deep peroneal nerve blocks.

Continuously monitor the cuff pressure and wait at least 5 to 10 min to confirm the adequacy of analgesia before removing the cannula on the injured limb. Perform the surgical procedure. Keep the tourniquet inflated for a minimum of 20 minutes and a maximum of 60 minutes.

Monitor the patient carefully for any signs of anaesthetic toxicity (Box 22.2.1) over the next 15 minutes following cuff release, while organizing discharge from the monitored area.

Complications

No severe cardiac complications, deaths or methaemoglobinaemia have been reported using 0.5% prilocaine at the maximum dose of 2.5 mg/kg (0.5 mL/kg).[7] Discomfort from the cuff is possible, but rarely significant.

CONTROVERSIES AND FUTURE DIRECTIONS

- There is no evidence that injecting a standard commercial preparation of local anaesthetic with adrenaline (epinephrine) into a digit is harmful.
- Lipid emulsion therapy for LAST appears well established and has been used in other life-threatening lipophilic drug toxicity, such as with propranolol, verapamil and tricyclic antidepressant poisoning.
- Need for fasting prior to a Bier block.

22.3 Emergency department procedural sedation

Anthony J. Bell • Greg Treston • Adam Michael

ESSENTIALS

1 **Emergency physicians and nurses should all be trained to provide effective procedural sedation in the emergency department (ED).**

2 **Plan and prepare yourself, and assess the risk-benefit of each individual procedure.**

3 **Assess the timing and nature of recent oral intake, medications, available staff to assist, other simultaneous activity in the ED and patient comorbidities.**

4 **Determine the safe limit of targeted depth and duration of the sedation.**

5 **Sedation is a continuum. It is not always possible to predict how an individual will respond or at which point airway reflexes may be jeopardized.**

6 **Sedative agents should be titrated to clinical end points, rather than delivered in a cookbook fashion using generic mg/kg doses.**

7 **Each procedural situation should be based on its individual merits, balanced against the available resources of both the ED and the health service at that moment in time.**

Introduction and rationale

Procedural sedation is a core competency for the emergency physician, for the performance of brief, but painful procedures, and has become standard emergency medicine practice. Emergency department procedural sedation (EDPS) refers to the technique of administering sedatives or dissociative agents, with or without analgesics, to induce a state that allows the patient to tolerate unpleasant or anxiety-provoking therapeutic or diagnostic procedures, while maintaining cardio-respiratory function.[1,2]

However, significant variation exists in the practice of EDPS in relation to the approach, choice and combination of agent/s given.[3] Paediatric patients in particular represent a significant challenge; children are often frightened when in pain, and their presentation to the hospital disrupts the family's functioning.[4,5] Medical staff underestimate and undertreat pain in children.[6] Painful procedures in the ED are remembered vividly by children, their parents and adult patients. Denial of relief from pain that is proportionate to the expressed need for such relief must be judged as an unjustified harm and amounts to substandard and unethical medical practice.[7]

Underlying principles

Guidelines

The Australasian College for Emergency Medicine (ACEM),[8] the Royal College of Emergency Medicine, American College of Emergency Physicians (ACEP)[2] and the Canadian Association of Emergency Physicians (CAEP)[9] have all published on the underlying principles for successful procedural sedation and analgesia. All guidelines cover presedation preparation and assessment, presedation fasting, physician skills, staffing, equipment and environment, patient monitoring, documentation and postsedation care. There has been a gradual change in the perception accorded to EDPS being performed in EDs over the past decade, and the use of intravenous 'anaesthetic agents' for EDPS is widely accepted and is now part of mainstream emergency medicine specialist training.

Best practice guidelines require that two medical attendants, one of whom should be a specialist or advanced trainee with sedation competency, be present. Nursing staff are also required, and the procedure must be performed in a resuscitation-capable area of the ED. Physiological monitoring is mandated during the procedure and extending into the recovery phase. The practitioner must understand the agents available and choose based on the procedure being performed (e.g. the potential for pain, the likely duration of sedation and pain relief required and staff familiarity with the agent and its effects).[10]

Depth and duration of sedation

The optimal end point of any sedation episode depends on the procedure being performed and patient's characteristics. Sedation state classification ranging from minimal sedation (anxiolysis) through moderate sedation (formerly conscious sedation), deep sedation and general anaesthesia. Dissociative sedation is a separate state induced by ketamine.[11] The exact characteristics of respiratory and/or airway reflex depression in relation to depth of sedation are not well defined and can be quite variable.[1]

Titration of drug and constant verbal and tactile reassessment of the patient reduce the risk of oversedation.[2] Some degree of responsiveness to painful stimuli should indicate preservation of airway reflexes, decreasing the risk of aspiration if vomiting occurs.[12]

The duration of sedation is largely determined by the choice and dose of agent used and the procedure itself, as to whether this will be brief (e.g. shoulder reduction) or longer (e.g. compound scrub, or manipulation of fractures), with most ED procedures taking less than 20 minutes. The longer the sedation, the greater the risk of an adverse event.

Indications

Indications include, but are not limited to, fracture and dislocation reduction, incision and drainage of abscesses and cardioversion.[13] Less painful but anxiety-provoking procedures in children will also be facilitated by the use of dissociative sedation (e.g. lumbar puncture, suturing, ocular or auditory canal foreign body (FB) removal or intravenous (IV) cannulation in an uncooperative and anxious child).[3,11]

Departmental procedures and logistics

All departments that perform EDPS should have written guidelines, standardized data collection and suitably trained staff. Patient selection is informed by the pre-procedural risk assessment, by available departmental resources to successfully and safely perform the procedure and the sedation without jeopardizing patient care elsewhere in the department and by the ability to monitor and safely discharge the patient.[14]

Preprocedural risk assessment

Preprocedural assessment is of critical importance before embarking on EDPS. Adverse outcomes are associated with advanced age of patient, deep sedation, high body mass index (BMI) and intra-procedural use of fentanyl in combination with either propofol or midazolam. Procedure type and fasting status do not appear associated with adverse intra-procedural adverse respiratory events.[15] However, procedural *failure* is related to patient weight greater than 100 kg and to certain procedure types, notably prosthetic hip reductions and digit and temporomandibular joint (TMJ) relocations. In terms of agents used, ketamine has a lower rate of respiratory adverse events but has the overall highest procedural success rate.[16]

Each procedural sedation situation should be critically assessed by the treating ED physician, with particular consideration given to:

Age

A young patient's level of anxiety and cooperation will depend upon past medical experiences, anxiety of the parent/s and the reassurance given by medical staff.[11]

Children often present the challenge of initial lack of cooperation with the sedation process. Elderly patients, whilst mostly cooperative, may have underlying impairment of cardiorespiratory reserve and are at greater risk of respiratory depression or hypotension.

American Society of Anesthesiologists classification

The American Society of Anesthesiologists (ASA) classification system[15] is a global score used to classify the physical status of patients before planned surgery (Box 22.3.1). ASA class I and ASA II patients are usually preferred as candidates for procedural sedation in the ED. If an ASA class III patient requires sedation out of necessity, this should not preclude performance of the procedure. The management of respiratory depression becomes a more active issue with increasing ASA in all age groups.[16,17]

Airway

An adverse past anaesthetic history or a focussed airway assessment with attention to mouth opening, pharyngeal visualization (Mallampati score), neck movement, thyromental distance and dentition may signal potential difficulty should active airway intervention be required. An airway assessment checklist can be found in Box 22.3.2 and Fig. 22.3.1.

Past medical history

Some conditions predispose to gastro-oesophageal reflux (such as pregnancy or hiatus hernia), raising the theoretical risk of aspiration events during deep sedation. Unstable acute medical/neurological conditions (with the exception of arrhythmia requiring cardioversion) may carry too high a risk to justify proceeding with EDPS. Allergies to any agent in the past precludes use of that agent, and egg and/or soy allergy[18] will preclude the use of propofol in particular.

Occasionally a patient with significant comorbidities will present for a procedure requiring sedation. A careful assessment of the patient, the urgency of the procedure and the available alternatives, in consultation with anaesthetic or intensive care unit (ICU) colleagues, would be appropriate. Often only very small doses or sedation are required in the elderly to safely perform procedures in a painless fashion.

Box 22.3.1 American Society of Anesthesiologists classification

Class	
1	Healthy patient, no medical problems
2	Mild systemic disease (e.g. hypertension)
3	Severe systemic disease but is not incapacitating
4	Severe systemic disease that is a constant threat to life
5	Moribund, expected to live <24 h irrespective of operation

Box 22.3.2 Airway assessment for patient-controlled sedation

	Predictors of difficult airway
1	Mallampati score III & IV
2	Inability to open mouth >4 cm
3	Thyromental distances <6 cm
4	Limitation of neck movement
5	Difficulty in protruding lower jaw
6	History of difficult intubation

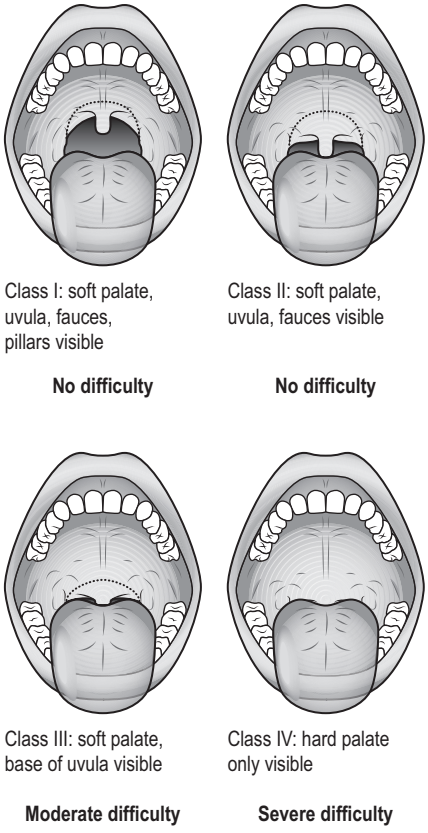

FIG. 22.3.1 Mallampati score.

Fasting status

Fasting guidelines

ED patients, particularly children,[3] undergoing urgent EDPS are commonly not fasted on presentation, nor at the time of the procedure. Furthermore, holding a patient for 6 hours in an overcrowded ED to achieve a goal of fasting time is impractical if an urgent procedure needs to be performed. Fasting guidelines are consensus based, not evidence based. The ASA recommends, by extrapolation, at least 2 hours and 6 hours from last intake of fluid and food, respectively,[15] prior to an ED sedation, despite a lack of evidence.[15,19] In fact, prolonged preprocedural fasting has been shown to increase the rate of vomiting in the recovery period.[20,21]

Aspiration risk

The risk of aspiration is low. Fasting status is just one consideration when individualizing decisions about choice of agent, approach to dosing, desired depth of sedation or even referral to the operating theatre.[12,22] EDPS does not use volatile inhalational anaesthetics or involve pharyngeal instrumentation which can induce emesis; however, there is a risk. There is no association between fasting status and adverse events during procedural sedation in the ED for a range of agents, including ketamine, midazolam/fentanyl, chloral hydrate, pentobarbital[20,23,24] or nitrous oxide.[12,18,25,26] A recent large retrospective observational study of paediatric propofol sedation outside of the operating theatre environment revealed only four cases of aspiration pneumonitis in almost 50,000 cases, all of whom recovered with conservative measures.[27]

Those patients at high risk of aspiration may benefit from an alternative approach or different technique.[28,29]

Postprocedure vomiting

This usually occurs well into the recovery period. Postprocedure vomiting is more common with ketamine or narcotics than it is with propofol or benzodiazepines.[12,30]

Procedural urgency

The end point of sedation in the ED should be tailored to the urgency of procedure and availability of appropriate staff.[1,9] Procedures may thus be considered:

- Emergency (e.g. cardioversion, fractures with neurovascular compromise needing reduction, intractable pain)
- Urgent (e.g. care of dirty wounds or lacerations, dislocation reductions, lumbar puncture (LP), facilitate neuroimaging in trauma)
- Semi-urgent (e.g. FB removal, care of clean wounds and laceration repairs)
- Elective procedures.

Table 22.3.1 Choice of agent and dosing recommendations

	Suggested IV drug dosages (Adult, 70 kg, normal BMI)		
Drug	***Initial bolus***	***Subsequent titrated IV boluses***	***Cumulative maximum dose***
Morphine	2.5 mg	2.5 mg	10–15 mg
Fentanyl	25–50 µg	25 µg	150–200 µg
Midazolam	2 mg	1 mg	10 mg
Diazepam	5 mg	2.5 mg	10 mg
Propofol	30 mg	20 mg	300 mg
Ketamine	20 mg	10–20 mg	150 mg
Ketafol ('10/10 mg/mL')	3 mL	1–2 mL	10 mL
Etomidate	7 mg	3 mg	20 mg

NB: These are conservative estimates and dose modification is advised where appropriate.

Parental involvement

ED survey data show the vast majority of parents want to be present for invasive procedures performed on their child in the ED.[31,32] Despite this, many parents are asked to leave the room.[33] Parental presence should be welcomed, but ultimately their decision to stay or go should be supported.[31,34] Should they decide to stay, provide them a preprocedural briefing as to what to expect and what they can do to support their child that includes encouraging the parent to be reassuring and to avoid transmitting anxiety to their child. The pre-brief is of particular importance when using ketamine, where the dissociative features and nystagmus may cause anxiety to the uninitiated. Provide the parent, where possible, a seated position face-to-face holding their child's hand. Regular positive updates as to progress of the procedure is good practice.

Informed consent

Informed consent must be obtained after explanation of specific risks of EDPS and the procedure itself. When using ketamine for procedural sedation, inform parents or family members who may be present in the sedation area to expect a staring sedated patient with nystagmus, possible salivation, probable lacrimation, possible myoclonic jerking and vomiting occurring in 10%–15% of patients at the end of the procedure. This is important to the family member's overall acceptance and experience of their relative's procedure. Likewise, although rare, the possibility of airway intervention beyond transient support should be raised when using propofol.

Documentation

Specific procedural sedation forms or records are recommended. When designed in accordance with current best practice, they improve documentation and may be the focus for educational initiatives and assist in audit, research and Quality Assurance (QA).[35–37] They can also act as a de facto protocol to ensure safe care during procedural sedation. They increase the chance of compliance with guidelines and ensure essential presedation checks and monitoring is performed. They should include provision for recording adverse events, including vomiting, aspiration or respiratory depression, as well as any interventions required.[12] Continual audit of ED sedation records should form part of the quality cycle in the ED to identify factors associated with both success and complications.

Choice of agent

The 'ideal' agent for EDPS in the ED should have rapid onset, short duration of action, rapid recovery profile, minimal side effects and an amnestic effect. The different classes of drugs used in EDPS include sedative-hypnotics, analgesics, dissociative sedatives, inhalation agents and antagonists (flumazenil and naloxone), used alone or in combination (Table 22.3.1).

Sedative hypnotics

Benzodiazepines

Midazolam Midazolam is one of the most commonly used benzodiazepines with amnestic,[38] anxiolytic and sedative properties. Side effects are dose dependant. Intravenous dosing for EDPS ranges from 0.025 to 0.05 mg/kg in older children and adults, up to 0.1 mg/kg in younger children. Other routes of administration include intramuscular (IM), oral, and intranasal, although onset of action is slower[11] and many experienced clinicians have abandoned the use of intranasal midazolam, in favour of more reliable sedative agents such as ketamine. There is additive respiratory depression with opiate and midazolam containing combinations for EDPS with prolonged recovery times when compared with propofol.[39,40–42] Furthermore, patients receiving midazolam have been reported to have more procedural recall and higher pain scores.[43]

Diazepam Diazepam is less potent than midazolam, but there is little or no difference in the propensity of the two drugs to produce respiratory depression.[44] Dosing should start at 0.1 to 0.2 mg/kg, with lesser subsequent doses. The antegrade amnestic effect of diazepam is significantly less than that of midazolam.[43,45] Diazepam causes more pain on injection and a lesser degree of early sedation.[46] The elimination half-lives of benzodiazepines do not necessarily correspond with their sedative pharmacodynamic effects, and there are no clinically important sedative recovery rate differences between midazolam and diazepam.[47,48]

Ultrashort-acting agents

Propofol Propofol is a nonopioid, nonbarbiturate sedative-hypnotic that acts at gamma-aminobutyric acid (GABA) receptors within the central nervous system (CNS), providing an amnestic effect, rapid onset (in <1 min) and short duration of action (5 to 15 minute), facilitating rapid recovery times. It is easily titratable and has some antiemetic properties.[21] Hypotension is transient if propofol is titrated in euvolemic patients with normal cardiac function. Propofol has been shown to be safe in a wide range of settings, including procedural sedation in the ED.[2,49,50]

The optimum dosing regimen for propofol in procedural sedation has yet to be defined. Options vary from single bolus,[44,51,52] titration,[19,53–56] bolus and infusion[42,57] or infusion alone.[58–60] Doses recommended include 1 mg/kg initial bolus and 0.5 mg/kg subsequent boluses for EDPS.[44,61,62] In children, initial doses of 2 mg/kg initial bolus have been used.[63,64] In adult sedation, an alternative is to reduce the dose to 0.3 to 0.5 mg/kg initial bolus followed by 20 mg boluses.[65] Dose reduction is also essential in those older than 65 years of age or those with decreased physiological reserve.[57] Higher total mg/kg doses are used in children compared with adults.[65,66]

Propofol sedation times are shorter, respiratory complication rates equivalent to midazolam alone,[42] etomidate[51] and midazolam/fentanyl[44] and discharge times are earlier than with midazolam.[67] At higher doses, propofol is associated with greater likelihood of oxygen desaturation.[52]

Respiratory depression is seen in up to 50% of ASA class 1 and 2 patients[54,68,69] and 61% in the critically ill.[18] Apnoea may occur but is transient.[12,18,19,42,51,52–54,56–58,61,66,68,69] It is important to note that the combination of opiate and propofol results in higher levels of respiratory depression than propofol alone.[70,71] Pre-oxygenation prior to sedation with supplemental oxygen used during the sedation is safe practice.

Etomidate Etomidate is a nonbarbiturate hypnotic; however, it is not globally available and propofol has become favoured. It has a rapid onset of less than 30 seconds, with 5 to 15 minutes duration of action. Starting dose for patient-controlled sedation (PSA) is up to 0.1 mg/kg with subsequent boluses of 0.05 mg/kg. It has a similar profile to propofol in terms of respiratory depression and duration of sedation but is more cardiovascularly stable. Propofol is generally preferred above etomidate because etomidate has a 20% rate of myoclonus plus the theoretical risk of adrenal suppression, emergence phenomena and higher vomiting rates post procedure.[72–75]

Opiates

Opiates are the most commonly used analgesics before, during and after sedation; however, they do not provide amnesia.[3] Morphine is most commonly used pre-procedure and fentanyl intra-procedurally.[3] Use of opiates intra-procedurally when using propofol sedation is associated with greater rate of adverse airway effects.[27]

Fentanyl

Fentanyl has been the opiate of choice for EDPS. It should be titrated up to 1 µg/kg IV, to avoid respiratory depression from a rapid push, and should be combined with a pure sedative agent. It may also be delivered intranasally, particularly in children, although higher doses are required. Fentanyl has a rapid onset, a lack of histamine release and has a more stable cardiovascular profile when compared with morphine. Its duration of action is 30 to 45 minutes. Fentanyl has a higher in-sedation respiratory depression event rate and should be anticipated and managed.[74] Ketamine is an alternative analgesic to fentanyl for EDPS.[15,76]

Morphine

Morphine will provide a longer duration of analgesia, extending to hours, and is very useful after the procedure for ongoing analgesia. It may have been administered pre-hospital or pre-procedure, and, if so, titrate dose accordingly.

Ultrashort-acting opiates

Newer ultrashort-acting opiates (e.g. remifentanil, alfentanil) are occasionally combined with propofol to provide sedation and analgesia, and enable rapid recovery.[77] Like fentanyl, respiratory depression is to be expected and may even occur at lower levels of sedation. Post-procedural analgesia may be required, limiting the role of ultrashort-acting narcotics in EDPS.[78,79]

Inhalational agents

Nitrous oxide

N_2O provides anxiolysis and mild analgesia. It has rapid onset and offset and is safe but has little sedative effect. It may be useful as an anxiolytic in needle-phobic individuals to facilitate IV access before definitive IV sedation can be provided.

Despite its popularity and its convenience for the practitioner, N_2O use results in poor sedation conditions and unreliable pain reduction. This, coupled with the high rate of intraprocedural emesis when using N_2O, leaves nitrous oxide as a 'possibly useful' adjunctive agent when performing a procedure under an alternative technique (such as local anaesthetic or Bier block). Common side effects include vomiting and dizziness. Airway reflexes are preserved. Nitrous oxide can leave the bloodstream and enter air-filled cavities; therefore nitrous is contraindicated in patients in whom expansion of these air-filled cavities could compromise patient safety (e.g. pneumothorax, pulmonary blebs, air embolism and bowel obstruction).

Dissociative sedative

Ketamine

In ED procedural sedation, ketamine is used with two distinct principal aims:

1. As the primary sedative and analgesic agent, or
2. In a sub-dissociative dose as an analgesic adjunct when using an alternative sedative agent (e.g. propofol).

As a dissociative anaesthetic agent, ketamine has wide use in third world and military applications.[80] Ketamine is associated with the lowest procedural failure rate of any sedative in common use for EDPS,[16] high levels of satisfaction and no procedural recall.[81] At sub-dissociative doses less than 0.3 mg/kg, ketamine acts as an analgesic. With progressively larger doses, ketamine produces a dose-related 'dissociative anaesthesia' between deep sedation and general anaesthesia, generally when the dose exceeds 0.5 mg/kg. It has a rapid onset and offset of action, with preservation of airway reflexes, but it can cause laryngospasm, more notably when given intramuscularly in higher doses. It is relatively contraindicated as a sole sedative agent in patients with severe ischaemic heart disease, other advanced vascular disease or uncontrolled hypertension because it is sympathomimetic. However, it is often useful as part of a balanced sedative cocktail in such patients.

Ketamine given either intravenously or intramuscularly is popular for ED paediatric procedural sedation. At standard doses, its use is safe, with preservation of oropharyngeal reflexes, and little respiratory depression.[6,8,22,82–85] At higher doses (exceeding 1.5 mg/kg), sub-clinical respiratory depression can be noted at rates similar to propofol,[70] but ketamine is associated with lower rates of actual airway intervention across the sedation dosage spectrum.[15]

In some EDs, practitioners are hesitant to use ketamine for fear of 'emergence delirium/phenomena'.[4,83–88] Emergence *delirium* has been described as either '*patients are agitated,*

restless, and combative, and do not seem cognizant of their surroundings. Patients refuse to be comforted, even by their parents',[89] and '*combative, excited, and disoriented behaviour that requires transient physical restraint'*.[90] However, emergence *phenomena* may be something as mild as a non-distressing visual hallucination (e.g. as being on a roller coaster) or as transient diplopia. Given the differing definitions, the rate of adult emergence delirium/phenomena occurring during the recovery phase after sedation varies from less than 1% to greater than 36%.[70,91–93]

Atropine can reduce hypersalivation[94] and postprocedure vomiting, but its use is optional because it rarely affects the conduct of the procedure.

Intramuscular ketamine can facilitate a 'no cannula' sedation technique in ED, making it particularly useful for sedation involving anxious and uncooperative pre-school-aged children. Further research into safe and reliable intranasal dosing schedules is underway.

Combinations utilizing ketamine

Midazolam and ketamine

Midazolam (or another benzodiazepine) has been used in combination with ketamine, in an effort to decrease the incidence of 'emergence delirium'; however, recent randomized trials in children show no effect on emergence agitation when midazolam is added to ketamine.[95–97] Midazolam use has also been associated with higher rates of airway and respiratory compromise during procedural sedation in children,[17] and thus use of adjunctive benzodiazepines with ketamine is not recommended. The only prospective randomized controlled trial (RCT) in adults addressing this issue showed that the prophylactic use of midazolam reduced recovery agitation by 10%.[98] Midazolam as an adjunctive medication when performing EDPS using ketamine has repeatedly been associated with lower rates of postprocedural emesis[95,96] but with higher rates of airway/respiratory complications.[17] Midazolam as a sole sedative agent has itself been reported to have a rate of emergence agitation of up to 42%.[99–101]

Ketamine and propofol ('Ketafol')

Local and international RCT studies have compared 'ketafol' with propofol,[102,103] midazolam/fentanyl[104] and ketamine alone.[105] Most studies were small and focused on minor outcome differences. Ketamine and propofol is a stable solution and can safely be administered from the same syringe.[106].

Although 'ketafol' usually implies a single syringe technique of premixed ketamine and propofol, experienced ED sedationists also utilize ketamine and propofol in separate syringes, with comparable or superior results.[107]

The rationale for the addition of ketamine to propofol is to provide intraprocedural analgesia and sedation.[108] The combination aims to optimize sedation safety and efficacy and pain relief, balancing the opposing haemodynamic and respiratory profile of each individual drug. In addition, the antiemetic effect of propofol may counteract the vomiting seen with ketamine use and may minimize the rate of emergence experiences.[105,109–112]

The authors favour sedation utilizing two separate syringes, ketamine at low dose providing analgesia but not dissociation and targeting depth and duration of sedation using propofol, with optimal doses being in the vicinity of ketamine 0.2 to 0.4 mg/kg and propofol 1.2 to 2.0 mg/kg, both given by titration. Recent studies have identified that higher doses of ketamine intra-procedurally result in greater rate of unpleasant emergence reactions in the postsedation period[113] and higher rate of unpleasant recall of pain or discomfort during the procedure.[107]

Other drugs

Dexmetetomidine

Dexmetetomidine is a selective alpha-2 adrenergic agonist with sedative, anxiolytic, and very mild analgesic properties. Chemically, it is related to clonidine but has greater affinity for alpha-2 adrenergic receptors than alpha-1 receptors.[114] Dexmetetomidine acts in the CNS on vasomotor centres in the medulla, where it causes decreased sympathetic tone, which results in increased inhibitory GABA activity, leading to sedation and (limited) analgesia.[115] It has been used for sedation of adults in the ICU and for paediatric sedation for (nonpainful) radiological investigations, such as computed tomography (CT) and magnetic resonance imaging (MRI), with some success. However, its utility is limited by hypotension and bradycardia mediated by its sympatholytic activity. There is minimal, if any, respiratory depression.

Current ED uses could be for decreasing agitation and motion in a child undergoing CT or MRI scan or as a sedative agent for intubated patients in the ED. Some report that its utility as a paediatric sedation agent is restricted to sedation for CT, MRI, or electroencephalography (EEG) and note that its use demands a longer induction and results in a longer recovery time than propofol when used for similar procedures.

Local anaesthesia

Local anaesthesia can be a very useful adjunct during EDPS, especially in cases of wound repair, cutaneous foreign body removal, and abscess incision and drainage. Infiltration of local anaesthesia in a field block allows for control of pain during the procedure, allowing for painless completion of the procedure with a lower dose of sedation medication, as well as providing some appropriate postprocedural analgesia. This is particularly important for children. Consideration should be given to the use of appropriate-dose local anaesthesia as local infiltration or field block, where indicated.

Preparation and monitoring

Resuscitation area

EDPS should ideally occur in a resuscitation-capable area of the ED, with two trained physician staff: one to perform the procedure and one to be responsible for the drugs and airway, with the assistance of an ED nurse.[8] Supplemental oxygen should be given for most cases of EDPS, particularly when using propofol. A Hudson mask or similar is usually preferable to nasal cannula as an oxygen-delivery system. Occasionally, when using ketamine for paediatric EDPS, the use of supplemental oxygen by mask may be excessively upsetting for the child prior to commencement of sedation, and it is perfectly acceptable to sedate the child, then apply oxygen. For removal of nasal foreign bodies or facial laceration repair under ketamine sedation, mask or nasal cannula O_2 may be omitted to facilitate access to the nares and midface.

For propofol sedation, a suitably trained and credentialed medical practitioner must be exclusively available to administer sedation to the patient, and the exclusive availability of an assistant (nurse, trainee or junior doctor) to this practitioner is recommended.[116]

Monitoring

Suction, oxygen, airway adjuncts and equipment should be prepared and physiological monitoring applied. Monitoring setup includes pulse oximetry, noninvasive blood pressure, heart rate, electrocardiography ECG rhythm and respiratory rate. End-tidal carbon dioxide monitoring is recommended, if available, and highly desirable in cases of propofol sedation. However, it is not considered mandatory for paediatric ketamine sedation, although if available and suitable for the patient and procedure performed, it should be used.[2,12] IV access is mandatory for all cases, with the exception of sedation using intramuscular or intranasal ketamine, or nitrous oxide sedation. See Table 22.3.2 for essential equipment requirements.

Sedation scoring

Interactive monitoring as verbal and tactile stimulation is used to constantly reassess the depth of sedation. Careful dose titration and subjective evaluation of patient responsiveness throughout the procedure is paramount.[41,49] Ramsay Sedation Score[117] or Wisconsin Sedation Scale[118] may

Table 22.3.2 Essential equipment requirements

S	Suction equipment (connected and checked) • Wall suction • Yankauer suckers and tubing • Paediatric suction catheters
O	Oxygen (connected and checked) • Supply • Age-appropriate masks including nebulizer attachment • Primed bag valve mask
A	Airway • Oro and nasopharyngeal airways • Appropriate selection endotracheal tubes • Stylettes and bougies • Laryngoscope (and video laryngoscope) and selection of blades (tested) • Difficult airway kit including. laryngeal mask airway (LMA)
P	Pharmacological agents (should be accessible but need not be drawn up) • Adrenaline and atropine • Naloxone and flumazenil • Bronchodilators • Medications for rescue rapid sequence induction (RSI)
M	Monitoring equipment • Full noninvasive physiological monitoring in situ • End-tidal CO_2 tubing and transducers (if available)
I	Intravenous access trolley • Crystalloids

Table 22.3.3 Ramsey sedation scale

If Awake	
Ramsey 1	Anxious, agitated, restless
Ramsey 2	Cooperative, oriented, tranquil
Ramsey 3	Responsive to commands only
If Asleep	
Ramsey 4	Brisk response to light glabellar tap or loud auditory stimulus
Ramsey 5	Sluggish response to light glabellar tap or loud auditory stimulus
Ramsey 6	No response to light glabellar tap or loud auditory stimulus

be used. All scales are subject to interobserver variability, are relatively imprecise and are not true objective measures of sedation. However, they require little formal training and are easily used (Tables 22.33 and 22.3.4).

Bispectral EEG analysis

Bispectral (BIS) EEG analysis has been studied but is not reliably predictive of conscious state in individual patients.[74,119,120] Enthusiasm for BIS in EDPS has waned because it has not proven its value over clinical sedation scoring alone.

Table 22.3.4 Wisconsin sedation scale

Level of Consciousness	*Stimulus*	*Score*
Agitated, anxious, in pain	Spontaneous without stimulus	6
Awake and calm	Spontaneous without stimulus	5
Drowsy with eyes open or closed, easily aroused	With mild to moderate verbal stimulus	4
Drowsy, arousable	Moderate tactile or loud verbal	3
Can be aroused to consciousness but slow	Requires sustained painful stimulus	2
Can be aroused but not to consciousness	Requires sustained painful stimulus	1
Unresponsive	No response to painful stimuli	0

Score	*Interpretation of Wisconsin sedation scale*
6	Inadequate sedation
5	Minimal conscious sedation
4	Conscious sedation, moderate
3	Conscious sedation, moderate to deep
2	Conscious sedation, deep
1	Deep sedation
0	Anaesthesia

Box 22.3.3 Discharge instructions

Recommended adult discharge criteria

1. Patient is alert and oriented or has returned to preprocedure state.
2. Patient ambulates safely.
3. Patient is comfortable and has discharge analgesia arranged.
4. Patient is discharged into care of a responsible adult.
5. Avoidance of driving or the like for a minimum of 12 h.
6. Avoid alcohol or other CNS depressants for 12–24 h.
7. Warn patients about potential for pain, unsteadiness or dizziness.

Capnography

Capnography can detect respiratory depression before clinical examination or oximetry.[121–123] Change in trace character or transient hypercapnoea[54,55,124] are the early warning signs of hypoventilation or impending upper airway obstruction, especially important in children or those with reduced functional reserve.[61] Such early detection can avoid further sedation being given and result in stimulating the patient or repositioning the airway. Only occasionally is airway adjuncts or bag valve mask ventilation required.[12,62,66]

Apnoea due to inadvertent deep sedation and detected by capnography is often managed by recommencing the procedure, which usually results in enough arousal to stimulate the patient's own respiratory effort. Positive pressure `ventilation is provided if apnoea persists.

Postprocedure considerations

Patients should be observed until they have returned to their baseline level of functioning.[2,13,17] The exact time will depend on the patient and the drugs administered.[125] No special efforts need be made to darken the room or shield a child from background routine visual and auditory stimuli of the ED after ketamine sedation. Patients receiving propofol do not need prolonged postprocedure monitoring, because resedation following propofol use is rare.[65] Once the patient has awoken from the sedative episode and can talk, nursing staff have an 'end point' for the cessation of physiological monitoring, confident that patients are unlikely to develop any adverse events at this time.[126] While it is a humane gesture to provide a cup of tea to an elderly patient or a drink of juice to a small child, it should not be mandatory that the patient ingest this prior to discharge from ED.[13] Discharge instructions should be provided (Box 22.3.3).

CONTROVERSIES

- Inadequate analgesia provision (oligoanalgesia) still exists in emergency departments (EDs).[127,128]
- Intraprocedural narcotic use is associated with greater pain recall in ED propofol procedural sedation.
- Ultrashort-acting narcotics do not appear to provide adequate postprocedural analgesia for most conditions requiring ED procedural sedation.

- The relationship between practitioner skill set and complications has been described, and credentialing programmes have resulted in reductions in complications and greater procedural success being achieved.[129,130]
- The role of alternative delivery modalities (e.g. patient-controlled sedation or target-controlled infusions) using ketamine or propofol has yet to be elucidated in EDs.
- Randomized controlled trials of novel agents or combinations may present evidence of safer alternatives for certain procedures.

SECTION 23

EMERGENCY IMAGING

Edited by *Biswadev Mitra*

23.1 Emergency department ultrasound

James Rippey • Adrian Goudie

ESSENTIALS

1 Ultrasound examination, interpretation and clinical correlation should be available in a timely manner 24 hours a day for emergency department patients.

2 Emergency physicians providing emergency ultrasound services should possess appropriate training and hands-on experience to perform and interpret limited bedside ultrasound imaging.

3 Ultrasound imaging by emergency physicians is useful for at least the following indications: major trauma, undifferentiated shock, respiratory distress, pain or bleeding in early pregnancy, leg swelling, right upper quadrant pain. Conditions it assesses for include traumatic haemoperitoneum, pneumothorax, pleural fluid, pericardial fluid, abdominal aortic aneurysm, right heart strain, left ventricular systolic dysfunction, hypovolaemia, intrauterine pregnancy, ectopic pregnancy, hydronephrosis, deep vein thrombosis and biliary tract disease. It is also useful to guide difficult vascular access and other invasive procedures.

4 Continued research is required in the area of ultrasound imaging and any other known or evolving bedside imaging techniques and modalities.

5 Emergency medicine training programmes should provide instruction and experience in bedside ultrasound imaging for their trainees.

6 The Australasian College for Emergency Medicine supports the use of bedside ultrasound by emergency physicians, as does the American College of Emergency Physicians, the College of Emergency Medicine in the UK and the International Federation for Emergency Medicine.

Background

Clinical ultrasound followed developments from the use of sonar, where the principle that sound waves could be used to locate objects was developed. Initially, ultrasound machines were large and cumbersome, but advances in technology have improved image quality while reducing machine size, so that today, small machines are able to produce high quality images. As a result of this improved technology, ultrasound is now available to clinicians in prehospital and diverse hospital environments. There was early adoption of the technique by obstetricians and gynaecologists worldwide and later by other specialties in Europe and Japan. Ultrasound is now used by many different specialties in most countries.

Clinician performed ultrasound, now commonly referred to as point-of-care ultrasound (POCUS), has a different approach to comprehensive diagnostic ultrasound, which is performed in radiology departments by specialist sonographers. POCUS is generally limited in scope and is targeted to answering a specific question (such as 'Is there an abdominal aortic aneurysm?'), rather than providing a full assessment of an anatomical area (Box 23.1.1). In this regard, it is often viewed more as an extension of the clinical examination, than a technique that competes with other imaging techniques (including comprehensive ultrasound).

The Australasian College for Emergency Medicine supports the use of bedside ultrasound by emergency physicians,[1] as does the American College of Emergency Physicians, the College of Emergency Medicine in the UK and the International Federation for Emergency Medicine, where it is seen as a core skill required of all trainees. It is expected that with increasing experience, the range of conditions for which ultrasound is used in emergency departments (EDs) will increase.

Basic physics of ultrasound[2]

Sound waves are mechanical waves that transmit energy through the vibration of particles.

Box 23.1.1 Current indications for emergency ultrasound

Trauma (haemoperitoneum, haemopericardium, pneumothorax)
Abdominal aortic aneurysm
Early pregnancy complications
Biliary disease
Renal stones and hydronephrosis

Lung ultrasound in acute dyspnoea
Proximal DVT exclusion
Procedural
Musculoskeletal

DVT, Deep vein thrombosis.

Ultrasound waves are defined as those that are above the usual range of human hearing (20 to 20,000 Hz). Current diagnostic ultrasound machines are based upon the pulse–echo principle, using pulses of sound waves at frequencies of 2 to 15 MHz, which are reflected back. Processing of these reflected echoes creates the ultrasound data and image.

The ultrasound transducer converts electrical impulses into pulses of sound (via the piezoelectric effect), which are then directed into the body. As the sound wave travels through tissue, it gradually loses energy, which is termed 'attenuation'. The degree of attenuation differs for different tissues and is also dependent on the frequency of the pulse wave. Upon reaching a tissue interface, some of the energy is reflected back as an echo, due to the differences in acoustic impedance (gel or other coupling material is used to minimize reflection at the probe/skin surface). This reflected echo then travels back through tissue, undergoing further attenuation, until it reaches the transducer, which converts the energy back to an electrical impulse. This returning impulse is then amplified and processed. The time taken for the pulse wave to travel to the tissue interface and back is converted into distance by using the average speed for sound in tissue. The intensity of the returning wave determines the brightness of the displayed pixel. The returning pulses from the different reflecting surfaces along the path of the ultrasound beam generate a single line of the ultrasound image. The ultrasound beam is steered across the field to generate the multiple lines of information that then form the 2D image (termed B-mode, for brightness modulation). Alternatively, if the direction of the beam is kept constant and the changing surfaces are mapped over time then an M-mode image is generated (M stands for motion).

The degree of attenuation is dependent on the frequency of the sound wave, so higher frequency pulses undergo greater attenuation. They also have shorter wavelengths, which improve the resolution of the ultrasound beam (the ability to distinguish two separate objects close together). This leads to one of the most important trade-offs in ultrasound, between resolution and penetration. To obtain high resolution, a high-frequency probe can be chosen, but these will be unable to image deep structures.

To form the image, the ultrasound machine makes certain assumptions about the ultrasound beam and sound impulse. Deviations from these behaviours will result in image artefacts, that is, when the image does not represent the tissue accurately. There are many artefacts, most of which reduce the information available from the image. However, the most clinically important artefacts also can be used diagnostically:

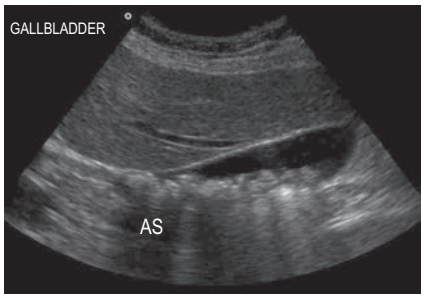

FIG. 23.1.1 Acoustic Shadowing from Gallstones. *AS*, Acoustic shadow.

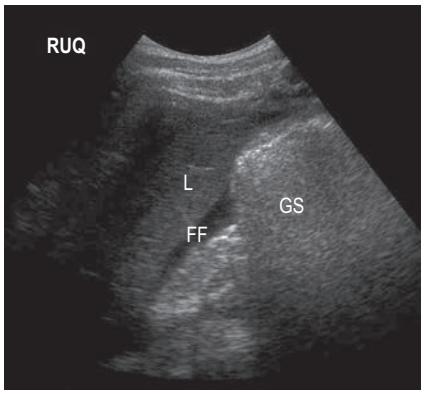

FIG. 23.1.2 Acoustic shadowing from bowel gas in a patient with free fluid. *FF*, Free fluid; *GS*, gas shadow; *L*, liver.

Shadowing: when all of the energy of the ultrasound pulse is reflected or absorbed at a surface (such as air or bone). In this situation, there will be no returning pulses from the tissue distal to the object. This creates a black area on the screen, known as an acoustic shadow. The presence of a shadow behind a brightly reflective surface can thus be used to diagnose a region of calcification, such as a calculus (Fig. 23.1.1). Stones and bones generally give 'clean' or black shadows, while gas gives 'dirty' or grey shadows due to the superposition of both shadow and reverberation artefact (Fig. 23.1.2).

Enhancement: when an area of interest (such as fluid in a cyst) absorbs less energy than the surrounding tissue, the pulses that have travelled through that area will have more energy than equidistant pulses that did not, resulting in a bright region deep to the area of interest on the image (Fig. 23.1.3). Enhancement is used to confirm the fluid-filled nature of lesions.

Transducer

Different ultrasound transducers are available varying in shape, frequency and the size of the contact area (termed footprint). Transducers may have a small footprint to fit into small areas, such as between ribs, from which the beam spreads in a large arc (e.g. a sector transducer). Alternatively, they may be larger with a flat or slightly curved surface where contact can be maintained, such as a linear probe. Special transducers have been designed for use within body cavities, such as transoesophageal, endovaginal and endo-anal probes. These transducers offer the advantage of reduced distance between the transducer and area of interest, which allows higher frequencies to be used resulting in improved resolution. Very high frequency transducers have been used for intravascular and superficial ocular scanning. Appropriate choice of transducer is important in ensuring the optimal image is obtained.

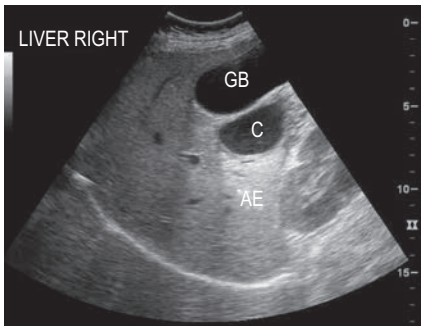

FIG. 23.1.3 Acoustic Enhancement from Fluid-filled Structures. Acoustic enhancement is seen where the ultrasound beam passes through the gallbladder and more prominently where it passes through the gallbladder and pancreatic pseudocyst. *AE*, Acoustic enhancement; *C*, pancreatic pseudocyst; *GB*, gallbladder.

The scope of emergency department ultrasound

Extended focused assessment with sonography for trauma[3–6]

Descriptions of the use of ultrasound by clinicians to evaluate trauma patients appeared in the European literature in the 1970s. Reports have subsequently appeared from countries around the world and the technique is now well established. Initially limited to the abdomen and pericardium (focused assessment with sonography for trauma [FAST]), the examination is now routinely extended to include the chest (extended focused assessment with sonography for trauma [EFAST]). With relatively brief training and experience, non-radiologists are able to diagnose haemoperitoneum, pericardial effusions, pleural effusions and pneumothorax with a high degree of sensitivity and specificity, although accuracy does improve with experience.

Clinical examination in abdominal trauma can be difficult and unreliable. Diagnostic peritoneal lavage (DPL), ultrasound (FAST) and computed tomography (CT) have been used to further evaluate this group of patients. In most cases, FAST has replaced diagnostic peritoneal lavage

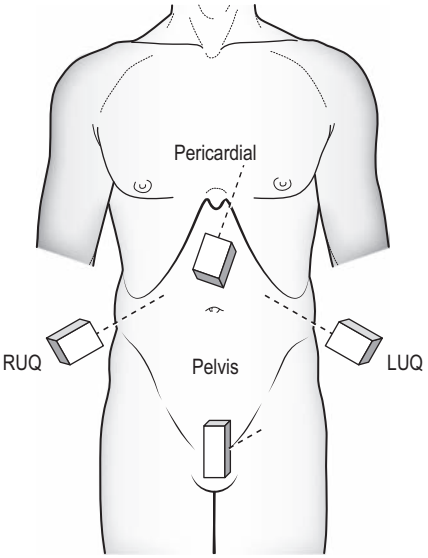

FIG. 23.1.4 Transducer placement for the four views for FAST scanning. *LUQ*, Left upper quadrant; *RUQ*, right upper quadrant.

as it is non-invasive and does not interfere with subsequent interpretation of CT images. CT scanning is highly accurate for diagnosing free fluid, solid organ injury and bony injury, and is slightly less accurate for hollow viscus and diaphragmatic injury.

Studies of ultrasound scanning in trauma have reported varying sensitivity. Much of this variation is due to differences in the gold standard used for the comparison and definition of 'true positive'. Haemoperitoneum (on further imaging, surgical or post-mortem examination), organ injury and clinical stability have all been used in different studies. It must be remembered that the primary role of a FAST scan is to detect free fluid in the peritoneal or pericardial spaces, for which it has high sensitivity and specificity. Solid organ or retroperitoneal haemorrhage may be detected but, even in expert hands, the accuracy is much lower (with as many as two-thirds of injuries being missed). FAST has been shown to be reliable and useful in both pregnant and paediatric patients.

Technique

FAST scanning evaluates four regions for the presence of free fluid: (1) pericardial, (2) perihepatic, (3) perisplenic and (4) pelvic (Fig. 23.1.4). The scan is then extended to the chest (EFAST) where the pleural spaces are examined posterolaterally for fluid, and anteriorly to exclude pneumothorax. The technique is rapid, generally being completed in under 5 minutes.

Free fluid appears as an echolucent area (i.e. black), which is generally linear or triangular in shape in the most dependent area of the peritoneal or pericardial space, although blood clots

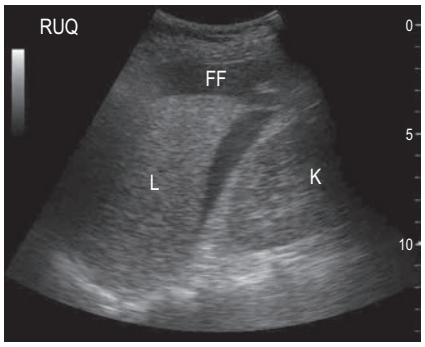

FIG. 23.1.5 Free fluid in the perihepatic view; fluid lies in the Morrison pouch between liver and right kidney. *FF*, Free fluid; *K*, kidney; *L*, liver.

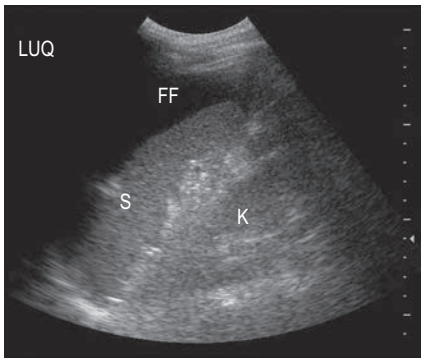

FIG. 23.1.6 Free fluid in the perisplenic view; fluid may lie anywhere around the spleen; in this case, it lies interposed between spleen and diaphragm. *FF*, Free fluid; *K*, kidney; *S*, spleen.

may be seen as echogenic (grey) collections (Figs. 23.1.5 to 23.1.7). While fluid is most commonly seen in the perihepatic space, all spaces should be examined before the result can be considered negative. Small amounts of fluid (<500 mL) may not to be detected.

When scanning the chest, the presence of lung sliding or lung pulse is an indication that the visceral and parietal pleura are in contact, excluding a pneumothorax at that point. The presence of a moving transition point between areas of lung sliding and absent lung sliding (the 'lung point' sign) is diagnostic of pneumothorax.

Limitations and pitfalls

- User dependent with learning curve.
- Inadequate views occur in up to 10%, especially if the bladder is empty or with subcutaneous emphysema.
- Cannot distinguish between blood and other forms of intra-abdominal or pericardial fluid, such as ascites or pericardial effusion.
- Retroperitoneal haemorrhage may be missed.
- Solid organ, hollow viscus or diaphragmatic injuries can occur without free fluid.

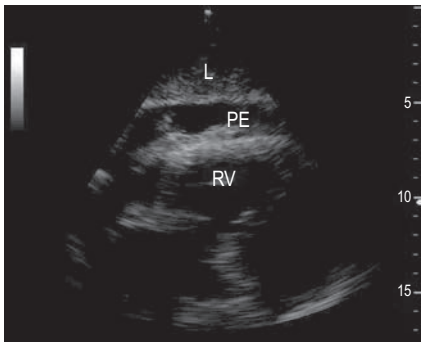

FIG. 23.1.7 **Pericardial Effusion With Clot.** *L*, Liver; *PE*, pericardial effusion with grey blood clots and black (echo free) blood; *RV*, right ventricle.

- Small amounts of free fluid may not be detected.
- Small amounts of pelvic fluid may be physiological in women.
- Fluid-filled bowel can be misinterpreted as free fluid.
- Pericardial fluid may decompress into the pleural cavity.
- Loss of lung sliding may be due to causes other than pneumothorax.

Clinical implications and utility

The limitations of ultrasound in excluding all intra-abdominal injuries requiring laparotomy and the increasing use of conservative management of some injuries, even in the setting of intra-abdominal free fluid, has resulted in there being no universally accepted clinical algorithm based upon EFAST scan results. However, in this regard, EFAST scanning is no different to any other clinical, laboratory or imaging information of the trauma patient, the results of which are routinely used in combination to determine the management plan. Various algorithms incorporating EFAST scanning have been proposed, which generally incorporate haemodynamic stability and EFAST scan result, such as in Fig. 23.1.8. Some algorithms incorporate a semiquantitative scoring system to estimate the amount of free fluid, with an increased volume of free fluid associated with a greater need for therapeutic laparotomy. A positive abdominal EFAST scan is highly predictive of significant intra-abdominal injury and, based upon the clinical condition of the patient, generally indicates the need for CT or surgical exploration. A negative EFAST scan, stable haemodynamics and clinical observation have been shown to be highly accurate in excluding significant intra-abdominal injury. Some authors advocate serial EFAST examinations in stable patients, suggesting this can reduce the requirement for CT.

Similarly, for pneumothorax, the integration of EFAST findings with other clinical, laboratory

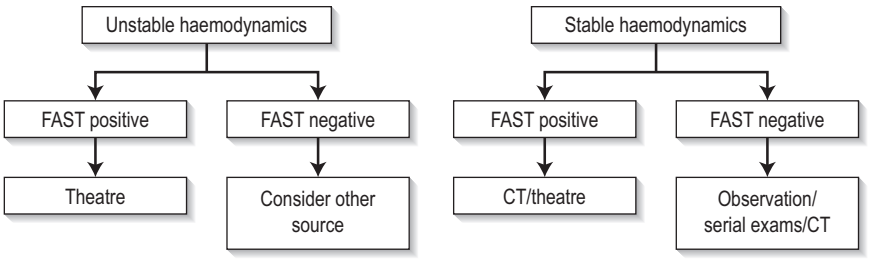

FIG. 23.1.8 Suggested Algorithm Using FAST Results. *CT*, Computed tomography.

and imaging findings will determine patient management. Conservative management of small pneumothoraces, even in the setting of positive pressure ventilation means that the ultrasound findings must be considered in the setting of the individual patient when management decisions are made.

In the Australasian setting, EFAST is generally accepted as fulfilling a complementary role to CT. Its portability and speed allow it to be used early in the evaluation of trauma patients (e.g. immediately after the primary survey) and this information is then incorporated with other clinical information to risk stratify the trauma patient to help to determine the requirement and timing for either laparotomy, thoracotomy or CT. Repeated examinations, particularly if the patient's condition changes, can be valuable. Providing the limitations of the technique are not ignored, it can rapidly provide vital information to assist with patient management.

Abdominal aortic aneurysm[7,8]

Abdominal aortic aneurysm (AAA), defined as pathological dilation of the aorta with a diameter >1.5 times the expected anteroposterior diameter of that segment; however, the most commonly adopted threshold is a diameter of 3 cm or more, which occurs in 1% to 9% of the population. Clinical assessment of the abdominal aorta is unreliable and may be especially difficult in the obese or unstable patient with abdominal pain. Clinical presentation of ruptured abdominal aortic aneurysm can be varied, with only 50% of patients demonstrating the classic presentation of hypotension, back pain and pulsatile mass. Other presentations may include abdominal, groin or flank pain, unexplained hypotension, syncope, haematuria or cardiac failure and AAA should be considered in any of these presentations.

Ultrasound is the primary mode of investigation of the abdominal aorta. Ultrasound performed by emergency clinicians has been shown to be rapid, highly sensitive and highly specific (>95%) in assessing aortic diameter. Ultrasound may occasionally detect rupture, but it is not reliable in excluding rupture. In addition to its utility in diagnosing AAA, ED ultrasound is very beneficial in rapidly excluding AAA in the wide variety of presentations listed above.

The risk of rupture of an AAA increases with the diameter. Although the risk of rupture if the aneurysm diameter is less than 4 cm is <0.5% per year and 1.5% per year for aneurysms 4.0 to 4.9 cm, rupture can still occur. Approximately 10% of ruptured aneurysms measure 5 cm or less.

Technique

The aorta should be identified anterior to the vertebral body and to the left of the inferior vena cava (IVC). It should be followed from the epigastric region to its bifurcation, just above the umbilicus, remembering that, in elderly patients, it may follow an ectactic course rather than following a strictly cranial–caudal course. It must be distinguished from both the superior mesenteric artery (SMA) (which runs anterior to the aorta) and the IVC (ensuring that the venous pulsation of the IVC is not mistaken for the arterial pulse of the aorta). Measurements should be taken both proximally and distally and, if an aneurysm is present, at the widest point. Measurements from both transverse and longitudinal planes should be taken. Measurements are taken from the outer wall to outer wall, including any mural thrombus (Fig. 23.1.9). If the renal arteries or SMA origin are identifiable then the relation to the aneurysm should be noted although, in the ED setting, this may not be possible. Any retroperitoneal haematoma or peritoneal free fluid should be noted.

Limitations and pitfalls

- Pain, obesity or bowel gas may prevent adequate imaging by ultrasound.
- Mistaking the IVC or SMA for the aorta.
- Measuring the lumen without including mural thrombus.
- Attempting to exclude rupture on ultrasound.
- Forgetting that the AAA may be an incidental finding and not the primary cause of the patient's symptoms.

Clinical implications and utility

In the patient with ruptured AAA who is haemodynamically unstable, ED ultrasound allows rapid and accurate diagnosis within the resuscitation area. Rapid diagnosis of these patients is essential to achieve successful treatment. In the stable patient, whose presentation may be atypical, ED ultrasound provides a rapid means of excluding the diagnosis (e.g. in the elderly patient who presents with 'renal colic'). If an AAA is detected in these patients, then further imaging will often be required to determine if the AAA is an incidental finding or the cause of the patient's symptoms. If the AAA is an incidental finding then formal follow-up should be arranged.

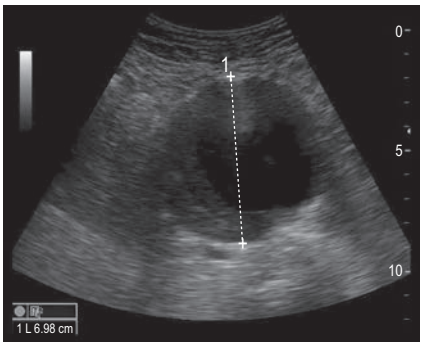

FIG. 23.1.9 Abdominal Aortic Aneurysm.

Early pregnancy[9,10]

Ultrasound is the primary imaging modality for early pregnancy and its complications.[11] In the ED setting, it is most commonly used for the pregnant patient with pain or bleeding. In addition to transabdominal scanning (TAS), transvaginal scanning (TVS) can be performed with patient consent using a specifically designed probe, which places the transducer close to the pelvic organs and utilizes higher frequencies to produce images of much greater detail than TAS. It does not require a full bladder and should not be a painful procedure. TAS still has an important role, as it allows a broader field of view that allows better assessment of large amounts of free intraperitoneal fluid and may diagnose other causes of pain. Emergency-physician-performed ultrasound for early pregnancy complications has been shown to be safe and to reduce the time patients spend in EDs.

Technique

TAS is performed initially, preferably when the patient has a full bladder, as the pelvic organs will be better visualized. The uterus is identified and examined in both longitudinal and transverse planes (recognizing that the longitudinal axis of the uterus may not necessarily be in a strictly sagittal plane). The endometrial thickness is noted and any fluid collections or gestational sac noted. The adnexa are examined to identify the ovaries and any masses. The pelvis is scanned for

free fluid. The upper abdomen can be examined to estimate the volume of free fluid if seen. The kidneys also can be examined to identify any alternate diagnoses.

TVS is performed after the procedure is explained and consent is obtained. A chaperone should be present if the sonographer is male. The patient is asked to empty their bladder and the pelvis is elevated slightly off the bed using a foam wedge or similar. The probe is covered with a sterile sheath (e.g. condom) with gel placed inside and outside the sheath. The probe is gently inserted into the vagina and advanced. The uterus and adnexa are then examined in both longitudinal and transverse planes as in TAS. After the scan is complete the probe must be cleaned and disinfected.

Limitations and pitfalls

- Confusing a corpus luteum cyst and ectopic pregnancy.
- Misinterpreting a pseudogestational sac for a gestational sac.
- Not considering heterotopic pregnancy in patients receiving fertility treatment.
- Failure to arrange follow-up if an intrauterine pregnancy is not identified, even if an ectopic pregnancy is not seen.
- Failure to recognize an eccentric or low gestational sac could be an interstitial, cervical or scar ectopic.
- Assuming an empty uterus in a patient with positive β-human chorionic gonadotrophin (β-HCG) is a complete miscarriage.

Clinical implications and utility

The primary aim of ultrasound in evaluating early pregnancy complications in the ED is to locate the gestational sac. Additional information should then be sought for the presence of free fluid, adnexal masses, embryonic size and embryonic cardiac activity (viability). The earliest ultrasound evidence of pregnancy is a small anechoic fluid collection surrounded by an echogenic ring, which can be seen on TVS at approximately 4.5 weeks. However, a pseudogestational sac (due to fluid within the endometrial cavity) can have very similar appearances. Definite signs that the sac is a true gestational sac appear at 5.5 weeks when the yolk sac can be visualized, or later when the embryo can be identified. A heartbeat may be visualized from 6 weeks onward. TAS will show the same features but 1 to 2 weeks later.

Pregnancies that are not identified by ultrasound are termed 'pregnancy of unknown location'. Most will either fail (miscarry or resolve spontaneously) or progress to normal pregnancy. However, 9% to 43% will eventually be identified as ectopic pregnancies (lower rates are seen in centres with more expert scanning ability as they have higher rates of definitively diagnosing ectopic pregnancy). Quantitative HCG levels have been used to determine when a gestational sac should be identifiable by ultrasound, termed the 'discriminatory zone'. For TVS, this is usually 1500 IU and for TAS 4500 IU (varying between institutions and depending on expertise and equipment). Even though a normal pregnancy may not be expected to be seen in patients with β-HCG levels below these levels, ultrasound should still be performed as it may still show diagnostic findings. In particular, ectopic pregnancies often have lower β-HCG levels than normal pregnancies of corresponding gestation and may be seen, as can the presence or absence of free fluid, which is valuable for risk stratification.

All patients with pregnancy of unknown location require close follow-up with serial β-HCG and repeat ultrasound.

If an intrauterine pregnancy is confirmed, the risk of ectopic pregnancy is very low in spontaneously conceived pregnancies. Heterotopic pregnancy is where both an intrauterine and extrauterine pregnancy coexist and occurs in up to 1:7000 pregnancies in spontaneously conceived pregnancies, but over 1:100 pregnancies in the setting of fertility treatment.

Failure to visualize an intrauterine pregnancy may be due to early dates in a normal pregnancy, failed intrauterine pregnancy (including complete miscarriage) or ectopic pregnancy. Other ultrasound findings in ectopic pregnancy include non-specific findings, such as pelvic blood and adnexal mass (Table 23.1.1).[12] Visualization of a gestational sac (with yolk sac or embryo) outside the uterus is diagnostic, but seen only in 8% to 26% of ectopic pregnancies (Fig. 23.1.10).

Unusual forms of ectopic pregnancy include interstitial, cervical and scar ectopics. In these cases, a gestational sac may be seen, but not within the true uterine cavity. It is recommended that pregnancies that appear low or eccentric should be reviewed by expert sonographers.

Distinguishing between miscarriage and ectopic pregnancy when no adnexal mass has been identified can be difficult on ultrasound. However, if the clinical symptoms have settled, no free fluid is identified on ultrasound and no adnexal masses have been identified, then it is safe to observe or discharge the patient for formal ultrasound review the following day and subsequent follow-up with repeat ultrasound and quantitative β-HCG (see Chapter 19.4).

If an intrauterine pregnancy is confirmed, the gestational age can be estimated by measuring the size of the embryo. Most machines will automatically calculate gestational age based upon this measurement. Cardiac activity can usually be identified by TVS once the embryo is approximately 5 mm (9 mm by TAS). Absent cardiac activity when the embryo is 7 mm or above suggests embryonic demise. Absent yolk sac or embryo on TVS when the gestational sac is 25 mm suggests an empty sac miscarriage (also referred to as a blighted ovum).[13] Other sonographic signs of poor prognosis for continued pregnancy exist, but they are generally beyond the scope of emergency ultrasound.

Table 23.1.1 Ultrasound findings of ectopic pregnancy

Ultrasound finding	Accuracy (%)
Absent IUP	5
Any free fluid (no IUP)	50
Mod–large free fluid (no IUP)	60–85
Adnexal mass (no IUP)	95
Adnexal mass + free fluid (no IUP)	97
Ectopic pregnancy seen	100

IUP, Intrauterine pregnancy.

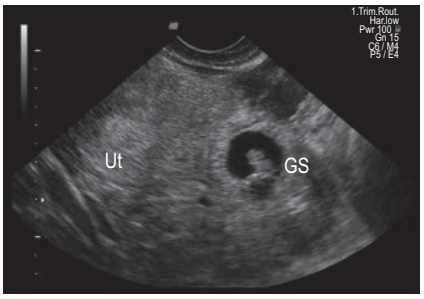

FIG. 23.1.10 Ectopic Pregnancy. A gestational sac *(GS)* containing an embryonic pole is seen outside the uterus *(Ut)*.

Right upper quadrant/gallbladder[14]

Upper abdominal pain due to biliary disease is a common presenting complaint to EDs and includes biliary colic, choledocholithiasis, cholecystitis and ascending cholangitis. Many of the patients suspected of having acute cholecystitis will have alternate diseases, and clinical examination is neither sufficiently sensitive nor specific for these patients. Ultrasound is the primary imaging modality for these patients, where it is used to detect the presence of gallstones (see Fig. 23.1.1), other sonographic signs of cholecystitis and bile duct obstruction. It is superior to both scintigraphy and CT for these patients.

Ultrasound has a high sensitivity and specificity for the identification of stones when performed by either radiology or ED staff. However, some stones may be missed and false-positive results also occur. The diagnosis of cholecystitis relies upon associated findings including sonographic Murphy sign, gallbladder (GB) wall thickening, GB distension and pericholecystic

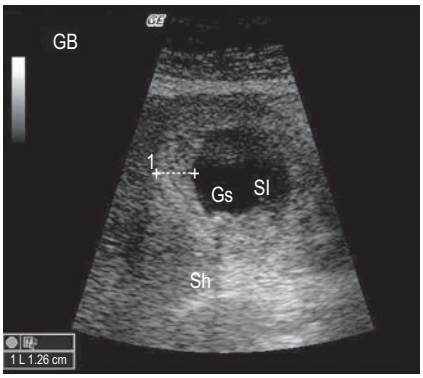

FIG. 23.1.11 Acute Cholecystitis. Transverse image of a gallbladder with thickened wall and pericholecystic fluid. Within the lumen are sludge *(Sl)* and multiple gallstones *(Gs)* which cast shadows *(Sh). Gb,* Gallbladder.

fluid (Fig. 23.1.11). GB wall thickening and pericholecystic fluid are both non-specific findings and may be seen in other hepatic or generalized diseases as well as in acalculous cholecystitis. Fasting can cause GB distension. The common bile duct, if visualized, should be measured and examined for stones, although this is technically more difficult and may be beyond the scope of a focused GB examination.

Technique

The GB is usually identified by scanning under the costal margin in a longitudinal plane. Positioning the patient in the left lateral decubitus position and/or deep inspiration may assist. The GB should be scanned throughout its length in both longitudinal and transverse planes. The sonographic Murphy sign is assessed by pressing with the ultrasound probe over the GB. Wall thickness should be measured and is normally less than 3 mm. Gallstones will appear as bright, echogenic masses with posterior acoustic shadowing. Stones tend to be mobile unless impacted in the GB neck or cystic duct. Stones impacted in these positions are technically more difficult to detect and may be missed if not painstakingly searched for. Sludge and polyps also appear echogenic but will not shadow. Whenever possible, the common bile duct (CBD) should be visualized, measured and followed; when dilated, distal CBD obstruction should be considered.

Limitations and pitfalls

- Incorrectly assuming the presence of gallstones explains the patient's symptoms, when they may be an incidental finding.
- Mistaking gas in the duodenum for gallstones in the GB.
- Mistaking a GB that is contracted and/or full of stones for a gas- and food-filled duodenum.
- Symptomatic stones impacted in the GB neck or cystic duct are easily missed.
- Small stones (<3 mm) may not cast shadows.
- Misinterpreting sludge or polyps as stones.
- Misinterpreting other causes of GB wall thickening as cholecystitis.

Clinical implications and utility

In a patient with abdominal pain, the finding of gallstones with a positive sonographic Murphy sign is strongly predictive of cholecystitis. The more sonographic signs of cholecystitis that are seen, the more likely the diagnosis. However, asymptomatic gallstones are common and may therefore represent an incidental finding, especially if the sonographic Murphy sign is absent. In elderly, diabetic or critically ill patients, 5% to 10% of cholecystitis can be acalculous. In those patients thought to have biliary colic or cholecystitis, a negative ultrasound should prompt a search for alternative diagnoses or consideration of further imaging, either formal ultrasound or, if an alternate diagnosis is believed likely, CT.

Renal ultrasound

The primary focus of renal ultrasound in the emergency setting is the detection of hydronephrosis in the presence of acute renal failure or renal colic.[15] As experience increases, users can often detect renal calculi, particularly when located at the vesicoureteric junction. The presence of a ureteric jet excludes complete ureteric obstruction on that side.

Technique

The kidneys are paired retroperitoneal organs lying on either side of the spine between T12 and L4. They have a convex lateral border and a concave medial border and hilum. The normal adult kidney is 9 to 12 cm in length, 2.5 to 4 cm thick and 4 to 6 cm wide. The kidney itself is composed of two distinct areas, the renal parenchyma and the renal sinus.

The adult kidney is scanned using a curvilinear 3.5 to 5 MHz transducer and a renal preset that provides the best contrast resolution and grey map for imaging the kidneys. The patient may be supine, although the kidneys are usually best seen with the patient in a lateral decubitus position. A combination of subcostal and intercostal approaches is often necessary. The kidneys should be imaged in at least two planes, including the sagittal or coronal plane and the transverse plane (Figs 23.1.12 and 23.1.13). On ultrasound, the kidney can be identified by its elliptical shape with a thin echogenic capsule. Normal renal parenchyma has slightly decreased or equal echogenicity relative to the hepatic or

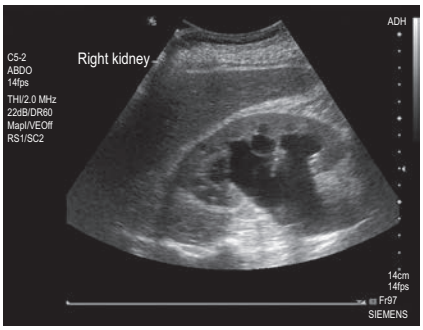

FIG. 23.1.12 Sagittal image of right kidney demonstrating moderate hydronephrosis.

FIG. 23.1.13 Coronal image of left kidney demonstrating a calculus in the renal pelvis with acoustic shadowing.

splenic parenchyma, although this is age dependent with it being comparatively hyperechoic in the elderly. The central renal sinus is particularly echobright due to the fat and fibrous tissue content. The renal pelvis and infundibulum are usually collapsed and not seen except in the setting of hydronephrosis when they become filled with urine, appearing anechoic. The bladder should be full and examined in both the sagittal and transverse planes to complete the study. It should be noted that an excessively full bladder may cause mild dilatation of the pelvicalyceal system; however, this will return to normal following micturition.

Ureteric jets occur when either ureter contracts propelling urine into the bladder. This occurs every 10 to 20 seconds in the euvolaemic patient with normal renal function and excludes complete obstruction on that side. However, the presence of a jet does not exclude the possibility of a non-obstructive renal or ureteric calculus.

Hydronephrosis is the dilatation of the renal pelvis and calyces and may be secondary to an anatomical obstruction or may be functional in nature (such as with ureteric reflux). Obstructive hydronephrosis may be intrinsic or extrinsic. Depending on the level of obstruction, it may be unilateral or bilateral with or without associated hydroureter. When hydronephrosis is identified, the cause for the obstruction should be sought.

Common intrinsic obstructive causes seen in the ED include obstructive or partially obstructive renal or ureteric calculi. Bladder outlet obstruction due to prostatic hypertrophy is another common cause of hydronephrosis. Extrinsic or invasive masses in the pelvis obstructing either the ureters or bladder outflow also should be considered.

Hydronephrosis may be described as mild, moderate or severe depending on the extent of dilatation of the renal collecting system:

- *mild*: dilatation of renal pelvis; may have some calyceal filling; however, the calyces remain cupped
- *moderate*: increasing dilatation extending into the pelvicalyceal system with distension and blunting of the calyces, but with preservation of cortical thickness
- *severe*: marked pelvicalyceal dilation with clubbed calyces and associated parenchymal cortical thinning.

Limitations and pitfalls

- Assuming hydronephrosis and obstruction are synonymous.
- Hydronephrosis takes time to develop and more so in the dehydrated patient.
- Hydronephrosis can persist transiently after obstruction is relieved.
- Mistaking an extrarenal pelvis for hydronephrosis.
- Mistaking parapelvic renal cysts for hydronephrosis.

Clinical implications and utility

Ultrasound is less sensitive than plain films or CT in detecting renal calculi. Small stones may often be obscured by the echogenic renal sinus and be hard to detect if they have a weak posterior acoustic shadow. Having said this, stones in the kidney that are greater than 5 mm in size have been shown to be detected in experienced hands with 100% sensitivity sonographically.[16] Renal stones appear as bright, echogenic foci with distal acoustic shadowing and sometimes twinkle artefact when interrogated with colour Doppler. Ureteric calculi are difficult to visualize as they are often obscured by bowel gas in their retroperitoneal position. Therefore a normal appearing kidney and the failure to visualize a calculus does not exclude a ureteric calculus that is non-obstructing or where hydronephrosis has not yet developed.

Deep vein thrombosis

The primary focus of ED ultrasound in the assessment of deep vein thrombosis (DVT) is in the diagnosis or exclusion of a proximal lower limb DVT.

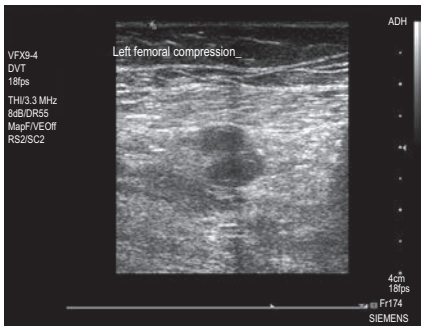

FIG. 23.1.14 Transverse image of the left femoral vein and artery with incomplete collapse of the femoral vein with compression, indicating intraluminal thrombus.

The clinical assessment of DVT is unreliable and inaccurate.[17,18] Positive findings on sonographic examination of only 11% have been reported for patients referred for suspected acute DVT on the basis of clinical features.[19]

Technique

Ultrasound is the imaging modality of choice for assessing for DVT. The technique relies primarily on B-mode imaging with intermittent venous compression, with the main diagnostic criteria used to exclude a DVT being complete collapse of the vein with apposition of the anterior and posterior walls of the vessel.

A broadband linear array transducer with a centre frequency of about 5 MHz is used to examine the femoral, popliteal and sometimes the calf veins. In larger patients, the curved linear array transducer with a centre frequency of 3.5 MHz (as used for abdominal studies) may be substituted. The curved linear array transducer is also used to examine the iliac veins. The machine should be configured to use the lower limb venous preset and the use of harmonic imaging may improve the contrast resolution between the vessel and the surrounding tissue. Transducer compression of the interrogated vessel should be in the transverse imaging plane. Starting at the level of the groin, with the patient in a supine position, the common femoral vein is identified lying medial to the common femoral artery and the vein is compressed to demonstrate collapsibility extending distally in a stepwise fashion with the vein compressed every 2 to 3 cm (Fig. 23.1.14). Where thrombus is present in the vein, pressure with the transducer will not result in its collapse. The popliteal vein may be best examined with the patient in a lateral or prone position with the knee slightly flexed. Colour and spectral Doppler may be used to supplement the findings of intermittent compression. Emergency physicians who had undergone standardized training to identify clot in the femoral or popliteal veins have shown an accuracy comparable to formal vascular studies.[20]

Limitations and pitfalls

- Mistaking the saphenous vein for the femoral vein.
- Not recognizing that the incorrectly termed 'superficial' femoral vein is a deep vein (it is correctly referred to as the 'femoral vein').
- Sensitivity of ultrasound for calf DVT detection is much lower than proximal DVT.
- Not recognizing a duplicated femoral or popliteal vein, with one patent and one thrombosed.
- Misdiagnosing chronic clot for fresh clot.
- Not ensuring that initial ED exclusion of proximal DVT is followed up by a formal repeat scan in 7 days if high clinical suspicion or positive D-dimer.

Clinical implications and utility

The accuracy of compression ultrasonography is highest in symptomatic patients, with studies comparing venography with compression ultrasound demonstrating an average sensitivity of 95% and specificity of 98%.[21] For proximal lower limb DVT, this technique has demonstrated sensitivity of up to 100%.[22] The use of colour and spectral Doppler to assess for vessel filling defects and flow patterns has not been shown to increase significantly the sensitivity for proximal DVT detection in the lower limb.[22–25] It has also been suggested that an abbreviated technique, using only two compression points (the saphenofemoral junction and the lower popliteal vein) has adequate sensitivity, provided repeat examination is performed in 5 to 7 days.[24,26,27] The accuracy of ultrasound in detecting isolated calf DVT, especially when applied to emergency POCUS ultrasound, is low with success rates as low as 40% reported.[28]

Thus the aim of focused ED ultrasound in the assessment of DVT is generally to confirm or exclude the presence of clot in the proximal deep veins of the lower limb. A negative compression ultrasound study of the proximal lower limb significantly reduces the likelihood of DVT and discharge from the ED without anticoagulation, with outpatient follow-up for a definitive study can be considered.[21,29–31]

Emergency echocardiography

Focused use of echocardiography in the ED represents one of the most valuable uses of ultrasound in emergency medicine. Applications include its use in cardiac arrest, undifferentiated hypotension, suspected pericardial effusion and tamponade, chest pain, pulmonary embolus

and ultrasound guided procedures. The use of cardiac ultrasound in emergency medicine is likely to increase significantly as more emergency physicians learn the technique and look to apply it increasingly in the clinical environment.

Echocardiography provides direct structural and functional information on cardiac structures only inferred by clinical examination, which has been shown to have limited accuracy, and with greater sensitivity and specificity than indirect tests, such as electrocardiography and chest radiography.[32–34]

Technique

Modern general ultrasound machines can provide good quality transthoracic echocardiography capability. A broadband phased array transducer with a centre frequency of 2 MHz and a small footprint to improve access between the ribs should be used. Ideally, the patient should be positioned on their left side.

The full, standard echocardiographic examination includes parasternal long and short axis views obtained at the left sternal edge in the 2nd to 4th rib spaces, the apical 4-, 5-, 3- and 2-chamber views that are obtained at the cardiac apex and the subcostal views obtained from a subxiphoid position. The standard examination would involve 2-D assessment of cardiac structure and function using B-mode, supplemented by the use of colour and spectral Doppler to assess valvular function and measure chamber pressures using the windows described above.

Where an abbreviated, emergency bedside echocardiographic examination is being used to screen for the presence of tamponade, right ventricular (RV) dysfunction, left ventricular (LV) dysfunction (including absence of contraction) and hypovolaemia alone, simply using B-mode and attaining the parasternal short and long axis views, the apical 4-chamber view and the subcostal view is generally enough.

In cardiac arrest, the subcostal view is used with the patient in the supine position. All preparations are made including charging the defibrillator while cardiopulmonary resuscitation (CPR) continues. During the rhythm check, a loop is recorded and reviewed once CPR recommences. It is imperative that the time without CPR is minimized and echocardiography should not interfere with this.

Emergency physicians have been shown to assess accurately LV function in the hypotensive patient.[35]

Limitations and pitfalls

- Good views may not be obtainable in a supine patient, especially if ventilated.
- Not appreciating the limitations of focused and abbreviated emergency echocardiographic studies when compared to formal detailed echocardiographic studies.
- Focused echocardiographic examination aims to detect for tamponade, RV dysfunction, LV dysfunction and hypovolaemia. It does not assess for diastolic dysfunction, regional wall motion abnormality, valvular dysfunction or aortic dissection, the detection of which generally take significantly more experience.
- Confusing pleural and pericardial effusions.
- Confusing pericardial fat pad and pericardial effusion.
- Not appreciating the fluid causing tamponade is not always anechoic, particularly when exudative, purulent or haemorrhagic.
- Not appreciating that a loculated clot or effusion may cause tamponade but not be seen, particularly in the postoperative patient.
- Not appreciating a normal echo does not exclude pulmonary embolism (PE).
- Not understanding that there is difficulty distinguishing between acute pulmonary hypertension from PE and chronic pulmonary hypertension.
- Not appreciating that while a large, round IVC with no respiratory variation infers elevated right-sided pressures, it does not mean administration of intravenous fluid will be futile. In tamponade and RV infarction, for example, additional preload despite a 'full' IVC is often useful.

Clinical indications and utility

In cardiac arrest, the aim of echocardiography is to assess LV activity as well as to exclude the presence of potentially reversible causes, particularly tamponade. In the setting of cardiac arrest, cardiac standstill on initial presenting echocardiographic assessment has important prognostic implications, irrespective of presenting electrical rhythm. Gaspari et al., in a multicentre observational study, demonstrated that the absence of cardiac activity is a very poor, but not absolute, prognostic sign, with only 0.6% of these patients surviving to discharge.[36] As is always the case, the user must integrate ultrasound findings into the clinical picture to make a final clinical decision. Cardiac standstill in the newly collapsed patient, the hypothermic patient, the young patient or the toxicological overdose should not be used as the sole criterion to cease resuscitative efforts.

Echocardiography is very useful in determining the cause of undifferentiated hypotension and shock. The primary aim of focused emergency echocardiography in this setting is to assess for tamponade, for RV dysfunction (that in the correct clinical setting would infer massive PE), for LV systolic dysfunction and for hypovolaemia. With increased echocardiographic expertise severe valvular dysfunction also can be rapidly detected.

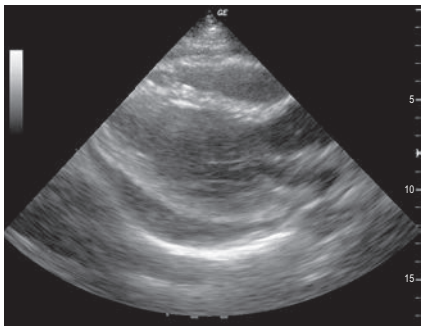

FIG. 23.1.15 Parasternal long-axis view of the heart demonstrating a moderately-sized pericardial effusion.

A pericardial effusion is seen as an anechoic collection of fluid between the visceral and parietal pericardium (Fig. 23.1.15), although an inflammatory pericardial effusion or haemopericardium may exhibit internal echoes. In differentiating between a pericardial effusion and a pleural effusion, a pericardial effusion tapers towards and anterior to the descending aorta and may extend a short distance between the aorta and left atrium; conversely, a pleural effusion will accumulate and extend behind the descending aorta, which is best seen in the parasternal long axis view. When a pericardial effusion is identified, its location and size should be documented and any evidence of tamponade looked for. The size of an effusion can be described as small, moderate or large. A small effusion is ≤1 cm in thickness and may be localized. A moderately sized effusion is between 1 and 2 cm and is generally circumferential unless loculated. A large effusion is described as being >2 cm. In a group of 515 patients at high risk for pericardial effusions (103 of whom had pericardial effusions), emergency physicians were able to detect an effusion with an overall sensitivity of 96%, specificity of 98% and accuracy of 97%.[37]

The risk of tamponade is more a function of the rate of accumulation than total volume of pericardial effusion. There are a number of different echocardiographic features used to define tamponade; however, its precise echocardiographic diagnosis remains complex and controversial. The most frequently used echocardiographic finding to support a diagnosis of tamponade is collapse of the right heart chambers during mid-to-late diastole and, specifically, RV diastolic collapse. In the ED setting, pericardial tamponade should remain a clinical diagnosis. In a patient with signs and symptoms consistent with tamponade, the focus of emergency echocardiography is the identification of pericardial effusion. Its presence is then interpreted and acted upon in the clinical context.

Transthoracic echocardiography lacks sensitivity for diagnosing PE. Echocardiography missed

16 of 39 patients presenting to an ED with PE, diagnosed by other modalities in a prospective observational study.[38] However, there are echocardiographic features associated with PE that, when identified and put into clinical context, can be highly suggestive or diagnostic. These include RV dysfunction or dilatation, McConnell sign (mid and basal RV akinesia with preservation of RV apical function), paradoxical septal motion, acute tricuspid regurgitation and the presence of clot in the right heart. While echocardiography may be a poor tool for diagnosing PE, it may be useful in assessing RV dysfunction caused by PE and may have a role in risk stratifying patients and influencing the decision to use thrombolytic therapy. RV dysfunction is associated with a significantly higher mortality.[39] Massive PE with associated hypotension, or when clot is seen in transit through the right heart, is generally managed with thrombolysis or less commonly embolectomy or various interventional radiological therapies. Specific criteria for the use of these aggressive strategies to treat submassive PE remains controversial, but current recommendations are for simple heparinisation and close observation, with invasive intervention only if hypotension develops. (see Chapter 5.5)

When the cause of shock is primarily due to pump failure, then echocardiography demonstrates a poorly functioning, often dilated left ventricle (LV) and/or atrium. Differentiating severe global LV dysfunction (as occurs in cardiogenic shock) from normal LV function or the hyperdynamic LV of hypovolaemia is readily done. More precise calculations of ejection fraction and cardiac output or regional wall motion abnormality are generally beyond the scope of the focussed echo exam.

In shock due to hypovolaemia, echocardiography demonstrates a small LV end-systolic volume with hyperdynamic LV motion. The IVC also tends to be small or collapsed and demonstrates increased respiratory variation. In the spontaneously ventilating patient, inspiratory collapse of over 50%, particularly when the IVC is small, infers a high likelihood of fluid responsiveness.

The use of echocardiography for the acute assessment of chest pain is extremely useful but requires significant expertise and is generally beyond the scope of the ED user. Transthoracic echo can detect the regional wall motion abnormalities associated with cardiac ischaemia and, in expert hands, the sensitivity and specificity are relatively high. Echo too may detect the RV dilatation and dysfunction associated with PE, the pericardial effusion that may be associated with pericarditis, proximal aortic dilatation and even an intimal flap or aortic regurgitation from dissection, but, for these conditions, has much lower sensitivity. Ultrasound can also detect numerous chest wall and pulmonary pathologies presenting with chest pain that may mimic cardiac pain and thoracic ultrasound is described in the next section.

Lung ultrasound

Lung ultrasound is being increasingly used by critical care clinicians and respiratory physicians to assess the patient with undifferentiated shortness of breath. It is also used to answer a diverse range of specific clinical questions, such as is there a pleural effusion, is there a pneumothorax or is there pulmonary oedema? Finally, it is used to guide pleural procedures, such as effusion drainage or biopsy.

Suggested algorithmic approaches, such as Lichtenstein's 'BLUE protocol' for the patient with acute respiratory failure, claim a diagnostic accuracy of 90.5%.[40] This protocol assesses for cardiogenic pulmonary oedema, pneumonia, decompensated chronic obstructive pulmonary disease (COPD), asthma, PE and pneumothorax.

It should be recalled that neither bone nor air allows the passage of ultrasound. Because of this, one cannot assess directly behind a rib where an acoustic shadow occurs, nor deep to an air interface, such as the normal pleural surface. This means that thoracic ultrasound can focus on the bony thoracic cage where fractures of ribs and the sternum can be readily detected or on the pleural space where effusions, pleural masses or free air (as in pneumothorax) can be detected and, finally on the lung itself. In aerated lung, assessment can be made only of the visceral pleural surface (and a tiny rim of lung tissue directly adjacent to this). If the lung is not aerated, as occurs with solid tumours, consolidation, collapse or infarction, the solid area of lung deeper to the surface can be explored with ultrasound.

Sonographic assessment of aerated lung relies on two things. First, movement of the lung, with the two pleural surfaces sliding against one another during ventilation and, second, on artefact created by reverberation of ultrasound. This reverberation occurs at the pleural surface and within minute collections of interstitial fluid or fibrosis. Normal ventilating lung is therefore characterized by 'lung sliding' where the very slightly irregular visceral pleural surface can be seen moving to-and-fro past the parietal pleura with inspiration and expiration. Even in normal lung, tiny foci of interstitial or alveolar fluid or fibrosis create short path reverberation artefacts, which appear as bright vertical lines deep to the pleural surface. When these are short they are called comet tails and when they are long they have been termed 'B-lines'. When there is an increasing amount of interstitial or alveolar fluid (or fibrosis) as seen in pulmonary oedema, pneumonitis, acute respiratory distress syndrome, lymphangitis carcinomatosis and pulmonary fibrosis the number and prominence of these vertical 'B-lines' increases dramatically. More subtle sonographic changes in the pleural surface may allow differentiation between these subgroups; however, often it is clinical correlation that makes the picture clearer.

With pneumothorax lung sliding is lost, as are the vertical comet tail and B-line artefacts. The lung point can sometimes be found where the two pleural surfaces meet and allow some degree of assessment of pneumothorax size. In addition, with pneumothorax, the free air beneath the parietal pleural surface creates a smooth mirror-like effect. Long path reverberation artefacts, known as 'A-lines', occur where horizontal repetitions or reflections of the pleural surface are seen below the actual pleural surface. Lung sliding can also be absent in COPD, bullae or conditions where the lung surface is 'sticky' from inflammation of any cause.

In addition to the diagnostic utility of thoracic and lung ultrasound, having access to ultrasound for procedural guidance is extremely useful. Ultrasound can be used to assess an area of opacity seen on chest x-ray, to determine whether it is solid or liquid and the relation to the diaphragm and heart. If a pleural effusion is confirmed, it can be further characterized as being simple or loculated and as to whether there is debris floating within it. Aspiration or tube placement can then be done after calculating the thickness of the chest wall, the depth of the effusion and the best direction from which to approach. The procedure can be done in real-time or after the patient is positioned, the skin is marked and trajectory planned.

Technique

The pleural surface is interrogated using either the curvilinear abdominal or the high frequency linear transducer. Several different methods for assessment have been described and depend on clinical suspicion, which must be used to guide and then interpret the scan. Integration of lung ultrasound and emergency echocardiography is the best approach to assessing the patient with undifferentiated acute dyspnoea.

In the absence of pleural adhesions or loculations, pneumothorax collects in the most apical portion of the thoracic cage and should be examined for there. If the patient is a supine trauma patient, assessment anteriorly along the midclavicular line from clavicle to diaphragm, with the probe in longitudinal orientation is effective.

If considering pleural effusion or haemothorax, examining the bases and costophrenic angles from the front, side and back, usually with the patient sitting up, is best. To assess the lung parenchyma, maximizing the view of the pleura, lining the probe up in the line of the intercostal spaces and so avoiding ribs, is ideal.

For a non-trauma patient who presents in acute respiratory distress, sitting up, the author tends to examine the chest methodically:

- Anteriorly in the midclavicular line:
- with the probe longitudinally to maximize lung sliding, explore from clavicle to diaphragm.
- Laterally in the midaxillary line:
- initially with the probe in longitudinal position at the lung base to assess the costophrenic angle for fluid, collapse or consolidation,
- then higher with the probe aligned with the intercostal spaces to interrogate the pleural surfaces and lung higher up.
- Posteriorly just medial to the scapulae, which are rotated out the way by flexing the shoulders forward:
- initially with the probe longitudinal at the lung base to assess the costophrenic angle for pathology,
- then higher up the chest with the probe orientated along the line of the intercostal spaces (almost transverse).

Limitations and pitfalls

- Surgical emphysema, obesity or patient position may prevent adequate imaging by ultrasound.
- Assuming lack of lung sliding is diagnostic of pneumothorax – without considering other causes such as COPD, bullae, severe asthma, pleural adhesions, etc., and failing to search for the lung point to confirm the diagnosis.
- Many pathologies can cause an increase in the number of B-lines, not just pulmonary oedema; remember to correlate clinically.
- Pericardial fat pads can be confused with consolidation.

Clinical implications and utility

ED ultrasound allows the rapid assessment of patients in acute respiratory distress at the bedside. Whilst the major sonographic patterns described above are easy to differentiate, relatively diverse pathologies may have similar sonographic patterns. As with all of POCUS integration of the ultrasound findings with careful clinical assessment and appropriate clinical judgement is essential in ensuring the correct diagnosis is made.

Ultrasound-guided vascular access

Vascular access, both venous and arterial, and central and peripheral, is commonly performed in the ED. Widespread availability of machines and increasing familiarity and expertise among the emergency medicine community in using ultrasound to guide all forms of vascular access has had major positive implications to patients in recent years.

Traditionally, central venous access has been secured using the 'landmark technique', where surface anatomical features are used to predict the location of the internal jugular, subclavian and femoral veins. However, access using this technique has been associated with a 20% failure rate and a 10% complication rate, including inadvertent arterial puncture, excessive bleeding, vessel laceration, pneumothorax and haemothorax.[41,42] Improved success rates and decreased complication rates have been described using ultrasound-guided central venous access, including reduction in needle puncture time, increased overall success, reduction in carotid puncture, reduction in pneumothorax and a reduction in catheter-related infection.[43,44] National guidelines from the UK[45] and the USA[46] support the use of ultrasound guidance for central venous catheter (CVC) placement. Inadvertent arterial CVC placement can still occur when using ultrasound guidance with the catheter traversing the internal jugular vein before entering the underlying carotid or subclavian artery. Using ultrasound to confirm wire placement prior to dilation, and transducing pressures prior to CVC use are recommended to ensure early recognition and mitigation of this potentially major complication.

Ultrasound guidance is also useful in aiding peripheral vascular access. The basilic, brachial and cephalic veins are frequently not visible clinically, but are readily cannulated using ultrasound guidance. Basilic vein cannulation has been shown to be very successful in the ED setting in patients in whom other peripheral access was difficult.[47]

Technique

A medium to high frequency broad bandwidth linear array transducer is used with a centre frequency of 7.5 to 10 MHz. Specific presets to optimize the needle's visibility have been developed, but a musculoskeletal preset is usually adequate. The procedure is most easily performed with the ultrasound screen, the patient and operator all in line, with orientation checked and optimized. A sterile transducer cover and ultrasound gel are essential. A longer cannula is also particularly useful as the vessels being targeted are generally deep and increased length is required to reach them and ensure adequate vessel purchase.

Two techniques have been described, the static and dynamic techniques. The static technique may be used for very superficial or very large vessels, but is generally considered inferior to the dynamic technique. The static technique is used to locate the vessel, measure its dimensions, confirm relationships of surrounding structures and determine depth below the skin. The vessel is then centred on the screen and the skin marked at the centre of the transducer, corresponding to the vessel's subcutaneous position. This mark is then used for the puncture site without ultrasound visualization of the needle as it enters the vessel.

The dynamic technique uses real-time ultrasound guidance visualizing the needle tip as it enters the vessel. Higher success rates have been demonstrated with the dynamic technique than with the static technique.[48]

Real-time ultrasound-guided cannulation using both in plane and out of plane transducer orientation relative to the needle have been described. The out of plane orientation is easier to obtain and provides information related to adjacent structures; however, the needle tip is less clearly seen. The in-plane orientation is more difficult to achieve but provides information related to vessel orientation and slope, and provides visualization of the needle in its entirety as it passes through the tissues and enters the vessel.

Clinical implications and utility

In many centres, emergency staff (both medical and nursing) are gaining familiarity and expertise with ultrasound-guided vascular access of all sorts. The increased use of ultrasound to place peripheral cannulae and peripherally inserted central catheter (PICC) lines has meant less trauma for our patients and, in many cases, less need for central line placement.

Miscellaneous applications

Scrotal ultrasound

Patients may present to the ED with scrotal or testicular pain, a scrotal mass or following scrotal trauma. Acute scrotal pain in the absence of trauma may be due to testicular torsion or epididymo-orchitis. Scrotal swelling may be due to hydrocoele, hernia or testicular mass. Scrotal trauma may be associated with testicular rupture, haematoma and testicular ischaemia. Ultrasound is the imaging modality of choice for assessing for testicular pathology and injury.

The scrotum is examined using a high-resolution linear array transducer with the patient in a supine position with the scrotum supported by a towel between the patient's legs.

In testicular torsion, the testis rotates on its axis leading to twisting of the spermatic cord with compromise of both venous drainage and arterial supply. To diagnose torsion, it is important to demonstrate normal flow within the normal testis and absent flow in the affected side.[49] However, blood flow may be very difficult to identify in normal paediatric testes. In addition with intermittent torsion–detorsion flow may appear normal or even increased in the affected testis. Partial torsion can occur with normal colour Doppler flow detected. Therefore ultrasound cannot exclude testicular torsion, which remains a clinical diagnosis.

Epididymo-orchitis is the most common cause of scrotal pain in postpubertal men. Sonographically, the epididymis is characteristically thickened. Increased blood flow is demonstrated with colour Doppler in the epididymis or testis, or both. A reactive hydrocoele is common.

Ocular ultrasound

Ocular ultrasound has been used by ophthalmologists as an adjunct to examination for over 40 years. In the emergency setting, it is most useful to examine the eye in those patients where swelling prevents direct visualization of the eye and for disorders for which direct ophthalmoscopy has poor accuracy. After applying gel to the high-frequency linear probe it is gently applied to the closed eyelid and the globe examined in two planes from side to side. The posterior chamber should appear round and echo free. The optic nerve can be identified posteriorly. A retinal detachment appears as a relatively thick and echogenic membrane that may show colour flow on Doppler. In rhegmatogenous retinal detachments, the membrane undulates with eye movement (older detachments tend to move less with increasing fibrosis). Retinal detachments do not cross the optic nerve. Smaller areas of a thick elevated membrane that do not undulate may be seen with other types of detachments or other pathologies, but all of these will generally be beyond the scope of the emergency physician and require an ophthalmologist to distinguish. A vitreous detachment appears as a much thinner, avascular membrane that may only be seen when perpendicular to the beam, which also moves with globe movement. Vitreous haemorrhages appear as either dots or larger echogenic regions which move more quickly than retinal detachments. Studies have shown good accuracy when employed by emergency physicians to diagnose retinal detachment.[50]

Ultrasound has also been used to diagnose globe rupture, foreign bodies and lens dislocation. Some groups have described its use in the diagnosis of intracranial hypertension, by looking at the optic nerve sheath diameter. However, while individual groups have found good accuracy, differences in technique and wide variation in the quoted normal ranges have limited the general applicability of this technique.

Appendicitis

Misdiagnosis of appendicitis on clinical assessment is associated with a negative appendectomy rate of 15%, with rates as high as 40% to 50% reported in some series.[51] Delays in intervention can result in appendiceal perforation with associated increased morbidity and mortality.[52] The aim in assessing a patient with clinically suspected appendicitis is to adequately identify the appendix to confirm or refute the diagnosis, identify complications, such as perforation, or to identify other causes of the patient's presentation. The appendix is identified as a blind-ending, tubular, aperistaltic structure arising from the posteromedial caecum 1 to 2 cm distal to the ileocaecal junction. The patient should be examined in a supine position using a high-frequency linear array transducer to optimize image resolution. The normal appendix is compressible with a wall thickness equal to or less than 3 mm.[53] Increased wall thickness (outerwall to outerwall) of greater than 6 mm with loss of compressibility (Fig. 23.1.16), loss of definition of the mucosa, submucosa and muscularis propria and the visualization of an appendicolith support a diagnosis of appendicitis. Additionally, the detection of peri-appendiceal inflammatory changes in the presence of an abnormal appendix increases the likelihood of appendicitis.[54] Failure to identify the appendix is common and does not exclude appendicitis.

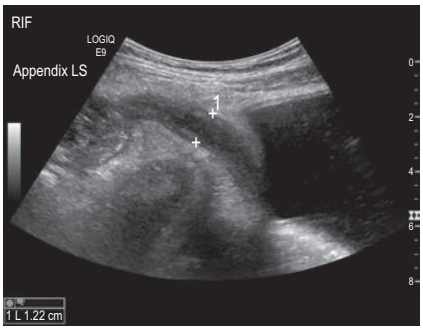

FIG. 23.1.16 **Acute Appendicitis.** Longitudinal view of the appendix, seen originating from the caecum and draping over the iliac vessels into the pelvis where its tip lies adjacent to the bladder.

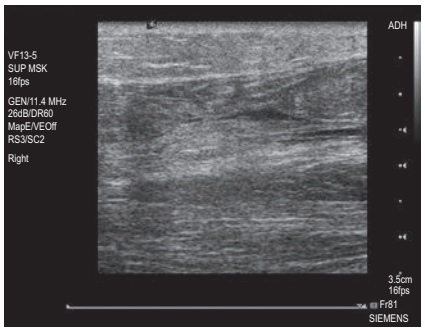

FIG. 23.1.17 Longitudinal view of the tendo Achilles showing a full thickness tear at the level of the musculotendinous junction.

Musculoskeletal and soft tissue applications

There are numerous musculoskeletal and soft tissue applications for diagnostic ultrasound in emergency medicine. These include foreign body identification, evaluation of suspected tendon tears (Fig. 23.1.17), muscle tears and haematomas, abscess confirmation and localization, joint effusions (Fig. 23.1.18) and fractures. Most musculoskeletal imaging is done using a broadband, high-resolution, linear array transducer with centre frequency of about 10 MHz.

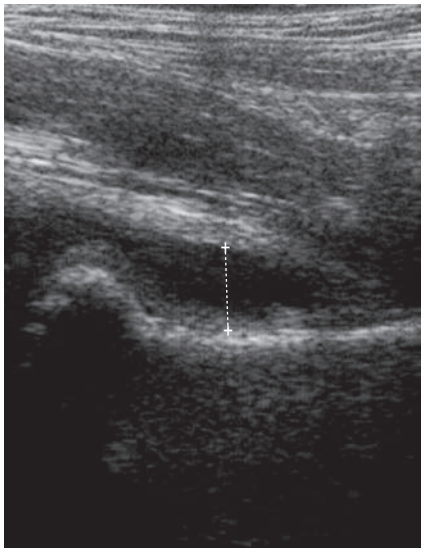

FIG. 23.1.18 Longitudinal view of the right hip demonstrating joint effusion.

Ultrasound-guided procedures

Ultrasound is a useful modality for identifying fluid collections and guiding diagnostic or therapeutic aspiration, including thoracocentesis, paracentesis and arthrocentesis. It is also increasingly used by both anaesthetists and emergency physicians to guide nerve blocks.

Training and credentialling[1]

In Australasia, both the Australasian College for Emergency Medicine (ACEM) and the Australasian Society for Ultrasound in Medicine (ASUM) make recommendations and provide credentialling pathways in emergency ultrasound. ASUM provides the nationally recognized qualifications the Diploma in Diagnostic Ultrasound (DDU) and the Certificate in Clinician Performed Ultrasound (CCPU).

In 1999, ACEM proposed a policy supporting the use of ultrasound by emergency physicians for at least the detection of traumatic haemoperitoneum, abdominal aortic aneurysm, pericardial fluid, ectopic pregnancy, renal and biliary disease. The subsequently published policy document supported a credentialling process for training in FAST and AAA studies and included recommendations on training requirements. These requirements mandated a minimum of 25 FAST exams with at least 5 positive scans for intraperitoneal, pleural or pericardial fluid and 15 AAA exams of which 3 should demonstrate an

aneurysm for credentialling purposes. All of these training exams should be confirmed by a gold standard (other study, surgical findings, clinical course, etc.) and be reviewed by a suitably qualified reviewer. The requirements also included attendance at an ultrasound workshop that would cover the basic information for an emergency physician to perform and interpret EFAST and AAA studies. Guidelines for the Minimum Criteria for Ultrasound Workshop were published by ACEM in 2000. These policies were reviewed in 2011, and requirements for credentialling in Basic Echo in Life Support were added.

ASUM is the recognized national training, qualifying and credentialling body in medical ultrasound. ASUM offers two qualifications to medical practitioners performing ultrasound: the CCPU and the DDU. Both of these qualifications are endorsed by ACEM for the purposes of training and credentialling in emergency ultrasound and describe a scope of practice that extends beyond those described by the College. Further details can be obtained from the ASUM website.

In 2005, the Royal College of Radiologists in the UK, in consultation with the clinical colleges, published a document entitled 'Ultrasound Training Recommendations for Medical & Surgical Specialties'. This document defines three levels of competency with suggested training and practice requirements for each level and has been endorsed by the College of Emergency Medicine (UK).

The 2001 American College of Emergency Physicians (ACEP) Policy Statement, Emergency Ultrasound Guidelines, reviewed the previous criteria for achievement of competency to perform focused clinical ultrasound. These recommendations included a 16-hour introductory course and a minimum of 25 ultrasound examinations for each defined primary modality.

Although the minimum training requirements for emergency physicians to become proficient in focused emergency ultrasound remains unclear, the recommendations from ACEP, ACEM, ASUM (for the CCPU) and the training recommendations of the Royal College of Radiologists (UK) for clinical ultrasound are similar and have been promulgated in a consensus document by the International Federation for Emergency Medicine.

The increasing technological sophistication, portability and affordability of ultrasound machines has led to an increasing demand for ultrasound as a diagnostic tool to be devolved to the clinician managing the patient. This is no more so than in emergency medicine where ultrasound has the potential of establishing a broad range of applications and indications that extend beyond EFAST and AAA detection as is described by the training curricula and guidelines above. The challenge now lies in developing adequate training and supervision networks to allow these skills to be learnt and maintained.

CONTROVERSIES AND FUTURE DIRECTIONS

- The scope of practice of emergency ultrasound is likely to continue to expand within EDs. Although the core uses for emergency physicians will continue to focus on unstable patients, the broad utility of ultrasound and its ability to add information to clinically challenging situations is likely to result in its application to a broader patient group.
- The major rate-limiting step remains initial access and supervision of training.
- Paradoxically, skill maintenance in these so-called 'more advanced' applications of emergency ultrasound may be easier to achieve given that the majority of emergency physicians have far greater exposure to these patient groups than those with suspected haemoperitoneum in the setting of trauma or ruptured AAA.
- The amount of training required by clinicians to achieve competency and to maintain the sensitivity and specificity of an ultrasound study remains to be determined.

23.2 Computed tomography scanning in emergency medicine

Stephen J. Dunjey • Swithin Song

ESSENTIALS

1 **Computed tomography (CT) scans are a major diagnostic modality in emergency medicine.**

2 **Emergency physicians are ordering CTs more frequently than previously for a variety of reasons.**

3 **Artefacts are occasionally encountered in CT scans, and clinicians should be familiar with these artefacts.**

4 **Contrast media reactions and carcinogenic effects of radiation are recognized potential adverse effects of CT scanning.**

Introduction

Computed tomography (CT) was developed in 1971 by Godfrey Hounsfield and Allan Cormack and adopted into medical practice. By the early 1980s, CT scanning was in general clinical use in the United States, and within a generation, most large emergency departments acquired their own dedicated scanners. Emergency medicine has embraced the utilization of CT scans, as it significantly aids in clinical diagnosis. It has revolutionized the approach to patients with traumatic injury, neurological emergencies, abdominal pain and chest pain. It is cost-effective and fast. It is, however, a modality that presents some risks to patients, and clinicians need to be prudent in their use. It is also an area of considerable development, with CT scanners becoming faster and more precise, and therefore increasing utility.

Development science

CT scan machines consist of a gantry around a patient, with an x-ray source on one side of the gantry and detectors on the opposite side, moving in synchrony. Early scanners imaged one slice at a time ('step and shoot'), with the table stationary while a static image was acquired. This produced a series of parallel slice

images (tomographic images) of a region of the body. The beam produced by the source can be adjusted, producing widths from 1 to 20 mm. Traditionally, images were produced which displayed the volume of data as axial slices (perpendicular to the long axis of the body), but current scanners are able to display the collected data as multiplanar slices which improves diagnostic yield (Figs 23.2.1 to 23.2.3).

Helical (spiral) CT scanners move the patient rapidly and continuously through a circular gantry opening that is equipped with a source and multiple detectors, which are continuously rotating and provide volumetric acquisition. The source describes a helical trajectory relative to the patient.

FIG. 23.2.1 Axial CT of head.

FIG. 23.2.2 Coronal CT of head.

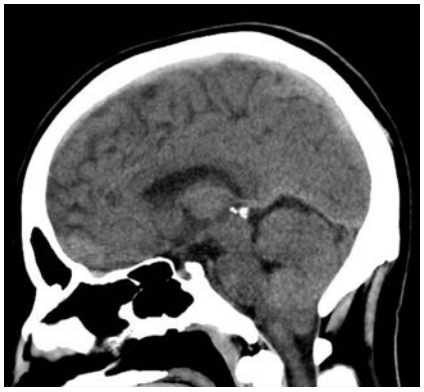

FIG. 23.2.3 Sagittal CT head.

Windows

The objects displayed in a scan can be differentiated from adjacent organs by their differential attenuation of the x-ray beam based on their individual density. The density of the tissues is measured in Hounsfield units (HU). Water has a density of 0, and tissues denser than water have values greater than 0, while less-dense tissues have negative values. The accepted convention is for high-density structures to be displayed in lighter shades and low-density structures to be displayed in darker shades. The denser a structure, the lighter the shade displayed. The scale extends up to about +4000 for very dense metals, with cancellous bone about +700 and dense bone about +3000. Blood is in the range of +35 to +45 and muscle about +40. At the other end of the scale, air is −1000, lung −700 and fat −84 (Figs 23.2.4 and 23.2.5).

Humans can only perceive a limited number of grey shades, and so to highlight the tissues of interest, the full range of density values is not displayed. Instead, the display shows a narrow portion of the full range to allow clear differentiation of one tissue from another and pathological tissue from normal tissue.

For example, bone windows are a preset that will shift the grey scale displayed to centre on the range of densities which are typical of bone and allow detection of subtle abnormalities, such as fractures. As a consequence of focusing the display on such high-density structures, there is a marked decline in the ability to assess soft tissues on bone windows.

FIG. 23.2.4 Axial CT of lung using lung windows preset.

Display convention

The accepted convention for displaying images is for the right side of the patient to be on the left side of the image.

Artefacts

There are some imaging artefacts that affect the quality of the images generated and hence the diagnostic quality of the scan. These artefacts are classified as physics-based artefacts, patient based, scanner based and multi-section based. Most emergency physicians (EPs) are familiar with patient movement (Fig. 23.2.6) and metallic artefacts (Figs 23.2.7 and 23.2.8).

Physics-based problems include beam hardening (resulting from the absorption of low-energy photons after passage through an object, leaving only high-energy photons and a higher energy beam), which can produce the streaks and dark bands. Undersampling is another physics-based problem, in which the distance between CT samples is large enough to create mis-registration of information about small objects or sharp edges. Partial volume averaging is when the densities in a single CT is averaged rather than displaying separate

FIG. 23.2.5 Axial CT chest using preset for CT angiogram.

individual densities. This occurs because every CT slice displayed is a 2D representation of a finite 3D thickness of tissue.[1] Ring artefacts, a scanner-based problem, occur due to mis-calibration or failure of one or more detector elements (Fig. 23.2.9).

Current uses and indications

While the overall usage of CT scanning is dramatically increasing, evidence suggests a higher rate of increase in emergency medicine. A 2011 study showed that in the United States between 1995 and 2007, the number of CT studies performed increased from 2.7 million to 16.2 million—nearly a sixfold increase.[2]

By the end of the study period, the presenting complaints topping the list of those undergoing CT were abdominal pain, headache and chest pain. The percentage of patient visits associated with CT for all complaints increased most substantially among those who underwent CT for flank, abdominal or chest pain. Other high-use areas include shortness of breath, trauma and headache, being more marked in the elderly.

Indications for emergency department CT scans have increased, as CT is diagnostically more sensitive than plain x-rays, supplanting plain films in assessing skull fractures, cervical spine injury and renal colic.

The long-held belief of the accuracy of clinical examination is being challenged in this era of good diagnostic tests. In the last decade, there has been a dramatic increase in the number of CT scanners, with moderate-sized country hospitals and most large urban emergency departments having their own dedicated scanners. During the same period, scanners have become faster with improved diagnostic accuracy. All of these factors drive the increase in scans performed. CT scans are now used for chest pain (for suspected acute coronary syndrome, coronary artery disease and aortic dissection), not just for suspected pulmonary embolism. Surgeons now aim to avoid unnecessary surgery and are increasingly unwilling to take patients for exploratory laparotomies without a prior CT scan to provide a definitive or tentative diagnosis.

FIG. 23.2.6 Pseudofracture of C6 from patient movement.

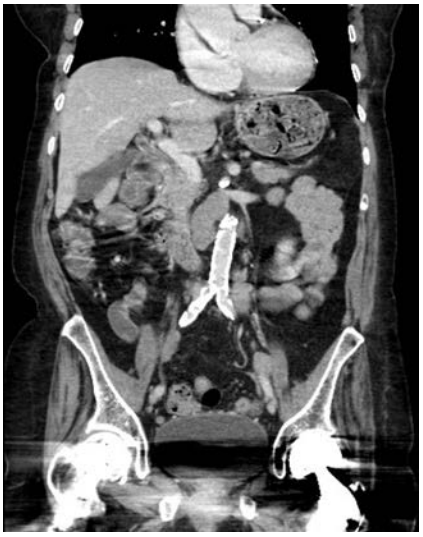

FIG. 23.2.8 Coronal CT abdomen with metallic artefact obscuring bladder.

Problems

There are some significant problems that continue to present challenges for physicians requesting CT studies.

Weight constraints

Most scanners have a patient weight limit, with the maximum of about 250 kg depending on the unit used, or a patient circumference limit. Some manufacturers are developing bariatric scanners.

Unstable patients

A CT suite is usually limited in its provision of resuscitative care. Even with oxygen and suction outlets and full monitoring, these spaces are primarily designed for imaging, not resuscitation. Although current CT scanners can perform in a short time interval, the process of manoeuvring patients into the room, off the trolley and changing over tubing and monitoring has changed little over the years. Consequently, scanners that can perform a whole-body scan in a few minutes have made surprisingly little difference to the time in the CT scan suite. Patients still die in the relative isolation of these suites, and it is still important for physicians to ensure that their patients are as stable as possible prior to leaving the resuscitation area. Patients who cannot be stabilized because of the severity of their injuries should go straight to the operating theatre rather than be imaged.

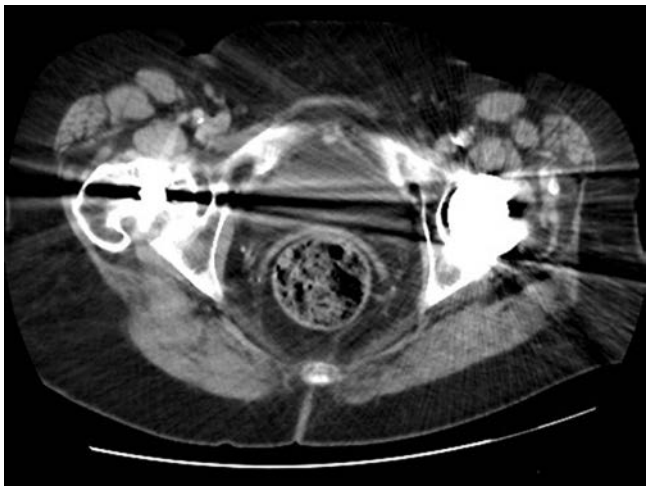

FIG. 23.2.7 Metallic artefacts from hip prostheses.

FIG. 23.2.9 Ring artefacts in a very bariatric patient.

Allergy to computed tomography contrast media

There is significant lack of understanding in the medical community regarding reactions to contrast media. Contrast molecules are so small that that they are not capable of acting as antigens, and although they can create an allergic type reaction, it is probably not IgE mediated. Reactions range from minor skin reactions up to more severe anaphylactoid reactions (bronchospasm, angio-oedema, hypotension). IV contrast reactions are more common in atopic individuals and those with previous allergic reactions, but the most important risk factor is a previous contrast reaction. Determining the incidence of such reactions is difficult because of underreporting and because concomitant illness can produce similar symptoms in some patients. The American College of Radiologists manual on contrast media suggests rates of 0.2% to 0.7% overall, with the rate of serious reactions of about 1 or 2 per 10,000.[3]

Iodine is an essential element, and it is not possible to be allergic to it. Although shellfish are a rich source of iodine, allergy to shellfish is due to the proteins found in the muscle of the shellfish, and so the widely held belief that shellfish allergy precludes the use of contrast agents is not based on fact.

For patients who are at risk of a reaction, it is wise to have medication on hand to manage a severe response easily. The usefulness of prophylactic steroids for emergency patients is dubious. One recommendation suggests:

Do not delay emergent studies for steroid premedication. Only lengthy 12-hour premedication protocols have shown any effect on reaction rates and this small benefit was manifested primarily by decreasing minor reactions. No steroid protocol has shown a significant benefit in decreasing severe or fatal reactions.[4]

Contrast-induced nephropathy

Contrast-induced nephropathy is a concerning complication for those receiving IV contrast media. It has been estimated to have a mortality rate of up to 36% in hospital and a 19% 2-year survival, as well as prolonged hospitalization. Contrast media have also been estimated to be used in approximately 50% of scans currently performed, and CT scan usage is increasing at an exponential rate.

Under normal physiological conditions, nearly all of the contrast medium is eliminated through the kidneys. The resulting concentration in the renal tubular system is up to 100 times the concentration in plasma and approaches ≤30% of the concentration of the injected solution. With contrast concentrations of this magnitude, it is not surprising that this could be a cause of acute kidney injury.

Recent evidence challenges long-held beliefs about contrast-induced nephropathy (CIN). A turning point has been the adoption of a more uniform way of diagnosing and describing the illness (change in the baseline creatinine of ≥25% and/or an absolute elevation of creatinine from baseline values of 0.5 mg/dL).

Studies focusing on contrast-enhanced CT show an overall incidence of CIN, with the current generation of non-ionic contrast media, to be in the range of about 5%. Very recent work examining contrast media away from cardiac catheterization has questioned whether the media induce CIN at all, and suggests that there is no difference in rates of acute kidney injury in unwell patients receiving contrast versus those who are scanned without contrast.[5] Traditionally, risks for developing CIN include renal insufficiency, age (older than 55), hypovolaemia, longstanding diabetes and patients taking metformin. It appears that baseline renal insufficiency is the only well-supported independent risk factor.

There have been many agents used as attempted prophylaxis against development of CIN, including *N*-acetylcysteine (NAC), vasodilators, such as fenoldepam, calcium channel blockers, theophylline, but the only well-accepted measure for at-risk patients is adequate hydration. This position is supported by the American College of Radiology, but the ideal volume and rate of administration is not known. Isotonic fluids, such as normal saline, are preferred. Most guidelines suggest 6 to 12 hours of infusion prior to the procedure and for up to 4 hours afterward.[6] Clearly these recommendations are impossible to implement for emergent patients.

Radiation

CT scanning is a source of ionizing radiation, which is capable of overcoming the binding energy of electrons and is able to knock them out of orbit, creating ions. Although x-rays can ionize DNA directly, it is the production of hydroxyl radicals from ionization of water molecules that produces strand breaks and base damage. Although there is some capacity to repair damaged DNA, unresolved damaged DNA can induce cancer. At the doses delivered in normal scanning, there is a small risk of radiation-induced carcinogenesis. This is supported by the historical evidence supplied by Japanese survivors of the atomic bombs dropped in 1945. The group who received low doses of radiation in the range 5 to 150 mSv (mean 40 mSv, which approximates the organ dose from a typical CT involving two to three scans in an adult) showed a significant increase in the risk of cancer.

Spiral (or helical) CT is rapidly becoming the dominant type of scanner used and, under typical use (with a pitch of 1 or greater), the radiation dose is comparable to conventional CT. Slice thickness, the number of slices obtained and the pitch affect radiation exposure. Pitch is a ratio defined as the distance the table travels during one rotation of the radiation source divided by the section thickness

In pregnancy

Radiation damages DNA, and a foetus with rapidly dividing and differentiating cells is more susceptible to these effects than adults. Large doses of radiation can lead to growth retardation, birth defects, cancers, mental retardation and even fetal death, but modern diagnostic studies are well below the threshold that would cause such catastrophic effects.[7] Exposure to less than 5 rads has not been associated with deleterious effects on a foetus.

In context, an abdominal x-ray exposes a foetus to about 100 mrad, a lumbar spine x-ray to 50 to 150 mrad, a CT of pelvis to 250 mrad and a CT of abdomen or lumbar spine to 3.5 rad.

Apart from the risks of radiation, there are often questions about the safety of contrast media. It is generally considered safe to give contrast media in all trimesters of pregnancy, although there are theoretical risks of thyroid depression in the foetus/neonate because contrast media molecules are small enough to cross the placental barrier and to be excreted in breast milk. Some centres direct pregnant or lactating women to discard breast milk for up to 24 hours after contrast administration, although this is likely unnecessary.

In childhood

There has been a marked increase in the use of diagnostic CT scanning in the paediatric population, driven in part by the decrease in time to perform a scan, which eliminates the need for anaesthesia.

The largest growth has been in the diagnosis of acute appendicitis, in which CT is cost effective and accurate, although ultrasound represents a safer option.

The increased risk of carcinogenesis is even more marked in the paediatric population for two reasons: they are more radiosensitive, and they also have more years of life in which to develop a radiation-induced cancer.

Overuse

Widespread acceptance of the use of CT scanning, the development of new indications, its speed and accuracy in diagnosis, liability

issues and the improved access to scanning are among a long list of reasons why the number of scans generated by emergency departments is increasing.[8]

While this change is mirrored throughout medical practice, the potential for inappropriate overuse of CT in emergency medicine is an area of concern. Unnecessary scans expose patients to radiation (particularly if there are consecutive or multiple scans done in a short period) and are expensive (particularly if compared with modalities like plain x-ray or ultrasound).

Some estimates have suggested a sevenfold increase in total medical radiation exposure from the 1980s to 2006 for the population of the United States. While CT scanning in that period only accounted for 17% of x-ray imaging, it was responsible for 49% of the total estimated dose.

In the same population, emergency medicine generates about one-third of the CT scans performed. The benefits for patients in EDs are not disputed.

Some studies suggest that there are significant numbers of inappropriate tests ordered from emergency departments, in part driven by a fear of medical liability.

EPs respond by pointing out that although the CT radiation dose is significant (10 to 20 mSv, which is associated with a lifetime risk of fatal cancer in about 1 per 2000 scans), more than 1 in 2000 patients will have potentially life-saving information provided by a CT. To many frontline doctors, the long-term risks are theoretical and poorly quantified compared with the risk of missing significant pathology in the here-and-now.

One area of medicine in which CT scanning has revolutionized care is trauma management. Rapid, high-quality scanning has unequivocally led to better outcomes in many patients but, even here, questions are being asked. The pan-scan has been enthusiastically embraced and quickly become a standard of care before any rigorous scientific evaluation.

An Australian study compared radiation exposure with trauma patients before and after the introduction of a diagnostic algorithm employing a 64-slice scanner.[9] Their findings were challenging, suggesting that patients were 1.7 times more likely to receive a radiation dose exceeding 20 mSv compared with a conventional CT work-up, but did not significantly benefit from the procedure in terms of the incidence of missed injuries (0.6% vs. 0.9%).

Only one-fifth of the patients in the study fulfilled the criteria for major trauma. The authors went on to suggest that the pan-scan may be 26 times more likely to harm the patient in the long term than assist them in the acute setting.

CT scanning should not be requested in a frivolous fashion, without regard for potential long-term health risks. The speed of the investigation and the quality of the diagnostic information should always be balanced against the knowledge that the scan may harm the patient.

Clinical decision rules

EPs are responsible for ensuring that they make sensible and appropriate decisions for their patients and that their choice of CT as a modality takes account of the risks to the patient. It is unfortunately true that there has been such a proliferation of guidelines that sometimes clinicians are hard pressed to know which one to follow. There are, for example, no less than three widely accepted and well-validated decision rules for determining the need for CT in head injury (Canadian Head CT rule, New Orleans Criteria, NEXUS II). The American College of Radiologists has developed a comprehensive list of appropriateness criteria that relate possible investigations to the presenting complaint, covering the full gamut of clinical presentations and made in conjunction with appropriate input from clinicians.

Diagnostic accuracy of emergency physicians

EPs are often required to interpret a CT scan. Early studies did not suggest this was done well. Many studies have examined the ability of EPs and registrars (Emergency Medicine residents in North America) to interpret head CT scans. In the specific clinical setting of stroke, compared with the gold standard of interpretation by neuroradiologists, EPs performed relatively poorly in recognition of both haemorrhage and early ischaemic changes (accuracy 60%), but neurologists and general radiologists only achieved a result of 80%.

A study examining EPs' abilities to assess head CT for trauma concluded that, without extra training, EPs should not be interpreting such scans. While there is debate about whether the nonconcordance between EPs and radiologists leads to poor clinical outcomes, there are numbers of studies that demonstrate the improvement that is possible with focused teaching.

There is no doubt that improvement in training must occur because, despite the advent of teleradiology, there will still be occasions when the situation dictates that an EP perform the initial interpretation of a CT scan.

Advances in CT scanning

There have been a number of technological innovations in the last decade that have improved imaging diagnostic quality, reduced radiation dose, and expanded the diagnostic capabilities of CT scanners.[10] These innovations include **higher slice systems, iterative reconstruction, new detector technology, spectral CT imaging and advances in cardiac imaging.**

New standards of care were introduced when 64 slice scanners became available and were widely deployed across all health care systems. Since that time, **higher slice systems were introduced** (80, 128, 256, 320 and 640 slice) and soon superseded the older systems. Proponents for the new systems point out that the increased price tag is justified by the increased image area coverage, reduced radiation and reduction in the need for repeat scans. They improve image quality, reduce stitching artefacts and benefit cardiac scans by completing scans in milliseconds and hence avoiding movement artefacts.

Iterative reconstruction is an innovation that reduces radiation dose and improves image quality. This is achieved with software that revises the image repeatedly with multiple iterations to clarify the image, pixel by pixel, and clean up artefacts. This promotes diagnostic image quality with low-dose scanning.

New detector technology utilizing microelectronic circuits reduces electronic noise and produces sharper images.

Spectral CT imaging is based on viewing the same anatomy at two different kV energies, which breaks down x-ray photons by chemical elements, similar to the way a prism breaks down light. This is done either with a dual source scanner, or by using fast kV switching between different energies during the scan (or using detector elements that record different kV levels during a scan). The result is that different anatomical features are enhanced at different energy levels, and it may avoid the need to scan a patient multiple times. The software can highlight or eliminate chemical compounds based on anatomic number. This means that one can create contrast and non-contrast images from one scan (since iodine contrast can be removed by spectral filters to create a virtual non-contrast scan), and can also differentiate between contrast and a calcified plaque in a blood vessel. One can also differentiate between different types of kidney stone, reduce metal artefact and more clearly identify pulmonary emboli.

Cardiac imaging advances mean that cardiac CT scanning, which was an anatomical imaging modality (without functional quantification of blood flow/perfusion) is now being offered with CT perfusion assessment software that tracks the iodine contrast concentration in the myocardium throughout the cardiac cycle. Areas of low contrast correspond with areas of perfusion defects. Cardiac CT scan, it is argued, will allow for more timely discharge of patients without coronary causes and reduce the need for unnecessary nuclear medicine cardiac scans or cardiac coronary artery catheterizations.

23.3 Magnetic resonance imaging in emergency medicine

James Rippey

ESSENTIALS

1 **Magnetic resonance imaging (MRI) is becoming more readily available in Australian hospitals and is becoming part of many imaging diagnostic algorithms.**

2 **The most common indication for MRI in the emergency department (ED) is suspected acute spinal cord pathology.**

3 **MRI is well suited to imaging soft tissues, particularly the central nervous system, musculoskeletal tissues and abdominal organs.**

4 **Lack of ionizing radiation makes MRI a good choice for younger patients and pregnant women, although it is generally avoided in the first trimester.**

5 **Disadvantages for EDs include the time taken for a scan and difficulties with monitoring and resuscitation in the scanner, making MRI unsuitable for most unstable patients.**

Introduction

Magnetic resonance imaging (MRI), like each of the other imaging modalities, has its unique strengths and weaknesses. Emergency diagnostic imaging algorithms are complex and vary according to the clinical condition, the question being asked, patient factors, local availability and expertise. In Australasia, there are rapidly increasing numbers of MRI machines, together with appropriately trained staff. Many diagnostic algorithms are being revised to include MRI as a realistic imaging alternative. While the indications for urgent MRI are increasing, the major indication for emergency MRI remains suspected acute spinal cord pathology.

The main strength of MRI lies in its ability to image soft tissues at extremely high resolution, both spatially and with unparalleled levels of soft tissue contrast. It also has the ability to create two-dimensional slices in any plane; these multiplanar capabilities allow comparison of adjacent tissues from any angle.

Different MRI techniques allow different anatomical and pathological features to be demonstrated. MRI is particularly good at imaging the structure and pathology of brain, spinal cord and nerves, muscle, tendons and ligaments, cartilage, bone marrow and solid abdominal organs. The advent of magnetic resonance angiography (MRA) makes it an alternative to computed tomography angiography (CTA), particularly in those with contraindications to CT contrast media or those more vulnerable to ionizing radiation. Finally, the ability to perform electrocardiogram (ECG) -gated imaging has enabled unsurpassed dynamic noninvasive cardiac imaging.

MRI has imaging limitations in cortical bone and air-filled spaces (particularly lung) and thus tends not to be the imaging choice for assessing these tissues.

The lack of ionizing radiation makes MRI an attractive alternative to CT, particularly in younger patients, especially children and women of childbearing age. MRI's apparent safety in pregnancy is another advantage.

Currently, the main limitations of MRI lie in its lack of availability, expertise and associated high costs. From the perspective of emergency medicine, even when availability is not an issue, a major disadvantage is the time it takes to complete a scan. The patient is in an inaccessible, confined space, usually with limited monitoring for the duration of the 30- to 60-minute scan. MRI is therefore unsuitable for the unstable patient. If a patient is stable and intubated, specialized anaesthetic and monitoring equipment and expertise in using it is required to ensure patient safety.

Patients with metallic foreign bodies or electronic implants are often unable to have MRI, which can also limit its use.

Technical issues

Put very simply, the steps of an MRI involve putting the patient into a powerful magnet, sending in a radio wave and turning the radio wave off; the patient then emits a signal which is received and used for reconstruction of the image.

Components

The traditional MRI suite is centred around the MRI scanner, with its mobile patient table that moves the patient in and out of the MRI tunnel (Fig. 23.3.1). Current machines have a bore (internal diameter of the tunnel) of up to 70 cm and utilize short bore architecture that allows the tunnel to be approximately half the length of that required in the previous generation of MRI scanners. The machine houses a superconductor magnet, the strength of which is measured in Tesla. Most current machines operate at 1.5 or 3 Tesla. A 3-Tesla magnet creates a magnetic field around the patient 60,000 times the strength of the earth's magnetic field. In addition to the magnet, there are radiofrequency transmitter

FIG. 23.3.1 Typical 3-Tesla short bore, 70-cm opening diameter magnetic resonance imaging machine.

and receiver coils that send and receive radiofrequency pulses. These briefly disturb the magnetic field and ultimately create the MRI image. Another three sets of gradient coils provide additional linear electromagnetic fields important for spatial information—determining the origin of the signal in the three-dimensional space. It is these coils banging against their anchoring devices that cause the loud noises associated with MRI.

The high magnetic field generated by MRI means metallic objects within range can become projectile missiles, and great care has to be taken to ensure metal objects are well secured or do not enter the room. The magnet can also interfere with electronic equipment, such as computers, monitors and medical equipment such as pacemakers, and these must be kept away. Finally, the receiver coils are highly sensitive and are designed to detect very minor fluctuations in returning radio waves (which are a form of electromagnetic radiation). External radio waves can interfere with the waves received by the coils, and this noise will create artefacts interfering with image production. To minimize this, the entire MRI room is secured inside a Faraday cage, whose external conducting surface blocks or markedly attenuates any outside potentially interfering radio waves. The MRI control room and computer terminals with operating console are located immediately adjacent to, but outside the MRI room, in a similar fashion to the CT control room.

Creating an image

MRI depends on the alignment of hydrogen nuclei or positively charged protons within organic compounds in the body. Hydrogen nuclei act like tiny bar magnets. Under the influence of the external MRI magnet, mobile hydrogen ions align and spin in the orientation of the MRI magnet's field, creating a magnet of the patient's body. In addition to aligning and spinning on their own axis, protons also rotate or 'precess', as would a spinning top with a slight wobble, around a central axis.

Pulses of electromagnetic energy, called radiofrequency or RF pulses, are then sent into the area being imaged. This briefly disturbs the orientation and precession of the aligned protons. A transient reduction in the longitudinal magnetic field results, and a new magnetic vector in the transverse direction, called transversal magnetization, is created. Once the RF pulse is stopped, the protons relax back to their initial aligned state and the longitudinal and transverse magnetic vectors return to their original state. The realignment rate depends on tissue characteristics and water content. As the magnetic vectors realign, electric currents are induced and the MRI signal and signal intensity created. The receiver coils receive these minute pulses of newly created electromagnetic radiation, and these are interpreted to create the ultimate image.

Different magnetic resonance imaging techniques

Numerous different MRI imaging sequences and techniques have been developed to create the optimal images for varying body tissues and pathology. The following is not an exhaustive list.

T1 and T2 imaging

These are the most common MRI images with which we are familiar.

T1-weighted images (anatomical) create high-definition anatomical images with optimal tissue contrast resolution. In these images, fat is white and water is black. The resultant image gives detailed representation of the internal structure of soft tissue organs. T1 is a time constant that refers to the time it takes for the changes in longitudinal magnetization induced by the RF pulse, to return toward the original state. Measuring this tends to define structural tissue proteins and fats optimally.

T2-weighted images (pathological) highlight pathological processes where there is increased water content within tissues (Fig. 23.3.2). Most pathological processes involve an element of tissue oedema, and, whether it be trauma, infection, infarction or neoplasia, these images highlight water. Water is seen as white in these images. T2 is a time constant that refers to the time it takes for the changes in transversal magnetization induced by the RF pulse, to return toward their initial state. Measuring this tends to highlight water optimally.

Other MRI techniques each aimed at highlighting other anatomical or pathological features are shown in Fig. 23.3.3. The *left* image (A) is a FLAIR (fluid-attenuated inversion recovery) sequence that nulls fluid and can highlight periventricular demyelination; the *central* image (B) is a T2 gradient image which detects haemoglobin and its breakdown products; the *right*-hand image (C) is a diffusion apparent diffusion coefficient (ADC) image detecting cell injury in early stroke.

Angiography and gadolinium

MRA can be done with or without contrast media (Fig. 23.3.4 shows non-contrast MRI). Flow itself alters the MR signal simply by moving the protons that have been exposed to the RF pulse. This can leave what is called a flow void phenomenon, and, using this, the machine can create an angiographic image.

Where a contrast agent is used, the paramagnetic rare earth gadolinium (Gd) is the agent of choice. Its use creates excellent angiographic images. In addition, Gd does not cross the normal blood–brain barrier. However, if this is disrupted, as can occur in many pathological processes, Gd improves lesion detection and

diagnostic accuracy. Gd is not an iodinated contrast medium and is generally very well tolerated.

The sagittal images of the lumbar spine shown in Fig. 23.3.5 demonstrate a tumour involving the L1, causing some cord compression. The *left* image is T1, the *centre* T2 and the *right* a T1 fat-saturated post-Gd image where the tumour with its abnormal vasculature is most obvious.

Diffusion- and perfusion-weighted imaging

MRI imaging changes occur early after stroke and can be detected prior to any visible change on CT. Diffusion-weighted imaging assesses water diffusion across cell membranes. There is no water movement across cell membranes when cells are damaged. Diffusion imaging is used to define areas of newly infarcted cerebral tissue. These changes can occur as early as 10 minutes after infarction. Perfusion imaging aims to detect the potentially salvageable cerebrovascular accident 'penumbra' surrounding the non-viable ischaemic core, with a view to decision-making regarding thrombolysis and revascularization.

Cardiac imaging

Cardiac imaging is done by using ECG gating and imaging the heart over several cardiac cycles. Sequentially timed images taken from separate cardiac cycles are stitched together to create an animation representative of a single cardiac cycle. The result is a very high resolution, dynamic study of heart function and blood flow within the heart (Fig. 23.3.6).

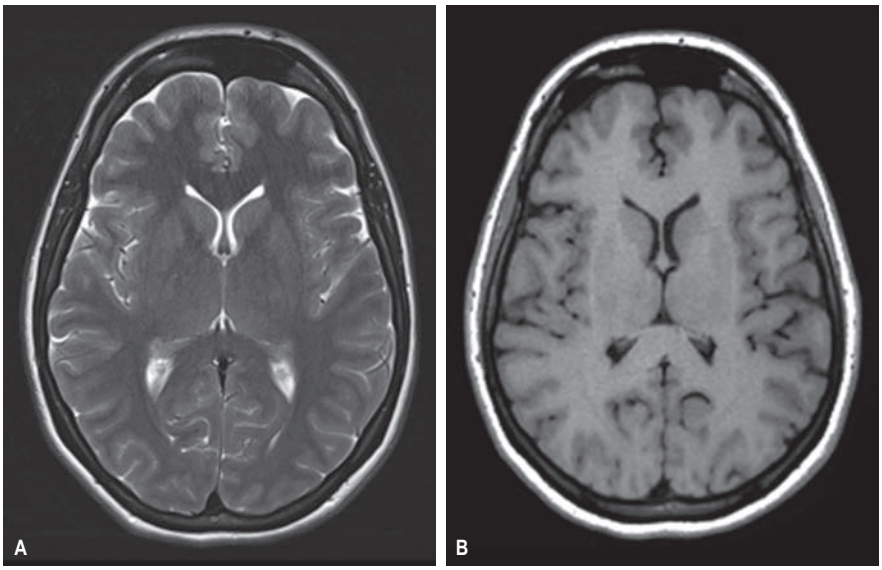

FIG. 23.3.2 (A) T2-weighted magnetic resonance image of the brain where water is bright and pathology involving oedema is best demonstrated. (B) T1-weighted magnetic resonance imaging where water is black and anatomic features are well demonstrated, maximizing soft tissue contrast.

Monitoring patients in the magnetic resonance imaging

The patient in the MRI suite is particularly vulnerable. His or her physical movement is restricted while in the MRI tunnel, he or she is inaccessible to immediate assistance and there are particular challenges with traditional patient monitoring in the MRI environment. This makes MRI unsuitable for the unstable patient and makes those requiring sedation or general anaesthesia a far greater challenge.

As a minimum requirement, visual camera and verbal monitoring are mandated for all MRI machines, ensuring some degree of immediate communication between radiographer and patient.

If any sedation is required, it is essential the patient have oxygen saturation monitoring. There are MRI-compatible units, with no ferromagnetic components, often fibreoptic, suited to this purpose and available in most units.

Patients who are under general anaesthetic require highly specialized anaesthetic staff and equipment. This form of remote anaesthesia requires unique training and practice. MRI-compatible and prepared equipment is required. This includes specially prepared ventilators and monitors. Attention to detail is required regarding all the equipment involved. Even inappropriate ECG dots and leads can heat and cause injury.

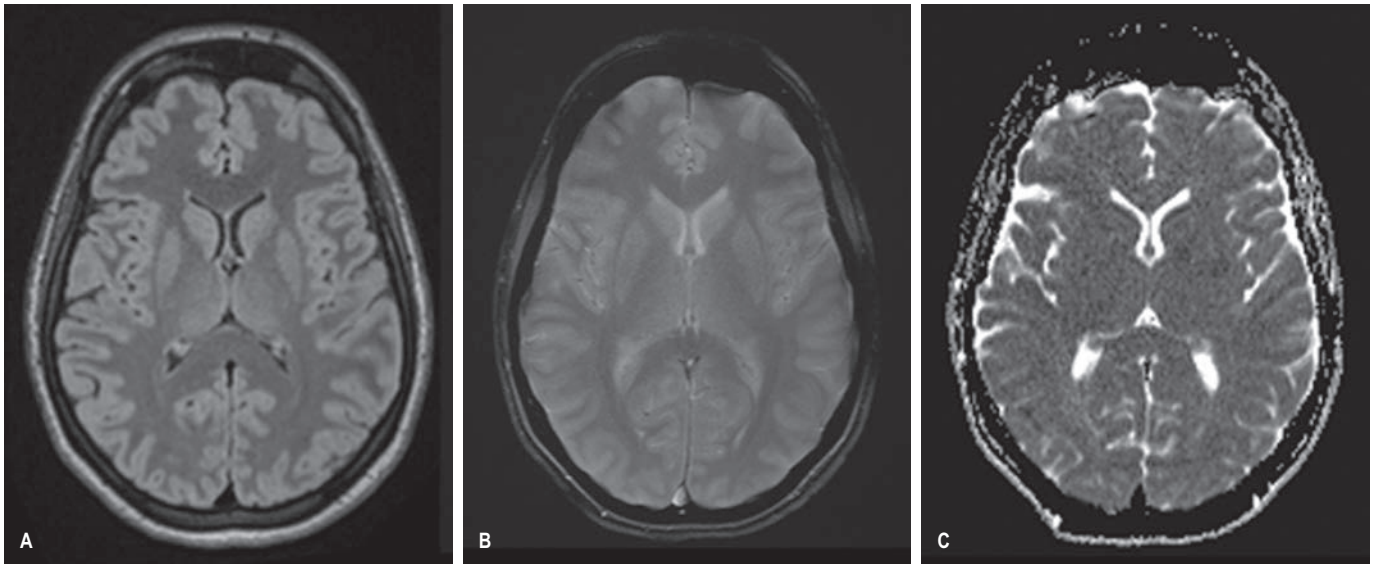

FIG. 23.3.3 Other Magnetic Resonance Imaging Techniques. *Left*: (A) FLAIR (fluid-attenuated inversion recovery) sequence; *centre*: (B) T2 gradient image; *right*: (C) diffusion ADC image.

Indications for magnetic resonance imaging

In most parts of the world, access to MRI, with its great cost and requirement for highly specialized radiography and radiology staff, is extremely limited. Australasia falls into the category where truly emergent MRI requests can usually be met by most tertiary hospitals. Arranging the scan in a public hospital generally requires consultant-to-consultant discussion and involvement of the inpatient specialty team.

Where there are reasonable imaging alternatives to MRI, diagnostic imaging guidelines have been designed to create effective alternative pathways.

Suspected acute spinal cord and cauda equina pathology

MRI is the investigation of choice when it comes to imaging the spinal cord, spinal nerves, intervertebral discs and ligaments of the spine. Where there are long tract signs and suspicion of an acute spinal cord–threatening lesion, most would proceed directly to MRI. In the setting of trauma, a CT to define bony injury is usually performed prior to MRI.

MRI clearly defines any pathological process affecting the cord, cerebrospinal fluid (CSF) space and surrounding soft tissues. In the emergency setting, trauma with cord injury (Fig. 23.3.7) or contusion may occur, and MRI gives additional information regarding spinal ligamentous injury. Other common cord-threatening pathology includes malignancy, which may originate in the vertebrae, most commonly the bodies, and extend into the spinal canal or may invade the canal through the spinal foramina. Malignant deposits, particularly metastases, may also originate within the spinal canal, involving the cord or dura. Infective processes, such as discitis and epidural abscess, are not infrequent causes of acute cord compression and are more common in IV drug users, the immunosuppressed and those who have had spinal procedures. Vascular phenomena, such as epidural haematoma, arteriovenous (AV) malformation with bleed, aneurysms and spinal cord infarction can all be defined by MRI. Degenerative conditions, such as disc prolapse (Fig. 23.3.8) and spinal canal stenosis from any cause, may also threaten the cord.

Rapidly defining the cause of the spinal cord lesion enables surgical planning or, if a malignant process, consideration and planning for radiotherapy.

FIG. 23.3.4 Noncontrast magnetic resonance imaging demonstrating the circle of Willis.

Stroke

MRI is an excellent modality for defining any brain pathology, and stroke is no exception. In addition to confirming the presence of stroke and excluding the presence of haemorrhage, MRI can detail the extent of brain injury, the vascular supply and any ischaemic penumbra and can assess for dissection or other predisposing vascular causes.

Unfortunately, even if immediately available, performing an MRI and then preparing and reporting the images often puts the patient outside the window of benefit for thrombolysis. CT is far more accessible and provides adequate information for the majority of cases, and this is currently the accepted 'gold standard'.

The exception is the posterior circulation and suspected brainstem infarction where MRI is superior to CT and generally required before interventional attempts at revascularization.

Headache

CT scan is usually the first choice for investigation of headache, but MRI may be considered among patients at high risk of the effects of ionizing radiation. MRI is performed where consideration for intervention for brain tumours, acoustic neuromas and pituitary tumours is being made. Where patients are young or cannot have iodinated contrast and sinus venous thrombosis is being considered, MR venography would be performed over CT venography; however, in most people, CT is adequate to define sinus venous thrombosis and other sinister causes of headache.

Angiography

MRA and CTA are considered similar in their utility for imaging blood vessels. Dissection is well imaged with either modality, and factors that would swing one in favour of MRI include a young patient age (MRI avoids radiation) and allergy to CT contrast.

Occult fracture detection

In the Australasian setting, it is unusual to attain an MRI to assess for occult fracture. Hip and scaphoid fractures are the classic examples where early detection and intervention can benefit the patient. CT scan has lower sensitivity than MRI for detecting occult hip fractures, but it remains reasonable. Where concern remains, a bone scan will give the answer. Similarly, for scaphoid fractures, CT or bone scan or immobilization and delayed repeat plain films at 10 days are reasonable alternatives.

Soft tissue musculoskeletal injury

MRI is increasingly being used to assess for soft tissue injury when complex injuries are suspected. Requests generally come from the orthopaedic team involved in the patient's care. MRI can image injuries to muscles, tendons, ligaments, joint capsule and cartilaginous surfaces extremely well (Fig. 23.3.9). Acute shoulder and knee injuries are most commonly assessed with MRI, but complex elbow, wrist, foot and ankle injuries can also be assessed by MRI.

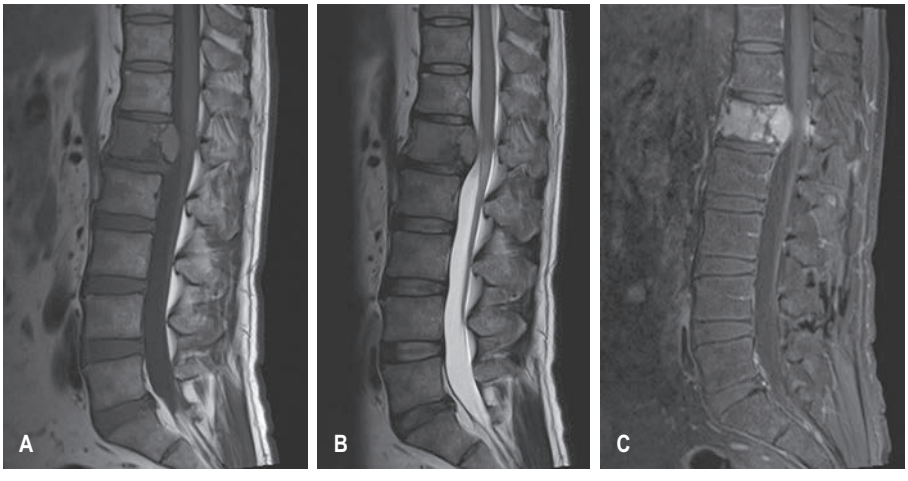

FIG. 23.3.5 Sagittal images of the lumbar spine showing tumour involving the L1, causing some cord compression. The *left* image (A) is T1, the *centre* (B) is T2 and the *right* (C) is a T1 fat-saturated post-gadolinium image where the tumour with its abnormal vasculature is most obvious.

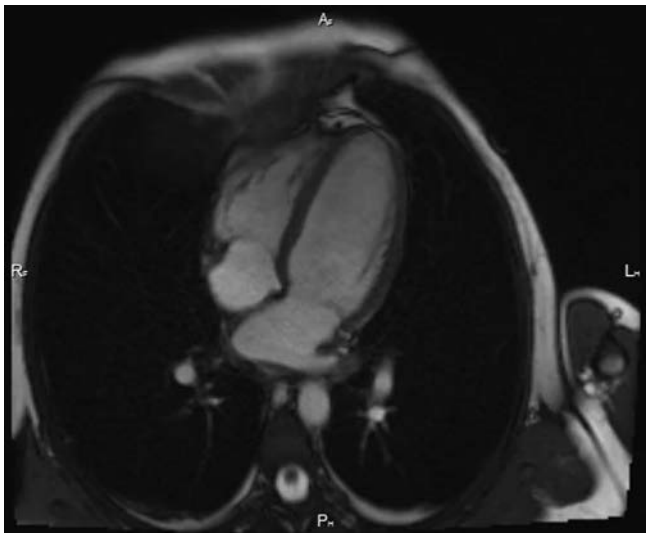

FIG. 23.3.6 Magnetic resonance imaging four-chamber cardiac view.

FIG. 23.3.9 Coronal knee magnetic resonance imaging showing ACL and MCL ligamentous disruption.

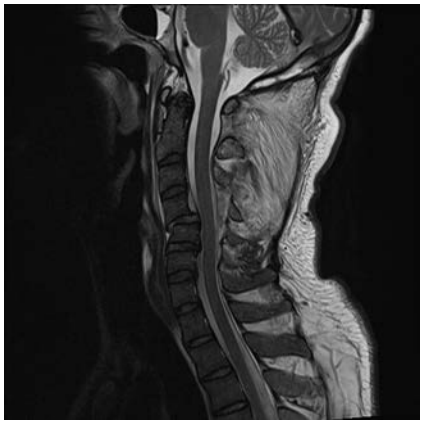

FIG 23.3.7 T2 sagittal image of an acute cervical spine injury with bifacetal dislocation and marked anterior displacement of the body of C4 on C5, with some cord oedema. The anterior and posterior longitudinal ligaments are well demonstrated.

FIG. 23.3.8 T2 image shows L4/5 disc prolapse with marked narrowing of the spinal canal and cauda equina compression.

Where there is complex fracture/dislocation and the relationship of adjacent bones and bone fragments need defining, CT is more appropriate.

Magnetic resonance cholangiopancreatogram (MRCP)

MRI can image the liver and biliary tree well. Ultrasound is generally the first imaging modality used to investigate for biliary pathology. Where concern remains and ultrasound imaging has not been definitive, MRCP can help. This is most common with distal biliary obstruction where ultrasound has not been able to image the extreme distal common bile duct. An effective alternative is endoscopic retrograde cholangiopancreatogram (ERCP) and endoscopic ultrasound. The advantage of ERCP is that therapeutic interventions, such as stone retrieval or stenting, can be carried out at the same time.

Appendicitis in pregnancy

Ultrasound is the first indicated investigation. MRI may sometimes be used where there is diagnostic uncertainty.

Contraindications, precautions and limitations

There are numerous contraindications to MRI, and pre-MRI safety checklists can be found at www.mrisafety.com. MRI technicians should be made aware of any implanted metallic, prosthetic, electronic or drug delivery device. The pre-MRI questionnaire also covers past medical history, particularly renal dysfunction and allergies.

Ferrous and metallic materials

The high magnetic field generated by MRI can move and heat metallic materials. While most joint and heart valve prostheses are now MRI compatible, older prostheses, implanted metallic medical devices, aneurysm clips and metallic shrapnel, especially intraocular metallic foreign bodies, are contraindications to MRI.

Metallic drug transdermal drug infusion patches often contain metal and can heat.

Some tattoos and permanent makeup contain iron oxide and can heat in the MRI environment, although this is rare.

Electronic implants

The intense magnetic field can affect electronic and magnetic equipment. Cardiac pacemakers, implantable cardioverter defibrillators, implanted nerve stimulators, cochlear implants and other electronic implants can be affected. Some are now MRI compatible; however, most are a contraindication to MRI. The website www.mrisafety.com has lists of thousands of implants and devices that have been tested in MRI machines and is recommended by RANZCR as a resource for obtaining information on patient's implanted devices.

Noise

The MRI is very loud, with constant banging heard. Ear protection is recommended.

Pregnancy

There has been no demonstrated adverse effect from MRI or Gd-based contrast media to the mother or embryo/foetus. However, the evidence in this setting is limited and, with regard to MRI exposure, the ALARA (as low as reasonably acceptable) principle is followed. MRI should be pursued only where potential benefits outweigh the risks. In general, it is considered prudent to avoid MRI in the first trimester.

Gadolinium

Gd can rarely cause nephrogenic systemic fibrosis (NSF). This disabling disease is more likely in patients with underlying renal disease. It is recommended that patients older than 60, those with hypertension or diabetes or a history of renal disease (including transplant or a single kidney), those within a month of a liver transplant or those with an acute deterioration in renal function have renal function tested prior to MRI. If their renal function is not normal, further discussion and consideration of the risk benefit ratio of Gd should be made in conjunction with the MRI radiologists.

Weight and size limits

Different MRI machines can tolerate different patient weight and size limits. Some tolerate patients up to 250 kg. Occasionally, it is the patient diameter or shape rather than absolute weight that limits entry to the MRI tunnel.

Claustrophobia

The MRI tunnel frequently causes claustrophobia. Non-pharmaceutical management may include patient education, allowing a patient companion to accompany the patient, continuous verbal contact, headphones with audio, use of prone and or feet first positioning, use of a blindfold, fan, bright lights, aromas or other relaxation techniques or watching videos or movies via mirrors.

Despite these measures, sedation is sometimes required and should be done only with oxygen and saturation monitoring and a single dedicated and trained person responsible to supervise and monitor the sedation.

Conclusion

The increasing availability of MRI within Australasia, together with improving imaging times and a diverse range of MRI techniques, mean MRI is becoming the imaging modality of choice for an increasing number of indications.

Currently, it is generally used in conjunction with other imaging modalities, particularly if they have been unsuccessful, in imaging soft tissue structures and pathology.

The required isolation of the patient for the duration of the scan and difficulty in monitoring and managing anaesthetized patients in the MRI mean it is not the place for unstable critically unwell patients.

CONTROVERSIES AND FUTURE DIRECTIONS

- Although currently most commonly limited to tertiary centres, as with other expensive technologies, magnetic resonance imaging (MRI) is likely to diffuse more widely through the hospital system.
- The indications for MRI from emergency departments are likely to expand as scanners become more widely available.
- Scanners which can accommodate the sitting patient are being developed, and these may enable wider access to MRI.

SECTION 24

ENVIRONMENTAL EMERGENCIES

Edited by *Mark Little*

24.1 Heat-related illness

Ian Rogers

ESSENTIALS

1 **Exercise-associated collapse is the most common heat- and exercise-related illness. It is due to an impaired compensation for the drop in blood pressure that occurs when muscle pumping ceases and venous return drops at the cessation of exercise. It responds rapidly to supine posture followed by rest and oral fluids. No other medical interventions are usually required.**

2 **Heatstroke is a true medical emergency, where rapid cooling using tepid spraying, fanning and ice packs is essential to minimize morbidity and mortality.**

3 **Water immersion may cool patients more rapidly but is not always practical in the emergency department. Its major role may be in the pre-hospital setting where early intervention may be life-saving.**

4 **Patients with drug-related hyperthermia may die from the complications of the high temperature, not from direct drug toxicity. Early and aggressive treatment of hyperthermia using similar methods to that for heat stroke and before complications occur is vital.**

Introduction

Heat-related disorders have a broad range of potential aetiologies and manifestations. In some the primary disorder is a failure of thermal homoeostasis, whereas in others the hyperthermia is secondary to other processes. The major heat-related illnesses to consider are exercise-associated collapse (EAC), heatstroke, and the drug-related heat illnesses neuroleptic malignant syndrome, serotonin toxicity and malignant hyperthermia. Whilst still in common use[1] the term 'heat exhaustion' should be discouraged as it has no defining pathophysiology or clinical syndrome, and has become a catch-all term for any illness in the context of a thermally stressful environment.

Epidemiology and pathophysiology

EAC is the most common heat-related illnesses presenting either to medical tents at sporting events or to emergency departments (EDs). EAC manifests at the end of a race when muscle pump enhanced venous return ceases and cardiac output drops. This leads to collapse, often with a brief loss of consciousness. The primary mechanism is a failure of prompt baroreceptor responses and not haemodynamically significant dehydration. Severe heat-related dehydration is rare.

The other, more serious, heat-related disorders are all associated with, or have the potential for, significant hyperthermia which if not treated promptly results in similar pathophysiology at a cellular and organ system level. A core body temperature around or greater than 41.5°C results in progressive denaturing of a number of vital cellular proteins, failure of vital energy-producing processes and loss of cell membrane function. At an organ system level these changes may manifest as rhabdomyolysis, acute pulmonary oedema, disseminated intravascular coagulation, cardiovascular dysfunction, electrolyte disturbance, renal failure, liver failure and permanent neurological damage.[2,3] Any or all of these complications must be expected in severe heat illness.

The hallmark of heatstroke is failure of the hypothalamic thermostat, leading to hyperthermia and the associated additional pathophysiological features described above. Clinically, heatstroke can be divided into 'exertional heatstroke' due to exercise in a thermally stressful environment, and 'classic heatstroke', which occurs in patients with impaired thermostatic mechanisms. Common risk factors for heatstroke are listed in Box 24.1.1.

Certain drugs produce hyperthermia by mechanisms in addition to interference with thermostatic function. These mechanisms and the appropriate treatment are described in detail elsewhere.

Prevention

Prevention of exertional heatstroke should focus on the education of at-risk groups. Dehydration is not as important aetiologically in heatstroke as once thought. Exertional heatstroke is most often reported in shorter, high intensity exercise where marked dehydration is unlikely. So although adequate fluid intake is needed for prolonged exercise it is not a key factor in heatstroke prevention. As high ambient temperatures and high humidity predispose to exertional heatstroke, exertion in these environments should be limited. Sporting organizations and workplaces are encouraged to minimize risk by using tools that take such factors into account. These tools include the wet bulb globe temperature measurement and formal heat stress scoring systems.

Clinical features

Exercise-associated collapse

The clinical presentation of EAC will be familiar to all emergency practitioners as it mirrors that of poor cerebral perfusion from any other cause. Patients complain of nausea, vomiting, malaise and dizziness. There may be a history of collapse, and there is likely to be a tachycardia and (orthostatic) hypotension. The orthostatic hypotension typically manifests at the end of physical exertion by collapse, often with brief loss of consciousness. In this syndrome, and in distinction to heatstroke, the core temperature will be less than 40°C and neurological function will rapidly return to normal once the patient is supine.

Heatstroke

The classic clinical features of heatstroke are neurological dysfunction, core temperature above 41.5°C and hot, dry skin. However, relying on this classic triad to make the diagnosis will result in a number of cases being missed. Loss of consciousness is a constant feature of heatstroke[3] but by the time of ED presentation conscious state may be improving, although some neurological abnormality will persist. Temperature readings may be misleadingly low, due either to effective prehospital care or to measurements at inappropriate sites, such as the oral cavity or axilla. Profuse sweating is a much more common feature than previously thought.[3] Other clinical features may include tachycardia, hyperventilation, seizures, vomiting and hypotension.

Clinical investigation

Diagnosis of the hyperthermic disorders is based on the history, clinical picture and exclusion of alternative diagnoses. Investigations are thus directed towards excluding other possible causes of temperature elevation (e.g. infection, metabolic disorders) and evaluation of the specific complications of hyperthermia.

Patients with a presumed clinical diagnosis of EAC should still have serum electrolytes and creatine kinase measured to exclude exercise associated hyponatraemia and rhabdomyolysis respectively. Should mental state not rapidly normalize with supine posture then an urgent finger prick or serum glucose estimation is needed. Collapsed athletes should also have an ECG to identify unrecognized cardiac abnormalities.

All other heat disorders warrant a far more extensive laboratory and radiological work-up, as multiorgan system dysfunction is the rule.[2,4] Tests must include an ECG, serum electrolytes, disseminated intravascular coagulation (DIC) screen, liver function tests, muscle enzyme assays, renal function and urinalysis, serum glucose and a chest x-ray.

Treatment

Exercise-associated collapse

EAC responds rapidly to supine posture (ideally with the legs elevated), rest and oral fluids. Intravenous normal saline is rarely required as few athletes will be profoundly dehydrated. The use of 'routine' intravenous (IV) normal saline in collapsed athletes should be actively discouraged as it will worsen exercise associated hyponatraemia where there is usually already fluid overload with persistent and inappropriate antidiuretic hormone levels.

Heatstroke

This is a true medical emergency. Early recognition and aggressive therapy in the field and in hospital can prevent substantial morbidity and mortality. The key management is aggressive cooling. Cooling rates of at least 0.1°C/min should be achievable. Several cooling methods have been proposed, including evaporative cooling, iced water immersion, ice slush, cool water immersion, iced peritoneal lavage and pharmacological methods.[1,5] A combination of methods is most widely used in EDs. All of the patient's clothing should be removed and the patient sprayed with a fine mist of tepid water while gentle fanning is commenced (a ceiling fan is ideal). At the same time, areas with vascular beds close to the surface (neck, axillae and groins) should be packed with ice bags. This technique facilitates patient access and monitoring when compared to methods such as ice-bath immersion even though an iced bath may offer more rapid cooling. In the field ice-bath immersion may be preferred, but in the ED covering the patient with regularly replaced towels that have been soaked in iced water may offer a compromise between the efficacy of immersion cooling and the need for monitoring and accessibility. Intravascular cooling devices, while able to rapidly cool, are cumbersome to set up and not widely available. As such in heat stroke, where time is of the essence, their use is not encouraged. Although ice cold IV fluids can also aid in rapid cooling, fluid requirements in heatstroke can be difficult to estimate and balance.

In hospital, shivering, seizures and muscle activity may need to be controlled with pharmacological agents such as chlorpromazine, benzodiazepines and paralyzing agents. Aspirin and paracetamol are ineffective and should be avoided. Intravenous fluids need to be used cautiously and may need titrating to central venous pressures. Maintain adequate oxygenation but avoid hyperoxia. Ventilatory support may be required. Urine flow needs to be maintained with initial volume loading, and later with mannitol or frusemide, to prevent secondary renal injury, especially from rhabdomyolysis. Electrolyte, acid–base and clotting disturbances should be closely monitored and treated by standard measures. Heat stroke due to drug-related causes is treated using the same cooling methods as described above; however specific drug therapies may be indicated and are described elsewhere.

Prognosis and disposition

In heatstroke both the maximum core temperature and the duration of temperature elevation are predictors of outcome. Prolonged coma and oliguric renal failure are poor prognostic signs.[2]

Mortality is still of the order of 10%, but most survivors will not suffer long-term sequelae.[2,3] Any patient with suspected heatstroke should routinely be referred to the intensive care unit for ongoing care. Most cases of EAC will be suitable for short-stay ED treatment or indeed simply for treatment on-site in an event medical tent.

CONTROVERSIES

1 Although debate is likely to continue about the most effective cooling therapy in heatstroke, this is largely of academic interest as all methods seem to achieve the desired outcome of rapid temperature drop. Of more interest will be research that focuses on the cellular mechanisms of the damage seen with hyperthermia. Such research may lead to the development of pharmacological agents that can prevent or treat heatstroke.

2 Whilst the term 'heat exhaustion' is still frequently used, its use should be actively discouraged as it has no defining pathophysiology or distinct clinical syndrome.

3 The long-standing dogma that vigorous hydration prevents heat illness is now challenged. A greater concern now is to highlight the risks of promotion of aggressive hydration strategies in sport.

24.2 Hypothermia

Ian Rogers

ESSENTIALS

1 Hypothermia is categorized into mild (32°C to 35°C), moderate (29°C to 32°C) and severe (<29°C) on the basis of a rectal or other core temperature reading.

2 Moderate-to-severe hypothermia produces progressive delirium and coma, hypotension, bradycardia and failure of thermogenesis.

3 The electrocardiograph will often show slow atrial fibrillation and an extra positive deflection in the QRS (the J or Osborn wave) in leads II and V_3 to V_6 with worsening hypothermia.

4 Endotracheal intubation is safe in hypothermia. Ventilation and acid–base status should be manipulated to maintain uncorrected blood gases within the normal range.

5 Endogenous rewarming, consisting of drying the patients and placing them in a warm, dry and wind-free environment, should form part of all rewarming protocols.

6 In most cases of moderate-to-severe hypothermia rewarming can be achieved with endogenous rewarming plus forced-air rewarming blankets without the need to resort to more aggressive techniques.

7 In the arrested hypothermic patient rewarming should be with cardiopulmonary bypass or warm left pleural lavage.

Introduction

Hypothermia is defined as a core temperature of less than 35°C. This can be measured at a number of sites (including oesophageal, right heart, tympanic and bladder). Rectal remains the routine in most emergency departments (EDs), despite concerns at how rapidly it equilibrates to and reflects true core temperature. Conventionally, hypothermia is divided into three groups: mild (32°C to 35°C), moderate (29°C to 32°C) and severe (<29°C) on the basis of measured core temperature. In a field setting, where core temperature measurements may not be possible, moderate and severe are often grouped together as they typically share the clinical features of absence of shivering and altered mental state. These categorization systems can be used both out of and in hospital as a guide to selecting rewarming therapies and prognosis. Mild hypothermia is considered the stage where thermogenesis is still possible; moderate is characterized by a progressive failure of thermogenesis; and severe by adoption of the temperature of the surrounding environment (poikilothermia) and an increasing risk of malignant cardiac arrhythmia. Nevertheless, there are substantial differences between individuals in their response to hypothermia.

Epidemiology and pathophysiology

Hypothermia may occur in any setting or season.[1] True environmental hypothermia occurring in a healthy patient in an adverse physical environment is less common in clinical practice than that secondary to an underlying disorder. Common precipitants include injury, infection, systemic illness, drug overdose and immersion, and are outlined in more detail in Table 24.2.1. The elderly are at greater risk of hypothermia because of reduced metabolic heat production and impaired responses to a cold environment. Alcohol is a common aetiological factor and probably acts by a number of mechanisms, including cutaneous vasodilatation, altered behavioural responses, impaired shivering and hypothalamic dysfunction.

Table 24.2.1 Hypothermia aetiologies

Environmental	Cold, wet, windy ambient conditions Cold water immersion Exhaustion
Trauma	Multitrauma (entrapment, resuscitation, head injury) Minor trauma and immobility (e.g. # fractured neck of femur (NOF), # fractured neck of humerus (NOH)) Major burns
Drugs	Ethanol Sedatives (e.g. benzodiazepines) in overdose Phenothiazines (impaired shivering)
Neurological	Cerebrovascular accident (CVA) Paraplegia Parkinson's disease
Endocrine	Hypoglycaemia Hypothyroidism Hypoadrenalism
Systemic illness	Sepsis Malnutrition

Clinical features

The clinical manifestations of hypothermia depend on both the degree of core temperature drop as well as the features of the underlying aetiology. Individual variation in presentation is common.

Mild hypothermia manifests clinically as shivering, apathy, ataxia, dysarthria and tachycardia. Moderate hypothermia is typically marked by a loss of shivering, altered mental state, muscular rigidity, bradycardia and hypotension. In severe hypothermia signs of life may become almost undetectable, with coma, fixed and dilated pupils, areflexia and profound bradycardia and hypotension. The typical cardiac rhythm of severe hypothermia is slow atrial fibrillation. This may degenerate spontaneously, or with rough handling, into ventricular fibrillation or asystole. In the field, moderate and severe hypothermia are often grouped together, with the key clinical feature of absent shivering suggesting the loss of the ability to rewarm without medical intervention.

Many complications may also manifest as part of a hypothermia presentation, although at times it may be difficult to separate cause from effect. These include cardiac arrhythmias, thromboembolism, rhabdomyolysis, renal failure, disseminated intravascular coagulation and pancreatitis.

Clinical investigation

Mild hypothermia with shivering and without apparent underlying illness needs no investigation in the ED.

Moderate or severe hypothermia mandates a comprehensive workup to seek common precipitants and complications that may not be clinically apparent.

Biochemical and haematological abnormalities are frequently associated with hypothermia,[1] although there is no consistent pattern. Blood tests indicated include sodium, potassium, glucose, renal function, calcium, phosphate, magnesium, lipase, creatine kinase, ethanol, full blood count and clotting profile. Blood gases if taken should be accepted at face value, rather than adjusting for the patient's temperature.

Impaired ciliary function, stasis of respiratory secretions or aspiration may be expected in moderate-to-severe hypothermia, so chest radiography should be routine. Other radiology may be indicated if a trauma-related aetiology is suspected.

A 12-lead electrocardiograph (ECG) and continuous ECG monitoring should be routine in moderate-to-severe hypothermia. The typical appearance is slow atrial fibrillation, with J or Osborn waves most prominent in leads II and V_3 to V_6 (Fig. 24.2.1). The J wave is the extra positive deflection after the normal S wave. These changes become more common and prominent with increasing severity of hypothermia, typically occurring below 32°C.[2]

Treatment

General

The general and supportive management of hypothermia victims largely follows that of other critically ill patients. However, some syndrome-specific issues demand careful attention.

Muscle glycogen is the substrate preferentially used by the body to generate heat by shivering. All hypothermics, therefore, need glucose. In mild cases this can be given orally as sweetened drinks or easily palatable food. With more severe hypothermia gastric stasis and ileus are common, and glucose should be given intravenously: 5% dextrose can be infused at 200 mL/h. Additional volume resuscitation should be gentle, bearing in mind the contracted intravascular space in severe hypothermia, and that hypotension that would be classified as severe at a core temperature of 37°C is a normal physiological state at 27°C. All intravenous fluids should be warmed to minimize ongoing cooling. Endotracheal intubation by a skilled operator is safe in severe hypothermia. Intubation is indicated as in any other clinical condition to provide airway protection or to assist in ventilation.

Ventilatory support and, where necessary, manipulation of acid–base status, should be titrated to maintain uncorrected blood gas pH and partial pressure of CO2 (PCO_2) within the normal range.

The slow atrial fibrillation so common in more severe hypothermia is a benign rhythm and requires no chemical or electrical correction. It will revert spontaneously with rewarming. Pulseless ventricular tachycardia and ventricular fibrillation should largely be managed along conventional lines. However, if initial direct current (DC) shocks are unsuccessful, then others are unlikely to be so until the patient is warmer. Repeat countershocks are generally reapplied with every 1°C increase in core temperature. Magnesium may be the antiarrhythmic drug of choice in hypothermia.

The pharmacokinetics and dynamics of most drugs are substantially altered at low body core temperatures. Indeed, for many of the common drugs used in an ED they are unknown. Insulin is known to be inactive at <30°C. Hyperglycaemia, due in part to loss of insulin activity, is common in hypothermia, but should probably be managed expectantly until sufficient rewarming has occurred to ensure full endogenous insulin activity.

Rewarming therapies

Strategies for rewarming in hypothermia have only a limited evidence base on which to base recommendations and little has changed in recent decades, despite some enthusiasm for more complex devices such as endovascular temperature control catheters.[3] Although more invasive and rapid techniques are advocated for more severe hypothermia, there is little evidence to support this advice. The traditional concern of afterdrop (a paradoxical initial drop in core temperature with rewarming) is probably of little or no relevance in a clinical setting.[4]

Rewarming therapies are broadly divided into three groups: endogenous rewarming, which is allowing the body to rewarm by its own endogenous heat production; external

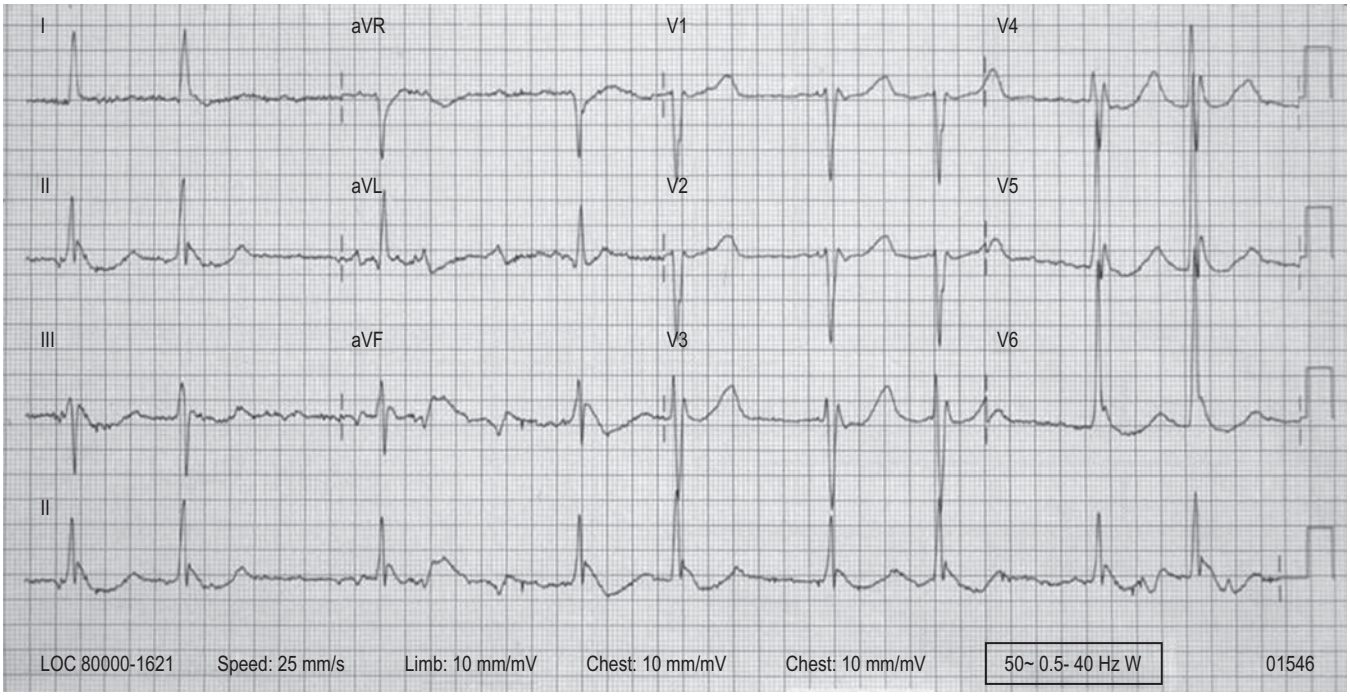

FIG. 24.2.1 ECG in hypothermia: slow atrial fibrillation, shivering artefact and J waves in leads II, V_3 to V_6 in a patient with a core temperature of 29.1°C.

Table 24.2.2 Rewarming therapy classification

Endogenous rewarming	Warm, dry, wind-free environment Warmed intravenous fluids (to prevent cooling)
External exogenous rewarming	Hot bath immersion Forced-air blankets Heat packs Body-to-body contact
Core exogenous rewarming	Warmed, humidified inhalation Left pleural cavity lavage Extracorporeal circulation

exogenous rewarming, which is supplying heat to the outside of the body; and core exogenous rewarming, which is applying the heat centrally. The classification of the commonly utilized rewarming therapies is outlined in Table 24.2.2.

Endogenous rewarming is a mandatory component of any emergency rewarming protocol. It consists of drying the patient, covering them with blankets, placing them in a warm and wind-free environment, and warming any intravenous or oral fluids that are administered. Endogenous rewarming alone can be expected to rewarm at a rate of about 0.75°C/h. For most patients above 32°C (the level at which shivering thermogenesis is typically preserved), endogenous rewarming is the only therapy required. The exception is the exhausted patient in whom shivering has ceased at a core temperature higher than expected. Although more sophisticated techniques, such as bath immersion, will more rapidly rewarm a mildly hypothermic patient, there is no evidence that an increased rewarming rate improves prognosis in this group.

In moderate hypothermia, endogenous heat production is likely to progressively fail and more aggressive exogenous rewarming therapies are indicated. Hot-bath immersion has the theoretical disadvantage of causing peripheral vasodilatation, with shunting of cool blood to the core and further cooling. This might be expected to increase core afterdrop and produce circulatory collapse. In fact, rewarming rates of at least 2.5°C/h with minimal afterdrop have been achieved using baths at 43°C.[4] Nevertheless, substantial practical difficulties are obvious with monitoring a more seriously ill patient immersed in a bath. This method of rewarming can only be recommended for otherwise healthy patients who are expected to make a rapid recovery from accidental environmental hypothermia (e.g. immersion in very cold water).

The therapy that has been best studied and most widely used in moderate hypothermia is forced-air rewarming.[5] Forced-air rewarming is achieved by covering the patient with a blanket filled with air at 43°C. These devices direct a continuous current of air over the patient's skin through a series of slits in the patient surface of the blanket. This method produces minimal, if any, afterdrop, is apparently without complication, and should produce rewarming at about 2.0°C/h. Warm humidified inhalation may be added to this, and its value is largely by preventing ongoing respiratory heat loss.[6] Body-to-body contact and chemical heat packs are often recommended as field treatments for all degrees of hypothermia. In mild hypothermia, whilst they provide comfort it seems that the benefit of any heat they deliver is negated by an inhibition of shivering thermogenesis. In more severe cases, where shivering is absent, it may be that even the small amount of exogenous heat they deliver is beneficial.

In severe hypothermia more aggressive exogenous rewarming therapies may be indicated in order to rapidly achieve core temperature above 30°C, the threshold below which malignant cardiac arrhythmias may occur spontaneously. Bladder, gastric or peritoneal lavage with warm fluids are all relatively ineffective methods of heat transfer,

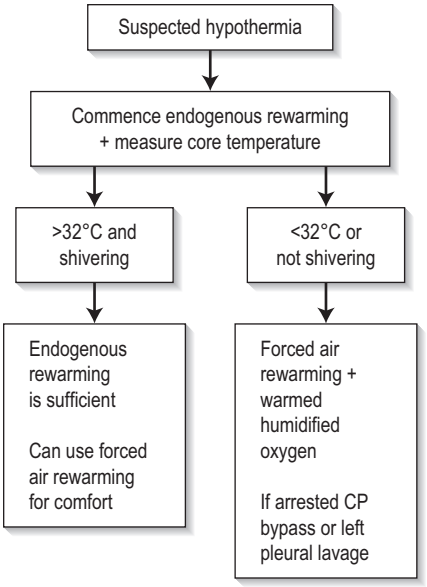

FIG. 24.2.2 A recommended rewarming algorithm in hypothermia. CP, cardiopulmonary.

and as such are not recommended for use in emergency situations. When available, full cardiopulmonary bypass achieves rewarming rates of about 7.5°C/h without core afterdrop. Pleural lavage using large volumes of fluid warmed to 40°C to 45°C through an intercostal catheter may be nearly as effective.[7] Both techniques have the advantage of delivering heat to the heart which acts as a heat pump to distribute rewarming to key core organs, but are clearly invasive and carry associated risks. These risks are certainly acceptable in a hypothermic arrest, but in the non-arrested patient a slower rate of rewarming using forced-air and warm humidified inhalation may be more appropriate.

A suggested rewarming algorithm is shown in Fig. 24.2.2.

Prognosis and disposition

Attempts at developing a valid outcome prediction model for hypothermia are likely to be frustrated by its multifactorial aetiology. Recovery with appropriate treatment is likely from accidental environmental hypothermia when there is no associated trauma. To date, the coldest patient to survive accidental hypothermia neurologically intact had an initial measured temperature of 13.7°C.[8] Although increasing severity of hypothermia does worsen prognosis, the major determinant of outcome is the precipitating illness or injury. Reported mortality rates vary from 0% to 85%.

Mild hypothermics without associated illness or injury can be safely managed at home in the care of a responsible adult. Moderate hypothermia may be treatable in a short-stay observation ward, but often requires a longer inpatient stay to manage underlying illness or injury. Severe hypothermics are at risk of multiorgan system complications and should be considered for admission to an intensive care unit.

CONTROVERSIES

1. The question of which rewarming therapy to use will only be answered when the focus moves to randomized clinical trials measuring clinically relevant outcomes, such as morbidity and mortality, rather than surrogate markers such as rewarming rate and core afterdrop.
2. The role of more technologically advanced rewarming techniques is not yet clear, and as yet no advantage has been shown over longstanding and low technology approaches.

24.3 Dysbarism

David R. Smart

ESSENTIALS

1 **Dysbarism is the term given to medical complications of exposure to gases at higher than normal atmospheric pressure. It includes barotrauma and decompression illness.**

2 **An understanding of the pathophysiology of dysbarism requires an understanding of the gas laws.**

3 **Barotrauma occurs as a consequence of excessive expansion or contraction of gas within enclosed body cavities. It principally affects the middle ear, the sinuses and the lungs. Lung barotrauma may result in gas embolism, pneumomediastinum or pneumothorax. Inner-ear barotrauma is rare but serious and may mimic vestibular decompression illness.**

4 **Decompression illness occurs when gas bubbles develop within the body. This may occur as a complication of pulmonary barotrauma or when a diver whose tissues are supersaturated with nitrogen (or other breathing gas such as helium), ascends too rapidly.**

5 **The clinical manifestations of decompression illness may affect many body systems and are extremely variable in nature and severity. Loss of consciousness or neurological symptoms and signs (including cognitive dysfunction) indicate serious decompression illness.**

6 **If a diver becomes unwell during or after diving, then diving is the likely cause of the illness, until proven otherwise. Early consultation with a diving medicine specialist is mandatory, especially where retrieval to a recompression facility may be necessary.**

7 **The seriously injured diver should be managed lying flat and urgently referred for recompression treatment. The diver should not exceed 300 m altitude during retrieval for recompression treatment.**

8 **Nondiving causes of dysbarism include caisson work, altitude decompression, recreational use of compressed gases (nitrous oxide and helium) causing pulmonary barotrauma and gas embolism and medical adverse events where gas enters the circulation. These cases are likely to benefit from early recompression with hyperbaric oxygen.**

Introduction

This chapter focuses on medical problems that develop secondary to breathing gases at higher than normal atmospheric pressure (dysbarism). This usually occurs in the context of scuba (self-contained underwater breathing apparatus) diving, a popular recreational activity in Australasia. Diving is generally very safe and serious decompression incidents occur approximately 1:10,000 dives. However, because of a high participation rate, between 200 and 300 cases of decompression illness are treated in Australia each year.[1] It is estimated that 10 times that number of divers experience less serious health problems after diving. Emergency physicians are often the first medical staff to assess the diver after a diving accident and it is essential they understand the risks and potential injuries.

Diving physics and physiology

An understanding of pressure and some gas laws is essential to understand the pathophysiology of diving injuries. The air pressure at sea level is 1 atmosphere absolute (ATA). Multiple units are used to measure pressure (Box 24.3.1). For every 10 m a diver descends in seawater, the pressure increases by 1 ATA. This pressure change impacts on gas spaces within the body according to Boyle's law.

Boyle's law states that, at a constant temperature, the volume of a gas varies inversely to the pressure acting on it:

$$PV = k$$

where P = pressure, V = volume and k = constant.

Box 24.3.1 Atmospheric pressure at sea level in various units

1 Atmosphere absolute (ATA)
101.3 kPa (SI units)
1.013 Bar
10 m of sea water (MSW)
760 mm of mercury (mm Hg)
14.7 pounds per square inch (PSI)

Table 24.3.1 Depth vs pressure and gas volume (Boyle's law)

Depth (m)	*Absolute pressure (ATA)*	*Gas volume (%)*
0	1	100
10	2	50
20	3	33
30	4	25
40	5	20

The proportionate change in volume is greatest near the surface (Table 24.3.1).

Dalton's law states that the total pressure (P_t) exerted by a mixture of gases is equal to the sum of the pressures of the constituent gases (P_x, P_y, P_z):

$$P_t = P_x + P_y + P_z$$

Therefore as divers breathe air at increasing atmospheric pressure, the partial pressures of nitrogen and oxygen increase:

$$\begin{aligned} \text{Surface} &= 1 \text{ ATA} \\ &= 0.8 \text{ ATA } N_2 + 0.2 \text{ ATA } O_2 \\ 10 \text{ m} &= 2 \text{ ATA} \\ &= 1.6 \text{ ATA } N_2 + 0.4 \text{ ATA } O_2 \\ 40 \text{ m} &= 5 \text{ ATA} \\ &= 4.0 \text{ ATA } N_2 + 1.0 \text{ ATA } O_2 \end{aligned}$$

A diver breathing air at 40 m is inhaling a gas with a partial pressure of oxygen equivalent to breathing 100% oxygen at the surface. At partial pressures above 3 ATA, the PN_2 affects coordination and judgement ('nitrogen narcosis'). Oxygen may also become toxic at partial pressures greater than 1 ATA. Recreational scuba diving generally has a limit of 40 m because of these effects.

Henry's law states that at a constant temperature the amount of a gas that will dissolve in a liquid is proportional to the partial pressure of the gas in contact with the liquid:

$$Q = kP_{gas}$$

where Q = volume of gas dissolved in a liquid, k = constant and P_{gas} = partial pressure of the gas.

Henry's law is relevant in diving illness because it is the basis of decompression illness (DCI). As the ambient pressure increases, the diver is exposed to increasing partial pressures of nitrogen (or other gas such as helium), which dissolves in bodily fluids. The amount of nitrogen absorbed depends on both the depth (which determines the partial pressure of nitrogen) and the duration of the dive. Tissues also take up nitrogen at different rates depending on their blood supply and permeability. Eventually, the tissues become saturated with nitrogen and no further absorption occurs. As the diver ascends and ambient pressure decreases, the partial pressure of nitrogen in some tissues will exceed ambient pressure, resulting in tissue supersaturation. If the diver ascends slowly enough, nitrogen diffuses out of the tissues and is transported, safely dissolved in the blood, to the lungs for elimination. This is known as 'off-gassing'.

If the diver ascends too rapidly, sufficient nitrogen bubbles will form in their body to cause decompression illness. Oxygen does not cause problems because it is rapidly metabolized by the tissues.

Barotrauma

Barotrauma occurs when changes in ambient pressure lead to expansion or contraction of gas within enclosed body cavities. The change in gas volume distorts or tears adjacent tissue. Injury by this mechanism may occur to the middle ear, inner ear, sinuses, lungs, eyes (via the diver's mask) and rarely, the gut. Different injury patterns occur in breath-hold divers (snorkellers) compared to those breathing compressed air. Both breath-hold and scuba divers may experience injury of the middle and inner ear, sinuses and eyes if they do not equalize pressures in the gas spaces as they descend. Breath-hold divers are unlikely to injure their lungs as their lung volumes reduce as they descend and return to their original volume as they ascend to the surface by the increasing ambient pressure.

Middle-ear barotrauma

Pathophysiology

Middle-ear barotrauma (MEBT), the most common medical disorder of diving, usually occurs during descent. Increased ambient pressure results in a reduction of middle-ear volume. If equalization of the volume via the eustachian tube is inadequate, a series of pathological changes results. The tympanic membrane (TM) is deformed inwards, causing inflammation and haemorrhage. Middle-ear mucosal oedema is followed by vascular engorgement, effusion, haemorrhage and, rarely, TM rupture.

Clinical features

Symptoms of middle-ear barotraumas include ear pain, tinnitus and conductive hearing loss. Mild vertigo may also be experienced. More severe vertigo and pain occur if water passes through a perforated TM. Severe vertigo and significant sensorineural hearing loss should alert the emergency physician to possible inner-ear barotrauma (IEBT) (see below). MEBT severity is graded by visual inspection of the TM (Table 24.3.2). An audiogram is useful to document any hearing loss.

Treatment

Treatment of MEBT consists of analgesia, decongestants and ear, nose and throat (ENT) referral if there is TM perforation or suspected IEBT. Antibiotics are indicated for TM rupture because of potential contamination with water. The patient should not dive again until symptoms and signs have resolved, any TM perforation has healed, and the eustachian tube is patent.

Inner-ear barotrauma

Pathophysiology

Sudden pressure changes between the middle and inner ears can cause rupture of the round or oval windows or a tear of Reissner's membrane. This usually occurs during rapid descent without equalizing or forceful Valsalva manoeuvres.

Clinical features

Symptoms include sudden onset of tinnitus, vertigo, nausea and vomiting, vestibular symptoms and profound sensorineural hearing loss, which may not be apparent until the diver has left the water.[2] Onset of symptoms after the dive while performing an activity that increases intracranial pressure (e.g. heavy lifting) suggests IEBT. Coexistent middle-ear barotrauma is absent in about one-third of cases.

The main differential diagnosis is DCI involving the inner ear or vestibular apparatus. Frequently it is difficult to distinguish between IEBT and vestibular DCI, although the latter is frequently accompanied by other symptoms or signs of DCI. Because of this overlap in clinical syndromes, early specialist advice should be sought.

Table 24.3.2 Grading of severity of middle-ear barotrauma

Grade 0	Symptoms without signs
Grade 1	Injection of TM along handle of malleus
Grade 2	Slight haemorrhage within the TM
Grade 3	Gross haemorrhage within the TM
Grade 4	Free blood in middle ear
Grade 5	Perforation of TM

TM, Tympanic membrane.

Treatment

Treatment of IEBT consists of avoidance of activities that increase intracranial pressure and urgent (same day) ENT referral for more detailed assessment and audiometry. Surgical repair may be undertaken when vertiginous symptoms are severe. Vomiting should be treated with antiemetics and the diver kept supine with their head on a pillow. If DCI is excluded, then a 45° semirecumbent position is preferred. If DCI cannot be excluded the diver should have a trial of recompression. In one series, exposure to pressure did not worsen IEBT. The benefit of steroids in IEBT has not been confirmed.[2]

It was thought that further diving was contraindicated after IEBT, but recent case data suggest that diving might be possible following full recovery of hearing.

External ear barotrauma

Ear-canal barotrauma is very rare and only occurs if there is a complete obstruction of the canal (usually by wax or ear plugs), creating a noncommunicating gas cavity between the obstruction and the TM. Treatment is symptomatic. ENT specialist referral may be necessary if the TM cannot be visualized.

Sinus barotrauma

Pathophysiology

Mucosal swelling and haemorrhage occur if the communication of the sinuses with the nasopharynx is blocked and equalization of sinus pressure is not possible during descent. The frontal sinuses are most commonly involved.

Clinical features

Sinus pain usually develops during descent. Maxillary sinus involvement can refer pain to the upper teeth or cheek. There may be resolution of the pain at depth, due to mucosal oedema and blood filling the volume deficit left by gas compression. Pain and epistaxis may occur as the diver ascends. The pain usually persists after diving. Tenderness will be noted over the affected sinus. In doubtful cases, a sinus computed tomography (CT) scan will assist the diagnosis.

Treatment

Treatment includes analgesia, decongestants and recommendations to avoid diving until asymptomatic. Antibiotics may be required if secondary infection occurs.

Mask squeeze

If divers fail to exhale air into their masks on descent, the reduced volume inside the mask can cause pain, petechiae and conjunctival haemorrhage. In assessing these divers, it is important to confirm that they have normal visual acuity and fundi are normal. The condition is usually self-limiting.

Gastrointestinal barotrauma

Expansion of gas within the gastrointestinal tract on ascent can occasionally cause colicky abdominal pain. Rupture of the stomach is rare but has occurred where panic or equipment failure has led to air swallowing and rapid ascent. The affected diver presents with abdominal pain and distension. Shoulder pain may be due to diaphragmatic irritation or coexisting DCI. Subdiaphragmatic free air may be visible on an erect chest x-ray. The differential diagnosis includes pulmonary barotrauma, because air can enter the peritoneum via the mediastinum and oesophageal or aortic openings in the diaphragm. The diagnosis is confirmed with endoscopy and surgical repair is necessary.

Dental barotrauma

Severe tooth pain may occur with descent or ascent if air is trapped under a decaying tooth or recent filling. Percussion of the involved tooth is painful. Treatment is with analgesia and dental repair.

Pulmonary barotrauma

Pathophysiology

Breathing compressed air at depth, the diver's lungs contain greater amounts and density of gas than on the surface. Divers are trained to breathe continuously during ascent or to exhale continuously if they have lost their air supply. Pulmonary barotrauma results when a diver ascends without exhaling adequately and the expanding gas in the lungs exceeds the lung's elasticity, tearing alveoli. This occurs most commonly when a diver runs out of air, panics and ascends too rapidly. Even a change in pressure over 1 m near the surface is sufficient to cause lung barotrauma. It has been reported in student divers training in swimming pools and in helicopter escape training. It can also occur with a normal ascent if there is a localized area of lung that does not empty properly, as is possible in divers with asthma, reduced pulmonary compliance or air trapping.

The resultant clinical syndromes depend on the sites at which the air escapes and include arterial gas embolism (AGE), pneumomediastinum and pneumothorax.

Clinical features

Onset of symptoms is usually rapid. If pneumomediastinum or pneumothorax is detected after diving, it is essential to look for features consistent with associated gas embolism. These include impairment or loss of consciousness, cognition impairment including loss of memory, or neurological abnormalities. Sometimes the abnormalities are subtle (or transient) and tests of cognition and memory should be performed in addition to a detailed history and thorough examination.

Treatment

If AGE is suspected, then the affected individual should be kept supine and urgent recompression treatment is required. Management of AGE is discussed under the heading of decompression illness. Lung barotrauma is regarded as the cause of AGE. Subtle signs of extra-alveolar air suggesting pulmonary barotrauma are present in nearly half with more sophisticated imaging, such as CT.

If divers present with a pneumomediastinum or pneumothorax, then they may have up to 50% chance of AGE. The signs of AGE in these circumstances may be subtle with only a brief period of loss of memory or dizziness.

Pneumomediastinum and subcutaneous emphysema in the absence of AGE can usually be managed conservatively. If symptoms are severe, 100% oxygen can accelerate resolution of the trapped gas. If recompression is required for coexistent AGE, then the pneumomediastinum does not require any specific additional management unless a pneumothorax is present.

Isolated pneumothorax resulting from pulmonary barotrauma is very uncommon. Pneumothorax from pulmonary barotrauma should be managed identically to non–diving-related causes and recompression is not necessary. If recompression is required for coexisting AGE, a chest tube with a Heimlich valve should be placed before commencing treatment, because the size of any remaining pneumothorax will increase markedly on depressurization.

Following acute management of pneumomediastinum and pneumothorax, the divers should be referred to a diving medical specialist for long-term follow-up, because the conditions will impact upon their future diving fitness.

Decompression illness

Classification and criteria for diagnosis

Diving accidents involving bubbles were traditionally divided into *decompression sickness* (DCS; due to nitrogen bubbles coming out of tissue) and *arterial gas embolism* (AGE; due to pulmonary barotrauma releasing air into the circulation). DCS was then classified as type I or II. Type I DCS involves the joints or skin only; type II involves all other pain, neurological injury, vestibular and pulmonary symptoms.

In the 1990s, the term DCI was proposed to include both DCS and AGE, for the following reasons:

- It can be difficult to distinguish clinically between cerebral arterial gas embolism (CAGE) and neurological DCS.
- AGE can be caused by arterialization of venous bubbles released from tissues.
- Prehospital and emergency management prior to recompression is identical.
- The division of DCS into type I and type II is inadequate for research purposes and divers classified as type I have been found to have subtle subclinical neurological manifestations.
- Symptomatic classification is adequate to guide management.
- The current classification system describes DCI in terms of four components:
  - onset (acute/chronic)
  - evolution of symptoms (spontaneously resolving/static/progressive/relapsing)
  - body system affected (musculoskeletal/cutaneous/lymphatic/neurological/vestibular/cardiorespiratory)
  - presence/absence of barotrauma.

For example, a diver may be classified as having acute progressive neurological DCI with no evidence of barotrauma. The classification has been generally adopted in Australia and New Zealand, but not in North America. DCI is a satisfactory term from a management perspective but, from a scientific perspective, it does not describe differing aetiologies and pathophysiology.[1]

Pathophysiology[3]

DCI occurs if excessive nitrogen comes out of solution to form bubbles which gain access to the venous and lymphatic systems or if bubbles form within tissues themselves. The formation of bubbles requires tissues to be supersaturated with nitrogen and for ascent to be excessively rapid. As bubbles form in tissues, they distort tissue architecture, which results in impaired function, pain and inflammation and is probably responsible for most musculoskeletal symptoms.

Many bubbles entering the venous system do not cause symptoms. In fact, using ultrasonic detection methods, intravascular

microbubbles are detected after approximately 60% of routine dives. It appears that these bubbles are safely filtered by the lung and diffuse into the alveoli.

Bubbles entering the arterial system are more likely to cause serious problems. This can occur under several circumstances. Large volumes of bubbles may overwhelm the pulmonary filter and arterialize. Bubbles may also bypass the lungs via a right-to-left shunt. Up to one-quarter of the population may have a patent foramen ovale (PFO). Under normal circumstances, the foramen is kept closed by the pressure difference between the left and right atria. However, after diving, the pressure differential may reverse during a Valsalva manoeuvre or with acute increases in right-sided pressures associated with a large pulmonary gas load. A PFO is associated with cerebral, spinal, vestibular and cutaneous decompression illness.[4,5]

Alternatively, gas can enter the circulation following pulmonary barotrauma. Air entering the pulmonary arterial system is carried to the pulmonary capillaries where it is trapped and reabsorbed by the alveoli. Air entering the pulmonary venous system, however, will pass through the heart and result in AGE.

Gas bubbles entering the circulation (either from tissues or barotrauma) cause both mechanical and biochemical abnormalities. Trapping in the pulmonary circulation may result in elevation of right heart and pulmonary pressures, leading to increased venous pressures, reduced cardiac output and impairment of tissue microcirculation. Arterial bubbles can cause end-organ ischaemia, although most pass through the capillaries and into the venous system. Most of the deleterious effects are a consequence of secondary inflammation of the vascular endothelium.

Bubble–endothelial interaction activates complement, kinin and coagulation systems and precipitates leucocyte adherence. This results in increased vascular permeability, interstitial oedema and microvascular sludging. The end result is ischaemia and haemoconcentration. Increased vascular permeability of the cerebral circulation will produce cerebral oedema. Vasospasm and reduced flow occurs approximately 1 to 2 hours after bubbles have passed through the arterial tree. This explains the commonly observed clinical course of a diver with a cerebral AGE experiencing an initial deterioration (bubble emboli), followed by spontaneous improvement (bubbles pass through the cerebral capillaries) and then a subsequent secondary deterioration. Animal studies have demonstrated that bubbles travel against arterial flow because of their buoyancy and lodge in the highest point of the body (hence the logic of maintaining supine position after decompression accidents).

Prevention

A number of dive tables and computer algorithms have been developed in an attempt to avoid nitrogen supersaturation of tissues and improve diver safety. Limits are placed on depth, time and ascent rates to allow safe decompression after diving. However, as with all mathematical models which attempt to predict biological behaviour, the dive tables are far from perfect. One series has shown that 39% of DCI cases were within the limits of the table they were using and 24% within the limits of the conservative Canadian Defence and Civil Institute of Environmental Medicine (DCIEM) tables. The occurrence of DCI is a probabilistic event where risk increases with increasing depth, time, numbers of dives, numbers of ascents and rates of ascent.

Flying after diving can precipitate DCI. Even if there are no bubbles at the end of the dive, excess nitrogen remains in the tissues and is slowly off-gassed. Further reduction in ambient pressure at altitude can cause bubbles or enlarge pre-existing asymptomatic ones. Current guidelines advise against flying for 12 hours after a single short no-decompression dive and 24 hours following multiple or decompression dives.

Clinical features

Onset of any symptoms during or in the hours after diving should be regarded as DCI until proven otherwise. Failure to recognize and treat milder cases can lead to permanent morbidity because the disease can progress as the bubble load increases with time. Common non-neurological symptoms include profound fatigue, myalgia, periarticular pain and headache. Shoulders and elbows are the joints most commonly involved. The pain is usually a dull ache, which may initially be intermittent and migrate from joint to joint, but later becomes constant. Movement aggravates the pain, but local pressure with an inflated sphygmomanometer cuff may improve it. Paraesthesia and numbness may accompany the pain suggesting concomitant neurological disease.[3]

Early onset of symptoms or signs (up to 1 hour), especially those that are neurological in nature, indicates a serious decompression emergency and recompression is a time-critical treatment. Milder syndromes of decompression illness may develop up to 24 hours after a dive or even later if there is a precipitant, such as heavy exercise or ascent to altitude (e.g. flying).

In general, pulmonary barotrauma that results in AGE has a dramatic clinical presentation and the onset of major neurological symptoms and signs occurs within seconds to minutes after the dive. DCI caused by intravascular bubbles from barotrauma can be rapidly fatal and has a mortality of 5% in sport divers who reach a recompression chamber alive. In Australia, it is the second most common cause of diving-related death after drowning. The brain is the organ most commonly affected, probably because of the vertical positioning of the diver on ascent. Cerebral gas emboli can cause sudden loss of consciousness, convulsions, visual disturbances, deafness, cranial nerve palsies, memory disturbance and asymmetric multiplegias. Hemiplegia is much less common than asymmetric multiplegias. Symptoms usually begin within 10 minutes of surfacing. Sudden loss of consciousness on surfacing should be assumed to be due to cerebral gas emboli. Spontaneous improvement may occur with first aid measures, but relapse is common.

Coronary arterial emboli rarely may present as acute myocardial infarction or arrhythmia. Abdominal organs and skin may also be embolised. Elevation of serum creatine kinase (predominantly from skeletal muscle), serum transaminase and lactate dehydrogenase levels in divers with AGE suggests that emboli are distributed more extensively than previously recognized. Peak creatine kinase (CK) may be a marker of the degree and severity of AGE.[1]

Onset of DCI due to gas bubbles coming out of solution can be equally as dramatic (especially after rapid ascents from deep dives), but frequently evolves over hours postdive. DCI caused by bubbles released from tissues usually causes symptoms within 1 hour of completing a dive and 90% of cases have symptoms within 6 hours. Neurological symptoms occurring around 30 minutes after a dive suggest an associated PFO.[4,5] Neurological DCI may present as personality change, headache, memory loss, visual defects, convulsions, confusion and altered level of consciousness. A flat affect may be the only symptom. The vestibular system can also be involved, with dizziness, vertigo, vomiting, nystagmus and ataxia.

Spinal-cord involvement occurs in up to 60% of cases of neurological DCI. The exact cause of spinal DCI is still debated. It may be a result of venous infarction of the cord due to obstruction of the epidural vertebral venous plexus. Other explanations include ischaemia and inflammation from bubble emboli or the formation of local bubbles within the spinal cord (autochthonous bubbles). Symptoms include back pain, paraesthesia and paraplegia, with bowel and bladder involvement. It is potentially disastrous to misdiagnose back pain coming on a few minutes after a dive as musculoskeletal pain and not consider spinal cord DCI.

If the bubble load overwhelms the pulmonary filter, a diver can present with a syndrome known as pulmonary DCI or 'the chokes'. The symptoms of this syndrome include dyspnoea, pleuritic substernal chest pain, cough, pink frothy sputum, cyanosis and haemoptysis. It indicates the diver has sustained a large intravascular gas load, so

a careful inquiry about other symptoms of DCI is mandatory and, if present, recompression is advised. Diving-related pulmonary oedema and saltwater aspiration syndrome are the major differential diagnoses.

A variety of rashes may be caused by cutaneous bubbles; however, these syndromes affect less than 10% of divers. The most common presentations are pruritus with no rash, a scarlatiniform rash with pruritus and *cutis marmorata*. *Cutis marmorata* begins as a spreading erythema but subsequently develops a marbled appearance of pale areas surrounded by cyanotic mottling.

Assessment of the injured diver

The injured diver requires simultaneous assessment and treatment. One hundred percent oxygen treatment should be continued during the assessment. If the history suggests AGE, the patient should be kept in the horizontal position to avoid re-embolization.[1,3] If symptoms are progressing rapidly, the examination should be brief but thorough so as to ensure rapid access to recompression. In serious cases, some of the historical information may be obtained once the diver is receiving treatment in the recompression chamber.

The diagnosis of DCI is made on history and examination. A full dive history must be obtained, in addition to the medical history. Important details include the number of dives over recent days, depth, bottom time (the time from beginning descent to beginning direct ascent), performance of any decompression or safety stops, dive complications such as rapid ascents, surface interval between dives and the time interval between completing the dive and onset of symptoms. Previous dive experience, equipment used and gases breathed should also be recorded. A history of using surface supply equipment (the 'Hookah' apparatus) should alert the examining physician to the possibility of carbon monoxide poisoning and carboxyhaemoglobin measurement is required. Cold water, hard exercise during the dive, increasing age, multiple ascents and repetitive dives are predisposing factors in the development of DCI. Any exposure to altitude (>300 m) or heavy exercise postdive should be recorded.

A thorough examination, particularly of the neurological system, to detect subtle abnormalities is required. It is also helpful to perform basic tests of cognitive function, such as the mini–mental state examination. For milder static DCI syndromes with delayed presentation, the sharpened Romberg test provides useful information. It is performed by asking the patient to stand heel-to-toe with open palms on opposite shoulders. The patient is stable. They are then asked to close their eyes and timed until they lose balance or achieve 60 seconds. A score of less than 60 seconds is suggestive of DCI in an injured diver. This test should not be performed if the history was suggestive of AGE or if there are neurological symptoms or signs.

Clinical investigations

Recompression should only be delayed for investigations if they will directly alter management. A full blood count and electrolytes are useful in that intravascular fluid depletion is common in severe DCI and the degree of haemoconcentration may correlate with eventual neurological outcome. Serum CK and liver function tests (LFTs) may be indicators of gas embolism; however, these do not influence clinical management. The blood glucose level should be checked in divers with impaired consciousness. Divers with neurological presentations should not be moved from the horizontal position until they are recompressed. If CAGE due to pulmonary barotrauma is suspected and CT is available, a supine CT scan of the thorax assists diagnosis of pneumothorax or pneumomediastinum. Emergency bedside ultrasound can be used to confirm/rule out a pneumothorax. Magnetic resonance imaging has no role in the acute investigation of DCI.

Treatment

First aid

Initial resuscitation is along standard basic and advanced life support protocols. One hundred percent oxygen provides the maximum gradient for diffusion of nitrogen (or other inert gas) out of the bubbles. A large consecutive comparative series involving over 2000 divers has demonstrated that first aid oxygen significantly improves outcomes for divers with decompression illness.[6] Oxygen should be administered in the prehospital setting and continued until and during recompression. Failure to improve on oxygen does not rule out DCI. Conversely, complete improvement on oxygen does not obviate the need for recompression. The diver should be transported supine or in the left lateral position if unable to protect their airway. The diver should be prevented from sitting or standing up, to avoid bubbles redistributing from the left ventricle to the brain. If intubation is required, the endotracheal tube cuff should be filled with saline just prior to recompression to avoid a change in volume and a tube leak as ambient pressure increases.

Intravenous isotonic crystalloids should be commenced and titrated to response. Glucose-containing fluids are to be avoided because they may exacerbate CNS injury. Divers who present after several days with mild symptoms may be adequately managed with oral fluids. A urinary catheter should be inserted for spinal cord DCI with bladder involvement. Hypothermia should be corrected.

Retrieval

Long-distance retrieval can either be by air transport pressurized to 1 ATA or by portable recompression chambers. There is little debate that the longer the delay in recompression of severe DCI, the worse the outcome. However, Australian experience suggests that the number of cases where a portable chamber would have made a difference is so small that their use is unwarranted, largely because of the time required to prepare and transport portable chambers. Commercial aircraft are pressurized to 0.74 ATA (2440 m) and not appropriate to retrieve DCI patients, unless arrangements can be made to fly lower and pressurize to sea level. Road retrieval is not suitable over great distances or where an altitude of 300 m will be exceeded. Consultation with a hyperbaric physician should occur if retrieval is difficult.

Recompression

Recompression in a hyperbaric chamber is indicated even if the diver becomes asymptomatic with first aid, because otherwise many will relapse. The relapse may be more severe than the original presentation, due to the pathophysiological changes already initiated by bubbles in the microvasculature and tissues or redistribution of bubbles. Response to recompression is determined by time to recompression and the initial severity of injury. Recompression should always occur as soon as possible. Treatment commenced later than 4 hours after injury is associated with a poor response. Mild cases often respond despite longer delays to recompression.

Two types of hyperbaric chamber are available to administer recompression treatment:

- *Multiplace* chambers can accommodate more than one person, including a clinician attendant and are compressed on air while the patient breathes 100% oxygen via a head hood, demand regulator or endotracheal tube. Air breaks to lessen the risks of oxygen toxicity are provided by removing the head hood in a multiplace chamber. Full monitoring and mechanical ventilation are possible. All hyperbaric facilities in Australasia use multiplace chambers.
- *Monoplace* chambers accommodate one patient only and are usually compressed with 100% oxygen. These are more frequently used to treat nondiving medical illness; however, in other countries, they may be used for definitive treatment of divers.

Hyperbaric oxygen has the following beneficial effects:

- Reduction in bubble size in accordance with Boyle's law. This relieves the obstruction caused by intravascular bubbles and the tissue distortion of extravascular bubbles.

- Increased the outward diffusion gradient for nitrogen, further reducing bubble size. Reduction of endothelial inflammation caused by the bubbles.
- Relief of tissue ischaemia and hypoxia.

There are no published randomized trials comparing recompression protocols and hence no international agreement on how to manage DCI. The general consensus is that initial treatments should begin with a standard 2.8 ATA (18 m) table breathing 100% oxygen. Some studies have suggested a benefit from initially recompressing deeper, however, this procedure is not universally accepted and subject to considerable debate.[7]

The identical Royal Navy 62 (RN62) and US Navy 6 recompression tables have become the standard of care for initial treatment of diving accidents in Australia and New Zealand.[1,3] These are 18 m tables, lasting 4.75 to 7.25 hours (Fig. 24.3.1). Recompression is followed by gradual decompression. A response to treatment is usually evident after two oxygen periods at pressure. If there is a partial response then there is the option of extending the table at 2.8 ATA. If there is minimal or no response and there is no doubt about the diagnosis, then it is reasonable to proceed to a deeper table (most units use the Comex 30 table). Because of the risks of oxygen toxicity at greater than 2.8 ATA, a combination of helium and oxygen (heliox) is used. Further daily recompression is carried out until the patient stops improving or becomes asymptomatic and then one additional treatment is performed. Follow-up treatments are usually at 18 m, using either the RN61 table (18 m for 45 minutes, ascent to 9 m over 30 minutes, 9 m for 30 minutes then ascent over 30 min) or the 18:60:30 table (18 m for 60 minutes then ascent over 30 minutes).

In-water recompression is dangerous and difficult and should only be considered if retrieval is impossible. Hypothermia and oxygen toxicity pose serious risks during in-water treatment and supervision by experienced appropriately trained personnel is essential.

Adverse effects of hyperbaric oxygen

Adverse effects of hyperbaric oxygen are uncommon. Even in nondivers, significant middle-ear barotrauma interrupting treatment occurs in 1/170 treatments. Claustrophobia is even rarer at 1/910 treatments.

The most serious adverse effect is oxygen toxicity and the attendant must continually watch for signs of its development. Toxicity is due to the formation of oxygen free radicals, which overwhelm the body's antioxidants. It can affect the brain and the lung.

Cerebral oxygen toxicity can occur with exposures above 2 ATA oxygen. The most common presentation of cerebral oxygen toxicity is muscle twitching, particularly of the lips and face. The incidence of convulsions in divers treated at 2.8 ATA on the RN62 is 0.29%.[8] Other possible symptoms include apprehension, vertigo, visual disturbance, nausea, confusion and dizziness. If the oxygen is removed at this stage, progression to generalized convulsions may be avoided. Convulsions can, however, occur without premonitory symptoms. Treatment is as for any generalized convulsion, although removal of the oxygen will almost always stop it. Decompression should not be attempted during the convulsion as this may cause pulmonary barotrauma. Oxygen can be safely reinstituted 15 minutes after all symptoms have resolved. Predisposing factors to cerebral oxygen toxicity include fever, steroids, a past history of epilepsy and carbon monoxide poisoning. Incidence is directly proportional to time of exposure and inspired oxygen partial pressure. Pulmonary oxygen toxicity manifests initially as an asymptomatic reduction in vital capacity, followed by cough and retrosternal pain. It may occur with prolonged exposure to partial pressure of inspired oxygen, $P_IO2 > 0.5$ ATA ≥0.5 ATA. The symptoms usually abate when treatment is completed. Up to 10% reduction in vital capacity has been measured during extended treatments, which reverses within 24 hours.

Adjuvant therapies for DCI

Lignocaine was suggested as potentially being neuroprotective for cerebral arterial gas embolism based on cardiac research. However, despite showing initially promise for patients undergoing open-heart surgery, subsequent larger randomized controlled trials (RCTs) failed to demonstrate benefit. In a double-blind RCT, the nonsteroidal antiinflammatory drug tenoxicam had demonstrated benefit in shortening recovery times following decompression illness. There was a reduction in total recompression requirements.[9]

Prognosis after treatment

Relapses may occur after initial recompression. All neurological cases should be observed in hospital to allow immediate recompression if deterioration occurs.

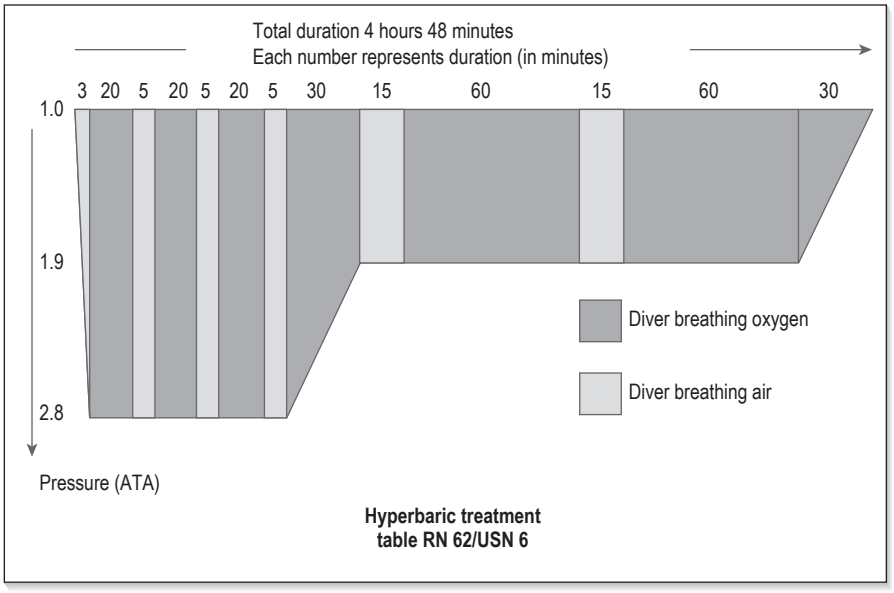

FIG. 24.3.1 Royal Navy Treatment table 62/US Navy treatment table 6.

Residual symptoms occur in up to 30% of cases and are more likely where recompression is delayed. Delays to treatment are not unusual with a mean time to recompression of 68 hours in one series. There is no clear time interval after diving that recompression becomes ineffective. Many divers with DCI still respond to treatment even when delayed for 7 to 10 days and therefore any diver with unexplained symptoms after diving should be referred to a diving medicine specialist.

Flying after treatment and return to diving

Recommendations for flying and diving after treatment for DCI vary greatly and are not evidence based. Flying should be avoided for at least 1 week after treatment to avoid relapse. It is reasonable to permit resumption of diving after 4 weeks if there are no residual symptoms or signs. Because of the risk of recurrence, further diving is contraindicated if the DCI is thought to be due to pulmonary barotrauma, or where there are residual neurological signs or symptoms.

Other issues

Vertigo and headache in divers

These two symptom complexes are challenging to assess and diagnose. There are several possible serious causes of vertigo in divers. Vertigo developing while the diver is underwater is extremely dangerous; it can induce panic and lead to a rapid ascent. It can disorientate the diver and if vomiting occurs, there is risk of airway obstruction. All cases of vertigo in divers (even if resolved) require specialist assessment.

The most common cause, alternobaric vertigo, begins just as divers commence their ascent and is caused by unequal middle ear pressures. It usually lasts only a few minutes. Middle-ear barotrauma can also cause mild vertigo. Other causes include inner-ear DCI, inner-ear barotrauma and TM rupture. Persistent acute vertiginous symptoms may indicate a more serious cause, such as neurological DCI or IEBT.[2] Headache occurring during or after diving has a number of possible diving-related causes, such as sinus and mask squeeze, carbon dioxide accumulation, carbon monoxide toxicity, decompression illness, patent foramen ovale, ill-fitting wetsuits, temporomandibular dysfunction and marine envenomation. It is recommended that for all divers presenting with vertigo or headache, there is early consultation with a diving medicine specialist.

Oxygen toxicity

Cerebral oxygen toxicity in the diver underwater causes the same problems as in the hyperbaric chamber. Divers are more likely to develop toxicity underwater than in the chamber because immersion, exercise and carbon-dioxide retention increase the risk. The use of oxygen-enriched gases, such as nitrox, may increase the risk of cerebral oxygen toxicity. Enriched-air divers should ensure they stay at depths that maintain an oxygen partial pressure of less than 1.4 ATA.

Nitrogen narcosis

Nitrogen narcosis is due to the anaesthetic effect of nitrogen dissolved in lipid membranes. Symptoms are similar to those of alcohol intoxication. Some divers experience it at 30 m and almost all by 50 m. Loss of consciousness occurs at 90 m. This condition will not present to the emergency department because it is immediately reversible on ascent. However, it may result in other diving accidents, such as rapid ascent or near drowning. Because of nitrogen narcosis, divers planning to dive deeper than 50 m use alternative breathing gases such as heliox.

Gas contamination

Contaminants may be added during filling or already in the diver's tanks. Common contaminants include carbon dioxide, carbon monoxide and oil. Increasing partial pressures of the contaminants at depth may result in toxicity. Contamination is rare but must always be included as a potential cause when injured divers present, especially with headache, shortness of breath or loss of consciousness at depth.

Diving-related pulmonary oedema

Pulmonary oedema in the diver may be caused by DCI, near drowning or immersion itself. Pre-existing cardiovascular disease, increasing age (>40), female gender, hypertension and beta blockade appear to be risk factors for immersion-induced pulmonary oedema. Symptoms often begin while the diver is still at depth, distinguishing it from DCI. The condition has been reported when immersed but not diving (e.g. swimming). Treatment is supportive and recompression is not required provided DCI can be excluded. However, if detected, the occurrence of pulmonary oedema as a result of diving has long-term ramifications for future diving fitness.

CONTROVERSIES

- *What position is best for managing the injured diver?* There are no controlled trials assessing the best position to manage an injured diver. The current recommendation is to maintain a supine position for all suspected or confirmed neurological presentations, based on expert opinion and known pathophysiology.
- *Should intravenous or oral fluids be administered?* Based on expert consensus and known pathophysiology, the injured diver is usually dehydrated. Fluid management is regarded as an important adjunct to recompression. In an acute diving accident <12 hours, where consciousness or airway reflexes are impaired or where there is nausea and vomiting, IV salt-based crystalloids should be administered, due to the need for 100% oxygen and the possible risk of oxygen toxicity during the initial treatment phase at 2.8 ATA. In the less acute presentation of static DCI, oral fluids may be acceptable, although there are some risks if an oxygen toxicity seizure occurs during treatment at 2.8 ATA.
- *Should we compress divers deeper than 2.8 ATA during treatment?* This is very controversial, with reports of deep tables being used successfully in Hawaii.[7] To date, there are no completed randomized controlled trials comparing outcomes of different treatment pressures.

24.4 Radiation incidents

Paul D. Mark

ESSENTIALS

1 **Radiation accidents are rare but require well-planned protocols for successful management. The principal challenge will be managing large numbers of people who have concerns about their exposure to radiation, or contamination with radioactive material as a result of an incident.**

2 **The management of life-threatening illness or injury always takes precedence over the radiation aspects of the patient's condition.**

3 **Removing the patient's clothing and washing exposed skin and hair can reduce the level of external contamination by up to 90%.**

4 **The presence of qualified radiation physicists with appropriate radiation monitoring equipment is invaluable when dealing with (potentially) contaminated patients.**

5 **Effective triage for exposure to radiation is based on early clinical symptoms and lymphocyte counts.**

6 **Following whole-body irradiation, survival is likely only from the haemopoietic and milder gastrointestinal syndromes.**

7 **Blocking and chelating agents can successfully reduce the incorporation of radioactive substances into body tissues if they are given early.**

8 **Early involvement of a haematologist can assist in triaging patients for cytokine modulators to facilitate autologous marrow recovery.**

9 **Haemopoietic stem cell transplantation can increase the survival rates of more severely affected patients but resources around the nation are limited.**

Introduction

In August 1945, the first atomic fission bombs were detonated above the Japanese cities of Hiroshima and Nagasaki with devastating effects. Most radiation incidents, however, have been accidental with the most serious occurring in 1986 at Chernobyl in the former Soviet Union when a nuclear reactor unit exploded, dispersing radioactive material over a wide area. One hundred and thirty six people developed the acute radiation syndrome, of which 28 died. The majority of incidents, however, have involved small numbers of people and many have occurred as a result of deliberate bypassing of safety procedures.

There were no deaths from exposure to radiation or cases of radiation sickness following the 2011 Fukushima accident but over 160,000 people had to be evacuated from their homes to ensure this.

In Australia, the Australian Radiation Incidence Registry records all accidents where exposures occur that are not 'within the limits known to be normal for the particular source of radiation and for the particular use being made of it'. Strict licensing and control systems, coupled with improving technology and training, have helped to minimize the number of Australian radiation incidents.

The advent of terrorism has increased the risk of multiple casualty incidents.

Radiation sources and incidents

Worldwide, the most common radiation sources are

- X-ray equipment: used for medical diagnosis and treatment, industrial and commercial inspections, irradiations and research.
- Accelerators: used for medical treatments, industrial irradiation, the production of radioisotopes and research.
- Radioactive materials: used for medical diagnosis and treatment, industrial radiography, quality control and tracing techniques, soil density and moisture tests, and research. Radioactive material may be unsealed or contained within sealed containers.
- Nuclear processing and reactor plants: used for processing uranium and plutonium for fuel purposes and nuclear weapons, power production and research.

With x-ray equipment and accelerators, the victim may be exposed to radiation but this does not make the tissues radioactive. These patients pose no threat to others, including medical attendants.

Unsealed radioactive material has the potential to cause radioactive contamination. This may be external on clothing or skin or internal following inhalation, ingestion or absorption through body orifices, mucous membranes and wounds. Following internal contamination, radioactive material may become incorporated into the patient's tissues.

Other than for accidents involving nuclear processing and reactor plants, or nuclear explosions, incidents usually lead to either exposure or contamination.

There are no nuclear reactors in Australia except for the occasional visiting nuclear powered warship. These vessels are closely monitored while in Australian ports.

Terrorism

The most likely means for terrorist organizations to deploy radiation is a radiation dispersal device (RDD) or 'dirty bomb'. These weapons

use conventional explosives to spread radioactive substances.

RDDs are sometimes called 'weapons of mass disruption' because of the fear they engender in the population, multiple casualties, contamination of widespread areas and the economic cost.[1] Immediate injuries are generally the result of blast or thermal effects. Few contain sufficient material to cause acute radiation injury. Only those trapped near the site of detonation run this risk. However, radioactive material will be spread over a large area and many people might be exposed to the risks of low-dose radiation. Hospital staff treating the victims of RDD explosions are at negligible risk provided they wear appropriate protective equipment. Unlike surface burst nuclear weapons, RDDs do not cause fallout downwind of the detonation.

Radioactive material without the explosive component may constitute a radiation exposure device (RED) and could potentially be hidden in a crowded space, such as a theatre, where it could cause occult irradiation. Industrial sources are the most prevalent REDs in the civilian sector. An improvised nuclear device (IND), like a small nuclear weapon, produces blast, thermal and radiation energy, exposing people to high-dose external radiation, inhalation of radioactive materials, particulate contamination and ingestion of radioactive materials in the food chain.

Measuring radioactivity

Radioactivity of an isotope is expressed as the average number of atoms that disintegrate per second. The becquerel (Bq) is the International System of Unit (SI unit) for one nuclear disintegration per second. The activity of a given mass of a radioactive substance with a short half-life will decrease with time.

Ionization in air caused by radiation can be measured by portable dosimeters to give an estimate of the levels of radioactivity at the site of an incident. This is used to calculate the exposure level of a patient with acute radiation illness. The units used are Roentgens. Dosimeters are also used in hospitals to measure the level of radiation to which staff members have been exposed or to monitor patients during decontamination.

The absorbed dose of radiation is the amount of ionization energy deposited in matter by ionizing radiation. One gray (Gy) is equivalent to one joule per kilogram. The effect of a given dose of radiation depends on the type of radiation emitted and the tissue type irradiated.

Type of radiation emitted

Different types of ionizing radiation transfer energy to tissue at different rates. The sievert (Sv) is the international unit of effective radiation dose and is obtained by multiplying the absorbed dose measured in Gy by a quality factor to reflect the different effects of each radiation type and their potential biological damage. For beta and gamma radiation 1 Sv =1 Gy. Alpha and neutron radiation deposit more energy in tissue so the quality factor is higher.

Alpha particles, composed of two protons and two neutrons, do not penetrate the dermis but may cause local damage if ingested, inhaled or absorbed through open wounds. Beta radiation, consisting of electron-like particles, travels about a metre through the air and is stopped by clothing. It often causes radiation injury to exposed skin. Gamma particles have no mass and are similar to x-rays, penetrating the body freely and causing the acute radiation syndrome if the trunk is involved. Neutrons are produced only during nuclear detonations and, while they can technically make an irradiated victim emit radiation, this is not clinically significant.

Grays are the preferred measure for determining acute effects while sieverts are more useful in predicting chronic effects.

The average natural background radiation is 2 mSv per annum in Australia. The Australian National Occupational Health and Safety Commission's standard for a worker is a maximum effective dose of 50 mSv in any year (or 20 mSv/year averaged over 5 years).

Pathophysiology

Radiation damages tissue both directly and indirectly by the production of free radicals from water molecules. Direct damage to cell membranes may cause changes in permeability and the release of lysosomes. Germinal, haemopoietic and gastrointestinal epithelial cells are relatively radiosensitive. The cells of bone, liver, kidney, cartilage, muscle and nerve tissue are relatively radioresistant. The delayed effects of radiation depend on whether the dose is lethal or sublethal to the tissue involved.

Lethal (deterministic) injuries are threshold dependent. Cells are killed when they receive more than a certain radiation dose, which varies with different tissues. Clinical expression occurs when the amount of cell killing cannot be compensated for by proliferation of viable cells. The acute and chronic radiation syndromes are deterministic. The earliest delayed effect of acute radiation injury, cataract formation at about 10 months, is an example of this type of injury.

For sublethal (stochastic) injuries there is no threshold level of radiation and the consequence is based on statistical probability. Sublethal injury to chromosomes is the most important effect of ionizing radiation. Double-strand breaks are not easily reparable, especially if the damage occurs simultaneously to both strands. This results in broken chromosomes with no template for repair. The exposed ends of chromosome fragments may join up at random, resulting in morphological chromosomal abnormalities. Sublethal damage to chromosomes is implicated in the development of tumours. Although the incidence of malignancy in adults is increased by radiation exposure, the age at which malignancies are clinically expressed does not change. The estimated increase in lifetime risk of fatal cancer is 0.008%/mSv of gamma radiation exposure.[2] Therefore an individual who is exposed to 100 mSv (twice the acceptable Australian occupational annual exposure) has a 0.8% increase in the lifetime risk of fatal cancer.

Radiation exposure to the gonads may produce temporary or permanent infertility in men depending on the dose. With temporary infertility, there is preservation of the secondary sexual characteristics. In the female, however, all ova are present at birth and larger radiation doses are required to produce sterility. Radiation-induced infertility in females is associated with premature menopause.

Children are more prone to radiation-induced carcinogenesis because they have a higher number of future cell divisions and a longer life span. The fetus is exceptionally susceptible to radiation injury.

Acute radiation exposure

Radiation exposure accidents usually involve penetrating radiation, such as high-energy x-rays or gamma rays. The effects are primarily due to the loss of cells in the body. Acute exposure is more dangerous than chronic, as it does not allow time for cell replacement or tissue recovery. Clinically, radiation exposure may produce a generalized acute radiation syndrome or a localized irradiation injury.

The acute radiation syndrome

The acute radiation syndrome refers to the effects of radiation on one or more body systems. The haemopoietic tissue alone is affected at doses of 1 to 4 Gy and produces pancytopenia with its consequent risks of infection, bleeding and anaemia. Above 6 Gy, gastrointestinal effects are also manifest and the prognosis is poorer. The neurovascular syndrome occurs with doses above 20 Gy and is manifest by leaky capillaries, hypotension and a progressive decline in mental function with eventual death in weeks to months. The symptoms depend on the part of the body irradiated, the dose and the time over which it is delivered.

Clinical features

The course of the illness can be divided into four phases:

- the prodromal phase, which generally lasts up to 48 hours;
- a latent period, lasting hours to weeks;

- the manifest illness period;
- death or recovery.

The prodromal symptoms are due to the effects of radiation on cell membranes and the release of vasoactive amines. The symptoms are nonspecific, with anorexia, nausea, vomiting, weakness, fever, conjunctivitis, erythema and hyperaesthesia. The time to emesis, presence of diarrhoea and duration of symptoms are markers of the severity of the exposure.[1]

The phase of manifest illness corresponds to the loss of cells. The haemopoietic syndrome occurs alone with whole-body radiation doses of between 1 and 4 Gy. It is due to loss of stem cells in the bone marrow. At these doses, some stem cells survive and recovery is therefore possible. The latent period lasts from 2 to 20 days and is followed by a rapid fall in the number of white blood cells and platelets. Recovery commences about 30 days after exposure, regardless of the exact dose.

The gastrointestinal syndrome predominates with radiation doses greater than 6 Gy. The prodromal symptoms are more severe. Early bloody diarrhoea suggests death within 2 weeks. The gastrointestinal symptoms recur during the manifest illness phase and can be very severe leading to dehydration and electrolyte imbalance. This syndrome is due to the loss of stem cells in the small intestinal mucosal crypts. It is superimposed upon the haemopoietic syndrome with both occurring after a short latent period of under a week.

The neurovascular syndrome occurs with doses of greater than 20 Gy and is characterized by leakage of fluid into tissues and hypotension. The latent period is just a few days. Leakage into the brain causes neurological symptoms. These effects are superimposed on those due to gastrointestinal and haemopoietic damage. At very high doses, greater than 30 Gy, there is incapacitation usually within the first few minutes and certainly within 40 minutes. The effects are largely due to disruption of cell membranes and electrochemical inactivation of neurons. Death can be anticipated within hours. In a nuclear detonation, however, death from other injuries is more likely in those close enough to receive this level of exposure.

Absorbed dose estimation

Dose reconstruction from a small source is readily calculated by a radiation physicist once the activity of the source, the distance and time a person spent near it are known, but exposure from larger sources requires computer modelling and real-time environmental radiation measurements. Initial assessment must therefore be based on clinical and laboratory information, specifically:

- The presence and timing of emesis and other prodromal symptoms
- Lymphocyte depletion over time and other haematological changes
- Amylase, C-reactive protein (CRP) changes over time

Dicentric analysis is the gold standard but also takes time.

Protracted vomiting within one hour postirradiation is indicative of a dose in the 6 to 8 Gy range. For a time to emesis of approximately 2 hours, the effective dose is likely to be at least 4 Gy. Vomiting at 4 hours is indicative of a dose in the 2 Gy range. If the patient has not vomited within 10 hours the dose is likely to be <1 Gy. However the absence of vomiting does not preclude a significant exposure and hence triage must not be based solely on vomiting alone.[3]

Whole-body irradiation may produce early erythema but rarely within 24 hours and only after doses greater than 6 Gy.

Clinical investigations

The threshold for admission on initial presentation will depend on the number of casualties but, in general, patients who do not vomit within 6 to 8 hours can be managed as outpatients. A useful triage tool for patients *without* other injuries or chronic illnesses utilizes a combination of the neutrophil/lymphocyte count and the presence of emesis at 4 or more hours postexposure:

$T = N/L + E$, where $E = 0$ if no emesis and $E = 2$ if emesis.

If T is >3.7, the patient requires admission for further evaluation as the radiation dose is likely >1 Gy.[4]

Acute radiation exposure is confirmed by laboratory investigation. Lymphocyte counts should be taken every 6 to 12 hours for 48 hours.

A lymphocyte count of 1000/mm^3 at 24 hours suggests a dose of at least 2 Gy and the eventual development of the haemopoietic syndrome. A count of 500/mm^3 suggests a radiation dose of 6 Gy and the subsequent development of both the gastrointestinal and haemopoietic syndromes. A fall of 50% in the lymphocyte count in the first 24 hours is suggestive of a potentially lethal radiation exposure.

The lymphocyte count at 48 hours is useful for admitted patients to further refine the likely dose and clinical course:

- No symptoms and lymphocytes >1500/mm^3 after 48 hours—unlikely to require clinical support but should be observed periodically.
- Nausea, vomiting, erythema and lymphocytes between 800 and 1500/mm^3 at 48 hours—probable serious injury, which will require clinical support.
- Pronounced nausea, vomiting, diarrhoea, erythema and lymphocytes between 100 and 800/mm^3 at 48 hours—probable life-threatening injury, which will require maximal clinical support.
- Early vomiting and bloody diarrhoea, erythema and lymphocytes <100/mm^3 at 48 hours—lethal injury.

The US Department of Health and Human Services has an online calculator, which uses lymphocyte depletion kinetics and emesis to estimate the radiation dose.[5]

The lymphocyte count may be less useful if there is significant concomitant trauma or at low levels of exposure. A dose-dependent increase in serum amylase is evident after 24 hours.

Cytogenetic studies using blood collected at 48 hours in a lithium heparin tube examine the number and structure of chromosomes. Radiation dose is reflected in the number of excess acentric and dicentric forms. T lymphocytes are relatively long-lived and reliable dose estimates can be made up to 5 weeks after collection of the sample. Newer methods are quicker and can detect very low doses (0.1 Gy).

Treatment

Supportive treatment includes maintenance of fluid and electrolyte balance, nutritional supplementation, antiemetics such as ondansetron, and antidiarrhoeals. Colony stimulating factors should be commenced as soon as possible if the radiation dose was >2 to 3 Gy and be continued until the lymphocyte count reaches 1000/mm^3.[3,4] Control of infection commences in the prodromal phase, with identification and aggressive treatment of any potential infection, so that the patient is in optimal condition to survive a period of manifest haemopoietic depression. To reduce the infection risk, patients may be kept home during the latent period and admitted to hospital when neutropenia develops. Hospital management involves strict isolation and laminar airflow units. The prophylactic administration of antibacterial, antiviral, antifungal and antihelminthic therapy is reserved for the most severely neutropenic. Nonabsorbable agents are commonly used to sterilize the gastrointestinal tract. Anaerobic agents should be included if there is gut injury.

Management of neutropenia follows the principles established in the management of bone marrow suppression secondary to chemotherapeutic agents. Fever is investigated and managed with empirical therapy in the first instance. If as many as 10% of the stem cells remain intact, the blood cells will repopulate. Platelet transfusion must be commenced early, especially if surgical procedures are required. The role of stem cell transplantation is evolving. Early reintroduction of enteral nutrition is important to maintain gastric acidity and prevent infectious organisms spreading from the gut to the respiratory system. Povidone-iodine or chlorhexidine is used for skin disinfection and shampoo. Meticulous oral hygiene must be maintained.

Prognosis

The $LD_{50/60}$ is the dose at which half the victims succumb within 60 days. Without treatment, the $LD_{50/60}$ is 3.5 to 4 Gy. With supportive care, antibiotics and transfusions, the $LD_{50/60}$ is almost doubled to around 5 to 6 Gy. Early colony stimulating factors and intensive care increase the $LD_{50/60}$ to 6 to 8 Gy. Bone marrow transplantation may be used in patients exposed to 8 to 10 Gy and occasionally patients have survived.

Survival from the cardiovascular and neurovascular syndromes does not occur.

Combined injuries

Combined injury occurs when there is additional trauma, either physical or thermal, in addition to the radiation injury. The effects of the radiation exposure may become apparent earlier and may be more severe when other injuries are present. Healing of tissues, including callus formation at fracture sites, will be delayed even with subclinical radiation doses. Radiation exposure increases the mortality when combined with other injuries or pre-existing conditions that result in immunosuppression, blood loss and danger of infectious complications. All administered blood products should be irradiated to remove the T-cell population and minimize graft-versus-host reactions. Platelets should be transfused if the platelet count falls below 20×10^9/L and, if surgery is anticipated, it should be maintained higher than 75×10^9/L. Emergency surgery, including the excision of dead tissue and the closure of wounds, should be completed within 48 hours while some white blood cells remain. For thermal burns, early excision of potentially septic tissue and skin grafting are indicated. Wound closure is an important means of reducing vulnerability to infection. Nonurgent surgery should wait until any bone marrow suppression resolves.

Radiation pneumonitis may develop some time following the exposure and be confused with acute respiratory distress syndrome (ARDS).

Local irradiation injuries

The majority of local irradiation injuries occur when operators of x-ray diffraction units inadvertently place their fingers or hands in the direct x-ray beam. Other accidents have occurred when radioactive sources, often from industrial radiography equipment, are detached and then picked up and placed in the pockets of workers. There have been misadministrations of radiation to patients undergoing radiotherapy. The higher the dose the greater the severity and the earlier the onset of the local injury. The smaller the area irradiated, the higher the dose required to produce a particular change.

Clinical features

Early symptoms may include erythema, tenderness, itching, tingling and a changed sensitivity to heat and cold. At 14 to 28 days hair epilation occurs at 3 Gy, erythema recurs at 6 Gy, dry desquamation at 10 to 15 Gy, wet desquamation at 15 to 25 Gy and deep ulceration/necrosis at >25 Gy.[3] If the area irradiated includes the epigastrium, nausea and vomiting may also occur. The degree of radiosensitivity of the skin depends on the thickness of the epidermis. The most sensitive areas are those that are also moist and subject to friction, such as the axillae, groins and skin folds. The least sensitive areas are the nape of the neck, scalp, palms and soles.

If irradiated skin appears normal at 72 hours, any subsequent changes are likely to be less severe. Erythema may be delayed for up to 30 days but is then unlikely to progress to ulceration. Pain is minimal unless ulceration occurs or the dose is extreme. Magnetic resonance imaging (MRI) and Doppler studies may help define the extent of the damage. Late effects include progressive tissue atrophy, fibrosis and chronic radiodermatitis with tissue breakdown. There may be stiffness and tenderness and decreased sensitivity to temperature change.

Treatment

Mild injuries may be simply observed. An effort should be made to protect the area from additional trauma. Progress may be monitored with serial photographs. Topical corticosteroids may help. For more severe injuries, particularly with pain, local debridement and skin grafting may be necessary but should be delayed until the full extent of the lesion is known. Ideally, surgeons experienced in managing chronic vascular disease should be consulted. Amputation is reserved for gangrene. Skin grafts are indicated for areas of exposed cartilage or bone or for severe scarring. Topical antibiotics are often prescribed in an attempt to reduce infection. Vascular therapy with hyperbaric oxygen and pentoxifylline may be useful. In the long term, the irradiated area must be watched for the possible development of neoplastic change.

Contamination with radioactive material

The care of individuals who are contaminated with radioactive material requires similar preparation and precautions as for those contaminated with hazardous chemicals. Radioactive contamination has the advantage that it can be readily detected by instruments when on the skin. With the exception of Chernobyl, survivors of radiation accidents have not been sufficiently contaminated so as to pose a threat to emergency or hospital personnel using appropriate precautions and procedures.

Prevention at a site using radioactive materials

All staff using shielded or unshielded radiation sources in their daily work must be thoroughly trained in their safe use. Facilities using unshielded radioactive material must have procedures in place to deal with spillage and other accidents and all workers must be adequately trained in emergency procedures.

Preparedness at site

Emergency equipment must include appropriate monitors for detecting ionizing radiation or contamination, facilities for decontaminating victims and plastic bags for biological and other samples. Appropriate blocking or chelating agents should be stocked at the facility. Emergency planning must include early warning of the receiving hospital so that adequate preparations can be made prior to the arrival of patients.

Scene management

For incidents involving small numbers of patients, members of the rescue team should put on the protective clothing normally used by personnel working with radioactive material at that site. This includes gloves, facemask and cap. Gowns may be covered with large plastic aprons to make them waterproof. Additional measures, such as taping plastic bags over shoes, may be used if the normal protective clothing is judged inadequate. The implementation of life-saving procedures may make it necessary to forgo some of this protection. Contamination of the rescuer will be low and decontamination can be carried out later.

Serious illness or injury is not due to radiation *per se* and should be treated on its own merits. Unless the patient's condition is serious, external decontamination begins at the scene so as to minimize internal contamination and incorporation of the radionuclide into the body tissues and to reduce the risk of contaminating other persons and the hospital environment. As much as 80% of contaminating material may be on the clothing.[6] Accordingly, the victim's outer clothing should be removed at the earliest practicable stage. If monitoring is not available, it should be assumed that all outer clothing is contaminated. The person removing the contaminated clothing must wear protective clothing and limit contact with the outside of the victim's clothing. The victim is then wrapped in plain sheets and transferred to hospital. If small contamination spots on the skin cannot be easily removed at the scene, they should be dressed and the victim transported to hospital.

At larger incidents, it may also be necessary to establish a controlled area, the periphery of

which is located just beyond the region where contamination is detected above background levels. Rescue team members should wear the maximum level of personal protective equipment available. This should be removed at the perimeter of this area prior to both patient and rescuers leaving. Monitoring of all personnel leaving the area should be undertaken if facilities are available.

Portable vacuum units with high efficiency particulate air filters have reportedly been used to facilitate rapid decontamination outdoors.

Emergency department

The elements of planning for the management of radiation accident patients are similar to those for other types of emergencies, namely prevention, preparedness, response and recovery.

Facilities using unsealed radioactive sources should be identified in advance. These include nuclear medicine departments, scientific laboratories and nuclear facilities. An emergency department (ED) response plan should be developed and emergency response team membership designated. Equipment for monitoring, decontamination and contamination control should be in place. Regular practice is essential.

A decontamination area must be designated and be itself capable of adequate decontamination. Ambulant patients and lower acuity stretcher-bound patients should be decontaminated outside the ED. Waste water may be legally discharged into normal draining systems if it does not exceed specified limits. In the clinical setting of a few patients, this is unlikely. Incidents involving contaminated or possibly contaminated patients rapidly deplete a receiving hospital's emergency response. If multiple patients with possible contamination are being managed, the hospital may need to defer where possible the arrival of other patients.

Hospital protocols should include plans for dealing with relatives, the press and the public. The timely release of appropriate information is important. Persons issuing this information should be well versed in radiation medicine, as the avoidance of questions and confusion in answers may generate public uncertainty and panic. Security personnel will be required to restrict the entry of unauthorized persons to the treatment area.

Decontamination process

Life-saving procedures resulting from trauma or burns should take priority over consideration of the radiation aspects of the patient's condition, even if preparations to minimize the spread of contamination have not been completed. A radiation physicist with appropriate monitoring equipment should be present in the ED. However, if patients arrive before monitoring is available, treatment of severe injury should proceed immediately and subsequent decisions regarding decontamination should be based on the patient's likely exposure.

In the ideal situation, all patients should be monitored at triage and, if found to be contaminated, those without severe injury should be showered and remonitored prior to admission to the ED. This is especially so if whole-body contamination has occurred, for example from a gaseous plume from a reactor accident. Washing starts with the hair and works downwards. Patients should bend forward while washing their hair so that any contamination is not washed into their eyes, nose or mouth. Wounds should be covered with a waterproof dressing before showering to avoid washing contaminated water into them.

Because some patients with severe injury will require immediate admission to the ED, adequate preparations are necessary. The floor of the entry and some treatment cubicles should be covered with plastic and any nonessential items removed. Access to this controlled area must be strictly supervised and there should preferably be a buffer zone. Disposable fluid-repellent gowns are ideal but surgical gowns covered by plastic aprons are satisfactory. Lead aprons as used in x-ray departments are not satisfactory; these prevent exposure but not contamination and are heavy and hot to wear. Plastic bags are taped over the shoes and the cuffs of overalls should be taped and secured to the outsides of overshoes. Facemasks are required to protect against airborne contamination but they do not protect the face from being touched by contaminated hands. Trauma masks with clear plastic visors are the best option. Two pairs of gloves should be worn. The inner ones should be surgical gloves taped to the sleeves. The outer gloves are not taped down and should be changed frequently. Hair cover is desirable. Personal radiation dosimeters should be worn outside clothing by key treating personnel in closest proximity to casualties.[7] Rubbish bins lined with garbage bags serve as waste receptacles and should be emptied promptly to minimize the amount of radiation in the department.

Once the patient is in the controlled area, all clothing should be removed and other medical conditions assessed and treated. Blocking agents can be administered if they have not already been given. All mucosal surfaces should be swabbed to aid in the assessment of likely internal contamination. These include nostrils and ears, the mouth and rectum. The swabs should be placed in sealed labelled plastic bags and sent for radiation assessment and identification of the chemicals involved. Blood samples should be drawn for a baseline complete blood count, differential and absolute lymphocyte counts and later cytogenic analysis. A serum amylase is also important, as the parotid is very sensitive to radiation.

External decontamination utilizes the principles of barrier nursing and contamination control. Staff should stand back from the patient except when actually examining them or performing procedures. Radiation exposure is inversely proportional to the distance from the source squared. Hospital personnel should be rotated during the decontamination procedure to minimize the perceived risk to any one individual. Pregnant staff should not be involved. Staff members should shower following completion of their turn in decontamination.

The priority areas for external decontamination are wounds and orifices, as it is through these that the risk of subsequent internal contamination is greatest. Other priority areas include the hands, face and head, as early contamination removal reduces spread. Decontamination of intact skin is the last priority.

Wounds are decontaminated in the same manner as when removing dirt or bacteria. Deeper wounds should be opened up and thoroughly irrigated. Burnt areas also should be carefully irrigated. Metal fragments should be removed with forceps. Deep debridement and excision of a wound is rarely necessary in extreme cases where highly toxic material is embedded in the tissues. Decontamination efforts should continue until the radiation level is at background levels or there is minimal reduction with further washing.

The mouth is decontaminated by gentle irrigation and frequent rinsing with 30% hydrogen peroxide solution. Brushing of the teeth with toothpaste is helpful, as toothpaste contains chelating agents. External ear canals should be irrigated and nasal douches can be effective. The eyes are rinsed by directing a stream of water or saline from the inner canthus to the outer canthus, so that material is not forced into the lacrimal duct. Hair should be shampooed several times with the head deflected backwards over a basin to keep water from the eyes and ears. A hair dryer is used to dry the hair. Clipping of hair may occasionally be necessary.

The skin is washed initially with warm water and mild soap. If this is ineffective, 0.5% hypochlorite or stronger detergents can be used. If the skin becomes damaged or red and sore, cleansing should be discontinued. If contamination is only discovered after patients are admitted to an ED, the entire area through which they have passed should be taped off, surveyed with the help of a radiation physicist and, if necessary, decontaminated. Staff should put on protective clothing and remove nearby patients so as to create a spacious treatment area. Following a radiation incident, all equipment, instruments and work areas used in treating contaminated patients must be thoroughly cleaned.

Monitoring decontamination

Radiation physicists should check the background level of radiation in the ED from time to time so that they have a baseline from which to assess each patient's exposure. Scanning should occur slowly to avoid missing radiation. Headphones should be used or the sound turned off to avoid alarming patients.

Internal contamination

Internal contamination causes no acute clinical effects and it is usually not feasible to confirm its presence before commencing treatment directed at the reduction of absorption, prevention of incorporation into tissues and promotion of elimination. Significant internal contamination has traditionally occurred through wounds or body orifices in small-scale accidents. It could readily occur on a wider scale following the explosion of an RDD, a reactor accident or a nuclear detonation. Absorption would be by inhalation of contaminated air and/or ingestion of foodstuffs contaminated by fallout. Radionuclides that have short effective half-lives, such as technetium used in nuclear medicine ($t_{1/2}$ = 5 hours), pose no danger. For isotopes with effective half-lives measured in days, the decision to treat will depend on the likely intake especially via the lungs, whether the drug is concentrated in tissue, such as iodine in the thyroid or uranium or americium in bone, whether the emission is high energy as with cobalt and whether the chemical itself is toxic. The effective half-life combines radioactive and chemical properties and describes the rate of elimination without decontamination.

To assist in the determination of the extent of internal contamination, a 24-hour urine sample should be collected. If gastrointestinal contamination is suspected, a 24-hour stool sample should also be collected.

The commonest isotopes found in Australia are iodine^{131}, cobalt^{60}, caesium^{137}, tritium^{3}, americium^{241} and uranium$^{235/238}$.

Selection of the appropriate technique or drug depends on knowledge of the radionuclide involved and its physical form.[4,8] For example, natural uranium is not a significant radiation hazard but enriched uranium found in fuel rods or weapons emits significant levels of gamma radiation if sufficient quantity is present.

Administration of stable iodine in the form of potassium iodate or potassium iodide tablets will reduce uptake by the thyroid gland by up to 90% if given less than 2 hours after intake and by about 50% if in less than 3 hours. Penicillamine will chelate cobalt and Prussian blue will chelate caesium. Sodium bicarbonate and tubular diuretics will increase the excretion of uranium. These agents may be useful for up to 2 weeks. Mobilizing agents, such as antithyroid drugs, increase the natural rate of turnover of a biological molecule and thereby increase excretion. Gastrointestinal decontamination is unusual but an enema might be used to empty the bowel.

Likely developments over the next 10 years

- The cumulative effects on patients of low-dose radiation from repeated diagnostic examinations are by far the largest source of radiation exposure from human activity. Critically appraising the need for complex and repeated examinations and utilizing imaging algorithms to select the most appropriate modality is increasingly important.
- The specialists most used to managing inpatients with acute radiation illness are haematologists and oncologists. Advances in care in these specialties are likely to improve the treatment available.
- There is more of a focus on planning for possible multicasualty incidents now with considerable research into countermeasures that might reduce the effects of radiation and quicker means of dicentric analysis. Thiol compounds with radical scavenging properties, or derivatives thereof, may prove useful.[9]
- The most effective life-saving opportunity in the first 60 minutes following a nuclear explosion will be to shelter people safely in possible fallout areas in the nearest basement or in the middle of buildings, but not in cars. This is called sheltering in place. In most cases, effective self-decontamination can be performed if straightforward instructions are provided. The appropriate time to evacuate the fallout area should be determined by authorities on the basis of environmental monitoring and communicated to the population in a timely fashion.[10]

24.5 Drowning

David Mountain

ESSENTIALS

1 The incidence of non-fatal drownings requiring medical assessment to fatal drownings is around 2 to 20 times greater than fatal drowning.

2 The highest rates of drowning occur in children from 1 to 4 years of age and young adult males. In adults that die, many are intoxicated.

3 A total of 10% to 20% of fatal drownings have minimal aspiration with asphyxia probably due to laryngospasm, shunting and mucus plug formation. Differences between fresh- and salt-water drowning are unimportant for management.

4 Hypothermia following warm-water (>10°C) drowning carries a very poor prognosis. Hypothermia following cold-water (<10°C) drowning occasionally sees intact neurological outcome after prolonged (>30 minute) resuscitations.

5 Better outcomes are associated with initiation of good-quality CPR, with assisted ventilation being the essential component (i.e. aBc), within 10 minutes of witnessed drowning.

6 Spontaneously breathing patients should be managed on their side. Active lung drainage procedures and the Heimlich manoeuvre are contraindicated.

7 Positive end-expiratory pressure/continuous positive airway pressure are useful therapies in the hospital. Artificial surfactant and inhaled nitric oxide have equivocal results. Extracorporeal membrane oxygenation is being used more frequently for severe lung injury but without good outcome data in drowning.

Introduction

Australia, the driest inhabited continent, has one of the highest reported incidences of drowning in the developed world. It is a major cause of death and disability in youths with peaks in young children and young adult males. Nomenclature and definitions are now generally agreed with all respiratory distress (of any level, e.g. cough, wheeze, rales) from immersion or submersion defined as drowning (fatal or non-fatal).

Good outcomes are mainly determined by pre-hospital factors, particularly witnessed drowning, short immersion times, early cardiopulmonary resuscitation (CPR), prehospital signs of life, and early access to emergency medical services (EMS). An accurate history, well-run resuscitation and informed judgement on prognosis will optimize outcomes, resource use and aid patient management and family interactions. Patients with spontaneous respiration and/or neurological responsiveness on arrival in the emergency department (ED) are expected to recover unless acute respiratory distress syndrome (ARDS) supervenes. Treatment after a non-fatal drowning is mainly supportive, although extracorporeal membrane oxygenation (ECMO) and direct lung therapy may improve future outcomes.

In many areas, preventative and educative measures (e.g. pool fencing, life vests, life guards, boat licensing) have reduced fatality rates dramatically. Emergency physicians should be strong advocates for these initiatives.

Epidemiology

Rates of drowning have significantly declined worldwide over the last 2 to 3 decades but it is still a major cause of death and disability in young populations. Overall, males drown more frequently, in most age groups with ratios up to 9:1. This seems to have declined recently with ratios around 2 to 4:1. Groups with highest rates of drowning include infants 0 to 4, (up to 10× higher than 5 to 15, particularly males), young adult males (15 to 30 years), epileptics (up to 20× higher), overseas visitors, the mentally disabled and those from deprived/under-resourced communities with poor public health initiatives. More recently, richer populations are over-represented in countries with high rates of home pools. In young adult males, bravado, inexperience and alcohol lead to many deaths. Alcohol is found in 14% to 60% of adult drownings. The majority of male adult drownings are related to recreational activities. In the elderly, underlying medical illnesses and suicide attempts are more frequently seen. Most of these factors (except age) are associated with worse outcomes. Cold water has been associated with worse outcomes overall (shorter time to submersion in icy waters), although very occasionally younger patients may survive prolonged immersions potentially by rapid brain cooling.

The ratio of those who initially survive (but require medical attention) to fatal drownings is not accurately known because of differences in nomenclature, definitions and the inability to collect all attendances related to drowning, but is estimated at between 2 and 20:1. In a well-conducted observational study from the Netherlands, the ratio of patients admitted to the intensive care unit (ICU) following drowning compared with those who died before admission was 2:1.

Prevention

Prevention of drowning is a major area for ongoing research and an area emergency physicians should strongly advocate for preventative strategies of proven benefit. Marked reductions in drowning rates in developed countries are suggestive prevention works.

Patrolled beaches with shorter submersion times, early, good quality CPR with assisted breathing and early EMS activation are associated with better outcomes. Important educational initiatives include early swimming/survival lessons, CPR training, parental supervision of children, using supervised swimming areas, avoiding mixing alcohol and water activities and appropriate water safety equipment. Protective pool fencing, enforcement of water vehicle alcohol laws, and water and safety regulations enforcement for water activity are also important.

Definitions and terminology

Much confusion has been caused in research and management by imprecise definitions. Phrases commonly used have been near-drowning, dry, wet, active, passive or silent, late or secondary drowning, immersion, submersion, suffocation and asphyxia. Most of these were ill defined and confusing.

In 2015, International Liaison Committee on Resuscitation (ILCOR) concurred on the Utstein style definition: drowning is a process resulting in primary respiratory impairment from submersion/immersion in a liquid medium. Implicit in this definition is that a liquid/air interface is present at the entrance of the victim's airway, preventing the victim from breathing air. The victim may live or die after this process, but whatever the outcome, he or she has been involved in a drowning incident.

'Near-drowning' is redundant as drownings are either fatal or non-fatal. Similarly, 'wet' and 'dry' drownings are redundant as all drowning is wet with differing amounts of aspiration. Descriptions by bystanders for activity in drowning are now only described as 'witnessed' and 'unwitnessed' drowning, according to whether or not entry to the water was observed. The term 'secondary drowning' was used to describe both causative problems drowning (e.g. intoxication, illness) or death due to secondary problems (e.g. ARDS, encephalopathy) and was inherently confusing. Therefore precipitating factors or sequelae should be specifically described. Immersion describes any is the inability to maintain a fluid-free airway interface, whereas submersion implies the whole airway is underwater. They are rarely important distinctions for management or epidemiology.

Pathophysiology

The sequential pathophysiology of drowning is well described:

- Initial submersion/immersion leads to voluntary apnoea if drowning is due to initial loss of consciousness (e.g. cardiac arrhythmia or other catastrophic illness). Unless voluntary, most adult victims panic and struggle, with spitting or expulsion of fluid from nasal and oral cavities with associated increases in blood pressure (BP) and pulse rate (PR). Slow PR may occur secondary to primitive dive reflexes or cold-induced reflex brady-arrhythmias, particularly in children or intoxicated adults, in cold water and late on in drownings.
- After an interval dependent on presubmersion oxygenation, intoxication, injuries, illness, fitness and the degree of panic and struggle, synergistic hypercapnia and hypoxia lead to an involuntary breath known as the 'breaking point', normally reached in under a minute. During this stage, large quantities of water are often swallowed/aspirated. If an individual hyperventilates before diving (a highly dangerous activity), plasma CO_2 concentrations may remain so low that hypoxic unconsciousness occurs before the breaking point is reached. This is known as 'shallow water blackout'.
- Fluid inhalation causes sudden increases in airway pressures, bronchoconstriction, pulmonary hypertension and shunting. In 10% to 20%, laryngospasm reduces further aspiration, with a mucus and foam plug forming (previously called 'dry drowning').
- Secondary apnoea occurs, closely followed by unconsciousness.
- Involuntary gasping respirations lead to lungs flooding and alveolar injury, surfactant loss, increased ventilation/perfusion (V/Q) mismatch, shunting and hypoxia. Vomiting of swallowed fluid is common, potentially causing pulmonary aspiration.
- Hypoxia causes marked bradycardia, hypotension and irreversible brain injury within 3 to 10 min (except occasionally in icy water induced rapid hypothermia), culminating in respiratory or cardiorespiratory arrests.

In fatal drownings, the average lung fluid retrieved is 3 to 4 mL/kg, less than 10% of lung volume. However, the effect on the lungs is dramatic. Experimentally, fresh water and sea water cause alveolar injury by different mechanisms. Fresh water denatures surfactant and damages the alveolar cells. Sea water tends to draw in fluid, wash out surfactant and cause foam formation. Aspirated vomitus and/or chemicals may further complicate the clinical picture. Soap and chlorine in water do not appear to affect outcome. Clinically, the type of water inhaled rarely makes a difference, unless grossly polluted. Electrolyte disturbances are normally minimal and transient except in prolonged arrests, owing to the small volumes aspirated (more than 20 mL/kg are required for major disturbances).

Clinical features and organ-specific effects

Airways/lungs

The major features are intense laryngospasm, bronchospasm, pulmonary hypertension and marked V/Q physiological shunts. Even without overt respiratory embarrassment after drowning, shunts of up to 70% may occur and take up to a week to resolve. In the alveoli, there is surfactant loss, formation of protein-rich exudate and alveolar cell injury, often exacerbated by aspiration pneumonitis, chemicals and secondary infection (in up to 15% of intubated patients), leading to ARDS. The importance of the pulmonary insult in determining outcomes is seen by the level of lung involvement and respiratory distress, from arrest, down to cough or asymptomatic patients clearly stratifying death and morbidity (Table 24.5.1).

Table 24.5.1 Grading of drowning severity—pre-hospital based on cardiorespiratory status

Drowning grade	*Dead*	*Grade 6*	*Grade 5*	*Grade 4*	*Grade 3*	*Grade 2*	*Grade 1*	*Rescue*
Submersion time	>1 h/ unknown	<1 h						
Signs at scene/ rescue	Clearly dead	No pulse No breaths	Pulse No breaths	Rales—all fields Hypotension	Rales—all fields BP normal	Rales—some BP normal	Cough only	No signs
Mortality rate (%)	100	88–93	31–44	18–22	4–5	1	0	0%
Management	Transport	CPR—ABC resus	Rescue ventilation	O_2—prob ETT	O_2—poss ETT	O_2	Check nil other probs	Nil required
Expected level of care	Forensic	ICU	ICU	ICU	HDU–ICU	ED review	Scene first aid	Nil required

Table 24.5.2 Modell/Conn classification of mental status following drowning

Grade	*Description of mental status*	*Equivalent GCS*	*Expected Likelihood of good outcome (neurologically intact) (%)*
A	Awake/alert	14–15	100
B	Blunted	8–13	100
C	Comatose	6–7	>90
C1	Decerebrate	5	>90
C2	Decorticate	4	>90
C3/4	Flaccid coma or arrest	3	<20

GCS, Glasgow coma scale.

Brain

The major brain effects are secondary to hypoxic encephalopathy. It is the major cause of death in drownings and a major determinant of survival for drowning arrests (Table 24.5.2). Cerebral oedema, convulsions and persistent vegetative states are observed frequently. Trauma or an underlying medical complaint should be considered in the differential diagnosis in unwitnessed or unexplained events in water resulting in drowning. It is essential to consider this in those drowning involving water transport or motor vehicles, patients with obvious signs of injury involved in shallow pool drownings, patients who are intoxicated and the elderly.

Cardiovascular

Most drowning patients are haemodynamically stable after resuscitation. Most prolonged drownings in arrest will have some degree of hypovolaemia and should have 10 to 20 mL/kg of Nsal. Hypothermic patients may develop any arrhythmia and should be gently handled and aggressively rewarmed (see Chapter 24.2). In older patients, underlying ischaemic heart disease should be considered. Long QT syndrome, and other channelopathies or cardiomyopathies may be associated with arrhythmia in some immersions. Unexplained immersion arrests in patients under 40 should prompt consideration of congenital/familial cardiac syndromes.

Haematological

Haemolysis occurs occasionally in fresh-water drownings.

Renal

Acute tubular necrosis or tubular injury from hypoxia infrequently occur. Electrolyte disturbances are rarely significant.

Gastrointestinal

Vomiting is frequently observed (up to 80% in some series) but may be a marker for better outcomes. It is secondary to ingestion of large volumes of water, potentially aggravated by poor positioning or use of Heimlich/active lung emptying techniques, with aspiration a significant risk. Diarrhoea is infrequently seen. Hypoxic gut injury may contribute to late multiorgan failure, ARDS and sepsis.

Orthopaedic

Cervical spine injury should always be considered in drownings related to diving into water or with co-existent injuries. Coexistent trauma is more frequent with alcohol, water sports or boating-related drownings.

Treatment

Pre-hospital

Hypoxia (particularly brain hypoxia) is the major cause of early drowning mortality and morbidity, and many late problems. Rapid institution of effective pre-hospital care, particularly early retrieval, supplemented (or exhaled responder) breathing/oxygenation (potentially in water for expert providers, e.g. surf lifesavers) and rapid EMS activation are important factors in determining good outcome following drowning. Early access and activation of EMS is essential. All patients seen alive within 1 hour of removal from cold water (<10°C) should be transported for definitive care. Retrievals by non-expert, untrained bystander swimmers have high rates of retriever drownings (up to 10%) and fatalities. However recreational surfers in some series saved high numbers of distressed swimmers, probably due to their knowledge of local conditions, flotation devices, swimming ability and high rates of first-aid training/experience.

The level of pre-hospital care varies with the clinical severity of the case (see Table 24.5.1), ranging from asymptomatic (the majority) to cardiopulmonary arrest. Initial retrieval from water should be horizontal (avoiding hypovolaemic arrest), and assessment of ABCs may be done with the patient on their side allowing airway fluid drainage if breathing or on their back followed by institution of CPR (with an ABC emphasis) if respirations or pulse are absent. There is little role for in-water resuscitation, excepting patrolled beach deep water retrievals by properly equipped expert lifesavers who can easily get to shore. Lung drainage procedures (e.g. abdominal compressions) and the Heimlich manoeuvre are dangerous, as they increase gastric aspiration and are contra-indicated. The priority is to re-initiate breathing and, in arrests, A and B are priorities. In particular, rescue breathing (or bagging if available) is obligatory (two breaths if good chest movement), but normally five breaths are required for inadequate chest movements because of poor lung compliance. Victims often vomit upon resumption of spontaneous respiration, and if obtunded, they should be transported on their side (if not intubated) to minimize further aspiration. All symptomatic patients should have supplemental high-flow oxygen. IV fluids for hypovolaemia with 250 to 500 mL boluses of N-Saline are appropriate if IV access is possible and does not delay transport. Wet clothing should be removed gently and the patient dried, wrapped and covered to minimize heat loss. Only if neck trauma is likely should the C-spine be immobilized. People with patient knowledge and/or drowning witnesses should be encouraged to go to the hospital or travel with EMS. A clear rapid history should be taken by EMS and documented.

Emergency department

History

Important factors in the history of arrested drowning include environment of drowning and potential associated factors, such as water temperature/type, submersion duration (or time last seen), time CPR starts, CPR quality and response to first assisted breaths / CPR, time of first spontaneous breath, and/or return of spontaneous cardiac output, initial Glasgow coma scale (GCS) and GCS after resuscitation (Utstein style). A collateral history for health problems (including psychiatric issues), intoxicants, vomiting and potential trauma is also useful.

Initial resuscitation

Initial assessment and resuscitation continue the priorities from pre-hospital being directed towards the assessment and maintenance of ABCs. Monitoring should include oximetry, capnometry, telemetry, BP and core temperature (urinary or rectal probes if obtunded).

Airway management may be just supplemental oxygen or clearing and positioning the airway. Endotracheal intubation is indicated if respiration is ineffective, saturation is poor, lung fields have extensive rales or GCS <8. Patients who cannot maintain PaO_2 of 90 mm Hg on a non-rebreathing mask should be considered for early intubation, although non-invasive ventilation is an alternative in the cooperative patient. Extensive persistent rales suggest a high risk for late respiratory compromise and potential ARDS. Bronchospasm should be treated with nebulized β-agonists, without steroids, unless the patient is a known asthmatic. In the unconscious patient, a nasogastric tube should be placed early after intubation to minimize pulmonary aspiration. All intubated patients require small tidal volume, early positive end-expiratory pressure (PEEP; 10 to 20 cm) and end-tidal CO_2 monitoring.

Most obtunded, arrested patients will require IV fluids, as hypovolaemia is common. Cardiac complications should be managed according to standard treatment regimens, except patients with hypothermia (<33°C). Hypothermic patients (see Chapter 24.2) should be handled gently with antiarrhythmic drugs avoided if possible until rewarming occurs. All rhythms without output require CPR. In general, asystole following drowning has the same dire prognosis as from other causes, particularly if present after adequate pre-hospital resuscitation. Occasional witnessed cold-water (<10°C) arrests in younger patients have had good outcomes after prolonged (60+ min) resuscitations. Hypotension is managed with judicious (e.g. small bolus) fluids and inotropes if unresponsive, with invasive monitoring if persistent, particularly in patients with pulmonary oedema.

The management of hypothermia is described elsewhere in this book (see Chapter 24.2). Where cervical spine injury is a distinct possibility (especially following shallow diving or water vehicle accidents), cervical spine immobilization should be maintained until the C-spine is cleared.

Ongoing management

Intubated patients, especially with obvious chest x-ray infiltrates, should have PEEP and low volume ventilation. Commence with low pressures (5 to 10 cm H_2O) but increase rapidly as tolerated until adequate oxygenation is achieved or hypotension or high airway pressures supervene. Pressure-controlled ventilation may be added but may increase barotrauma and alveolar injury. Use should be discussed with the ICU providing ongoing care. These modalities improve outcome for near-drowning patients with secondary lung injury. Ventilatory weaning should begin as soon as possible after 24 hours in order to reduce barotrauma. Non-invasive ventilation may be a bridge to intubation or avoiding intubation in some but should always be discussed with ICU. Maintenance of normoglycaemia, normovolaemia, normocarbia, seizure control plus avoiding hyperthermia, hypoxia and hypotension are important for cerebral outcomes. Dehydration and prolonged hyperventilation are dangerous. Induced hypothermia post-arrest from drowning has been an area of some controversy (discussed later). Targeted temperatures between 32°C and 36°C are recommended.

Experimental therapies

A number of other therapeutic modalities have been trialled in an effort to improve the outcome of lung and brain injuries caused by near-drowning. These include the following:

- Induced hypothermia. Popularized by Conn, this therapy offers the theoretical advantage of cerebral protection. Unfortunately, drowning patients were actively excluded from most therapeutic hypothermia trials, ironically because this group was most likely benefitting from environmental hypothermia! Induced hypothermia trials after cardiac arrest from ventricular fibrillation (VF) renewed interest in this area but recent ILCOR recommendations suggest only targeting to a 33°C to 36°C temperature.
- Pharmacological cerebral protection. Barbiturate infusions, steroids, magnesium and chlorpromazine have all been trialled. None has been shown to be of benefit, and all may have deleterious effects.
- Intracranial pressure monitoring. Its use is controversial and lacking in outcome data, and depends on which ICU cares for the patient.
- Prophylactic antibiotics. These are of no value except following drowning in grossly polluted water. In such cases, a second-generation cephalosporin is recommended. Drownings in hot spas and tubs may require anti-pseudomonal cover.
- Hyperbaric oxygen therapy and nitric oxide therapy are of unproven benefit.
- Exogenous surfactant therapy. Has no proven benefit, with some animal research suggesting increased lung injury.
- Extracorporeal oxygenation. Successfully applied in some centres for severe lung injury, particularly hypothermic children. It may be used as a bridge for drowning related ARDS, which should be more reversible than inflammatory ARDS. There are no definitive trials showing benefit.

Clinical investigations

Ordering of investigations in the ED is guided by the clinical status of the patient—in particular, mental and cardiorespiratory status. All symptomatic patients require continuous pulse oximetry and a chest x-ray, which should be repeated at 4 to 6 hours. Using the Modell/Conn classification of mental status (see Table 24.5.2), patients in group A only require a chest x-ray and oximetry. Patients in group B may also require a full blood count, electrolytes and creatinine, blood sugar, arterial blood gases and an ECG. The ECG/rhythm strips should be checked for prolonged QT or ventricular arrhythmias in younger patients with a history of unexpected rapid submersions looking for congenital/familial cardiac problems. Arrythmias are rare in most drowning patients, excepting bradycardias. If patients do not improve rapidly after ED supplemental oxygen, they should be investigated and managed like group C patients. Patients in group C are recommended to have liver function tests, creatine kinase and troponins, alcohol levels, coagulation profiles, urine dipstick and a computed tomography (CT) head scan if coma persists. Cervical spine x-rays and trauma films are only indicated if trauma is likely. Intracranial pressure monitoring, EEGs, MRI and so on are not normal ED care and should be considered in ICU.

Prognosis

Mortality rates of 15% to 30% and severe neurological disability rates of up to 25% are reported in ICU series (these are highly selected studies). Patients with prolonged (>30 minute) cardiac arrests, poor initial response and no signs of life on ED arrival have almost universal mortality or catastrophic neurological outcomes (see Tables 24.5.1 and 24.5.2). Patients with GCS >8 but persistent hypoxia, early recovery from arrest and/or persistent rales are at high risk of ARDS and multi-organ failure and have relatively high later mortality (persistent rales 4% to 5% to recovered arrest 40%).

Potential prognostic features have been extensively evaluated to try and reduce rates of severely neurologically handicapped survivors, avoid prolonged CPR, and provide staff and relatives with accurate prognostic information. The most useful predictors of neurological outcome relate to the initial resuscitation (field predictors). Factors associated with good outcomes include witnessed drowning, early retrieval times (<10 minutes submersion), good-quality CPR provided within 10 minutes, vomiting, early EMS attendance, a spontaneous breath within 30 min of retrieval and return of spontaneous circulation before ED. Early respiratory efforts post resuscitation are associated with good

neurological outcome, provided ARDS does not supervene. Pre-hospital factors associated with poor outcome include male sex, cold or fresh water, unwitnessed or prolonged submersion (particularly >25 minutes), prolonged arrests (particularly asystole >30 minutes, almost universally poor outcomes) and long pre-hospital times. Absolute EMS predictors of poor outcome have not been identified, and all drowning patients arriving at ED deserve full assessment and resuscitation efforts, short of clear signs of prolonged death (e.g. lividity, rigor) or clearly unsurvivable combinations of prognostic features. In general, outside of witnessed young, icy water–induced arrests, asystole for longer than 30 minutes can have resuscitation stopped unless trials of ECMO are rapidly available at a nearby hospital.

Emergency department prognostic factors have been identified, although no combination of factors reliably predicts all poor outcome patients. Good ED prognostic features include pupillary response, perfusing cardiac rhythm or any motor response to pain. Asystole, if the only rhythm seen, is predictive of poor outcomes and should lead to consideration of CPR cessation. Hypothermia has been called a favourable prognostic indicator but is highly debatable. Although witnessed ice-cold water immersions are occasionally associated with neural recovery after prolonged resuscitation (probably due to rapid brain cooling), hypothermia normally suggests prolonged submersion and poor prognosis. A recent Dutch series of paediatric patients retrieved from icy waters found all 98 with >30 minute resuscitations died or had severe neurological deficits.

In-hospital factors associated with poor outcome include GCS <5 on transfer to ICU (<20% intact survival; see Table 24.5.2), fixed dilated pupils at 24 hours and any abnormal CT head within 36 hours. A normal CT scan is of minimal prognostic value.

Disposition

All symptomatic drowning victims should be closely observed for 6 hours with pulse oximetry. Any patient with abnormal CXR, widespread rales or hypoxaemia after 6 hours should be admitted to HDU/ICU. Those requiring intubation, persistently obtunded, post-arrest or hypoxaemic require ICU. Truly asymptomatic patients or, non-progressive minor rales with stable adequate oximetry for 6 hours, may be discharged home after observation, but should return if they develop respiratory symptoms.

CONTROVERSIES

- Developing accurate prognostic indicators to decrease persistent severe neurological disability states is important. Most authorities agree that almost all drownings should be aggressively initially resuscitated, but 15% of ICU patients survive in persistent vegetative states, suggesting current resuscitation may be excessively aggressive.
- New treatment modalities for secondary lung injury, including nitrous oxide, artificial surfactant and particularly ECMO, individually or sequentially, is still being studied. Therapeutic hypothermia for the comatose post arrest patient has been de-emphasized, but a temperature should be targeted to below 36°C.
- Use of NIV to avoid intubation in the hypoxic patient with respiratory distress is poorly studied and should occur in discussion with the ICU.

24.6 Electric shock and lightning injury

Daniel M. Fatovich

ESSENTIALS

1 **Death from electric shock is due to ventricular fibrillation, the lethal arrhythmia occurring at the time of the exposure. Routine admission for ECG monitoring is unnecessary.**

2 **Most deaths are caused by low-voltage (<1000 V) exposures.**

3 **The amount of current passing through the body is determined mainly by tissue resistance, which is dramatically reduced by moisture.**

4 **Electrical injury resembles a crush injury more than a burn. The tissue damage below skin level is invariably more severe than the cutaneous wound would suggest.**

5 **There is a diversity of clinical manifestations seen with electrical injury.**

6 **Lightning injury is different from high-voltage electrical injury and has a unique range of clinical features. The management is predominantly expectant.**

ELECTRIC SHOCK

Introduction and epidemiology

Electricity is an integral part of our everyday world and electric shock is common. Patients may present to the emergency department (ED) with resulting injuries that range from trivial to fatal (termed electrocution). Although permanent disability can occur, it is reassuring to note that if the initial exposure is survived, subsequent death is unlikely. For each death caused by electricity, there are 2 serious injuries and 36 reported electric shocks.

There are approximately 20 electrical fatalities each year in Australia. Victims are predominantly male and young. Death is just as likely to occur at home as in the workplace, most often in summer. Electricians and linesmen are most at risk. The ratio of low-to-high-voltage deaths ranges from 3:1 to 7:1. The presence of water is associated with fatality. Electrical burns represent 3% to 5% of admissions to burns units.

Physics of electricity and pathophysiology of electrical injury

Electrical current passing through the body can cause damage in two ways:

- thermal injury
- physiological change.

The threshold for perception of an electrical current is 1 mA, which results in a tingling sensation. Current greater than 10 mA can induce muscular tetany and prevent the patient letting go of the current source. Paralysis of respiratory muscles occurs at 20 mA. The threshold for ventricular fibrillation is 100 mA (Fig. 24.6.1). Cardiac standstill and internal organ damage occurs at 2 A. The maximum 'safe' current tolerable for 1 s is 50 mA.

Ohm's law is fundamental to the understanding of the physics of electricity. This states that the amount of current passing through the body is directly proportional to voltage and inversely proportional to resistance (current [amperes] = voltage [volts] / resistance [ohms]).

Factors that determine the effects of an electrical current passing through the body are:

- type of current
- voltage
- tissue resistance
- current path
- contact duration.

Type of current

The vast majority of serious electrical injuries result from alternating current (AC), which is approximately three times as dangerous as direct current (DC). Alternating current can produce tetanic contraction of muscle such that the victim may not be able to let go of the current source. This is not a feature of direct current shock.

Human muscular tissue is sensitive to frequencies between 40 and 150 Hz. As the frequency increases beyond 150 Hz, the response decreases and the current is less dangerous. In Australia, a frequency of 50 Hz is used for household current because this is optimal for the transmission and use of electricity and also has advantages in terms of generation. As such, household current lies directly within the dangerous frequency range. It also spans the vulnerable period of the cardiac electrical potential and is thus capable of causing ventricular fibrillation.

Voltage

Voltage is the electromotive force in the system. In general terms, the greater the voltage, the more extensive the injury, but it must be remembered that the amount of current passing through the body will also be determined by resistance (Ohm's law). High voltage is defined as greater than 1000 V. Household voltage in Australia is 240 V. Voltages less than 50 V (50 Hz) have not been proved hazardous. Survival has been reported following shocks of greater than 50,000 V.

Resistance

Different tissues provide differing resistances to the passage of electrical current. Bone has the highest resistance, followed by, in decreasing

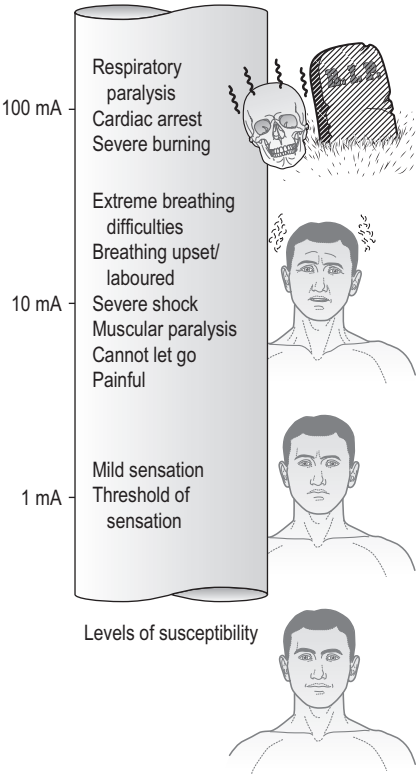

FIG. 24.6.1 The levels of electric shock and their effects.

order, fat, tendon, skin, muscle, blood vessels and nerves. Skin resistance varies greatly according to moisture, cleanliness, thickness and vascularity. Moist skin may have a resistance of 1000 Ω, and dry, thick, calloused skin may have a resistance of 100,000 Ω. By Ohm's law, dry skin resistance to a contact with a 240 V potential results in a current of about 2.4 mA, which is just above the threshold for perception. However, the resistance of wet or sweat-soaked skin drops to 1000 Ω, increasing the current flow to 240 mA, which is easily enough to induce ventricular fibrillation. Not surprisingly, moisture has been identified as a key factor in over half of electrocutions.

Current path

Prediction of injuries from knowledge of the current path is unreliable. Mortalities of 60% for hand-to-hand (transthoracic) and 20% for head-to-foot passage of current are quoted, but have not been verified. When current passes hand-to-hand (or hand-to-foot), only about 5% of the total current passes through the heart. If current passes leg-to-leg, no current traverses the heart.

Contact duration

The longer the duration of contact, the greater the potential for injury. Fortunately, most contacts are brief and frequently result in the victim being thrown back from the current source. This may result in a secondary injury, especially if the victim falls from a height.

Unfortunately, exposures to more than 10 mA of alternating current can induce sweating. Moisture decreases skin resistance and increases current flow, thereby reducing the ability to release the current source. This can progress to a fatal exposure.

Prevention

All members of the community must be encouraged to treat electricity with respect and to practise electrical safety. Licensed electrical contractors should be used to carry out any electrical repairs or installations. Water and electricity should never be mixed.

Residual current devices are useful in providing an additional level of personal protection from electric shock. These devices continuously compare current flow in both active and neutral conductors of an electrical circuit. If current flow becomes sufficiently unbalanced, then some of the current in the active conductor is not returned through the neutral conductor and leaks to earth. These devices operate within 10 to 50 ms and disconnect the electricity supply when they sense harmful leakage, typically 30 mA.

Clinical features

Electrical injury resembles a crush injury more than a burn. Invariably, the damage below skin level is more severe than the cutaneous wound suggests. The current passing through low-resistance structures produces massive necrosis of muscles, vessels, nerves and subcutaneous tissues.

The clinical manifestations differ from thermal burns in the following ways:

- There are direct effects on the heart and nervous system.
- Electrical injury classically involves deep structures.
- The small entry and exit wounds do not accurately indicate the extent or depth of tissue damage.
- A diversity of clinical manifestations is seen with electrical injury.

Burns

As electricity traverses the skin, energy is converted to heat. The smaller the area of contact, the greater the current density, heat production and the consequent skin and adjacent tissue destruction.

Electrothermal burns are best characterized by arc burns, which result from the external passage of current from the contact point to the ground. These may be associated with extensive damage to skin and underlying tissue. Secondary flame burns may occur when the current arc ignites clothing or nearby combustibles.

Electrical burns may range from first degree to third degree. The typical appearance is of a central depressed charred black area surrounded by oedema and erythema. Single or multiple exit wounds may be present.

Cardiac

Ventricular fibrillation is the usual cause of immediate death from electric shock and occurs at the time of the shock. Delayed arrhythmia resulting in death is exceptionally rare. Sinus tachycardia is common and non-specific ST- and T-wave changes may be observed. Atrial fibrillation occurs infrequently and usually resolves spontaneously. Acute myocardial infarction following electric shock has been reported.

Nervous system

Both acute and delayed neurological sequelae have been described following electric shock. Acute complications include respiratory arrest, seizures, altered mental state, amnesia, coma, expressive dysphasia and motor deficits. Reported delayed complications include spinal cord injury (myelopathy) with local amyotrophy and long tract signs, and reflex sympathetic dystrophy.

Peripheral nerve injury is usually associated with significant soft-tissue injury. It has also been reported in the absence of soft-tissue injury, and such cases appear to have a good prognosis.

Renal

Acute renal failure may occur secondary to myoglobinuria. Electric shock results in disruption of muscle cells with the release of myoglobin and creatine phosphokinase, similar to a crush injury. Transient oliguria, albuminuria, haemoglobinuria and renal casts are common, and there have been reports of high-output renal failure.

Vascular

Large and small vessel arterial and venous thrombosis are responsible for the tissue damage in electrical injury. Vascular complications have included immediate and delayed major vessel haemorrhage, arterial thrombosis and deep vein thrombosis.

Musculoskeletal

Tetanic muscle contractures can result in compression fractures of vertebral bodies, fractures of long bones and dislocations of joints. Injuries may also result from a secondary fall, rather than from the electric shock.

Other

Numerous complications involving other systems, including the eye (especially cataracts), have been reported.

Electric shock in pregnancy

Reports of electric shock in pregnancy are rare and the true incidence is unknown. A high mortality has been reported in the literature. However, this may represent publication bias and a prospective cohort study concluded that in most cases, accidental electric shocks during pregnancy do not pose a major foetal risk.

If there was an immediate problem, the mother may notice a sudden cessation of foetal movements. However, there is no preventative action possible in the ED. Other reported foetal complications of electric shock include intrauterine growth retardation, oligohydramnios and abortion.

Fortunately, therapeutic electric shocks, such as DC cardioversion and electroconvulsive therapy, are known to be safe in pregnancy. The critical factor is current path: accidental electric shocks include the uterus, whereas therapeutic shocks do not.

Treatment

Pre-hospital

Everyone should be aware of the pre-hospital management of electric shock. Most importantly,

the rescuer should avoid becoming a further victim. The victim can be separated from the electrical source by using rubber, a wooden handle, a mat or any other non-conductive substance or, if possible, by turning off the electricity supply. Cardiopulmonary resuscitation (CPR) should begin immediately, if indicated, and help summoned. CPR may need to be prolonged. Ventricular fibrillation is the most common lethal arrhythmia after electric shock, and early defibrillation provides the greatest chance for survival.

Emergency department

The majority of patients who present to the ED after electric shock are well. Following appropriate assessment to exclude primary or secondary injury, an ECG should be performed. Cardiac monitoring is not indicated if the patient is asymptomatic and has a normal ECG. Most patients can be reassured and discharged directly from the ED. Routine measurement of creatine phosphokinase levels or troponin is not required. It should be acknowledged that exposure to an electric shock is an unpleasant experience. Tetanus status should be checked.

Many patients have a degree of muscle pain following electric shock owing to the tetanic nature of alternating current. Simple analgesia is appropriate. Any secondary injury, such as fractures or loss of consciousness, should be treated as dictated by the injury.

If an arrhythmia is present, it will usually resolve spontaneously and not require specific treatment. Delayed lethal arrhythmias have not been reported in patients without initial arrhythmias.

Severe electrical injury with extensive soft-tissue damage should be managed as a crush injury. This is more likely following high-voltage exposure, which results in a large exudation and sequestration of fluids in the damaged area. Emergency management includes adequate volume replacement and treatment of acidosis and myoglobinuria.

Emergency physicians should be aware of the low potential for foetal harm following electric shock in pregnancy. It would be prudent to adopt a conservative approach of performing a foetal heart Doppler assessment with obstetric follow-up, including ultrasound.

Prognosis

The prognosis for the majority of patients surviving the initial shock is excellent. Those with significant soft-tissue injury or secondary injury may be left with long-term deficits.

Disposition

The majority of patients presenting to the ED following an electric shock will be suitable for discharge following assessment and reassurance, as detailed previously. Those suffering muscle pain secondary to tetanic contractions should be given simple analgesia and instructed to follow up with their general practitioner.

Patients with cardiac arrhythmias require admission for observation until the arrhythmia resolves. Those with evidence of neuropathy should be referred to a neurologist, as nerve conduction studies may be required.

Severe electrical injuries with extensive soft-tissue damage require admission to hospital and, sometimes, to an intensive care unit. All patients with electrical burns should be reviewed by a burns specialist, and referral to a specialist burns unit may be indicated. Minor burns may be suitable for elective review.

Secondary injuries, such as loss of consciousness or fractures, should be admitted or referred on their merits.

The Taser

The Taser is a development of the stun gun. It is used by police to fill the operational gap between the baton and the gun for controlling potentially dangerous and violent suspects. 'Tasered' victims are occasionally brought to the ED for assessment.

The device is a battery-operated unit resembling a handgun that fires two barbed electrodes on 7 m long copper wires at 60 m/s. The barbs attach to the subject's skin or clothing and deliver up to 50,000 V of electricity in rapid pulses over 5 s. The current can cross up to 5 cm of clothing.

Electricity delivered by a Taser is neither pure AC nor pure DC and is probably akin to rapid-fire low-amplitude DC shocks. The output is believed to stay near the surface of the body in the skin and muscles and does not penetrate into the internal organs. There is no evidence to date that this form of electrical delivery interfered with cardiac or neurological function in the 30,000 volunteers or in the reported operational uses.

One author concluded that the pre-existing injuries and toxic conditions leading to the patient being tasered are the most important problems requiring medical treatment after Taser use. It seems that the device is essentially safe on healthy people. However, there is limited evidence to base recommendations for the assessment and management of patients that are brought to the ED after being 'tasered'. Suggestions for management include:

- Most healthy subjects may be safely discharged after barb removal and a clinical assessment.
- High-risk patients are those with known cardiac disease including implanted pacemaker or defibrillator, pregnancy, drug or alcohol intoxication, bizarre behaviour at the time of arrest, other psychiatric disturbance or coincidental medical problems. Often the coexistent condition (e.g. intoxication or mental health issue) will need to be addressed.
- Any patient with chest pain or abnormal ECG should be assessed as per routine clinical practice.
- Pregnant women >24 weeks' gestation should be considered for cardiotocographic monitoring.
- Look closely for direct injury from the barbs or indirect injury from falls. Barb injuries should be approached as a potential penetrating injury and managed accordingly. There are likely to be small puncture wounds and minor burns at the barb sites. On occasion, medical intervention will be required if the barbs are not easily removed, if the barb tip breaks off in the skin or if the barbs have struck vulnerable areas (e.g. mouth, eyes, neck and groin).
- Most patients will complain of muscle aches and anxiety.
- It is clear that, when properly used as a method of restraining violent people, Tasers are less likely than guns to cause injury and death of the target (and of the police officer). They are also generally more effective than other methods of restraint. The deaths that have followed Taser use have occurred in people who were out of control and who had taken potentially fatal drugs. It is likely that the deaths would have occurred whether or not the Taser was used. However, the medical effects of multiple shocks on such persons are unknown.

LIGHTNING INJURY

Introduction and epidemiology

There are several deaths each year in Australia from lightning. For each death, there are five injuries. These events are always prominent, and emergency physicians should be familiar with the pathophysiology.

Many myths surround lightning injury; they include:

- Lightning strike is invariably fatal. In fact, the mortality is 30%. In addition, the probability of long-term impairment after recovery is low.
- A victim of lightning is charged and dangerous to touch. This false notion has led to the withholding of CPR, with fatal results.
- Lightning should be treated in the same way as high-voltage electrical injury. This is incorrect.

Table 24.6.1 Lightning versus high-voltage injury

Factor	*Lightning*	*High voltage*
Time of exposure	Brief instantaneous	Prolonged tetanic
Energy level	100 million V 200,000 A	Usually much lower
Type of current	Direct	Alternating
Shock wave	Yes	No
Flashover	Yes	No

(Adapted from Cooper MA. Lightning injuries. In: Auerbach PS, Geehr EC, eds. *Management of Wilderness and Environmental Emergencies.* New York: Macmillan; 1983:500–521.)

Physics

Lightning occurs most commonly during thunderstorms. Particles moving up and down in a thunderstorm create static electricity, with a large negative charge building up at the bottom of clouds. Electrical discharge (lightning) occurs as a result of the great charge difference between the negatively charged thundercloud underside and the positively charged ground. The duration of the lightning stroke is between 1 and 100 ms.

Lightning strike is very different from high-voltage electric shock (Table 24.6.1) and produces different clinical effects, requiring a different management approach.

An interesting phenomenon called 'flashover' seems to save many victims from death by lightning. Current passes around and over, but not through, the body. The victim's clothing and shoes may be blasted apart. Only cutaneous flame-type burns result.

Clinical features

Immediate

- Asystolic cardiac arrest, as opposed to the ventricular fibrillation of electric shocks. The heart is thought to undergo massive depolarization. Although primary lightning-induced arrest may revert quickly, it can be followed by secondary hypoxic arrest.
- Chest pain and muscle aches.
- Neurological deficits. A person struck by lightning may be rendered unconscious. On first regaining consciousness, they may be mute and unable to move. This is transient and usually resolves within minutes, but may take up to 24 h.
- Contusions from shock waves.
- Tympanic membrane rupture.

Delayed

- Keraunoparalysis. Lightning-induced limb paralysis is extremely common. Flaccidity and complete loss of sensation of the affected limb are observed. Peripheral pulses are generally impalpable, and the affected limb takes on a mottled, pale, blue appearance. The mechanism is unclear, but may be lightning-induced vasospasm. The condition is self-limiting and resolves within 1 to 6 hours.
- 'Feathery' cutaneous burns (Lichtenberg flowers). These burns, pathognomonic of lightning injury, may appear immediately but more often become visible a few hours after injury. Burns may be severe but heal remarkably easily.
- Cataracts. Occur more commonly than following electrical injuries.
- Myoglobinuria and haemoglobinuria are rare.

Other

- Sensorineural deafness
- Vestibular dysfunction
- Retinal detachment
- Optic nerve damage

Reports of lightning strike in pregnancy reveal a high rate of foetal death *in utero*, despite maternal survival.

Treatment

Pre-hospital

The important principle is that those who appear dead should be resuscitated first. Immediate institution of CPR in the field for those in asystole prevents secondary hypoxic cardiac arrest during the interval until cardiac function resumes spontaneously. Fixed dilated pupils should not be taken as an indicator of death after lightning strike.

Emergency department

Most lightning strikes are unwitnessed, and diagnosis may be difficult in the unconscious or confused patient. The diagnosis should be considered where such patients were found outdoors in stormy weather. The presence of multiple victims, exploded clothing, linear or punctuate burns, keraunic markings or tympanic membrane rupture all add weight to the diagnosis. The differential diagnosis includes cerebrovascular event, seizure disorder, spinal cord injury, closed-head injury, Stokes–Adams attack, myocardial infarction and toxin effects.

Standard trauma resuscitation measures should be adopted. Examination of the ears for tympanic rupture and eyes for lens/corneal defects, retinal detachment and optic nerve injury is especially important. If the conscious state deteriorates after arrival, cranial computed tomography scan is indicated. Examination of the cardiovascular system should include an ECG.

Burns are rarely more than superficial and are managed expectantly using standard treatments. Tetanus prophylaxis should be arranged.

Treatment of lightning-induced limb paralysis is expectant. If it does not resolve within a few hours, other causes should be considered. Fasciotomy is unnecessary.

Standard therapy for ocular complications, such as retinal detachment or cataracts, is indicated. Baseline visual acuity should be documented for future reference.

Prognosis and disposition

For survivors of the initial strike the prognosis is excellent unless significant secondary injury has occurred. Admission for observation is indicated for those with abnormal mental status or ECG, or with significant burns or traumatic complications. The burns usually heal well, and grafting is rarely required. For those with ocular complications, long-term ophthalmic follow-up is necessary.

24.7 Altitude illness

Ian Rogers

ESSENTIALS

1 **The high-altitude syndromes—acute mountain sickness (AMS), high-altitude cerebral oedema (HACE) and high-altitude pulmonary oedema (HAPE)—are all clinical diagnoses, where management may need to be undertaken without access to diagnostic testing.**

2 **AMS and HACE represent stages along a continuum owing to cerebral vasodilatation and cerebral oedema, while in HAPE the oedema manifests in the lungs.**

3 **Descent is the single best treatment for AMS, HACE and HAPE; however, milder cases in selected settings may be able to be managed with rest and/or oxygen.**

4 **Additional drug treatments may be used in the treatment of established altitude illness. The most often employed therapies are dexamethasone for AMS/HACE and nifedipine for HAPE.**

5 **Prevention is best achieved by controlled ascent, with adequate time for acclimatization.**

6 **Low-dose acetazolamide provides effective prophylaxis against AMS.**

Introduction

Altitude illness comprises a number of syndromes that can occur on exposure to the hypobaric hypoxic environment of high altitude. At any altitude, the partial pressure of inspired oxygen (P_IO_2) is equal to 0.21 times the barometric pressure minus water vapour pressure of 47 mm Hg. At an altitude of 5500 m, barometric pressure is halved. On the summit of Mount Everest (8850 m), the P_IO_2 is only 43 mm Hg, and a typical climber without oxygen can be expected to have a PaO_2 of <30 mm Hg and a $PaCO_2$ of about 13 mm Hg.[1] In addition to the hypoxic stress of altitude, a subject may also be exposed to cold, low humidity, fatigue, poor diet and increased ultraviolet radiation. For the emergency physician, the unique feature of altitude illness is that it requires recognition and treatment in the field, frequently without access to sophisticated diagnostic and imaging techniques, and often without access to rapid evacuation.

Epidemiology and pathophysiology

The human body has the capacity to acclimatize to hypoxic environments. This is principally achieved by increasing ventilation (the hypoxic ventilatory response effected by the carotid body), increasing numbers of red blood cells (via stimulation of erythropoietin), increasing the diffusing capacity of the lungs (resulting from increased lung volume and pulmonary capillary blood volume), increasing vascularity of the tissues, and increasing the tissues' ability to use oxygen (possibly owing to increased numbers of mitochondria and oxidative enzyme systems).

In some individuals, exposure to low PO_2 initiates a sequence of pathophysiological changes, which result in oedema formation in the brain and lungs. The altitude illness syndromes, acute mountain sickness (AMS), high-altitude cerebral oedema (HACE) and high-altitude pulmonary oedema (HAPE), are the result of this oedema formation. The exact mechanism of these pathophysiological changes is still debated, but vasodilatation is a key part.

In the brain, the development of oedema causes intracranial pressure (ICP) to rise. Initially, this is partially compensated for by displacement of cerebrospinal fluid (CSF) into the spinal space, and adjustment of the balance between production and absorption of CSF. However, once these compensatory mechanisms are overwhelmed, ICP can rise beyond the cerebral perfusion pressure. Without intervention, cerebral blood flow ceases and the patient dies.

In the lung, non-cardiogenic pulmonary oedema develops. A significant rise in pulmonary artery pressure appears to be a crucial pathophysiological factor.[2] Impaired sodium driven clearance of alveolar fluid may contribute to HAPE.[3] It has been postulated that uneven pulmonary vasoconstriction increases the filtration pressure in non-vasoconstricted lung areas, worsening the interstitial and alveolar oedema.

The tendency to develop altitude illness is idiosyncratic. The major predisposing factors are the rate of ascent and the altitude reached. It is not related to physical fitness or gender. Individuals vary in their ability to compensate for changes in ICP, and in their pressor responses to hypoxia. This may explain the reproducibility of AMS, HACE and HAPE in susceptible individuals, and why some, and not others, develop symptoms at the same altitude. The risk is higher in those who have an impaired ventilatory response to hypoxia in normobaric conditions, and with dehydration, vigorous exercise and the use of depressant drugs.

Prevention

The best form of prevention is gradual ascent to allow sufficient time for acclimatization.[4] Although individuals vary in how quickly they acclimatize, a sensible recommendation is sleeping no more than 500 m higher than the previous day once above 2500 m. Keeping warm, avoiding alcohol, maintaining hydration and eating a high-carbohydrate diet to improve the respiratory quotient may all decrease the incidence of altitude illness. Modest exercise on acclimatization days should be encouraged.

Acclimatization is not always practical or possible, and so pharmacological agents may be required.[4] Acetazolamide reduces the incidence and severity of AMS/HACE when used prophylactically in subjects experiencing rapid ascent.[5] Doses recommended have decreased as a result of ongoing research.[6] Chemoprophylaxis can be achieved with 125 mg bd, starting the day before ascent and continued for 2 days after reaching high altitude. Dexamethasone 4 mg bd may be equally effective, and may be more so when a rapid onset is required, such as in unacclimatized personnel involved in high-altitude rescue missions. Ibuprofen has more recently been suggested as chemoprophylaxis for AMS. Whether it simply masks symptoms or speeds acclimatization is debatable.[7]

Nifedipine 20 mg slow-release tds or 30 mg bd provides protection against HAPE in susceptible individuals. More recent research suggests that other drugs such as sildenafil, tadalafil and salmeterol may have a role in HAPE prevention, but it is generally advised that vasodilators not be combined.

Clinical features

AMS is common, occurring in about 30% of subjects exposed to moderate altitude (3500 m) and as high as 60% at higher altitude (4500 m). HACE and HAPE are significantly less common. The diagnosis of all of these syndromes is usually made purely on clinical assessment.

Acute mountain sickness

AMS is primarily a neurological syndrome, associated with some degree of respiratory compromise. The onset is usually 6 to 24 hours after arrival at high altitude. The majority of patients present in the early stages when the symptoms are like those of a hangover, and include headache, nausea, anorexia, weakness and lassitude. In the early stage of AMS, there are no abnormalities on physical examination, and the oxygen saturation, if measured, should be no lower than that expected for a given altitude. Mild AMS is usually benign and self-limiting.

If the illness progresses, the more severe form of AMS is characterized by dyspnoea at rest, nausea and vomiting, altered mental state, headache and ataxia. Ataxia is the most useful sign of progression to serious illness. Left untreated, severe AMS may progress to life-threatening HACE or HAPE.

AMS can be scored using the Lake Louise AMS score. This consists of five symptom groups: headache, gastrointestinal distress, fatigue or weakness, dizziness or light headedness, and difficulty sleeping. Each symptom is scored on a scale from 0 (not present) to 3 (severe or incapacitating), and the totals of the five symptom groups are summed. A total score of 3 or more is considered diagnostic of AMS.

High-altitude cerebral oedema

HACE is the progression of neurological signs and symptoms in the setting of AMS. There is a progressive decline in mental status, and truncal ataxia is a prominent physical finding. Focal neurological signs, such as third and sixth cranial nerve palsies, may develop as a result of raised intracranial pressure. Unrecognized and untreated, there may be rapid progression to coma and death due to raised intracranial pressure.

High-altitude pulmonary oedema

HAPE occurs in susceptible individuals who may have no underlying pulmonary or cardiac disease. It most commonly manifests on the second night at high altitude. In the early stages, the oedema is interstitial, and the patient may only have a dry cough and decreased exercise tolerance. Few abnormalities will be seen on examination at this stage. As more fluid accumulates, the patient develops tachycardia, increasing dyspnoea, marked weakness, cough productive of frothy sputum and cyanosis. Pulse oximetry, if available, confirms profound hypoxia. A chest x-ray will demonstrate widespread interstitial and alveolar infiltrates. It may occur in conjunction with AMS/HACE, or as an isolated clinical syndrome.

Table 24.7.1 Key treatments in severe altitude syndromes

HACE/Severe AMS	*HAPE*
Descent	Descent
Oxygen	Oxygen
Simulated descent (e.g. Gamow bag)	Simulated descent (e.g. Gamow bag)
Dexamethasone 8 mg stat then 4 mg 6-hourly	Nifedipine SR 20 mg 8-hourly

AMS, Acute mountain sickness; *HACE*, high-altitude cerebral oedema; *HAPE*, high-altitude pulmonary oedema.

Treatment

Early recognition is an essential component of the management of all acute altitude syndromes. Developing symptoms in a party member may have substantial impact on route planning choices, particularly whether to halt ascent or descend. The goal is to stop the pathophysiological process, with the key interventions summarized in Table 24.7.1.

Acute mountain sickness and high-altitude cerebral oedema

A patient presenting with symptoms of mild AMS should be advised to halt ascent to allow time for acclimatization. They should rest, as physical exertion aggravates symptoms, and take simple analgesics and antiemetics if desired. It is important that the patient be closely observed for the progression of symptoms.

With moderate symptoms, the management is the same as for mild AMS, with the addition of oxygen 2 to 4 L/min if available and, possibly, pharmacological agents. Acetazolamide, a carbonic anhydrase inhibitor, aids the normal process of ventilatory acclimatization by reducing the renal reabsorption of bicarbonate, resulting in metabolic acidosis and compensatory hyperventilation. It relieves symptoms, improves arterial oxygenation and prevents further impairment of pulmonary gas exchange. It also helps maintain cerebral blood flow despite hypocapnia, and opposes the fluid retention of AMS. The recommended treatment dose is 250 mg orally bd. Acetazolamide is a sulpha drug and contraindicated in those with known allergy. Dexamethasone is also an effective agent in this condition,[8] presumably by reducing capillary permeability and ICP. It does not aid in acclimatization. It may be given as an alternative, or in addition to acetazolamide. The recommended dose is 8 mg stat, then 4 mg every 6 hours.

If a patient shows signs of severe AMS progressing to HACE, then rapid and controlled descent is the highest priority. Oxygen 2 to 4 L/min should be administered. Further therapy may be required if the illness is severe, the patient's condition must be improved to allow descent, or where immediate descent is not possible. An additional therapeutic option added to drug treatments is hyperbaric therapy using a portable fabric hyperbaric chamber (e.g. Gamow bag).[4] These bags are expensive and need to be pumped continuously, but have the advantage of using air rather than oxygen.

High-altitude pulmonary oedema

Rapid and controlled descent, with oxygen, is the mainstay of management in a patient suffering from HAPE, although milder cases may be managed with oxygen without altitude change. In a large proportion of cases, this is sufficient. Oxygen flow should be titrated to maintain adequate oxygen saturation. Continuous positive airway pressure may be required. The patient should be rested and kept warm, as cold may further increase pulmonary hypertension through sympathetic stimulation.

Nifedipine should be considered as adjunctive therapy to oxygen and descent. It lowers the raised pulmonary artery pressure that characterizes HAPE and results in clinical improvement, better oxygenation and progressive clearing of alveolar oedema on chest x-ray. The recommended dose is 20 mg of the slow release formulation 8 hourly or 30 mg 12 hourly.[4]

CONTROVERSIES

1 The effectiveness of acetazolamide and dexamethasone in AMS prophylaxis is now generally well accepted, but which agent is more effective and in which circumstances they should be used is less clear. The side effects of acetazolamide at recommended doses can mimic AMS, and conversely, the euphoriant effects of dexamethasone can interfere with a subject's ability to accurately report symptoms. Dexamethasone and acetazolamide appear to differ in their effectiveness when trialled in field conditions compared with simulated conditions in hypobaric chambers. The

dose of each drug used is not the same across trials. The rate of ascent appears to influence the effectiveness of pharmacological prophylaxis. Further research may clarify their respective roles.

2 Further research is required to clarify the role of newer preventive strategies, such as ibuprofen for AMS, and sildenafil and salmeterol for HAPE.

3 Although descent is a mainstay of altitude illness treatment, a greater understanding of its pathophysiology and spectrum of illness will allow more patients to be effectively treated at altitude when appropriate facilities are available.

SECTION 25

TOXICOLOGY EMERGENCIES

Edited by *Mark Little*

25.1 Approach to the poisoned patient

Alan Gault

ESSENTIALS

1 **Self-poisoning is a manifestation of an underlying psychiatric, drug and alcohol, or social disorder.**

2 **A wide range of clinical manifestations of toxicity may be observed following drug overdose.**

3 **An accurate risk assessment predicts the likely clinical course and informs planning for subsequent investigation, management and disposition.**

4 **The mainstay of management is timely institution of an appropriate level of supportive care.**

5 **Gastrointestinal decontamination should be considered in all cases based on risk versus benefit. In select cases, these procedures may have a significant impact on clinical outcome, even when delayed.**

6 **Specific antidotes and enhanced elimination techniques are rarely indicated, but their timely use may be life-saving in specific circumstances.**

Introduction

Drug overdose in adults usually occurs in the context of self-poisoning, which may be either recreational or deliberate.

Deliberate self-poisoning accounts for 1% to 5% of all public hospital admissions in Australia.[1,2] The bulk of the medical management is carried out in the emergency department (ED), and emergency physicians are expected to be experts. Although management varies considerably depending on the nature and severity of the poisoning, some general principles apply.

Above all, it must be remembered that the acute overdose presentation is only a discrete time-limited event in the course of the underlying condition, which is usually psychosocial in origin.

Pathophysiology and clinical features

The effects of ingestion of pharmaceuticals or illicit drugs range from the non-toxic to the life threatening and may involve any system. Poisoning is a dynamic presentation, and the patient may present at varying points in its time course. Consequently, rapid clinical deterioration or improvement may be observed after the initial presentation and assessment.

Acute morbidity and mortality are usually a consequence of the cardiovascular, respiratory or central nervous system (CNS) complications of the poisoning. Less commonly, hepatic, renal or metabolic effects can be potentially life threatening.

The most frequent life-threatening respiratory manifestation of poisoning is ventilatory failure, which is usually a consequence of CNS depression causing apnoea or bradypnoea. Less commonly, it is secondary to muscle paralysis, direct pulmonary toxicity or non-cardiogenic pulmonary oedema (Box 25.1.1).

Cardiovascular manifestations of poisoning include tachycardia, bradycardia, hypertension, hypotension, conduction defects and arrhythmias (Box 25.1.2). Bradycardia is relatively rare and is associated with a number of potentially life-threatening ingestions, whereas tachycardia is commonly observed and is usually benign. It may be due to intrinsic sympathomimetic or anticholinergic effects of a drug or a reflex response to hypotension or hypoxia. Hypotension is also common and may be due to a number of different mechanisms (see Box 25.1.2). Hypertension is usually associated with illicit drug use and is important because it may produce complications such as intracerebral haemorrhage if severe and uncontrolled.

Box 25.1.2 Cardiovascular effects of poisoning

Tachycardia
Anticholinergics
- Pure anticholinergics, e.g. Benztropine

Antihistamines
- Phenothiazines

Atypical antipsychotics
- Tricyclic antidepressants
- Monoamine oxidase inhibitors

Sympathomimetics
- Amphetamines
- Cocaine
- Caffeine
- Theophylline
- Synthetic cannabinoid receptor agonists
- Venlafaxine

Tramadol
Digoxin
Drug withdrawal syndromes

Bradycardia
β-Blockers
Calcium channel blockers
Clonidine
Digoxin

Hypotension
Peripheral vasodilators
Myocardial depressants
Hypovolemia from fluid losses/third spacing

Hypertension
Sympathomimetics
- Amphetamines
- Cocaine
- Monoamine Oxidase (MAO) inhibitors

Anticholinergics

Rhythm/ECG abnormalities
QRS prolongation (fast sodium channel blockade)
- Tricyclic antidepressants
- Class Ia and Ic antiarrhythmics
- Local anaesthetics
- Hydroxychloroquine
- Dextropropoxyphene
- Propranolol
- Cocaine
- Orphenadrine

QT prolongation
- Antipsychotics
- Sotalol
- Citalopram
- Antihistamines
- Antibiotics—macrolides
- Antifungals—ketoconazole
- Arsenic
- Methadone

Ventricular tachycardia/fibrillation
- Cocaine
- Digoxin
- Chloral hydrate
- Theophylline
- Sodium channel blocking drugs (described previously)

Ischemia/Infarction
Cocaine
Amphetamines
Complications of hypoxia/hypotension

CNS manifestations of poisoning include decreased level of consciousness, agitation or delirium, seizures and disordered temperature regulation. A decreased level of consciousness is a common presentation of poisoning and is associated with many drugs, some of which are listed in Box 25.1.1. Although usually a direct drug effect, CNS depression is occasionally secondary to hypoglycaemia, hypoxia or hypotension. Common causes of agitation or delirium following overdose are listed in Box 25.1.3. Toxic seizures are potentially life threatening, and important causes are listed in Box 25.1.4.

Hypothermia is usually a complication of environmental exposure secondary to a decreased level of consciousness or altered behaviour.

Box 25.1.3 Toxic causes of agitation or delirium

appropriate supportive care over a relatively short period, a full recovery can usually be expected. A small number of potentially fatal poisonings may demonstrate progressive toxicity despite full supportive care, such as colchicine, iron, salicylate, cyanide and theophylline. In some of these cases, early aggressive gastrointestinal decontamination, timely administration of antidotes or the institution of techniques of enhanced elimination may be life-saving.

Mortality or morbidity may also result from specific complications of a poisoning. These include trauma, pulmonary aspiration, adult respiratory distress syndrome, rhabdomyolysis, venous thromboembolism, renal failure and hypoxic encephalopathy. These usually occur prior to arrival in the ED.

Pulmonary aspiration usually occurs during a period of decreased level of consciousness or a seizure. It is a leading cause of in-hospital morbidity and mortality following overdose.

Rhabdomyolysis occurs secondary to excessive muscular hyperactivity, rigidity, seizures, hyperthermia, direct muscle compression or rarely as a direct toxic effect. Acute renal failure can develop due to tubular deposition of myoglobin.

Assessment

Risk assessment

A risk assessment should be made as soon as possible in the management of the poisoned patient. Only resuscitation is a greater priority

Disposition

(From Murray L, Little M, Pascu O, Hoggett K. *Toxicology Handbook*. 3rd ed. Sydney, Australia: Elselvier; 2015 with permission).

(Box 25.1.6). Risk assessment is a distinct quantitative cognitive step through which the clinician attempts to predict the likely clinical course and potential complications for the individual patient at that particular presentation.[3] An accurate risk assessment allows informed decision making in regard to all subsequent management steps, including duration and intensity of supportive care and monitoring, screening and specialized testing, decontamination, enhanced elimination, antidotes and disposition. Factors that are taken into account when performing the risk assessment include the agent(s) and formulation, the dose, the time since ingestion, the clinical features present and patient factors (see Box 25.1.6). Specialized testing may refine the risk assessment. Access to specialized poisons information through poisons information centres and databases or a toxicology unit is often necessary to formulate an accurate risk assessment.

History

Every effort should be made to obtain information as to the type and dose of drug ingested, the time of ingestion and the progression of symptoms since ingestion. History provided by the patient, if they are awake, is usually reliable and should not be dismissed. If altered mental status precludes this, other strategies should be employed to gain the necessary information. These include ambulance officers or family searching for agents, counting missing tablets, checking recent prescriptions and questioning relatives about agents potentially available to the patient.

Physical examination

The focused physical examination of the poisoned patient aims to:

- identify any immediate threats to life and the need for intervention
- establish a baseline clinical status
- corroborate the history
- identify intoxication syndromes
- identify possible alternative diagnoses
- identify complications of the poisoning

The initial physical examination of the overdose patient in many ways parallels the primary survey of the trauma patient. The airway, breathing and circulation are assessed and stabilized as necessary. The level of consciousness should be assessed, presence of seizure activity noted and the blood glucose and temperature measured.

A more complete examination is carried out when the patient is stable. This should include a full neurological examination, including assessment of the level of consciousness and mental status, pupil size, muscle tone and movements and the presence or absence of focal neurological signs. Poisoning normally causes global CNS depression, and focal signs suggest an alternative diagnosis or a CNS complication.

Other features that should be specifically sought for are any evidence of associated trauma, hydration status, pressure areas, bowel sounds and urinary retention.

Several toxic autonomic syndromes, or 'toxidromes', have been described in relation to poisoning. The principal ones are listed in Table 25.1.1. Identification of these syndromes may narrow the differential diagnosis in cases of unknown poisoning.

Poisons information

Information on the clinical course and toxic doses of specific pharmaceutical and non-pharmaceutical poisons is available on a 24-hour basis throughout Australia by telephoning the Poisons Information Centres on 131126. These are staffed by trained poisons information specialists and are also able to refer cases to clinical toxicologists for consultation.

Treatment

The management of poisoning should be approached in a systematic way. Following initial resuscitation, further treatment is informed by the risk assessment (see Box 25.1.6).

Resuscitation, supportive care and monitoring

Supportive care is the key in managing poisoning. The vast majority of poisonings result in temporary dysfunction of one or more of the body systems. If appropriate support of the system in question is instituted in a timely

Table 25.1.1 Toxic autonomic syndromes or 'toxidromes'

Toxidrome	*Features*	*Common causes*
Anticholinergic	Agitated delirium Tachycardia Hyperthermia Dilated pupils Dry flushed skin Dry mouth Blurred vision Urinary retention Ileus	Antipsychotics Antihistamines Tricyclic antidepressants Benztropine Atropine Plant poisonings Carbamazepine

fashion and continued until the toxic substance is metabolized or excreted, a good outcome can be anticipated. In severe poisonings, supportive care may be aggressive, and possible interventions are listed in Table 25.1.2.

The specific supportive management of a number of manifestations or complications of poisoning warrants further mention, insofar as it may differ from the standard management of such conditions with other aetiologies.

Cardiopulmonary arrest from poisoning should be aggressively resuscitated. DC cardioversion is rarely successful in terminating toxic arrhythmias and should not take precedence over establishing adequate ventilation and oxygenation, cardiac compressions, correction of acidosis or hypovolaemia and administration of specific antidotes. Resuscitative efforts should be continued beyond the usual time frame. In cardiac arrest due to drugs with direct cardiac toxicity, the use of cardiopulmonary bypass or extracorporeal membrane oxygenation (ECMO) until the drug is metabolized may be life-saving.

Refractory hypotension secondary to cardioplegic or vasoplegic shock is often unresponsive to escalating doses of vasopressors or inotropes and often requires the consideration of specific therapies such as high-dose euglycemic therapy (HIET) or methylene blue, respectively.

In general, intravenous benzodiazepines are the drugs of choice for control of toxic seizures. Hypoxia and hypoglycaemia must be corrected if these are contributory factors. Patients with toxic seizures do not need long-term anticonvulsant therapy. Isoniazid-induced seizures are difficult to control without the administration of an adequate dose of the specific antidote, pyridoxine.

The management of pulmonary aspiration is essentially supportive, with supplemental oxygenation and intubation and mechanical ventilation, if necessary.

Toxic hypertension rarely requires specific therapy. Most cases are mild, and simple observation is sufficient. Agitation or delirium

is a feature of many intoxications associated with hypertension, and adequate sedation with benzodiazepines usually lowers the blood pressure. Severe hypertension most likely results from cocaine, amphetamine-type drugs or other sympathomimetic agents, and treatment may be indicated to avoid complications, such as cardiac failure, vascular dissection or intracerebral haemorrhage. If benzodiazepines fail to control the blood pressure adequately, the drug of choice is glyceryl trinitrate by intravenous infusion.

Management of rhabdomyolysis consists of treatment of the causative factors, fluid resuscitation and careful monitoring of fluids and electrolytes. The role of mannitol and urinary alkalinization in reducing the risk of renal failure is not clear. Established acute renal failure requires haemodialysis.

Decontamination

The aim of decontamination of the gastrointestinal tract is to bind or remove ingested material before it is absorbed into the circulation and able to exert its toxic effects.

However, it should not be regarded as a routine procedure in the management of the poisoned patient. The decision to decontaminate and the choice of method should be based on an assessment of the likely risk benefit and the resources required. Gastrointestinal decontamination should only be considered where there is likely to be a significant amount of a significantly toxic material remaining in the gut. It is never indicated when the risk assessment predicts a benign course. Efforts at decontamination should never take precedence over resuscitation and supportive care.

Three basic approaches to gastrointestinal decontamination are available: gastric emptying, administration of an adsorbent and whole bowel irrigation.

Gastric emptying can be attempted by the administration of an emetic, most commonly syrup of ipecac, or by gastric lavage. In volunteer studies, both of these techniques removed highly variable amounts of marker substances from the stomach even if performed immediately after ingestion and the effect diminished rapidly with time to the point of being negligible after 1 hour.[4,5] Clinical outcome trials have failed to demonstrate improved outcome as a result of routine gastric emptying in addition to administration of activated charcoal, except, perhaps, in patients presenting unconscious within 1 hour of ingestion.[6]

The principal adsorbent available to clinicians is activated charcoal (AC), which effectively binds most pharmaceuticals and chemicals, and is currently the decontamination method of choice for most poisonings. Materials that do not bind well to charcoal are listed in Box 25.1.7.

Box 25.1.7 Materials that do not bind well to activated charcoal

- Alcohols
  - Ethanol
  - Ethylene glycol
  - Methanol
  - Isopropanol
- Corrosives
  - Acids
  - Alkalis
- Hydrocarbons
- Metals and their salts
  - Arsenic
  - Lead
  - Iron
  - Potassium
  - Mercury
  - Lithium

Charcoal is 'activated' by treatment in acid and steam at high temperature. This process removes impurities and greatly increases the surface area available for binding. AC is packaged as a 50 g dose premixed with water or sorbitol, which is likely to be sufficient for the majority of ingestions. Adult patients are usually able to drink AC slurry from a cup. If the level of consciousness is too impaired to allow this, they should be intubated first. Administration of AC is absolutely contraindicated unless the patient has an intact or protected airway.

Volunteer studies demonstrate that the effect of AC diminishes rapidly with time and that the greatest benefit occurs if it is administered within 1 hour. These studies, however, do not include scenarios of massive ingestions, pharmaco-bezoars, slow/extended release preparations or ingestions where gut stasis has occurred as a result anticholinergic effects There is as yet no evidence that AC,[7] or that the addition of a cathartic, such as sorbitol, to AC conclusively improves clinical outcome.[8]

Apart from rarely employed endoscopic and surgical techniques, whole-bowel irrigation (WBI) is the most aggressive form of gastrointestinal decontamination. Polyethylene glycol solution (Golytely) is administered via a nasogastric tube at a rate of 1 to 2 L/h until a clear rectal effluent is produced. This usually takes about 6 hours and requires one-to-one nursing. In volunteer studies, this technique reduced the absorption of slow-release pharmaceuticals and so may be of benefit in life-threatening overdoses of these agents. Again, clinical benefit has not yet been conclusively demonstrated.[9] The use of WBI has also been reported in the management of potentially toxic ingestions of iron, lead and packets of illicit drugs. Whole-bowel irrigation is contraindicated if there is evidence of ileus or bowel obstruction and in patients who have an unprotected airway or haemodynamic compromise.

Table 25.1.3 Techniques of enhanced elimination

Technique	*Suitable agent*
Multiple-dose activated charcoal	Carbamazepine Dapsone Phenobarbitone Quinine Theophylline *Amanita* spp.
Urinary alkalinization	Salicylate Phenobarbitone
Haemodialysis	Ethylene glycol Methanol Salicylate Theophylline Valproic acid Lithium
Charcoal haeoperfusion	Theophylline

Enhanced elimination

A number of techniques are available to enhance the elimination of toxins from the body. Their use is rarely indicated, as only a very few drugs capable of causing severe poisoning have pharmacokinetic parameters that render them amenable to these techniques (Table 25.1.3).

Multiple-dose AC (various dosing regimens) may enhance drug elimination by interrupting enterohepatic circulation or by 'gastrointestinal dialysis'. Gastrointestinal dialysis is the movement of a toxin across the gastrointestinal wall from the circulation into the gut down a concentration gradient that is maintained by charcoal binding. For this technique to be effective, a drug must undergo considerable enterohepatic circulation or, in the case of 'gastrointestinal dialysis', have a small volume of distribution, small molecular weight, low protein binding, slow endogenous elimination and bind to charcoal.[10]

Urinary alkalinization enhances urinary excretion of drugs that are filtered at the glomerulus and are unable to be reabsorbed across the tubular epithelium when in an ionized form at alkaline pH. For elimination to be effectively enhanced by this method, the drug must be predominantly eliminated by the kidneys in the unchanged form, have a low pKa, be distributed mainly to the extracellular fluid compartment and be minimally protein bound.

Haemodialysis (HD) and haemoperfusion (HP) are both very invasive techniques and for that reason are reserved for potentially life-threatening intoxications. Only a small number of drugs that have small volumes of distribution, slow endogenous clearance rates, small molecular weights (HD) and bind to charcoal (HP) will have their rates of elimination significantly enhanced by these procedures.

Table 25.1.4 Useful emergency antidotes

Poisoning	*Antidote*
Anticholinergic poisoning	Physostigmine
Cyanide	Hydroxocobalamin Dicobalt EDTA Sodium thiosulphate
Digoxin	Digoxin specific Fab antibodies
Insulin	Dextrose
Iron	Desferrioxamine
Isoniazid	Pyridoxine
Methaemoglobinaemia	Methylene blue
Methanol and ethylene glycol	Ethanol Fomepizole
Organophosphates and carbamates	Atropine Oximes
Opiods	Naloxone
Paracetamol	*N*-Acetylcysteine
Sulphonylureas	Octreotide
Tricyclic antidepressants	Sodium bicarbonate
Warfarin, superwarfarins	Vitamin K

Antidotes

Very few drugs have effective antidotes. Occasionally, timely use of an antidote may be life-saving or will substantially reduce morbidity, time in hospital or resource requirements. Antidotes that may be indicated in the ED setting are listed in Table 25.1.4. However, it must be remembered that antidotes are also drugs and are frequently associated with adverse effects of their own. An antidote should only be used where a specific indication exists and should have clearly defined therapeutic end-points for its cessation. Because many antidotes are so infrequently used, obtaining sufficient supplies when the need arises can be difficult. Every ED must review its stocking of antidotes and have a plan for obtaining further supplies, should the need arise.

Differential diagnosis

It is essential to exclude important non-toxic diagnoses in the patient presenting with coma or altered mental status presumed to be due to drug overdose. These diagnoses include head injury, intracerebral haemorrhage or infarction, CNS infection, hyponatraemia, hypoglycaemia, hypo- or hyperthermia, post-ictal states and psychiatric disorders.

Box 25.1.8 Drug levels that may be helpful in the management of selected cases of overdose

Carbamazepine
Digoxin
Phenytoin
Valproate
Salicylate
Paracetamol
Iron
Phenobarbitone
Theophylline
Lithium

Clinical investigations

Investigations should only be performed if they are likely to affect the management of the patient. They are employed as either screening tests or for specific purposes.

In poisoning, screening tests aim to identify occult toxic ingestions for which early specific treatment might improve outcome. These are the 12-lead ECG and the serum paracetamol level. The ECG is used to exclude conduction defects, which may predict potentially life-threatening cardiotoxicity. The serum paracetamol is useful to ensure that paracetamol poisoning is diagnosed within the time available for effective antidotal treatment.

Other specific investigations may be indicated to exclude important differential diagnoses, confirm a specific poisoning, assess severity of intoxication, assess response to treatment or assess the need for a specific antidote or enhanced elimination techniques. These are determined by the risk assessment.

The patient with only minor manifestations of poisoning may require no other blood tests apart from a screening paracetamol level. Pregnancy should be excluded in women of childbearing age by β-HCG testing. More seriously ill patients may require electrolyte, renal and liver function tests and a full blood count, creatine kinase and arterial blood gases.

Routine qualitative drug screening of urine or blood in the overdose patient is rarely useful in planning management.

Measurement of serum drug concentrations is only useful if this provides important diagnostic or prognostic information or assists in planning management. Some drug levels that may be useful are listed in Box 25.1.8. For most cases, management is guided by clinical findings and not by drug levels. Some drugs commonly taken in overdose for which serum concentrations are of no value in planning management are listed in Box 25.1.9.

Box 25.1.9 Drug levels that are not helpful in the management of overdose

Antidepressants
Benzodiazepines
Cocaine
Antipsychotics
Opiates
Angiotensin Converting Enzyme (ACE) inhibitors
Calcium channel blockers
Beta blockers
Clonidine

Radiology has a limited role in the management of overdose. A chest x-ray is indicated in any patient with clinical features of aspiration pneumonia or pneumonitis. The abdominal x-ray is useful in evaluating overdoses of metals such as iron, potassium, lead, arsenic or batteries. A computed tomography scan of the head excludes other intracranial pathology in the patient with an altered mental status, whereas a CT of the abdomen may determine the presence of drug packages in the suspected body packer.

Disposition

Both the medical and the psychiatric disposition of the overdose patient must be considered, and a good risk assessment is essential to determining the timing and safety of these.

The majority of overdose patients who remain stable at 4 to 6 hours after the ingestion do not need further close monitoring and may be admitted to a non-monitored bed until manifestations of toxicity completely resolve. An emergency observation ward is ideal for this purpose.

Any patient who develops clinical manifestations of intoxication severe enough to require the institution of specific supportive care measures requires admission to an intensive care environment. A few patients will require admission for prolonged monitoring based on the risk assessment. For example, anyone with a history of ingestion of colchicine, organophosphates or slow release preparations requires admission because of the possibility of delayed onset of toxicity.

Psychiatric evaluation of deliberate self-poisoning cases is indicated as soon as the patient's medical condition permits. All such patients must be continuously supervised until the psychiatric evaluation has taken place.

CONTROVERSIES

- The role of and choice of method and indications for gastric decontamination. These procedures are no longer regarded as routine, but there are likely to be subgroups of overdose patients who may derive clinical benefit from gastrointestinal decontamination.
- The clinical effectiveness of intralipid in the setting of severe poisoning.

25.2 Cardiovascular drugs

Betty S.H. Chan • Angela L. Chiew

ESSENTIALS

1 **Calcium channel blockers, β-blockers, digoxin and sodium channel blocker poisonings are associated with potentially life-threatening toxicity.**

2 **The key to the management of calcium channel blocker and β-blocker toxicity rests with aggressive supportive care of the circulation including early use of hyperinsulinaemia euglycaemic therapy.**

3 **The onset of toxicity following overdose with slow-release formulations of calcium channel blockers may be delayed.**

4 **Early aggressive decontamination with whole-bowel irrigation is important in the management of slow-release calcium channel blocker overdose.**

5 **The key to management of sodium channel blockers is sodium bicarbonate therapy and hyperventilation.**

6 **Early identification of patients presenting with potentially severe digoxin toxicity and appropriate use of the specific Fab fragment antibody is lifesaving.**

7 **The management of clonidine poisoning is largely supportive.**

8 **Intravenous lipid emulsion therapy should be reserved for the treatment of severe local anaesthetic toxicity. It is not standard treatment in other overdoses.**

CALCIUM CHANNEL BLOCKERS AND β-BLOCKERS

Introduction

In overdose, calcium channel blockers (CCBs) and β-blockers present with similar clinical pictures of potentially life-threatening impairment of cardiac function. The management of both types of overdose is similar and they are discussed together.

Pharmacokinetics

Standard CCB preparations are rapidly absorbed from the gastrointestinal tract, with onset of action occurring within 30 minutes. Pharmacokinetic parameters are shown in Table 25.2.1. Verapamil and diltiazem undergo significant first-pass hepatic clearance. Verapamil is metabolized to norverapamil, which possesses 15% to 20% of verapamil's pharmacological activity and is renally excreted. Diltiazem is metabolized to deacetyldiltiazem, which has half the potency of the parent compound and undergoes biliary excretion. The elimination half-lives of all CCBs may be prolonged following massive overdose. Amlodipine has a longer plasma half-life (30 to 50 hours) than other CCBs.

Importantly, slow-release preparations of both verapamil and diltiazem are associated with much longer times to peak plasma concentration and clinical effect. Absorption of β-blockers is rapid, with peak clinical effects occurring within 1 to 4 hours. Pharmacokinetic parameters of the principal β-blockers are detailed in Table 25.2.2. Agents with high lipid solubility, such as propranolol, penetrate the blood–brain barrier better than the water-soluble agents and hence cause greater central nervous system (CNS) toxicity.

Pathophysiology

CCBs antagonize the entry of extracellular calcium into cardiac and smooth muscle, but not skeletal muscle. Upon entry into cells, calcium participates in mechanical, electrical and biochemical reactions. It is involved in excitation–contraction of cardiac and smooth muscles, as well as phase o depolarization in the sinus and atrioventricular (AV) nodes by calcium influx through channels.

(Modified from Kerns W II, Kline J, Ford MD. β-Blocker and calcium channel blocker toxicity. *Emerg Med Clin N Am.* 1994;12:365–389.)

CCBs affect myocardial contractility and slow conduction through the sinus and AV nodes. Contraction of smooth muscle is mediated by calcium influx, which is inhibited by CCBs. This results in vasodilatation and secondary reflex tachycardia from an increase in sympathetic activity.

Verapamil, a phenylalkylamine, produces more profound cardiac conduction defects and equal reductions in systemic vascular resistance when compared with other CCBs on a mg/kg basis. Verapamil is more likely to produce symptomatic decreases in blood pressure, heart rate and cardiac output than diltiazem, a benzothiazepine. The dihydropyridines, which include amlodipine, felodipine, lercanidipine, nifedipine and nimodipine, preferentially bind to vascular smooth muscle and predominantly decrease systemic and coronary vascular resistance.

β-Blockers prevent the binding of catecholamines to β-receptors (β_1, β_2). β_1-Receptors are located in the myocardium, kidney and eye and β_2-receptors in adipose tissue, pancreas, liver and both smooth and skeletal muscle.

Blockade of β-receptors results in blunting of the metabolic, chronotropic and inotropic effects of catecholamines. Some β-blockers, especially propranolol, may also impede sodium entry via myocardial fast inward sodium channels, thus slowing phase 0 of the action potential. This results in a prolonged QRS duration on the electrocardiogram and produces cardiotoxicity in overdose similar to that of the tricyclic antidepressants.

The different β-blockers have slightly differing pharmacological properties, including selectivity for β-adrenoreceptors, intrinsic sympathomimetic activity and membrane-stabilizing activity. The relative affinity for β-adrenoreceptors may influence expression of toxicity. Atenolol, esmolol and metoprolol are β_1-selective agents and therapeutic use of these drugs is less likely to produce the peripheral vasoconstriction, bronchospasm and disturbances in glucose homoeostasis that result from β_2 inhibition. However, pharmacological specificity decreases with increasing dose.

Clinical features

Calcium channel blockers

The severity of toxicity is determined by a number of factors, including the amount and characteristics of the drug ingested, the underlying health of the patient, co-ingestants and delay until treatment. The majority of serious cases and deaths result from the ingestion of verapamil or diltiazem, the most toxic of the CCBs. Ingestion of as few as 10 tablets of the higher dose formulation of verapamil or diltiazem can cause severe toxicity. Elderly patients and those with congestive cardiac failure may develop toxicity with ingestions of two to three times their normal daily dose. The principal clinical features are shown in Box 25.2.1. Ingestion of toxic amounts of standard preparations typically produces symptoms within 2 hours, although maximal toxicity may not occur for up to 6 to 8 hours. The slow-release preparations can produce significant toxicity with onset of symptoms more than 6 hours postingestion. The major threats to life are myocardial depression and hypotension.

Overdose of Dihydropyridines (DHPs) often produces tachycardia with normal blood pressure during the first 30 minutes, followed later by hypotension and bradycardia in large ingestions. Even though amlodipine has been reported to be less toxic than verapamil and diltiazem, it can cause severe shock in large overdoses. Vasoplegic shock is frequently observed in mixed overdoses of dihydropyridine (e.g. amlodipine) and angiotensin antagonists such as angiotensin receptor blockers or angiotensin converting enzymes inhibitors, possibly from a synergistic effect on peripheral vasodilatation. All CCBs can cause symptoms of cerebral hypoperfusion, such as syncope, lethargy, light-headedness, dizziness, altered mental status, seizures and coma.

Box 25.2.1 Clinical features of calcium channel blocker overdose

Central nervous system
- Lethargy, slurred speech, confusion, coma
- Respiratory arrest
- Coma

Gastrointestinal
- Nausea, vomiting

Cardiovascular
- Hypotension
- Bradycardia and other arrhythmias
- Sinus bradycardia
- Accelerated AV nodal rhythm
- 2° AV block
- 3° AV block with AV nodal or ventricular escape rhythm
- Sinus arrest with AV nodal escape rhythm
- Asystole

Metabolic
- Hyperglycaemia
- Lactic acidosis

AV, Atrioventricular.

β-Blockers

In one large series of patients with β-blocker overdose, 30% to 40% of patients remained asymptomatic and only 20% developed severe toxicity. Most of the life-threatening presentations or deaths that have been reported in the literature are due to overdoses of propranolol (>1.5 g) or sototol. Significant toxicity is also more likely to develop in patients with pre-existing cardiac disease or where there is co-ingestion of other drugs with effects on the cardiovascular system, especially CCBs and cyclic antidepressants. If β-blocker toxicity is to develop, it is usually observed within 6 hours of ingestion.

Sinus node suppression, conduction abnormalities and decreased contractility are typical. First-degree AV block, AV dissociation, right bundle branch block and intraventricular conduction delay have been reported.

Propranolol in overdose has a sodium channel blocking effect that is characterized by cardiotoxicity including prolongation of the QRS interval and ventricular arrhythmias that more closely resemble tricyclic antidepressant overdose. Sotalol has both β-blocker activity and class 3 antiarrhythmic properties. Class 3 drugs lengthen the duration of the QT interval owing to prolongation of the action potential in His–Purkinje tissue. Therefore ventricular arrhythmias, such as torsades de pointes, are more common with sotalol.

Hypotension occurs as a result of negative inotropic effect. In addition, CNS effects, such as depressed conscious level and seizures, can occur, especially with the more lipid-soluble and membrane-depressant agents, such as propranolol.

Clinical investigation

The ECG is essential in evaluating and monitoring toxic conduction defects. Serum drug levels are unhelpful. Patients with severe toxicity require monitoring of serum electrolytes and glucose. Serum calcium must be closely monitored if calcium salts are administered therapeutically.

Treatment

The primary aim in both β-blocker and CCB toxicity is to restore perfusion to vital organs by increasing cardiac output and the methods used are similar. Supportive management may include airway and ventilatory support, intravenous fluid administration, early implementation of hyperinsulinaemia euglycaemic therapy and administration of inotropes. Transcutaneous or transvenous pacing may be tried in cases with profound bradycardia, but often is of limited benefit. Severe cases may require invasive blood pressure monitor, cardiac output studies to measure cardiac index and peripheral vascular resistance using pulse-induced contour cardiac output (PiCCO) monitor.

If safe to do so, oral-activated charcoal should be administered as soon as practicable to all those presenting after ingestion of CCB or β-blocker ingestions. More aggressive decontamination, with whole-bowel irrigation, is indicated following overdose with slow-release CCBs.

A number of drugs play a role in the management of significant CCB or β-blocker poisoning, although none is a completely effective antidote. Suggested doses are shown in Table 25.2.3. Calcium, an inotropic agent, is the initial drug of choice for CCB toxicity and has also been used successfully for β-blocker poisoning. Administration must be closely monitored, with ionized calcium measured 30 minutes after commencing the infusion and then second-hourly. Catecholamines are useful in attempting to restore adequate tissue perfusion.

Hyperinsulinaemic euglycaemia therapy (HIET) is increasingly advocated as therapy for hypotension unresponsive to fluids and calcium salts, with many toxicologists using HIET early in the management of these poisonings when inotropes are being considered. This therapy is supported by animal work and multiple human case reports, but a randomized controlled trial is lacking. Insulin administration switches cardiac cell metabolism from fatty acids to carbohydrates. It restores calcium fluxes and improves myocardial contractility. The recommended initial dose of Actrapid is 1 units/kg IV followed by an infusion commencing at 1 units/kg/h, titrated against clinical response. In a case series of patients treated with HIET for β-blockers or CCB poisoning, the median loading dose and infusion rate were 80 and 150 units/h respectively, with a median glucose requirement of 37.5 g/h. Despite treatment, hypokalaemia and severe hypoglycaemia (<2.5 mmol/L) occurred in 80% and 41% of the patients, respectively. The duration of glucose requirement was found to be proportional to the rate and total dose of insulin administration. However, the optimal dose of insulin is still to be determined.

There are no clinical trials supporting glucagon's efficacy in either calcium channel or β-blocker poisoning. Due to the significant doses often required, it is frequently difficult to source adequate stocks of glucagon for use as an inotropic agent. As such, its use in the treatment of calcium channel or β-blocker poisoning is not routinely recommended.

Table 25.2.3 Useful drugs in the management of calcium channel blocker and β-blocker toxicity

	CCBs	*β-Blockers*
Calcium[28]	Calcium gluconate 10% 30 mL (child 0.6 mL/kg) IV over 10 min. **OR** calcium chloride 10% 10 mL (child 0.2 mL/kg) IV over 10 min. Repeat every 5 min as required. Further administration guided by serum calcium concentrations.	
Catecholamines	Adrenaline (epinephrine) infusion started at 1 μg/kg/min and titrate to maintain organ perfusion.	Isoprenaline or adrenaline (epinephrine) infusion titrated to maintain organ perfusion.
Sodium bicarbonate for propranolol poisoning		A bolus dose of sodium bicarbonate 8.4% 1–2 mmol/kg, every 3–5 min, 3 doses should see a narrowing of the QRS complex, resolution of arrhythmias. Repeat only if there is a response and recurrence of arrhythmias.
Hyperinsulinaemia euglycaemia	Actrapid 1 units/kg IV bolus followed by an infusion starting at 1 units/kg/h. Give with 50% dextrose 50 mL followed by infusion to maintain euglycaemia.	Actrapid 1 units/kg IV bolus followed by an infusion commencing at 1 units/kg/h. Give with 50% dextrose 50 mL followed by infusion to maintain euglycaemia.

CCB, Calcium channel blocker.

Severe propranolol toxicity is due to a combination of β-receptor and sodium channel blockade. Treatment includes intubation, ventilation, inotropic and sodium bicarbonate therapy. There are no clinically effective methods of enhancing the elimination of CCBs or β-blockers. When all else fails, extracorporeal life support has been shown to allow organ perfusion until reversal of cardiac dysfunction and elimination of the drugs.

Disposition

Following overdose of β-blockers or standard CCBs, patients should be observed in a monitored environment for at least 6 hours. Overdoses of slow-release CCBs require monitoring for at least 16 hours from the time of ingestion. All symptomatic patients should be admitted to a monitored environment until toxicity resolves.

DIGOXIN

Introduction

Both acute and chronic digoxin toxicity are potentially life-threatening presentations to the emergency department (ED). Early recognition and administration of the specific Fab fragment antidote, if indicated, usually results in a good outcome.

Pharmacokinetics

Digoxin is moderately well absorbed following oral administration, with a bioavailability in the range of 50% to 80%. The initial volume of distribution is relatively small, but it is then slowly redistributed, predominantly to skeletal muscle, to give a relatively large volume of distribution of approximately 7 L/kg. Digoxin is excreted predominantly unchanged by the kidney, with an elimination half-life of about 36 hours.

Pathophysiology

At a subcellular level, digoxin inhibits the function of Na–K ATPase, which leads to intracellular depletion of potassium and accumulation of sodium and calcium ions. Alteration of ionic fluxes affects cell membrane conduction. At toxic concentrations of digoxin, the effects on the cardiac conducting system produce decreased conduction velocity throughout the system, increased refractoriness at the AV node and enhanced automaticity of the Purkinje fibres. Vagal tone is also enhanced. In acute digoxin poisoning, the sudden loss of Na–K ATPase function produces hyperkalaemia.

Clinical features

Two distinct clinical presentations of digoxin toxicity are observed: acute and chronic. Both are characterized by cardiac arrhythmias and virtually all types of arrhythmia have been reported in the context of digoxin toxicity.

Acute digoxin overdose in adults is usually intentional and is regarded as potentially life threatening. The non-cardiac manifestations of toxicity are nausea, vomiting and hyperkalaemia. Nausea and vomiting occur early and may be the presenting complaint. The most common cardiac manifestations are sinus bradycardia, increased ventricular ectopy, sinoatrial node arrest and first-, second- or third-degree heart block. Ventricular tachycardia and fibrillation may occur. In significant acute overdose, progressive worsening of the conduction disturbance over a period of hours is usually observed.

Chronic digoxin toxicity is commonly in the elderly, and may be precipitated by therapeutic errors, intercurrent illnesses that decrease renal elimination of digoxin or by drug interactions. Common drug interactions include those with quinidine, CCBs, amiodarone and indomethacin.

Nausea and vomiting are also common manifestations of chronic digoxin toxicity and are frequent presenting symptoms. Neurological manifestations are characteristic of chronic toxicity and include visual disturbances, weakness and fatigue. The most common cardiovascular manifestations of chronic digoxin toxicity are arrhythmias and these may be sinus bradycardia, atrial fibrillation with slowed ventricular response or a junctional escape rhythm, atrial tachycardia with block, ventricular tachycardia and fibrillation.

Deaths in patients with an elevated digoxin concentration are likely to be caused by pump failure, renal failure, severe cardiac conduction impairment or ventricular arrhythmia that is caused by underlying cardiac disease rather than from chronic digoxin toxicity.

Clinical investigations

The most important investigations are the ECG, serum electrolytes, creatinine and serum digoxin concentration.

The ECG is invaluable in documenting the type and severity of any cardiac conduction defect. Serial ECGs may demonstrate worsening of the cardiac conduction defects as toxicity progresses.

In acute poisoning, the serum potassium rises as Na–K ATPase function is progressively impaired. Hyperkalaemia denotes significant acute digoxin toxicity. Prior to the availability of a specific antidote for digoxin poisoning, a serum potassium concentration of >5.5 mEq/L was associated with a high probability of lethal outcome. Hyperkalaemia seldom occurs in chronic digoxin poisoning, unless the patient has acute renal failure. In fact, these patients are sometimes hypokalaemic and hypomagnesaemic secondary to chronic diuretic use. Both these electrolyte disorders are important as they exacerbate digoxin toxicity. Significant chronic toxicity may be exacerbated in the presence of pre-existing cardiac disease.

Serum digoxin levels taken at 6 hours post ingestion are useful in assessing and confirming toxicity, but must be carefully interpreted

in the context of the clinical presentation. They do not accurately correlate with clinical toxicity. Therapeutic concentrations are usually quoted as 0.6 to 1.0 nmol/L (0.5 to 0.8 μg/L). Following acute overdose, the serum digoxin concentration is relatively high compared to tissue concentrations, until distribution is completed by 6 to 12 hours postingestion. However, early concentrations greater than 15 nmol/L indicate serious poisoning.

Treatment

The best outcome is associated with early recognition of digoxin toxicity.

Following acute overdose, the patient should be initially managed in a monitored area with full resuscitative equipment available. Immediate attention to the airway, breathing and circulation may be required. Intravenous access should be established and blood sent for urgent electrolytes and serum digoxin concentration. Digoxin is well bound by charcoal; administration may be difficult because of repetitive vomiting but attempts should be made to reduce systemic absorption with activated charcoal.

For chronic toxicity with minimal symptoms, management may involve no more than observation, cessation of digoxin administration, correction of hypokalaemia and hypomagnesaemia and appropriate management of any factors that contributed to the development of toxicity. Apart from brady-tachy arrhythmias that are associated with haemodynamic instability, patients who have increased automaticities with cardiac and gastrointestinal symptoms may be considered for digoxin-specific antibody. This is especially for patients who have renal failure with a creatinine clearance <30 mL/min.

The specific antidote to digoxin poisoning is Fab fragments of digoxin-specific antibodies, which should be administered as soon as possible in any potentially life-threatening digoxin intoxication. Commonly accepted indications for the administration of Fab fragments are listed in Box 25.2.2.

Digoxin-specific antibodies (Digoxin Fab)

These are derived from immunoglobulin (Ig) G antidigoxin antibodies produced in sheep.

Box 25.2.2 Indications for administration of Fab fragments of digoxin-specific antibodies following acute overdose

- Hyperkalaemia (*K* >5.5 mmol/L) associated with digoxin toxicity
- History of ingestion of more than 10 mg of digoxin
- Haemodynamically unstable cardiac arrhythmia
- Cardiac arrest from digoxin toxicity
- Serum digoxin concentration >15 nmol/L

Intravenously administered digoxin Fab bind digoxin in the intravascular space on a mole-for-mole basis. As binding continues, digoxin moves down a concentration gradient from the tissue compartments to the intravascular compartment. Bound digoxin is inactive. A clinical response is usually observed within 20 to 30 minutes of administration. The Fab-digoxin complexes are excreted in the urine.

The extraordinary clinical efficacy of digoxin-specific fragments has been well documented in a few multicentre studies. These studies demonstrated the safety of the product, with the adverse reactions reported being hypokalaemia (4%), rapid atrial fibrillation or worsening of congestive cardiac failure (3%) and allergic reaction (0.8%).

Forty milligrams of digoxin Fab (1 vial) will bind 0.5 mg of digoxin. In the past, the recommended dosing for digoxin Fab was to give half to full equimolar dose to stabilize a patient with severe digoxin toxicity. However, a recent study with acute digoxin poisoning suggested that it is safe to administer digoxin Fab in staggered doses of 1 to 2 vials in the first 24 to 48 hours, titrated against ECG changes and clinical response. On the other hand, digoxin Fab is not as effective in managing tachy-bradyarrhythmias in chronic digoxin poisoning as the cause could be multifactorial such as concurrent use of other antiarrhythmic agents, diuretics and angiotensin antagonists and underlying cardiac disease. In a series of chronic digoxin poisoning cases, bradycardia was common (median heart rate [HR]: 49 bpm) and gastrointestinal symptoms were present in 86% of patients. Free digoxin concentration dropped to zero following the administration of 1 to 2 vials of digoxin Fab but the median change of HR was modest, about 8 bpm.

It is recommended that smaller hospitals should stock at least 2 vials of digoxin Fab and be aware of the stored location and how to acquire further stocks should the need arise. Serum digoxin concentrations will be high following the administration of Fab fragments because most assays measure both bound and unbound digoxin.

Disposition

Acute overdoses require close observation for at least 24 to 48 hours. Those that develop toxicity require admission and an appropriate level of monitoring. Following successful administration of digoxin-specific Fab fragments, patients must be carefully monitored for hypokalaemia and worsening of any underlying medical conditions for which digoxin may have been prescribed therapeutically. All intentional ingestions require psychiatric evaluation prior to medical discharge.

Patients with mild, chronic digoxin toxicity (gastrointestinal symptoms only) may be discharged after cessation of digoxin therapy provided there are no significant arrhythmias, electrolyte disturbances, renal failure or other precipitating medical conditions. Following administration of Fab fragments, cases of chronic toxicity with conduction defects usually require medical admission for observation and treatment of intercurrent illness.

CLONIDINE

Introduction

Clonidine is a 2-imidazoline derivative; it is a central α_2-adrenergic agonist and an imidazoline receptor agonist. It was first developed in the 1960s as a nasal decongestant but is now currently used for the management of hypertension, attention deficit hyperactivity disorder (ADHD), withdrawal symptoms from drug and alcohol addiction, tobacco withdrawal and Tourette's syndrome. Its use in childhood behavioural disorders has meant it is more readily available to children and there is potential for dosing error or accidental paediatric exposure.

Pharmacokinetics

Clonidine is well absorbed with a bioavailability of almost 100%. The peak concentration in plasma and effect is observed within 1 to 3 hours. The elimination half-life is 6 to 24 hours with a mean half-life of 12 hours; half of the administered dose is excreted unchanged by the kidney.

Pathophysiology

Clonidine acts to produce a reduction in CNS sympathetic outflow at the vasomotor centre in the medulla oblongata. Clonidine is thought to reduce blood pressure through a reduction in cardiac output as well as its weak peripheral α-adrenergic antagonist properties. Clonidine also stimulates parasympathetic outflow and this may contribute to the slowing of heart rate as a consequence of increased vagal tone. Paradoxically, clonidine overdose can result in an initial hypertension from its partial α_1-adrenergic agonist effect.

Clinical features

Clonidine overdose most commonly causes mild CNS depression and bradycardia. Initially it can cause transient hypertension from vasoconstriction followed by hypotension. Other CNS symptoms include coma, seizure, miosis, reduced respiration and hypothermia. The median onset of symptoms following clonidine ingestion is 30 minutes and patients are usually

symptomatic on arrival at the ED. In adult studies of clonidine ingestion, bradycardia can persist for up to 24 to 48 hours. Severe poisonings or complications following overdose are rare in adults. Children however are more susceptible to a decreased level of consciousness and respiratory depression.

Investigations

The ECG is essential in evaluating and monitoring for bradycardia and conduction defects.

Treatment

The management of clonidine poisoning is primarily supportive. Patients are usually symptomatic on arrival and the benefits of administering activated charcoal are unlikely to outweigh the risk of aspiration in adults. Hypotension usually responds to intravenous fluids. Atropine and naloxone have been used as antidotes with variable responses. Occasionally, vasopressors may be required to maintain haemodynamic stability. Hypertension is usually short lived and rarely requires treatment. The role of naloxone (some propose large doses) to reverse CNS depression and/or bradycardia remains controversial as its effects on both can be variable.

Disposition

Patients should be observed in hospital until they are asymptomatic and bradycardia has resolved. They do not require ongoing cardiac monitoring for a stable sinus bradycardia.

CLASS 1C ANTIARRHYTHMICS

Introduction

Apart from the class one antiarrhythmics, many drugs in overdose cause sodium channel blockade. Drugs highly associated with sodium channel blockade and QRS widening are shown in Table. 25.2.4. Overdose with class 1c antiarrhythmic drugs is among the most serious ingestions and is associated with a high morbidity and mortality. Overdoses with these agents are rare but they may be rapidly lethal with profound cardiovascular collapse. Drugs in this class include flecainide and propafenone; they are used for the treatment of supraventricular tachycardia (SVT) and ventricular arrhythmias. Class 1c antiarrhythmics block the fast-inward sodium channel during phase 0 of the action potential. They have slow offset kinetics and cause complete blockade of sodium channel for a much longer duration than class 1a and 1b antiarrhythmics.

Table 25.2.4 Drugs associated with QRS widening and sodium channel blockade

Antidepressants	Tricyclic antidepressants Venlafaxine
Antiepileptic drugs	Carbamazepine Lamotrigine
Antihistamines	Diphenhydramine
Antimalarial drugs	Chloroquine Hydroxychloroquine Quinine
Antipsychotics[a]	Chlorpromazine
Cardiovascular drugs	Flecainide Propafenone Propranolol
Drugs of abuse	Cocaine
Local anaesthetics	Bupivacaine Ropivacaine
Opioids	Dextropropoxyphene
Others	Bupropion Dolasetron Orphenadrine

[a]Antipsychotic drugs are not highly associated with QRS widening, but are commonly taken in overdose.
(Modified from Toxicology and Wilderness Expert Group. Drugs highly associated with QRS widening and sodium channel blockade. In: *eTG Complete* [Internet]. Melbourne: Therapeutic Guidelines Limited; 2012: Table 17.1 [revised June 2011]; and Yates C, Manini AF. Utility of the electrocardiogram in drug overdose and poisoning: theoretical considerations and clinical implication. *Curr Cardiol Rev*. 2012;8(2):137–151. https://tgldcdp.tg.org.au/guideLine?guidelinePage=Toxicology+and+Wilderness&frompage=etgcomplete).

Pharmacokinetics

Flecainide has a high oral bioavailability and a rapid onset of action of 30 to 60 minutes. It has a long elimination half-life of 7 to 23 hours. In adults, ingestions of 800 mg or more should be considered as life threatening. Similarly, propafenone has a long elimination half-life.

Clinical features

In overdose, they have a rapid onset of clinical symptoms, typically with 30 minutes to 2 hours. Overdose symptoms include nausea, vomiting, hypotension, bradycardia, varying degrees of atrioventricular block and tachyarrhythmia. In severe cases, coma and seizures may occur. Severe intoxication is frequently fatal because of the rapid onset of hypotension and ventricular arrhythmias. With most fatalities have occurred within 3 to 15 hours postingestion.

Investigations

The ECG is essential in evaluating and monitoring the QRS duration, conduction defects and QT interval. The most common and important ECG change in overdose is QRS widening (more than 120 ms). Although QT prolongation occurs in flecainide overdose, torsades de pointes is rare.

Treatment

The mainstay of management of class 1c overdose is good supportive care including inotropic support, gastrointestinal decontamination and sodium bicarbonate. Treatment is similar to other sodium channel blocking agents, such as the tricyclic antidepressants and includes plasma alkalinization to a pH of 7.45 to 7.5 with hyperventilation. In patients with broad complex arrhythmias and hypotension early use of sodium bicarbonate of up to 3 bolus doses (1 to 2 mmol/kg) is recommended. However, it is important to note that not all sodium channel blocking agents will respond to sodium bicarbonate administration or alkalinization. When administering repeated boluses of sodium bicarbonate careful monitoring is required to ensure severe hypernatremia or hypokalaemia do not develop. Sodium bicarbonate treatment may be repeated only if symptoms recur and there is a demonstrated response of QRS narrowing and resolution of arrhythmias. Other treatment options to consider include transcutaneous or transvenous pacing for bradyarrhythmias and lignocaine may be used for ventricular dysrhythmias. Extracorporeal membrane oxygenation (ECMO) should also be considered in patients failing to respond to conventional therapy.

Disposition

Asymptomatic patients with a normal ECG 4 hours after ingestion of flecainide are unlikely to develop toxicity. Patients who are symptomatic should be admitted to a monitored area.

CARDIAC ARREST DUE TO CARDIOVASCULAR ACTIVE DRUGS

It is important for clinicians to be aware that cardiac arrest due to overdose of cardiovascular active drugs may necessitate prolonged cardiopulmonary resuscitation (CPR), resuscitative manoeuvres, use of emergency antidotes and consideration of heroic measures, such as

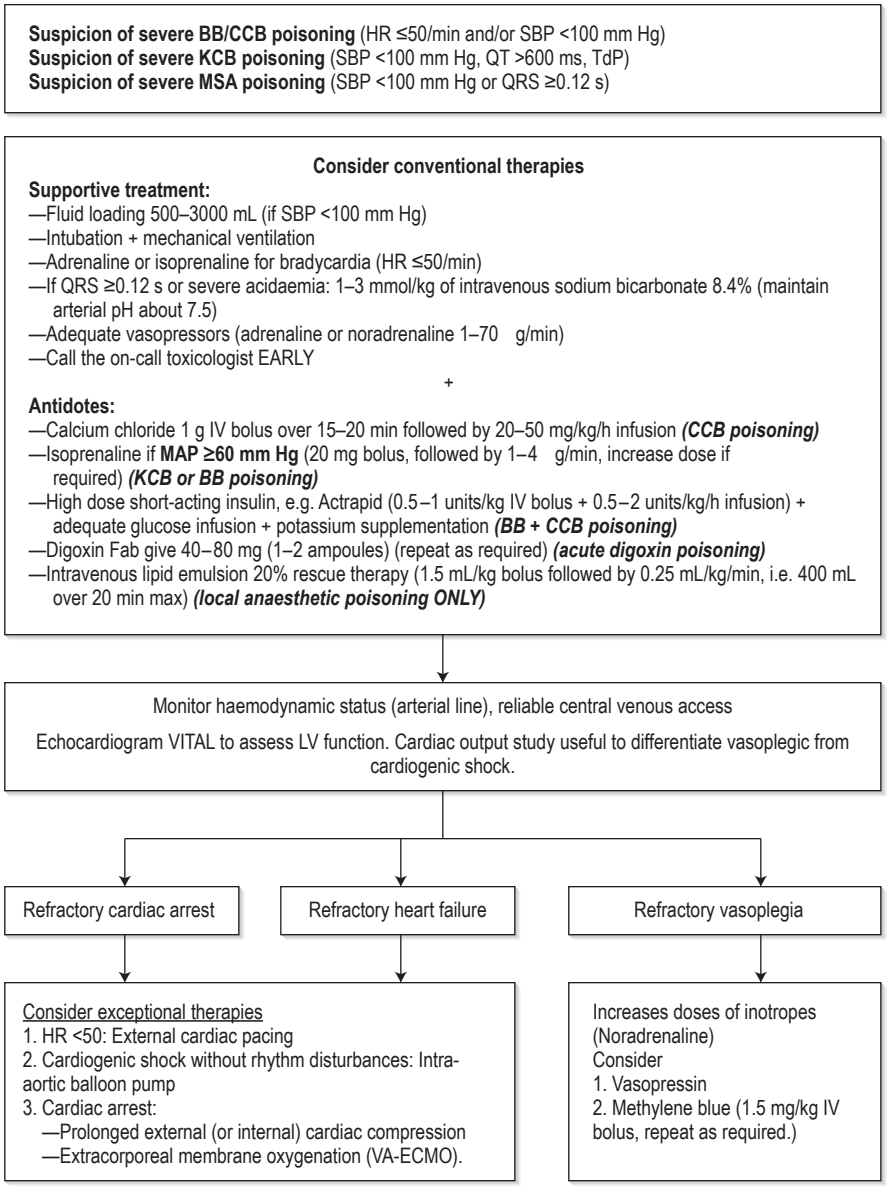

FIG. 25.2.1 Algorithm for the treatment of severe calcium channel blockers *(CCB),* β-blockers *(BB),* potassium channel blockers *(KCB)* and membrane stabilizing agents *(MSA)* poisoning. *HR,* Heart rate; *LV,* left ventricular; *MAP,* mean arterial pressure; *SBP,* systolic blood pressure; *VA-ECMO,* venous arterial-extracor poreal membrane oxygenation.

CONTROVERSIES

- The advantages of glucagon over other inotropic agents in the management of CCB and β-blocker overdose are questionable.
- The indications for initiation of hyperinsulinaemia euglycaemia therapy in CCB and β-blocker overdose are not well defined.
- There have been successful reports of ECMO to maintain an adequate cardiac output following severe CCB, β-blockers and sodium channel blocker overdoses, hence there may be a role in the management of otherwise fatal cases of cardiovascular collapse.

- In acute digoxin poisoning, the dosing regimen of digoxin Fab is likely to be repeated doses of 1 to 2 vials, titrated against ECG and clinical response. In chronic digoxin toxicity, 1 to 2 vials of digoxin Fab is adequate to neutralize digoxin in the central compartment but the clinical response may only be modest.

ECMO (Fig. 25.2.1) Consultation with a clinical toxicologist is always recommended prior to cessation of resuscitative efforts in these cases.

25.3 Antipsychotic drugs

Dino Druda

ESSENTIALS

1 **Antipsychotics can cause numerous adverse effects at therapeutic doses, which may limit compliance.**

2 **Extrapyramidal effects are less pronounced with second-generation antipsychotics.**

3 **Clozapine is associated with agranulocytosis and myocarditis with therapeutic use and requires strict surveillance.**

4 **Following overdose, antipsychotics predominantly cause central nervous system (CNS) depression and cardiovascular effects.**

5 **Amisulpride can cause significant QT prolongation, potentially resulting in torsades de pointes.**

6 **Management of antipsychotic overdose is primarily supportive.**

7 **Neuroleptic malignant syndrome is a rare, idiosyncratic adverse reaction, which may be lethal without timely diagnosis and treatment.**

Introduction

Antipsychotics form a heterogeneous group of medications that has evolved since chlorpromazine was first used to treat schizophrenia in the 1950s. The first-generation or 'typical' antipsychotics caused many adverse effects, especially movement disorders such as extrapyramidal syndromes (EPS). They also have little efficacy in treating the negative symptoms of schizophrenia. This led to the development of the second-generation or 'atypical' antipsychotics in the late 1980s. Generally these drugs have fewer tendencies to cause movement disorders and have efficacy in managing negative symptoms of schizophrenia, while maintaining efficacy in treating acute psychosis. For this reason, they have largely replaced the older antipsychotics as first-line pharmacotherapy for schizophrenia and psychotic disorders.

The previous 30 years has shown an increase in overall prescribing of antipsychotics in Australia (many for off-label indications), along with increasing presentations with self-poisoning. Despite a greater proportion of presentations with overdose of second-generation antipsychotics (particularly quetiapine and olanzapine), which are perceived as safer, there has been no reduction in morbidity or in-hospital mortality.

Pharmacology

There are numerous ways of classifying the antipsychotic drugs: typical or atypical as described above (Box 25.3.1), by their chemical structure, or according to neuroreceptor binding affinity.

Box 25.3.1 Typical and atypical antipsychotic drugs

Typical	Atypical
Chlorpromazine	Clozapine
Prochlorperazine	Olanzapine
Fluphenazine	Quetiapine
Haloperidol	Risperidone
Droperidol	Paliperidone
Flupenthixol	Amisulpride
Zuclopenthixol	Ziprasidone
	Aripiprazole

All antipsychotic drugs produce their beneficial therapeutic effects by antagonizing dopamine D_2 receptors in the mesolimbic system. The first-generation antipsychotics were classified as high or low potency depending on their affinity for these D_2 receptors. However, antagonism of the other D_2 receptors leads to many of the adverse clinical effects. Antagonism of D_2 receptors in the nigrostriatal pathway leads to movement disorders, antagonism of the D_2 receptors in the mesocortical area can contribute to the negative symptoms, and antagonism of D_2 receptors in the anterior pituitary stimulates prolactin secretion potentially causing gynaecomastia and galactorrhoea. Blockade of D_2 receptors in the anterior hypothalamus may affect temperature regulation, leading to hypo- or hyperthermia, and may be involved in the development of neuroleptic malignant syndrome (NMS). The antiemetic effect of some of the antipsychotics is due to antagonism of the D_2 receptors in the chemoreceptor trigger zone in the medulla.

Second-generation antipsychotics also derive therapeutic efficacy from affinity and antagonism at various serotonin (5-HT) receptors. Antagonism at the 5-HT_{2A} receptor is implicated both in increasing efficacy of treating negative symptoms of schizophrenia, and also in reducing the incidence of EPS.

Agents with high antagonism of muscarinic M_1 and M_2 receptors (e.g. olanzapine, quetiapine) can cause an agitated delirium and peripheral features characteristic of anticholinergic toxicity. Drugs that have a higher anticholinergic activity than dopaminergic tend to cause fewer extrapyramidal effects. High relative antagonism of histamine H_1 receptors leads to sedation and, to a lesser extent, hypotension. Antagonism at the α_1-adrenergic receptor can result in hypotension (e.g. clozapine, quetiapine). Clozapine also antagonizes the α_2-receptor, although the clinical significance of this is uncertain.

Some first-generation antipsychotics can block voltage-gated fast sodium channels, which in overdose, can lead to slowing of cardiac conduction, widening the QRS complex, and impairing myocardial contractility. Blockade of the delayed rectifier potassium channel causes delayed repolarization leading to QT prolongation.

Despite the heterogeneous nature of the antipsychotics, in general, they share similar pharmacokinetic properties. They are well absorbed after oral administration, with peak serum concentrations usually occurring within 2 to 6 hours of ingestion. This may be delayed following overdose of agents with significant anticholinergic properties. They are lipophilic, have large volumes of distribution and the majority of the agents are highly protein bound. They are extensively metabolized in the liver, with some having active metabolites.

Clinical effects

Adverse effects

Adverse effects at therapeutic doses may be dose related or idiosyncratic.

Extrapyramidal syndromes

These are a heterogeneous group of disorders characterized by abnormal neuromuscular activity. They can be particularly distressing to patients and may lead to difficulties with compliance. There are four well-recognized syndromes—acute dystonia, akathisia, parkinsonism and tardive dyskinesia. Of these, the first three are usually reversible, whereas tardive dyskinesia is irreversible, but occurs late, usually after months to years of treatment.

EPS are more common among the first-generation antipsychotics, especially those with high potency, such as haloperidol. Second-generation antipsychotics are associated with a lower incidence of EPS, although it must be appreciated that EPS can occur with the use of any antipsychotic. Reactions are usually idiosyncratic, although can occur following overdose.

Acute dystonia is characterized by sustained involuntary muscle contraction, which commonly involves the face, head and neck, but can also involve the extremities. Rarely, the larynx can be involved, which may be life threatening. Risk factors for developing dystonia include male gender, young age and previous history of dystonic reaction. Onset is usually within a few hours of exposure, but may be delayed for several days.

Akathisia is characterized by an unpleasant sensation of restlessness or unease and, often, the patient is unable to remain still. It can be difficult to diagnose and is sometimes attributed to the underlying psychiatric condition rather than to the treatment.

Drug-induced parkinsonism is similar to idiopathic Parkinson disease, with rigidity and bradykinesia, although the characteristic tremor may be less pronounced. It is more common in older patients and patients on high potency agents.

Tardive dyskinesia is characterized by repetitive, involuntary, purposeless movements, classically involving the muscles of the face and mouth, although the limbs and trunk may be involved. It usually appears after months or years of therapy with antipsychotics and is usually resistant to treatment.

Cardiovascular effects

Cardiovascular effects of antipsychotics with therapeutic use include tachycardia, postural hypotension and ECG changes. Postural hypotension may be multifactorial, with α_1-adrenergic blockade and direct myocardial depression playing a role. ECG changes may be diverse, with QRS prolongation, QT prolongation and non-specific ST-segment and T-wave changes being reported.

Seizures

All antipsychotics can lower the seizure threshold. However, seizures rarely complicate therapeutic use of antipsychotics, unless the patient has underlying risk factors, such as organic brain disease or epilepsy.

Metabolic syndromes

Chronic use of many of the antipsychotics is associated with the development of a metabolic syndrome, which can lead to weight gain, dyslipidaemia, hypertension and impaired glucose tolerance. These can be distressing and affect compliance with treatment. They also contribute to the development of cardiovascular disease and type II diabetes. Metabolic effects are particularly associated with olanzapine and clozapine.

Neuroleptic malignant syndrome

NMS is a rare idiosyncratic adverse reaction, which can occur with any of the antipsychotic medications. Risk factors, diagnosis and management of NMS are described later in this chapter.

Clozapine

Clozapine is associated with a number of idiosyncratic effects that can occur with therapeutic use and requires more vigilant surveillance. These include agranulocytosis and myocarditis. These should be considered in the differential diagnosis if a patient on clozapine becomes acutely unwell.

Overdose

Following overdose of antipsychotics, the most common and significant manifestations involve the CNS and cardiovascular system.

Dose-dependent CNS depression occurs, ranging from lethargy and somnolence to coma and seizures. Airway protective reflexes may be impaired, requiring intensive care. Many of the agents can cause significant anticholinergic toxicity, manifesting as delirium with associated peripheral effects.

The most common cardiovascular effects are tachycardia and hypotension. Tachycardia may be due to anticholinergic effects and also as a response to hypotension. Hypotension often occurs as a result of peripheral α_1-receptor blockade, leading to vasodilatation.

ECG changes may be present after overdose and can include QRS prolongation and QT interval prolongation. Significant arrhythmias are uncommon, apart from following overdose with amisulpride, which can cause torsades des pointes.

Some of the specific clinical features following overdose of individual agents are described below.

Amisulpride

Overdose of amisulpride causes sedation, bradycardia, hypotension and QT prolongation. Episodes of torsades de pointes have been reported and so amisulpride is considered to be particularly cardiotoxic. Onset of cardiotoxicity may be delayed for greater than 12 hours and QT prolongation can persist for many hours, with the potential to develop torsades de pointes abruptly. Ingestions greater than 4 g have been associated with development of prolonged QT and ingestions greater than 8 g can cause significant sedation and hypotension.

Chlorpromazine

Large overdoses >5 g, especially in drug-naïve patients, may cause significant CNS depression,

requiring intensive care due to loss of airway protective reflexes. Significant hypotension also occurs following overdose. Prolongation of the QT interval is also associated with chlorpromazine.

Clozapine

Acute overdose of clozapine causes CNS depression, which is more pronounced in clozapine-naïve patients, who may require intubation. Seizures are reported in overdose. Despite the known anticholinergic properties of clozapine, hypersalivation is common. Miosis is classically described, but mydriasis can also occur. Agranulocytosis does not occur after a single overdose.

Haloperidol

Sedation and EPS are common following overdose of haloperidol. Haloperidol has also been associated with QT prolongation and arrhythmias following large ingestions or intravenous administration.

Olanzapine

Onset of clinical features following overdose is within 6 hours. Sedation and anticholinergic effects are the most common manifestations, leading to a combination of agitation and drowsiness, which may require intubation. Miosis may be noted. Tachycardia is common, but significant ECG abnormalities are rare.

Quetiapine

Quetiapine is available in immediate (IR) and extended release (XR) preparations. Overdose causes dose-related CNS depression and tachycardia. Hypotension and seizures are also reported after larger ingestions. Ingested doses of greater than 3 g are associated with increased length of stay and ICU admission. Overdose of the XR preparation is associated with prolonged time to onset of effect and prolonged recovery from sedation when compared with IR.

QTc prolongation is often reported, but this may be a result of overcorrection for tachycardia rather than intrinsic cardiotoxicity. The clinical significance of this is unclear, with no reported cases of torsades de pointes.

Risperidone/paliperidone

Risperidone is relatively benign following overdose, with tachycardia and dystonia being the most common effects. Onset of dystonia may be delayed and may recur after treatment. Paliperidone is an active metabolite of risperidone, available in extended release formulation. As such delayed onset and prolonged toxicity, particularly tachycardia, may occur after overdose.

Ziprasidone

Ziprasidone is associated with QT prolongation, both with therapeutic use and following overdose. Torsades de pointes is reported after ziprasidone overdose with co-ingestants, but not in isolation.

Investigations

Antipsychotic toxicity is primarily diagnosed on history and examination for typical clinical features. Serum drug concentrations are not usually available in a clinically useful timeframe or helpful in the management of acute overdose. A clozapine concentration can be measured in patients taking clozapine who present unwell to hospital. For these patients, a WCC is helpful when looking for agranulocytosis and troponin may be elevated in cases of clozapine-induced myocarditis. If this is suspected, then ECG and echocardiography may also be required.

Initial ECG evaluation should occur for all patients following antipsychotic overdose and any abnormality of the QRS or QT intervals warrants continuous cardiac monitoring. If initial ECG is normal, then it should be repeated after 6 hours in asymptomatic patients. Prolonged cardiac monitoring is required for patients following overdose with amisulpride or ziprasidone.

Treatment

The management of antipsychotic toxicity is primarily supportive. Attention to resuscitation should occur initially. Mild sedation requires no specific treatment. Patients with significantly decreased conscious state with loss of airway protective reflexes will require intubation, ventilation and intensive care.

Decontamination with activated charcoal can be considered if the presentation is within an hour and there is no CNS depression. Otherwise, administration of activated charcoal should be delayed until after the airway has been secured with intubation. There is no evidence for any benefit from enhanced elimination techniques, either with multi-dose activated charcoal or extracorporeal techniques, so they are not routinely indicated.

Hypotension should initially be treated with an appropriate bolus of intravenous crystalloid solution. If there is no response, vasopressors may be required. Noradrenaline is preferred initially, as worsening hypotension following administration of adrenaline to patients after quetiapine overdose is reported. Patients with ventricular arrhythmias or prolonged QRS should be managed with sodium bicarbonate in a similar fashion to patients with significant tricyclic antidepressant (TCA) toxicity. Intravenous bicarbonate 8.4% (1 mL = 1 mmol) 1 to 2 mmol/kg boluses should be administered to obtain an arterial pH of 7.50 to 7.55. The pH may then be maintained in this range using hyperventilation in intubated patients. QT prolongation requires no specific management other than cardiac monitoring and correction of any potential contributing electrolyte abnormalities. Should torsades de pointes develop, it should be treated initially with IV magnesium sulphate 50% 2 to 4 mL (1 to 2 g or 4 to 8 mmol) infusion over 10 minutes. Chemical or electrical overdrive pacing may also be required to avoid further instances.

Seizures are often self-limiting, requiring no treatment. However, should intervention be necessary, benzodiazepines are used first line. Barbiturates and/or general anaesthesia are indicated for refractory seizures or status. There is no defined role for other anticonvulsants (e.g. phenytoin) in the management of drug-induced seizures.

Anticholinergic delirium should be managed initially with non-pharmacological measures to limit stimulation. Urinary retention should be identified and relieved with a urinary catheter, as this may contribute to agitation. Should medication be required, titrated doses of benzodiazepines (e.g. diazepam) should be used initially, although it must be appreciated that benzodiazepines may contribute to any CNS depressant effects of the ingested antipsychotic.

Acute dystonia is managed with an anticholinergic agent, such as benztropine (1 to 2 mg given IV or IM). Benzodiazepines may also be used. Repeat dosing may be required as the dystonia can recur.

Disposition

Patients should be observed for 6 hours after overdose of most antipsychotics. If they remain asymptomatic and have a normal ECG at this time, then they can be medically cleared for discharge. This observation period should be extended for 12 hours following significant ingestion of extended release preparations of quetiapine, ingestions of >4 g amisulpride and ingestions of ziprasidone.

Patients with significant symptoms should be observed until symptoms are resolving. Intensive care is required for patients requiring intubation and ventilation. In the event of any concerning ECG abnormalities, such as QT prolongation, then cardiac monitoring is recommended until these changes are resolving.

Neuroleptic malignant syndrome

NMS is a rare, idiosyncratic, potentially life-threatening adverse reaction that has been reported to occur with all the antipsychotics. There is a large variation in reported incidence, but recent pooled data suggest an incidence of 0.01% to 0.2%. The pathophysiology of NMS is not completely understood, but is thought to be

due to central dopamine blockade, especially in the nigrostriatal and hypothalamic pathways. Risk factors for the development of NMS include male gender, young age, high potency antipsychotic use, recent dose increase, parenteral administration, dehydration and organic brain disease.

Clinical features

The onset of NMS occurs typically over 1 to 3 days. The typical clinical features are a combination of altered mental status, hyperthermia (temperature >38°C), autonomic dysfunction and muscular rigidity. The altered mental status ranges from delirium and confusion to stupor and coma. Autonomic dysfunction can manifest as tachycardia, cardiac arrhythmias, respiratory irregularities and hypo- or hypertension. The muscular rigidity is classically described as 'lead-pipe' rigidity, with increased tone and resistance to passive movement. There may be superimposed tremor leading to cogwheeling. Other neuromuscular abnormalities include bradykinesia, dystonia, mutism and dysarthria.

Differential diagnosis

Numerous diagnostic criteria have been proposed for NMS, but none are universally accepted. Alternate diagnoses must be considered and excluded, particularly CNS infection. Other conditions to be considered include heatstroke, thyrotoxicosis, serotonin toxicity, anticholinergic syndrome, malignant catatonia, nonconvulsive status epilepticus, phaeochromocytoma and drug intoxication (monoamine oxidase inhibitors (MAOIs), sympathomimetics).

However, NMS must be considered in any patient on antipsychotic medication who is unwell, particularly when there is altered mental status, fever or muscle rigidity, especially if there has been a recent change in the antipsychotic regimen.

Investigations

There is no diagnostic test for NMS, although there are characteristic laboratory abnormalities in some cases. Increased muscle enzymes (creatinine kinase (CK), lactate dehydrogenase (LDH), aspartate transaminase (AST)) are often present in cases of NMS. Leucocytosis is also frequently observed. There may be other electrolyte disturbance, metabolic acidosis and coagulation abnormalities.

Investigations to rule out alternate diagnoses need to be carried out, including computed tomography scan of the brain and lumbar puncture to rule out CNS infection.

Treatment

Once NMS is diagnosed, aggressive supportive care is essential. The offending drug must be immediately withdrawn. Patients are often dehydrated so fluid resuscitation is required. Hyperthermia must be managed aggressively with passive and active cooling. If the temperature is >39.5°C, then intubation and neuromuscular paralysis should be considered. Thromboprophylaxis should be given due to increased risk of thromboembolism.

Benzodiazepines are often used early in the treatment of NMS and they may be effective in ameliorating symptoms in milder cases.

Bromocriptine is a centrally acting dopamine agonist that can only be administered orally or via nasogastric (NG) tube. The starting dose is 2.5 mg three times daily, increased to a daily maximum of 40 mg. It needs to be continued for 1 to 2 weeks, as premature discontinuation can lead to rebound symptoms. Potential adverse effects include vomiting and worsening of psychosis.

Dantrolene interferes with calcium release in skeletal muscle cells, reducing skeletal muscle activity. It may be useful in cases of NMS with prominent hyperthermia and muscle rigidity, although there are conflicting reports regarding efficacy and outcome benefit. It can be given by IV infusion at 2 to 3 mg/kg/day.

Electroconvulsive therapy (ECT) has been advocated for cases of NMS refractory to pharmacological treatments, although its efficacy is unclear.

CONTROVERSIES

- The optimum time for cardiac monitoring following significant amisulpride or ziprasidone overdose is not yet clearly defined.
- Many antipsychotics are highly lipophilic and there are case reports of lipid rescue therapy being used to treat significant toxicity. However, evidence for definite outcome benefit is lacking.
- The efficacy of specific therapies for NMS, such as dantrolene, bromocriptine and ECT, is controversial and evidence of outcome benefit is lacking.

25.4 Antidepressant drugs

Shaun Greene

ESSENTIALS

1 **Tricyclic antidepressant (TCA) overdose is associated with severe cardiovascular toxicity, seizures, coma and death.**

2 **Sodium bicarbonate is the specific treatment of TCA cardiotoxicity.**

3 **Selective serotonin reuptake inhibitors (SSRIs) produce mild clinical effects in overdose; however very large ingestions or co-ingestion with another serotonergic agent can produce clinically significant serotonin toxicity.**

4 **SSRIs rarely produce cardiovascular toxicity; however, citalopram and escitalopram are associated with QT prolongation and torsades des pointes.**

5 **Selective noradrenaline reuptake inhibitors produce serotonin and sympathomimetic toxidromes, with the risk of delayed onset of seizures and cardiovascular toxicity following large ingestions.**

6 **Overdose of a monoamine oxidase inhibitor can produce delayed onset of severe sympathomimetic stimulation, requiring treatment in an intensive care unit.**

Introduction

Severity of clinical toxicity following overdose (OD) of antidepressant drugs available in Australia varies according to the class of drug. Toxicity is dose dependent and produces clinical manifestations affecting multiple organ systems. Cardiovascular and neurological features can be life threatening. Early risk assessment and aggressive supportive care are essential in ensuring a good outcome.

Tricyclic antidepressants

Although efficacious in treating depression, tricyclic antidepressants (TCAs) are relatively more toxic than other classes of antidepressants in OD.[1] Significant toxicity including death is associated with ingested doses of more than 10 mg/kg in adults and 5 mg/kg in children. Of the TCAs available in Australia (Box 25.4.1), dothiepin is associated with the greatest toxicity. Cardiovascular system dysfunction and coma typically manifest rapidly following significant ingestion. Good outcome is dependent on aggressive airway management, utilization of sodium bicarbonate and provision of supportive care in a critical care environment.

Box 25.4.1 Tricyclic antidepressants available in Australia

Amitriptyline
Clomipramine
Dothiepin
Doxepin
Imipramine
Nortriptyline
Trimipramine

Pharmacology

The tertiary amine structure of TCAs nonselectively interacts with multiple receptors throughout the body, most of which are not implicated in positive antidepressant effects. Pharmacodynamic interactions include:

- Inhibition of central nervous system (CNS) serotonin and noradrenaline reuptake and modulation of genetic expression of serotonin, β-adrenergic and other CNS receptors contribute to antidepressant effects. This pharmacodynamic property does not contribute significantly to classical TCA toxicity, but is likely responsible for TCA-related serotonin toxicity (described later in this chapter).
- Binding to inactivated cardiac sodium channels producing rate-dependent inhibition of sodium conductance leading to membrane stabilizing effects, QRS prolongation and potentially lethal arrhythmias and impaired myocardial contractility. The effects of this on an ECG can be seen in Fig. 25.4.1.
- Stimulation of central postsynaptic histamine receptors producing CNS depression, sedation and coma.
- Antagonism of muscarinic acetylcholine receptors producing anticholinergic effects including tachycardia, agitation and urinary retention.
- Antagonism of peripheral α_1-adrenergic receptors producing peripheral vasodilatation.
- Varying degrees of antagonism at potassium, chloride and γ-aminobutyric acid (GABA) receptors.

TCAs are well absorbed following ingestion, undergo extensive first-pass metabolism, are hepatically metabolized (often producing active metabolites), are highly protein bound and are lipophilic and therefore widely distributed throughout the body. Half-lives are relatively long (10 to 81 hours) and often observed to be longer following OD.

Clinical features

The most common clinical features of significant TCA OD are CNS depression (varying from agitated delirium to coma) and sinus tachycardia; these manifest rapidly within 1 to 2 hours of exposure.[2,3] Risk assessment based on dose ingested and associated anticholinergic, CNS and cardiovascular clinical effects are described in Table 25.4.1. Agitated delirium secondary to anticholinergic receptor agonism is not always evident in more severe cases as coma predominates. Sodium channel blockade and α-receptor mediated peripheral vasodilatation lead to supraventricular and ventricular arrhythmias, hypotension and asystole in a dose-dependent manner. Generalized seizures can lead to systemic acidosis and worsening cardiovascular toxicity. Anticholinergic features may become more apparent during the recovery phase as histamine receptor-induced sedation resolves. In severe cases anticholinergic delirium can last for up to 48 hours.

Clinical investigations

A 12-lead ECG is the most valuable prognostic investigation following TCA OD. A terminal 40 ms axis between 120 and 270 degrees is a sensitive indicator of TCA presence but this is difficult to measure at the bedside.[4] Measurement of maximal limb lead QRS duration is a useful predictor of toxicity. Prolongation of >100 ms is associated with an increased incidence of coma, need for intubation, seizures, hypotension and arrhythmias. One study demonstrated no seizures or arrhythmias in patients with a QRS duration that remained <100 ms. Ventricular arrhythmias were predicted in one study by a QRS duration >160 ms. The finding of a positive R wave of >3 mm in

Table 25.4.1 Tricyclic antidepressants: dose-related risk assessment and clinical effects

Dose	*Effect*
<5 mg/kg	Minimal symptoms
5–10 mg/kg	Anticholinergic effects, mild sedation Major toxicity not expected
>10 mg/kg	Significant clinical toxicity likely to occur within 2–4 h of ingestion Anticholinergic effects Coma, myoclonic jerks, seizures (early in course, 3%–4% of cases) Sinus tachycardia, supraventricular tachycardia, torsades de pointes, ventricular fibrillation, idioventricular rhythm, second-/third-degree heart block with associated bradycardia, asystole, hypotension (myocardial dysfunction + peripheral vasodilation)
>20 mg/kg	Coma, hypotension, potential for seizures and arrhythmias. Duration toxicity potentially >24 h

amplitude in lead aVR or a ratio of >0.7 between the amplitude of R and S waves in aVR are sensitive markers for seizures and arrhythmias. A rightward frontal plane QRS vector (indicated by an S wave in lead I and an R wave in aVR) is associated with TCA toxicity. Although QT prolongation is observed in TCA therapy and toxicity, this finding is not predictive of clinical toxicity.

TCA plasma concentrations can be measured, but are poorly correlated with degree of clinical toxicity.

Treatment

Patients with significant clinical toxicity or those with a recent (previous 3 to 4 hours) reported ingestion of a potentially toxic amount of a TCA receive aggressive supportive care in a resuscitation area. Early securing of the airway via endotracheal intubation is indicated when there is any decrease in conscious state. Poor respiratory function and secondary hypoxia potentially worsen TCA toxicity.

Administration of activated charcoal should be considered within 1 hour of ingestion, provided facilities exist to protect the airway if decreased consciousness or seizures occur. Activated charcoal should be administered to patients requiring intubation via a nasogastric tube within 4 hours of ingestion, and should be considered in intubated patients with severe clinical toxicity at >4 hours post-ingestion.

Early aggressive use of sodium bicarbonate in conjunction with hyperventilation is indicated where there is any cardiovascular dysfunction in conjunction with QRS prolongation (>100 ms), hypotension unresponsive to initial intravenous fluid (see further discussion later) or in the presence of any arrhythmia.[5] Intravenous bicarbonate 8.4% (1 mL = 1 mmol) 1 to 2 mmol/kg boluses should be administered to obtain an arterial pH of 7.50 to 7.55; pH should then be maintained in this range using hyperventilation. Sodium bicarbonate provides hypertonic sodium, competitively overcoming sodium channel blockade. Alkalization improves sodium channel function and reduces the free concentration of TCA available to produce toxicity. Acid–base manipulation using sodium bicarbonate is more effective than hyperventilation alone in TCA toxicity. Sodium bicarbonate may be prophylactically beneficial in cases where there is a significant history of TCA ingestion and an isolated finding of QRS duration of >100 ms.

Other therapies, including concentrated hypertonic saline (3% sodium chloride) and lignocaine, may be beneficial in treating resistant arrhythmias. Antiarrhythmics, including class 1a, 1c, III, β-blockers and calcium channel antagonists are contraindicated.

Hypotension is treated with intravenous crystalloid (up to 20 to 30 mL/kg). Administration of sodium bicarbonate to obtain an arterial pH of 7.50 to 7.55 is indicated if hypotension persists.

Inotropes are indicated for resistant hypotension despite intravenous fluid administration and serum alkalinization. Noradrenaline is used first line, to treat negative cardiac inotropy and α-receptor–mediated peripheral vasodilatation.

Disposition

Patients who are well with no CNS depression and a normal ECG 6 hours post-reported TCA ingestion are safe for medical discharge. Those with any signs of significant toxicity require admission to a critical care environment.

Monoamine oxidase inhibitors

Pharmacology

Monoamine oxidase inhibitors (MAOIs) either reversibly or irreversibly inhibit function of the enzymes monoamine oxidase A and B (MAO-A, MAO-B), leading to increased CNS concentrations of adrenaline, noradrenaline, serotonin and dopamine. The pharmacodynamic effects of nonselective irreversible MAOIs (including phenelzine and tranylcypromine) are not overcome until MAO is resynthesized, resulting in dose-dependent toxicity that may last for days. Moclobemide, a selective reversible inhibitor of MAO-A, is more benign in OD, but may cause severe serotonin toxicity when combined with other serotonergic agents.

The MAOIs are well absorbed orally, undergo extensive first-pass metabolism, readily cross the blood–brain barrier and have moderate volumes of distribution. Peak concentrations occur within 2 or 3 hours of ingestion. Metabolites are renally eliminated.

Clinical features

OD of irreversible MAOIs is characterized initially by peripheral sympathomimetic stimulation and CNS excitation.[6] Symptoms do not usually manifest until 6 to 12 hours post-OD, but may be delayed up to 24 hours. Initial symptoms include nausea, headache, palpitations, agitation and restlessness. Initial signs include tachycardia, hyperreflexia, mydriasis, fasciculations and nystagmus. As toxicity progresses, there is progressive muscle rigidity, respiratory failure, decreasing conscious state, hyperthermia, rhabdomyolysis, coma and cardiovascular collapse. Clinical toxicity may last for days.

Lone OD of the reversible selective MAOI moclobemide generally produces only mild symptoms including tachycardia, nausea and anxiety.[7] OD of moclobemide with another serotonergic agent may lead to significant serotonin toxicity.

MAOI adverse effects in therapeutic doses include the development of serotonin toxicity when combined with other serotonergic agents. The tyramine reaction may occur following ingestion of tyramine-containing foods. Tyramine is an indirect-acting sympathomimetic. MAOI inhibition of tyramine metabolism can lead to a hyperadrenergic crisis with severe hypertension, intracranial haemorrhage, renal failure, disseminated intravascular coagulopathy (DIC) and rhabdomyolysis.

Treatment

Management of MAOI toxicity is primarily supportive. Patients presenting within 2 hours of ingestion of a MAOI may benefit from administration of activated charcoal. Patients with evidence of severe toxicity are managed in a resuscitation area with particular attention to supporting organ function and limiting complications. Hypertension is initially treated using titrated doses of intravenous benzodiazepines. Refractory hypertension requires treatment with short-acting antihypertensive agents such as intravenous nitrates or sodium nitroprusside, because of possible hypotension occurring as clinical toxicity progresses. Beta-adrenergic blockers are contraindicated; unopposed α-receptor stimulation may worsen toxicity. Hypothermia unresponsive to sedation with benzodiazepines must be treated aggressively along conventional lines. Serotonin toxicity requires specific care as outlined below. Moclobemide toxicity usually only requires supportive care.

Disposition

Patients who remain clinically well 6 hours post-ingestion of moclobemide or 12 hours post-ingestion of phenelzine or tranylcypromine are safe for medical discharge. Patients who are symptomatic following OD of an irreversible MAOI require admission to an intensive care unit.

Selective serotonin reuptake inhibitors

Selective serotonin reuptake inhibitors (SSRIs) are associated with fewer adverse effects both in therapeutic use and OD compared to TCAs.[8] They are utilized in treating depression, obsessive–compulsive disorder, panic/anxiety disorders, eating disorders and chronic pain syndromes. Box 25.4.2 lists SSRIs available in Australia.

Box 25.4.2 Serotonin reuptake inhibitors available in Australia

Selective serotonin reuptake inhibitors
Citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline

Combined selective serotonin and noradrenaline reuptake inhibitors
Venlafaxine, desvenlafaxine, duloxetine, reboxetine

Pharmacology

SSRIs increase synaptic concentrations of serotonin in the CNS via interaction with G-protein–coupled serotonin receptors. With extended use, downregulation of serotonin inhibitory autoreceptors occurs, leading to increased serotonin synthesis and decreased reuptake.

SSRIs are well absorbed post-ingestion. SSRIs and metabolites are substrates for and inhibitors of numerous hepatic microsomal enzymes, the most important being CYP2D6. Hepatic metabolism produces various metabolites; many are active and capable of prolonging therapeutic effect and also increasing the probability of adverse drug interactions.

Clinical features

Therapeutic use of SSRIs is associated with headache, insomnia, sexual dysfunction, gastrointestinal symptoms, dizziness and fatigue. Serotonin toxicity can occur in therapeutic use if exposure to another serotonergic agent occurs.

OD of a single SSRI is rarely associated with severe adverse effects. Mild CNS depression may occur, but is not severe. Nausea, vomiting, tachycardia, diaphoresis and dizziness are reported, but are generally mild and self-limiting.

Severe toxicity is more likely to occur with co-ingestion of another serotonergic agent, leading to serotonin excess. Box 25.4.3 lists selected drugs associated with serotonin toxicity. Serotonin syndrome is comprised of a cluster of clinical effects which vary in pattern and intensity. Clinical findings affect three distinct systems: autonomic, neuromuscular and CNS. Tremor, hyperreflexia, diaphoresis and clonus are commonly seen with mild–moderate serotonin excess. Life-threatening toxicity is characterized by hyperthermia, autonomic instability,

Box 25.4.3 Selected drugs associated with serotonin toxicity

Increased serotonin production and release
Tryptophan, lysergic acid diethylamide

Increased release of stored serotonin
Amphetamines (including MDMA (3,4-methylenedioxy-methamphetamine)), cocaine, lithium, mirtazapine

Impaired reuptake of serotonin into presynaptic nerve
Selective serotonin reuptake inhibitors (fluoxetine, citalopram, sertraline, fluvoxamine, paroxetine), bupropion, fentanyl, cocaine, tramadol, venlafaxine

Inhibition of serotonin metabolism
Monoamine oxidase inhibitors (moclobemide, phenelzine, tranylcypromine), methylene blue, linezolid

cardiovascular dysfunction, multiorgan failure, seizures and rigidity.

Citalopram and escitalopram prolong myocardial cell repolarization by blocking myocardial cell potassium channel efflux. QT prolongation and torsades des pointes have been reported following citalopram and escitalopram OD.

Treatment

Activated charcoal is only indicated following massive ingestion of an SSRI within the previous hour. Administration of activated charcoal up to 4 hours following ingestion of >300 mg escitalopram or >600 mg citalopram reduces the risk of QT interval prolongation.

Treatment is primarily supportive. Patients with clinical signs of mild–moderate serotonin excess typically only require titrated doses of benzodiazepines for symptom relief. Some patients may benefit from administration of a Serotonin 2A receptor ($5HT_{2a}$) antagonist such as cyproheptadine or chlorpromazine. Patients with severe serotonin toxicity require admission to an intensive care unit.

Regular ECGs and cardiac monitoring are indicated following ingestion >1000 mg citalopram (or 600 mg if activated charcoal has not been given within 4 hours of ingestion) or >400 mg escitalopram (or 300 mg if activated charcoal has not been given within 4 hours of ingestion). Cardiac monitoring is continued for at least 12 hours post-exposure in these cases or until the QT interval has normalized.

Combined serotonin and noradrenaline reuptake inhibitors

Duloxetine, reboxetine, venlafaxine, desvenlafaxine are the combined selective serotonin and noradrenaline reuptake inhibitor (SNRI) antidepressants available in Australia. The analgesic agent tramadol is also an SNRI.

Pharmacology

SNRIs inhibit both serotonin and noradrenaline reuptake in the CNS. Rapid downregulation of β-adrenergic receptors may increase the speed of onset of therapeutic effect compared to SSRIs.

SNRIs are rapidly absorbed after oral administration and are hepatically metabolized. Desvenlafaxine and venlafaxine are only available in Australia in modified release formulations.

Clinical features

OD produces an increase in synaptic concentrations of both noradrenaline and serotonin, with clinical features indicative of serotonin and sympathomimetic toxidromes. Onset of clinical effects including tachycardia, tremor, nausea, vomiting, dizziness and agitation may be delayed following ingestion of modified release preparations. Serotonin syndrome has been reported in 30% of patients following venlafaxine OD. Sedation is observed following large venlafaxine ingestions, and is likely due to histamine receptor antagonism. Venlafaxine is associated with a dose-dependent risk of seizures, with a risk of 5% and 75% following ingestions of 1 and 10 g, respectively. Seizures may be delayed up to 24 hours post OD. Hyperthermia and rhabdomyolysis may occur with large ingestions.

Severe cardiovascular toxicity is rare, except in massive SNRI ingestions (>8 g of venlafaxine).[9] QRS prolongation has been reported in patients following ingestion of >5 g of venlafaxine. QT interval prolongation has also been reported following venlafaxine OD. Cardiovascular dysfunction (cardiac failure, hypotension) has been reported in ingestions of >3 g of venlafaxine. Takotsubo cardiomyopathy has been reported in venlafaxine and desvenlafaxine therapeutic and supratherapeutic exposures. Desvenlafaxine is more potent than venlafaxine therapeutically (50 mg desvenlafaxine is equivalent to 75 mg venlafaxine) and therefore thresholds for toxic effects are likely to be lower with desvenlafaxine. Co-ingestion of another serotonergic agent may increase the risk of severe toxicity.

Treatment

Following large ingestions of SNRIs, patients should be managed in an area equipped with cardiac monitoring and facilities to manage seizures. Administration of activated charcoal may be beneficial if administered up to 1 and 4 hours post-ingestion of a standard-release and modified-release SNRI formulation, respectively. Patients requiring intubation should receive a single dose of activated charcoal via a nasogastric tube. Intubation and administration of activated charcoal within 4 hours of ingestion of >5 g of venlafaxine or >5 g of tramadol should be considered.

Agitation should be controlled using incremental doses of benzodiazepines. Seizures are normally self-limiting, but may require treatment with intravenous benzodiazepines.

Hypotension is treated initially with intravenous fluid. Arrhythmias associated with QRS prolongation should be treated with sodium bicarbonate (see Tricyclic Antidepressant section).

Disposition

Patients should be observed for at least 6 hours post-ingestion of standard release preparations and 16 hours post-ingestion of modified release preparations or until clinically well. Cardiac monitoring is indicated following large ingestions (>5 g venlafaxine). Ingestion of >5 g of venlafaxine mandates 24 hours of observation due to the risk of delayed seizures.

Mirtazapine

Mirtazapine is a tetracyclic antidepressant which acts as an antagonist at CNS α-receptors (α_2-> α_1), increasing release of serotonin and noradrenaline. Mirtazapine does not act as a serotonin reuptake inhibitor, and is a $5\text{-}HT_{2a}$ and $5\text{-}HT_3$ receptor antagonist. Mirtazapine has antihistamine receptor activity, leading to sedation in OD. Bioavailability is limited by high first-pass metabolism; however, this is saturatable, potentially leading to increased bioavailability in large ingestions.

OD of mirtazapine typically only causes minor effects including minor sedation, tachycardia and hypertension. Seizures and significant cardiovascular toxicity have not been reported. Treatment is supportive.

Bupropion

Pharmacology

Bupropion is a drug with a unicyclic structure used as a smoking cessation aid in Australia and as an antidepressant in a number of other countries. It has a structure similar to amphetamine and inhibits reuptake of dopamine, with a lesser effect on noradrenaline and serotonin. Bupropion is only available as a modified-release preparation in Australia. Bupropion and its active metabolite hydroxyl-bupropion have half-lives of approximately 20 hours. Mild anticholinergic properties may be evident following OD. Bupropion OD is characterized by a high risk of seizures; studies suggest hydroxyl-bupropion is responsible.

Clinical features

In therapeutic doses, bupropion may cause mild hypertension, postural hypotension, headache, agitation, seizures and gastrointestinal irritation.[10] Cardiac conduction abnormalities are not reported in therapeutic dosing.

Tachycardia, hypertension, nausea, vomiting, tremor and hallucinations may be observed following bupropion OD; however, severe agitation and seizures are the most significant clinical features; seizures are typically delayed up to 6 to 8 hours (in some cases up 16 hours) post-exposure and are dose dependent. In a series of 59 patients presenting following OD of modified release bupropion, seizures occurred in 30% of those ingesting <4.5 g, 50% with 4.5 to 9 g ingested and 100% of individuals who ingested >9 g.

QT and QRS prolongation, arrhythmias and hypotension have been reported following ingestions of >9 g of bupropion. Deaths have been reported following massive ingestions.

Treatment

Provision of meticulous supportive care is the mainstay of management. Patients should be managed in a monitored area with resuscitation

facilities available in case of seizures or cardiovascular deterioration. Activated charcoal should be considered in cooperative patients within 4 hours of ingestion. Intravenous benzodiazepines should be administered in incremental doses to control agitation, as it may increase the threshold for seizure activity. Resistant agitation may require sedation and intubation. Seizures are managed using benzodiazepines.

Hypotension is initially treated with intravenous crystalloid. QRS prolongation is treated with intravenous sodium bicarbonate (see Tricyclic Antidepressant section).

Disposition

Patients who are well with a normal ECG and no agitation or seizures 16 hours post-bupropion exposure are safe for medial discharge. Patients with significant agitation, ongoing seizures, or cardiovascular instability require admission to an intensive care unit.

25.5 Lithium

Jessamine Soderstrom

ESSENTIALS

1 **Chronic lithium toxicity is associated with significant morbidity and mortality, especially where diagnosis and treatment are delayed.**

- **a** **The diagnosis of lithium intoxication needs to be considered in any patient on lithium, and a serum lithium undertaken.**
- **b** **It usually develops due to impaired lithium excretion. The underlying factors must be identified and corrected.**
- **c** **It presents with neurological dysfunction.**
- **d** **Serum lithium levels have limited correlation with central nervous system levels and clinical severity.**

2 **Acute lithium overdose (in patients naïve to lithium), unless massive (>25 g) has a more benign course.**

- **a** **Gastrointestinal symptoms with nausea, vomiting and diarrhoea are common.**
- **b** **Serum lithium levels may be useful in monitoring the effectiveness of therapy but may not reflect clinical severity.**

3 **Acute on chronic lithium toxicity.**

- **a** **Their total body burden of lithium is potentially higher—hence the risk of neurotoxicity.**
- **b** **Vigilance is needed looking for signs of neurotoxicity.**

4 **Haemodialysis effectively enhances lithium elimination but is rarely required in patients with normal renal function. This intervention is more likely to be necessary in patients with impaired renal function or increasing evidence of neurotoxicity in chronic intoxication, and rarely in acute overdose.**

Introduction

Lithium, the metal with the lowest molecular weight, is usually dispensed as carbonate salt. It is widely used in the therapy of bipolar disorder and a number of other conditions. Both immediate-release and sustained-release preparations are available. This drug has a relatively narrow therapeutic index and chronic intoxication develops relatively frequently. Acute overdose is less common.

Pharmacokinetics

Standard lithium preparations are rapidly and completely absorbed after oral administration with peak serum levels occurring at 2 to 4 hours. Absorption and time to peak level is delayed after administration of sustained-release preparations and following overdose. Once absorbed, lithium is slowly redistributed from the intravascular space to the total body water. Lithium has a three-compartment model of distribution, which is helpful in assisting when thinking about the ongoing management and removal of lithium (Fig. 25.5.1).

Lithium is not metabolized and its elimination is almost exclusively renal. It is freely filtered at the glomerulus but, under normal circumstances, approximately 80% of filtered ions are reabsorbed in the proximal tubule and only 20% are excreted in the urine. Under these circumstances, renal clearance of lithium is approximately 10 to 40 mL/min and its elimination half-life is 20 to 24 hours.

Clinical features

Acute lithium overdose

Patients who take a significant overdose of lithium carbonate as with any other metal salt, develop rapid onset of gastrointestinal toxicity characterized by nausea, vomiting, abdominal pain and diarrhoea. This gastrointestinal disturbance can be very severe and may result in significant fluid and electrolyte losses. It is usually observed where more than 25 g are ingested but can occur following smaller doses. Gastrointestinal upset is not a prominent feature of chronic lithium toxicity.

Acute lithium overdose is much less likely to result in significant neurotoxicity than is chronic lithium toxicity. Neurotoxicity can develop following massive acute overdose if renal clearance is sufficiently impaired so as to allow redistribution of sufficient lithium from the intravascular compartment to tissue compartments before it can be excreted. This situation may develop if there is pre-existing renal failure, dehydration from gastrointestinal loss, sodium depletion or acute on chronic lithium toxicity.

Chronic lithium toxicity

Chronic lithium toxicity may develop in association with prolonged excessive dosing or, more commonly, as a result of impaired lithium excretion due to intercurrent illness or a drug interaction. Lithium excretion is impaired in renal failure and congestive cardiac failure because of reduced filtration at the glomerulus, and in water or sodium depletion states because of increased reabsorption of sodium (and lithium) in the proximal tubule. A number of drugs, including non-steroidal anti-inflammatory drugs (NSAIDs), selective serotonin reuptake inhibitors (SSRIs), neuroleptics, angiotensin converting enzyme (ACE) inhibitors, thiazide diuretics and topiramate, may either impair lithium excretion or exacerbate its toxicity.

The clinical features of chronic lithium toxicity are almost exclusively neurological and the following severity grading system is widely used:

- Grade I (mild): nausea, vomiting, tremor, hyperreflexia, agitation, muscle weakness, ataxia
- Grade II (serious): stupor, rigidity, hypotonia, hypotension
- Grade III (life threatening): coma, seizures, myoclonia, cardiovascular collapse.

The neurological manifestations of lithium toxicity may persist and may be permanent. There are distinctive histopathological abnormalities in the cerebral and cerebellar tissues.

The differential diagnosis for this presentation is broad and includes non-convulsive status epilepticus, serotonin and neuroleptic malignant syndromes, electrolyte abnormalities and central nervous system (CNS) pathologies, such as sepsis.

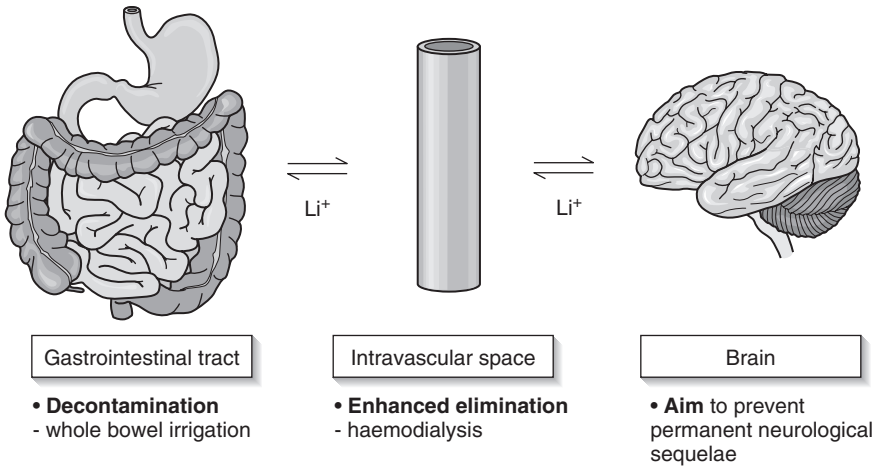

FIG. 25.5.1 Lithium: the three-compartment model of distribution.

While minor benign ECG changes may be observed, lithium toxicity is generally not associated with significant cardiovascular effects.

Chronic lithium therapy is also associated with nephrogenic diabetes insipidus and thyroid dysfunction, which may complicate the clinical presentation of toxicity.

Clinical investigations

Essential laboratory investigations in the assessment of lithium toxicity are serum electrolytes, renal function and serum lithium concentration. Serial serum lithium concentrations are often required. Other investigations are performed as indicated to evaluate and manage intercurrent disease processes and to exclude important differential diagnoses.

Therapeutic serum lithium concentrations are generally quoted as 0.6 to 1.2 mEq/L, although clinical evidence of lithium toxicity can be observed at concentrations within this range, particularly in the elderly. More commonly in cases of chronic intoxication, mild toxicity is observed at lithium concentrations of 1.5 to 2.5 mEq/L, severe toxicity at concentrations of 2.5 to 3.5 mEq/L and life-threatening toxicity at concentrations >3.5 mEq/L. Following acute overdose, serum lithium concentrations do not correlate with clinical severity as they do not reflect CNS concentrations; however, when performed serially, they are useful in guiding management. Peak serum lithium concentrations >4.0 mEq/L are frequently observed following acute overdose in patients who do not go on to develop neurotoxicity. Serum levels in chronic toxicity are more equilibrated with and therefore more accurately reflect CNS levels.

Treatment

Acute lithium overdose

The vast majority of acute poisonings can be managed solely with good supportive care. Intravenous access should be established and infusion of normal saline commenced during the initial assessment. Administration should be sufficient to correct any sodium or water deficits arising as a result of the toxic gastroenteritis and to ensure a good urine output. Excessive administration of normal saline or attempts at forced diuresis do not further enhance lithium excretion. A serum lithium concentration, renal function and electrolytes should be performed as part of the initial assessment and repeated as necessary to guide further management. In particular, the serial serum lithium levels every 6 hours should be followed falling and <2 mEq/L.

Activated charcoal does not bind lithium well and not be administered unless there has been a significant co-ingestion. Whole-bowel irrigation has been recommended for a large overdose of extended-release preparations.

Haemodialysis is rarely indicated following acute overdose in the patient with normal renal function who receives good supportive care. It may be necessary in the presence of renal failure or in the patient post-massive ingestion who goes on to develop neurotoxicity in the presence of a slowly falling serum lithium concentration.

Chronic lithium toxicity

The diagnosis of lithium toxicity should be considered in any individual on lithium therapy who presents to the emergency department unwell, in particular with evidence of neurological dysfunction. The diagnosis should be confirmed or excluded by ordering a serum lithium concentration as part of the initial work-up. A intercurrent illness that has resulted in impaired lithium excretion will usually be present and require assessment and treatment on its own merits.

Appropriate supportive care measures should be instituted on arrival. Once the diagnosis of chronic lithium toxicity is confirmed, further care is orientated towards management of the precipitating medical condition and enhancing lithium excretion by optimizing renal function and correcting any water or sodium deficits with intravenous normal saline. Therapy with lithium carbonate and any drugs contributing to lithium toxicity should be immediately discontinued.

Enhanced elimination of lithium by haemodialysis should be considered in severe or worsening chronic lithium neurotoxicity. The aim of this intervention is to minimize the duration of neurological dysfunction and to avoid permanent neurological sequelae. Lithium has physicochemical and pharmacokinetic properties that render it suitable for enhancing elimination by haemodialysis: low molecular weight, high water solubility, small volume of distribution, no plasma protein binding and an endogenous renal clearance rate much lower than that achieved by haemodialysis. However, there is no evidence in chronic lithium toxicity that haemodialysis improves clinical outcome or survival rates.

The indications for haemodialysis are difficult to define. It should be considered in any patient with an elevated serum lithium concentration and progressive or life-threatening neurotoxicity. It is recommended in the presence of impaired renal function, at lithium levels >4.0 mEq/L, in the presence of severe neurotoxicity or life-threatening dysrhythmias irrespective of lithium levels.

The endpoint of haemodialysis for both acute and chronic intoxication would be when lithium levels <1 mEq/L or clinical improvement is present.

Intermittent haemodialysis is the preferred extracorporeal treatment recommended, but continuous renal replacement therapy is an acceptable alternative (Box 25.5.1).

Box 25.5.1 Executive summary of recommendations from EXTRIP working group

General

ECTR is recommended in patients with Li poisoning (1D)

Indications

ECTR is recommended (1D)

If kidney function is impaired and the [Li^+] >4.0 mEq/L

In the presence of a decreased level of consciousness, seizures or life-threatening dysrhythmias irrespective of [Li^+]

ECTR is suggested (2D)

If the [Li^+] >5.0 mEq/L

If confusion is present

If the expected time to obtain a [Li^+] <1.0 mEq/L with optimal management is >36 h

Cessation of ECTR is recommended

When the [Li^+] <1.0 mEq/L or clinical improvement is apparent

After a minimum of 6 h of ECTR if the [Li^+] is not readily available

After interruptions of ECTR, serial [Li^+] measurements should be obtained over 12 h to determine use of subsequent ECTR sessions (1D)

Choice of ECTR

Intermittent haemodialysis is the preferred extracorporeal treatment (ECTR) (1D)

Continuous renal replacement therapy (RRT) is an acceptable alternative if intermittent haemodialysis is not available (1D)

After initial treatment, both continuous RRT and intermittent haemodialysis are equally acceptable (1D).

(From Decker BS, Goldfarb DS, Dargan PI, et al. Extracorporeal treatment for lithium poisoning: systemic review and recommendations from the EXTRIP Workgroup. *Clin J Am Soc Nephrol.* 2015;10(5):875–887.)

Disposition and prognosis

Patients with chronic lithium intoxication require admission for management of their fluid and electrolyte status, monitoring of renal function, and serum lithium concentration and management of intercurrent illnesses. Ideally, admission should be to an institution with a capacity to perform haemodialysis when toxicity is moderate or severe. Following haemodialysis, neurological recovery may be delayed well beyond the removal of lithium, and permanent neurological deficits have been reported (Syndrome of Irreversible Lithium-Effectuated Neurotoxicity [SILENT]).

Acute lithium overdose usually has an excellent outcome with good supportive care. The patient may be admitted to a non-monitored setting for intravenous fluids and serial measurement of electrolytes and lithium concentration. The asymptomatic patient with normal renal function and a lithium level falling to below 2 mEq/L is fit for medical discharge. This usually occurs within 24 hours. Psychiatric evaluation is mandatory and may take place while waiting for lithium levels to fall.

CONTROVERSIES

- The indications for and preferred method of gastrointestinal decontamination following acute lithium overdose remain undefined.
- The decision to commence haemodialysis in chronic lithium toxicity can be challenging as the clinical picture is often clouded by other confounding clinical factors.

25.6 Paracetamol

Andis Graudins • Anselm Wong

ESSENTIALS

1 **Paracetamol poisoning is one of the most common toxicological presentations to Australasian emergency departments.**

2 **The decision to treat patients with antidotal therapy following acute single ingestions should be made using the paracetamol treatment nomogram.**

3 **Acetylcysteine (NAC) prevents liver toxicity; however, this effect decreases with a delay to treatment. Patients presenting more than 8 hours post-ingestion should have NAC commenced while waiting for the return of serum paracetamol concentrations and liver function tests.**

4 **The paracetamol treatment nomogram cannot be used to assess the risk of hepatotoxicity following repeated supratherapeutic ingestions.**

5 **Paracetamol overdose should be excluded in all patients with suspected deliberate self-poisoning, especially when presenting with an impaired conscious state, and in anyone with evidence of unexplained hepatic impairment on liver function studies.**

6 **A modified-release formulation of paracetamol is available in Australia and exposure to this should be sought when taking the drug history.**

7 **The routinely recommended dose of NAC may not be sufficient to prevent development of hepatotoxicity following massive ingestion of paracetamol (>50 g or 0.5 to 1 g/kg). Clinical toxicologist advice is recommended.**

8 **In patients where timing of paracetamol ingestion or history of exposure cannot be reliably elicited to make a risk assessment, treatment with NAC should be commenced until the infusion is completed or the clinical scenario can be clarified and there is no biochemical evidence of liver toxicity.**

Introduction

Poisoning with paracetamol is common in Australia, as well as other Western countries. In the United States over 100,000 potential paracetamol poisonings are reported annually to the American Association of Poison Control Centers. In the United Kingdom, paracetamol poisoning accounts for over 40% of poisoning exposures presenting to emergency departments.

Pharmacokinetics and pathophysiology

Paracetamol (*N*-acetyl para-aminophenol, acetaminophen) is rapidly absorbed from the gastrointestinal (GI) tract in therapeutic doses with peak plasma concentrations occurring within 30 to 60 minutes with immediate-release tablet formulations and less than 30 minutes with liquid preparations. Bioavailability increases with the size of the dose, ranging from 68% following 500 mg to 90% following 1 to 2 g orally. Time to peak plasma concentration may be delayed in the presence of co-ingestants that delay gastric emptying, such as opioids, antihistamines and other anticholinergic agents. The volume of distribution for paracetamol is approximately 1 L/kg, with around 50% plasma protein binding. Metabolism occurs primarily in the liver with small amounts metabolized renally. Metabolites are renally excreted with less than 4% excreted unchanged in the urine. Elimination half-life is approximately 1.5 to 2.5 hour following therapeutic dosing. Paracetamol is metabolized by three mechanisms. With therapeutic dosing, approximately 60% is conjugated to glucuronide metabolites and 35% to sulphate metabolites. Microsomal enzymes metabolize less than 5% of paracetamol. CYP2E1 is the major iso-enzyme but CYP2A and CYP1A2 are also significant. Microsomal metabolism produces a reactive intermediary metabolite, *N*-acetyl-parabenzoquinoneimine (NAPQI). This is rapidly conjugated with glutathione to produce non-toxic mercapturic acid and cysteine metabolites that are renally excreted. Elimination half-life is the same for adults, children and elderly patients, but may be slightly elevated in neonates.

In overdose, glucuronidation and sulphation pathways are rapidly saturated, resulting in increased metabolism of paracetamol by the microsomal enzyme pathway. From animal studies, when glutathione stores are depleted by more than 70%, NAPQI accumulates in the liver and binds to hepatocytes, resulting in cell death and predominantly centrilobular hepatic necrosis.

Microsomal metabolism of paracetamol may be enhanced by chronic alcohol ingestion or starvation. Inhibition of microsomal metabolism may occur in the presence of acute alcohol ingestion and with the administration of 4-methylpyrazole. Therapeutic doses of cimetidine do not decrease excretion of mercapturate metabolites following therapeutic doses of paracetamol in humans. There are no human studies supporting the use of cimetidine in prevention of hepatotoxicity following paracetamol poisoning.

A modified-release formulation of paracetamol (Panadol Osteo) has been on the market in Australia for the management of arthritis pain since 2002. This formulation contains 665 mg of paracetamol in a bilayer tablet with one-third being immediate-release and two-thirds modified-release. It has been designed to release paracetamol slowly and to maintain a therapeutic concentration for up to 8 hours. Human volunteer data in simulated overdose suggest a delay to, and reduction in, peak paracetamol concentration. Comparison with immediate-release paracetamol at similar doses showed a reduction in peak paracetamol concentration and area under the curve by more than 50%, and a delay to peak paracetamol concentration from 1 to 3 hours. Pharmacokinetic data following deliberate self-poisoning with this formulation suggest that there may be a delay in peak serum concentration, which may go undetected with a single 4-hour serum paracetamol estimation. Panadol Osteo overdose also may be associated with prolonged and biphasic absorption and detectable paracetamol concentrations beyond the duration of the standard 20-hour *N*-acetylcysteine (NAC) treatment protocol. Massive ingestion of immediate-release paracetamol (>50 g), particularly with co-ingestants that slow GI motility (opioids, antihistamines, anticholinergic agents), also can be associated with delayed peak and prolonged elevation of serum paracetamol concentrations.

An isolated small rise in international normalized ratio (INR) has been observed in patients with paracetamol poisoning in the absence of hepatic impairment. Mild elevations in INR and reduced levels of functional Factor VII are observed in up to 66% of patients with an extrapolated 4-hour paracetamol concentration greater or equal to 1000 µmol/L (150 mg/L). This effect is related to the inhibition of vitamin-K-dependent activation of coagulation factors.

Clinical features

The clinical features of early paracetamol poisoning are non-specific and do not permit diagnosis on clinical grounds. Classically, untreated poisoning progresses through four stages of toxicity. Stage 1 lasts about 24 hours and is a subclinical period where the patient may exhibit only mild nausea, vomiting and malaise. During this period, paracetamol is being metabolized, glutathione stores are being depleted and hepatotoxicity is in its early stages. In severe poisoning, mild elevation of hepatic aminotransferases may be apparent as early as 16 hours post-ingestion. In stage 2, nausea and vomiting resolve. Patients may develop right upper quadrant pain and hepatic tenderness 24 to 48 hours post-ingestion. Liver function begins to deteriorate, with increasing aminotransferases, bilirubin and prothrombin time. Stage 3 is essentially a continuum of the above between 72 and 96 hours post-ingestion. Hepatic function deteriorates and chemical hepatitis, jaundice and encephalopathy may develop. Peak aminotransferases are seen around 72 hours post-ingestion. Stage 4 is either the stage of resolution with a fall in aminotransferase concentrations or (Aspartate transaminase (AST) tends to fall earlier than alanine transaminase (ALT)), less commonly, the development of fulminant hepatic failure. Renal failure may also develop as a consequence of paracetamol toxicity. This may either be independent of hepatotoxicity with direct renal toxicity from renal microsomal enzymatic metabolism of paracetamol to NAPQI or as a consequence of liver failure–induced hepato-renal syndrome.

Mitochondrial dysfunction (coma, lactic acidaemia, hypothermia, hyperglycaemia) may result from massive ingestion of paracetamol. This is independent of any hepatic impairment. Patients may present with a high anion gap metabolic acidosis. Other uncommon manifestations of paracetamol overdose may be acute renal failure or pancreatitis.

In general, most patients recover from paracetamol toxicity. The overall untreated mortality is less than 1% and that of untreated patients with hepatotoxicity is around 3.5%.

Assessment of risk of hepatotoxicity

The risk of hepatotoxicity following acute ingestion of paracetamol is dose dependent. In healthy adults, hepatotoxicity may result from ingestion of more than 200 mg/kg or 10 g, whichever is the least. In children less than 6 years old, ingestion of more than 200 mg/kg may result in toxic serum concentrations. The threshold for toxicity may be less in patients with underlying hepatic impairment (e.g. chronic alcoholic liver disease, chronic active hepatitis), severe malnutrition or in the presence of microsomal enzyme-inducing agents.

The paracetamol-treatment nomogram shows a clear relationship between the serum paracetamol concentration and the potential for subsequent hepatotoxicity following a single ingestion of immediate-release paracetamol. The nomogram begins at 4 hours post-ingestion to allow for the absorption and distribution of paracetamol. Serum concentrations taken less than 4 hours post-ingestion may be unreliable in predicting the potential for hepatotoxicity.

The risk of hepatotoxicity from untreated acute paracetamol ingestion can be estimated from the nomogram. Patients with a serum concentration falling above a line from 1300 µmol/L (200 mg/L) at 4 hours post-ingestion to 170 µmol/L (25 mg/L) at 16 hours post-ingestion (the 'probable toxicity' line) will have a 60% chance of developing hepatotoxicity (ALT > 1000 IU/L) if left untreated. This risk increases to 87% in untreated patients with paracetamol concentrations above 2000 µmol/L (300 mg/L) 4 hours post-ingestion. The current 'treatment line' in Australasia is the 'possible hepatotoxicity' line (Fig. 25.6.1), 1000 µmol/L (150 mg/L) at 4 hours post-ingestion to 125 µmol/L (16 mg/L) at 16 hours post-ingestion. This was adopted to allow for errors in calculation of the time of ingestion, provides an additional margin of safety for patients who may possess risk factors, and removes the need for potentially confusing additional lines. The safety of treatment decisions to commence NAC based upon this 1000 µmol/L (150 mg/L) at 4 hours nomogram line has been demonstrated in the United States in over 11,000 patients, where no patients treated with NAC within 15 hours of ingestion died. In contrast, the use of the higher line (1300 µmol/L at 4 hours) has been associated with cases of patients with a serum paracetamol concentration below this line that subsequently developed acute hepatic failure or suffered a fatal outcome.

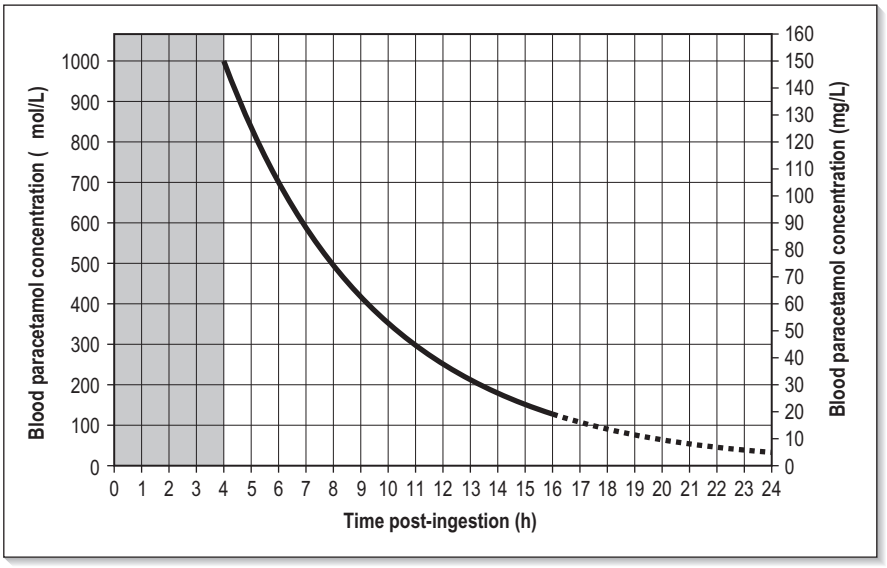

FIG. 25.6.1 Paracetamol treatment nomogram. For use in the risk assessment of acute paracetamol ingestion at a single point in time.

Repeated supratherapeutic dosing with paracetamol is associated with an increased risk of hepatotoxicity, particularly in those with the hepatic risk factors. Liver failure has been reported in retrospective case series with chronic use of as little as 4 g a day in patients with underlying acute illnesses with associated decreased oral intake. However, prospective evaluation of the risk of liver failure with therapeutic doses of paracetamol in chronic alcoholics does not suggest an increased susceptibility to liver failure in this subset of patients. It is important to note that the paracetamol-treatment nomogram is not useful in the assessment of hepatotoxic risk in these patients. In alcoholic patients, markedly raised hepatic aminotransferases (>1000 IU/L) suggest a toxin-induced hepatitis, as seen with paracetamol. Both alcoholic hepatitis and viral hepatitis rarely produce aminotransferase concentrations that are above 1000 IU/L.

Antidotal therapy with acetylcysteine

Acetylcysteine (NAC) is effective at preventing the development of hepatotoxicity (AST or ALT >1000 IU/L) following paracetamol poisoning in the majority of patients. It is metabolized to cysteine in the liver and is a precursor to glutathione, which is necessary for the inactivation of the toxic metabolite NAPQI. Additionally, NAC may act as a substrate for hepatic sulphation, thus reducing the amount of paracetamol being shunted to the microsomal pathway of metabolism. In Australia, NAC has been administered according to the 20-hour intravenous protocol described by Prescott (150 mg/kg over 15 minutes, 50 mg/kg over 4 hours, 100 mg/kg over 16 hours). Increasingly, more centres are adopting a simpler two-bag regimen (200 mg/kg over 4 hours, then 100 mg/kg over 16 hours) due to less frequent and severe adverse reactions and comparable rates of hepatotoxicity to the three-bag regimen. There is no need to empirically to commence NAC therapy in patients presenting within 8 hours of an acute overdose of immediate-release paracetamol. The risk incidence of developing hepatotoxicity when therapy is commenced within 8 hours of ingestion is very low (1% to 6%) and independent of the route of dosing (intravenous vs. oral). The incidence of hepatotoxicity increases to 40% if NAC is delayed from 10 to 16 hours following ingestion and may be as high as 87% if delayed from 16 to 24 hours in patients treated with the 20-hour intravenous regimen. However, NAC probably limits the degree of hepatic damage even in late presenting patients. In addition, the dose of NAC may need to be increased or prolonged beyond the standard 20-hour regimen in cases of massive ingestion of immediate-release or extended-release paracetamol (>50 g) or where serum concentration of paracetamol remains persistently elevated. Clinical toxicologist advice is recommended in these settings.

Adverse reactions to intravenous NAC are either non-immunoglobulin (Ig)E-mediated histamine release-reactions (urticaria, bronchospasm, hypotension), usually occurring during or soon after the administration of the intravenous loading dose or GI reactions (nausea, vomiting) related to sulphydryl groups on the molecule. Adverse reactions also may be seen following administration of oral NAC. These reactions are related to direct histamine release from mast cells. They are dose-dependent in nature and usually respond to slowing or cessation of the infusion for a short period. Occasionally, administration of antihistamines and/or adrenaline may be necessary. The incidence of non-IgE-mediated reactions may be as high as 20%. A prospective study varying the rate of infusion of the NAC loading dose found a small, non-significant difference in the incidence of non-IgE-mediated reactions between the standard 15-minute loading-dose rate to a 1-hour loading-dose rate (18% vs 14%, respectively). A retrospective review of the aforementioned two-bag regimen showed a decrease in severe reactions from 10% to 4% when compared to the original three-bag regimen. The history of a previous adverse reaction to NAC does not preclude its use in the event of subsequent presentations for paracetamol poisoning. Life-threatening reactions are rare but have uncommonly been reported in patients with pre-existing asthma.

Treatment

Management of paracetamol poisoning is tailored according to the specific clinical scenario.

Acute overdose presenting within 8 hours of ingestion

GI decontamination with activated charcoal (AC) should be considered in cooperative patients presenting within 2 hours of ingestion. Early administration of AC may reduce the risk of achieving a toxic 4-hour paracetamol concentration and subsequent need for antidotal therapy. Administration of AC more than 2 hours post-ingestion may be beneficial after massive paracetamol ingestion. Antidotal therapy with NAC is commenced if the serum paracetamol concentration falls above the paracetamol-nomogram line. Clinically well patients treated within 8 hours of ingestion do not require blood tests at the end of their 20-hour NAC infusion if they remain well (no nausea, vomiting, anorexia, abdominal pain or tenderness) and do not fall into one of the at-risk groups that may require prolonged NAC therapy.

Pregnant patients are treated in a similar fashion to other patients. Paracetamol crosses the placenta and in overdose may result in an increased risk of spontaneous abortion.

Acute overdose presenting 8 to 24 hours post-ingestion

In view of the increased incidence of hepatotoxicity with delayed antidote administration, NAC therapy should be commenced on presentation. Blood is then taken for serum paracetamol concentration and liver function tests (LFTs). Antidotal treatment may be ceased if the paracetamol level is non-toxic and liver function is normal. Otherwise, a full 20-hour course of NAC is administered. Prolonged NAC infusion, usually repeating the 16-hour bag (100 mg/kg), is indicated if repeat LFTs indicate rising aminotransferases prior to the end of the 20-hour course.

Acute overdose presenting more than 24 hours post-ingestion

Patients presenting more than 24 hour following paracetamol ingestion may still benefit from antidotal therapy with NAC. Therapy should be commenced if the patient has a detectable serum paracetamol level, there is evidence of aminotransferase elevation suggesting paracetamol hepatic injury or there is clinical evidence of paracetamol hepatotoxicity (nausea, vomiting, right upper quadrant pain). Patients may benefit from prolonged duration of NAC therapy if serum aminotransferases continue to rise after 24 hours of therapy. NAC should be continued at a rate of 100 mg/kg/12 h until INR and liver function begins to normalize or the patient requires liver transplantation.

Acute overdose with unknown time of ingestion

The time of ingestion of a single overdose of paracetamol may be unknown. This may occur in patients with altered mental status from co-ingestants or other causes. In view of the relative safety of NAC as an antidote, it should be commenced empirically in these patients to avoid delayed therapy using the 20-hour NAC regimen. Serum paracetamol, LFTs and INR are assayed. If a more accurate history of non-toxic overdose is elicited, or if aminotransferase enzymes are normal and paracetamol concentration is undetectable at the end of 20 hours of NAC therapy, treatment may be ceased.

The staggered acute overdose

In patients presenting with a history of more than one paracetamol overdose over several hours, a worst-case scenario can be adopted. This is done by assuming that the total dose of paracetamol was ingested as a single-dose at the earliest possible ingestion time and the total

Table 25.6.1 Paracetamol dosing associated with hepatic injury in adults and children over 6 years of age

Acute single ingestion	>200 mg/kg or 10 g (whichever is lower) over a period of <8 h
Repeated supratherapeutic ingestion	>200 mg/kg or 10 g (whichever is lower) over a single 24-h period >150 mg/kg or 6 g (whichever is lower) per 24-h period for the preceding 48 h >100 mg/kg or 4 g/day (whichever is less) in patients with predisposing risk factors (see text)

(Adapted from Dart RC, Erdman AR, Olson KR, et al. Acetaminophen poisoning: an evidence-based consensus guideline for out-of-hospital management. *Clin Toxicol.* 2006;44:1–18.)

ingested dose was greater than 200 mg/kg. The serum paracetamol concentration is plotted on the nomogram based on this time point. Treatment is initiated if it is above the nomogram line.

Repeated supratherapeutic ingestion

Current consensus guidelines suggest that in adults and children over 6 years of age with normal liver function, the risk of hepatic injury may be increased if more than 200 mg/kg or 10 g (whichever is the least) are ingested over a single 24-hour period, or more than 150 mg/kg or 6 g are ingested per 24 hours for the preceding 48 hours. Risk also may be increased in patients with underlying liver impairment ingesting more than 100 mg/kg or 4 g/24 h (Table 25.6.1). In these groups, a biochemical risk assessment should be made. If serum paracetamol is less than 132 µmol/L (20 mg/L) and serum aminotransferases are less than 50 IU/L, no treatment is required. If either assay is elevated, NAC should be commenced and LFTs reassessed after 8 hours. If these are not rising and the patient is well, NAC therapy may be ceased. Otherwise, the full 20-hour course should be administered or continued until aminotransferases begin to fall and INR is normalizing. The reason for analgesic overuse also should be sought and addressed.

Paracetamol-induced hepatic failure

The development of hepatic failure is uncommon following paracetamol poisoning. The risk is greater in late presenting patients. Patients with evidence of developing fulminant hepatic failure following paracetamol poisoning exhibit clinical signs of encephalopathy and liver failure. Poorer prognosis is associated with an INR >3 at 48 hours or 4.5 at any time, hypoglycaemia, severe thrombocytopenia, encephalopathy, serum creatinine >200 µmol/L, systolic blood pressure <80 mm Hg and/or pH < 7.3 despite fluid resuscitation, or rising serum lactate. Patients may benefit from prolonged NAC therapy along with supportive care in a specialized liver unit. A lower mortality is reported in patients with hepatic failure treated with NAC. Early consultation with a liver transplantation unit should be sought.

Modified-release paracetamol ingestion

Delayed peak serum paracetamol concentration and delayed crossing of the nomogram line is possible following overdose with extended-release paracetamol (Panadol Osteo). The administration of NAC more than 20 hours post-ingestion may be of benefit in view of the modified-release nature of this product. To avoid delays in acetylcysteine treatment, this should be commenced if the reported ingested dose is greater than 200 mg/kg or 10 g (whichever is the least). Serum paracetamol concentration should be estimated 4 or more hours post-ingestion and a second estimation collected 4 hours after the first. If both concentrations fall below the nomogram line and are decreasing, treatment may be discontinued, otherwise NAC should be administered for the full 20-hour dose. Larger ingestions (>30 g) of this formulation have the potential to result in prolonged paracetamol absorption and elevated serum concentrations well beyond 20 hours post-ingestion. Serial paracetamol estimations are useful in this setting to ascertain when the concentration falls to an insignificant level. If paracetamol concentration is detectable prior to completion of the 20-hour infusion or if LFTs suggest developing hepatotoxicity, treatment with NAC should continue with a repeat of the 100 mg/kg/16-h infusion until paracetamol concentration is undetectable and/or liver function is normalizing.

Liquid paracetamol ingestion (children <6 years old)

Healthy children (<6 years old) who are suspected of ingesting more than 200 mg/kg of liquid paracetamol can have concentrations measured at 2 hours post-ingestion. If the concentration is less than 1000 µmol/L (150 mg/L), NAC is not needed. If it is above this concentration, then a repeat paracetamol concentration should be measured 4 hours post-ingestion and treatment with NAC commenced if above the same threshold.

Massive ingestions of paracetamol

This may be suspected in three situations: (1) in patients with history of large ingestions of paracetamol (>500 mg/kg or >30 g); (2) where serum paracetamol concentration is very high and suggests a massive ingestion (>3000 µmol/L or 450 mg/L); and (3) in the clinical scenario of coma, unexplained metabolic acidaemia and raised serum lactate concentration. In these cases, the standard NAC dosing regimen may not be adequate to prevent hepatotoxicity developing. Consideration should be given to increasing the dose of NAC, particularly in the 16-hour maintenance infusion. An empiric doubling of the 16-hour infusion dose to 200 mg/kg/16 h is suggested in these cases as it provides more NAC to mitigate hepatotoxicity. Serum paracetamol concentration should be followed serially. If this remains detectable prior to cessation of the 20-hour regimen, NAC treatment should be continued beyond this period, repeating the 16-hour infusion dose, until paracetamol concentration is undetectable and there is no evidence of hepatotoxicity. In addition, haemodialysis can be considered in massive overdoses to normalize lactic acidaemia and to potentially enhance paracetamol elimination. Clinical toxicologist advice is recommended. Prompt initiation of acetylcysteine can prevent the development of hepatotoxicity.

CONTROVERSIES AND FUTURE DIRECTIONS

- Novel acetylcysteine regimens tailored to specific toxicity scenarios are slowly emerging. In the future, NAC dosing and duration may become more individualized based upon the risk of hepatotoxicity. This includes atypical paracetamol poisoning presentations, such as supratherapeutic ingestions, massive overdoses and extended-release paracetamol poisoning.
- The clinical significance of suggested 'risk factors' for the development of hepatotoxicity. Most of the suggested factors are theoretical and have never been validated.
- Variations in international recommendations on the threshold for treatment of acute paracetamol poisoning utilizing different nomogram cut-offs for toxicity.

25.7 Salicylate

Andis Graudins • Digby Green

ESSENTIALS

1 **Salicylate pharmacokinetics become complex and alter markedly following overdose.**

2 **Treatment and disposition decisions are made on clinical signs, biochemistry and serum salicylate level trends.**

3 **The aim of therapy is to minimize metabolic and central nervous system toxicity.**

4 **Urinary alkalinization is an effective method of enhanced elimination after salicylate overdose.**

5 **Mechanical ventilation of patients with severe salicylate toxicity can worsen acidosis due to the impeding of patient-generated high minute volumes with salicylate-induced hyperpnoea.**

6 **Chronic salicylate poisoning is an insidious condition, mostly seen in the elderly, manifested by an unexplained metabolic acidosis that may be incorrectly attributed to another medical condition.**

Introduction

Salicylate is widely used in a variety of pharmaceutical preparations and over-the-counter herbal products, cough and cold remedies, ointments and topical rubefacients. Salicylate poisoning is an infrequent presentation to Australian emergency departments, due largely to the preference of paracetamol as the analgesic of choice. Acute deliberate self-poisoning with salicylate results in a well-described dose-related constellation of symptoms and signs. Emergency physicians have a number of treatment modalities available to manage this condition.

Chronic salicylate intoxication, in contrast, is more likely in the elderly, with multiple co-morbidities and more commonly requires haemodialysis (HD). Chronic intoxication is associated with significant morbidity and mortality. Children rarely ingest sufficient amounts of aspirin to cause toxicity, but ingestion of small amounts (>5 mL) of topical agents containing methyl salicylate can result in severe toxicity in children <5 years of age. Attention should be given to the quoted units of measurement, standard or SI, to avoid incorrect interpretation of serum drug concentrations.

Pharmacology and pathophysiology

Aspirin (acetylsalicylic acid, ASA) is rapidly absorbed in the acid medium of the upper gastrointestinal (GI) tract and undergoes rapid hydrolysis to form salicylic acid. Peak serum salicylate concentration is reached within 2 hours of therapeutic dosing. Absorption is erratic and may be delayed following overdose partly due to pylorospasm and pharmacobezoar formation. Overdose with sustained-release or enteric-coated preparations may delay peak serum concentrations for up to 24 hours.

Salicylic acid has a pKa of 3.0 and exists predominantly in the unionized form at a pH of 7.4. It is highly plasma protein bound (85% to 90%) after therapeutic dosing, with a very small apparent volume of distribution (0.1 to 0.2 L/kg). Plasma protein binding saturates and free salicylate concentration rises in overdose. As pH falls, a greater proportion of salicylate exists in the unionized form, and movement into the extravascular compartments, including the central nervous system (CNS), is enhanced with resulting increases in the volume of distribution and tissue toxicity.

Salicylic acid is metabolized in the liver and kidney, and the conjugates are excreted renally along with small amounts of free salicylate. The elimination half-life following therapeutic dosing is around 4 hours. Salicylate metabolism is saturated when plasma salicylate concentration rises above the therapeutic range. Elimination kinetics change from first-order to zero-order, dramatically increasing the elimination half-life. Urinary excretion of unchanged salicylate is minimal when the urine pH is acidic. As urine pH increases, a greater proportion of filtered salicylate is in an ionized state and is unavailable for reabsorption in the proximal convoluted tubule. An increase in urine pH from 5.0 to 8.0 results in up to 1000-fold increase in ionized salicylate excretion.

At therapeutic doses, salicylate acts as an analgesic, antipyretic, antiplatelet and anti-inflammatory agent primarily by way of its inhibitory effects on prostaglandin synthesis mediated by irreversible inhibition of cyclo-oxygenase enzymes one and two (COX-1 and COX-2). Overdose results in toxic effects on the

Table 25.7.1 Dose-related effect of aspirin toxicity

Dose	*Effect*
<150 mg/kg	Minimal symptoms
150–300 mg/kg	Mild to moderate toxicity Salicylism with hyperpnoea, tinnitus and vomiting
>300 mg/kg	Severe toxicity Hyperpyrexia, metabolic acidosis, altered mental status, seizures
>500 mg/kg	Potentially fatal

CNS, acid–base balance, cellular metabolism, coagulation, lungs and the GI tract. CNS effects include an initial direct stimulation of the medullary respiratory centre producing an increase in rate and depth of respiration and a corresponding primary respiratory alkalosis, tinnitus, deafness and confusion. In severe poisoning, where systemic acidaemia enhances cerebral penetration of unionized salicylate, coma, convulsions and cerebral oedema may occur.

Metabolic effects include direct uncoupling of oxidative phosphorylation and inhibition of Krebs cycle enzymes leading to systemic acidaemia, hyperglycaemia, hyperthermia and derangement of carbohydrate, amino acid and lipid metabolism. Increased oxygen consumption and carbon dioxide production are also apparent. Dehydration results from increased insensible respiratory and cutaneous fluid losses, as well as from nausea and vomiting from GI irritation. Inhibition of platelet aggregation as well as vitamin-K-sensitive clotting factor function may produce a mild coagulopathy. Haemorrhage rarely occurs in humans or animals following severe salicylate poisoning. Salicylate-induced non-cardiogenic pulmonary oedema is also reported in association with severe poisoning.

Clinical features

The degree of toxicity following acute ingestion of salicylate is dose related (Table 25.7.1). The most useful features in risk assessment are the clinical signs and symptoms, the acid–base status, the serum salicylate concentration and the reported dose ingested.

The diagnosis of chronic salicylate poisoning is often missed. Recurrent dosing with aspirin, usually in the context of a viral illness or chronic pain, results in an accumulation of plasma salicylate and prolongation of the elimination half-life. Patients may present with non-specific symptoms or signs suggesting inflammatory or infective aetiology, such as confusion, delirium, fever, dehydration or hyperglycaemia. The history of excessive salicylate ingestion may not be elicited and the clinical findings erroneously attributed to other conditions, such as septicaemia, cardiogenic pulmonary oedema, cerebrovascular accidents or diabetic ketoacidosis. The presence of an unexplained metabolic acidosis may be the vital clue leading to the diagnosis. Delay in the diagnosis of chronic salicylate poisoning is associated with an increased morbidity and mortality.

Clinical investigations

Salicylate intoxication should be suspected in any patient with clinical signs suggestive of poisoning and unexplained respiratory alkalaemia and/or metabolic acidosis. Patients in whom the diagnosis is suspected should have blood drawn for serum electrolytes, urea, creatinine, blood glucose, international normalized ratio, serum paracetamol and salicylate concentration. An arterial or venous blood gas is necessary to assess acid–base status, and urine pH should be checked.

Patients with mild or early poisoning may present with a pure respiratory alkalosis due to respiratory centre stimulation and hypokalaemia. Urine pH may initially be alkaline as a response to hyperventilation. Adult patients with moderate-to-severe poisoning may present with a mixed acid–base disturbance of respiratory alkalosis and metabolic acidosis. Urine pH is commonly acidic in this setting due to increased excretion of hydrogen ions. Altered mental status with a metabolic acidosis with normal or falling serum pH signifies development of potentially severe salicylate poisoning. Co-ingestion of sedatives may depress respiratory drive leading to loss of respiratory compensation for the metabolic acidosis and an earlier deterioration in acid–base status.

The combined use of serial clinical observation, blood-gas estimations and serial salicylate measurements to monitor for ongoing absorption of aspirin will give the best indication of the degree of toxicity and the response to treatment.

Treatment

Patients presenting following salicylate ingestion should have intravenous access established, and blood drawn for serum salicylate estimation, electrolytes and blood sugar level. In moderate-to-severe poisoning these should be repeated every 3 to 4 hours in view of the potential erratic salicylate absorption. Intravenous rehydration is often necessary in view of the increased insensible fluid losses due to hyperventilation and pyrexia and vomiting from GI irritation. Attention to fluid balance is particularly important in the very young, the elderly or those with cardiac disease. Central venous and arterial pressure monitoring may be necessary in severe cases, as well as urinary catheterization and hourly urine measurement.

GI decontamination with activated charcoal should be performed on presentation, even in patients who present several hours following ingestion, in view of the potential for delayed aspirin absorption. Whole-bowel irrigation with polyethylene glycol-electrolyte solution may be considered in patients with ingestion of large amounts of enteric-coated or sustained-release formulations aspirin. One or two repeated doses of activated charcoal may be of benefit when ongoing absorption of salicylate is suggested by rising serial serum concentrations. Multiple-dose activated charcoal does not enhance salicylate elimination but may inhibit ongoing GI absorption from pharmacobezoars or aspirin concretions.

Pulmonary oedema should be treated with continuous positive pressure ventilation by mask or endotracheal intubation. Salicylate poisoning results in high minute volumes and respiratory alkalosis. Ventilation strategies are aimed at providing appropriate positive ventilation and preventing respiratory acidaemia. Seizures should be treated with parenteral benzodiazepines.

Urinary salicylate excretion can be enhanced by urinary alkalinization, which may reduce salicylate elimination half-life from 20 to 5 hours. The aim of urinary alkalinization is to increase urine pH above 7.5 to enhance the trapping of ionized salicylate in the urine. Indications include the presence of symptoms such as tinnitus, acid–base abnormalities or serum salicylate concentrations greater than 2.2 mmol/L (30 mg/dL). Patients with clinical symptoms and signs of salicylate toxicity should have urinary alkalinization commenced while awaiting blood test results.

Urinary alkalinization can be accomplished by an initial loading dose of intravenous sodium bicarbonate (0.5 to 1.0 mmol/kg) followed by an infusion of 100 to 150 mmol of sodium bicarbonate in 1 L of 5% dextrose solution at a rate of 100 to 250 mL/h adjusted to urine pH. Urine output should be maintained between 1 and 2 mL/kg/h. Serum potassium should be maintained within normal limits by the provision of supplemental potassium replacement. In the presence of systemic hypokalaemia, potassium ions are retained by the renal tubules in preference to hydrogen. This

Box 25.7.1 Indications for haemodialysis in salicylate poisoning

- Worsening metabolic acidosis despite supportive care and urinary alkalinisation
- Evidence of end-organ injury (i.e. cerebral oedema, seizures, rhabdomyolysis, pulmonary oedema)
- Renal failure and/or fluid overload
- Serum salicylate concentration >6.0 mmol/L or 100 mg/dL in acute poisoning
- Serum salicylate concentration >4.0 mmol/L or 60 mg/dL in chronic poisoning

Note: In elderly patients with chronic salicylate toxicity and metabolic acidaemia, the suggested serum threshold for haemodialysis may be lower than 4.4 mmol/L (60 mg/dL).

makes it extremely difficult to alkalinize the urine. Serial serum electrolytes, salicylate concentrations and urinary pH should be measured every 3 to 4 hours. The endpoints for therapy include: decreasing serum salicylate concentrations in the therapeutic range (1.1 to 2.2 mmol/L or 15 to 30 mg/dL), resolution of clinical signs of toxicity and normalization of acid–base status.

Extracorporeal removal of salicylate is infrequently required and the accepted clinical indications are listed in Box 25.7.1. Intermittent high-flow HD is the preferred option as it can rapidly normalize acid–base, fluid balance and electrolyte abnormalities, as well as remove salicylate from the blood. Sustained low efficiency haemodialysis (SLED) may be considered in the absence of the above. However, data are sparse on the effectiveness of this modality in severe poisoning.

Severe cases of salicylate intoxication may require endotracheal intubation and ventilation as a direct result of toxicity or co-ingestants. Intravenous sodium bicarbonate (1 to 2 mmol/kg) loading prior to intubation can be administered. Hyperventilation will be required to maintain the high minute volumes patients spontaneously generate to produce respiratory alkalaemia. In such severe cases of poisoning, continued urinary alkalinization and HD will be essential to treat worsening metabolic acidosis.

Disposition

In view of the potential for delayed and erratic salicylate absorption, patients require serial salicylate concentrations and observation for a minimum of 12 hours. Salicylate estimations earlier than 6 hours post-ingestion do not usually reflect peak serum concentrations following overdose.

Patients without clinical evidence of salicylate toxicity may be medically cleared in the presence of normal venous blood gas and two falling serum salicylate levels in or below the therapeutic range (1.1 to 2.2 mmol/L; 15 to 30 mg/dL) 3 to 4 hours apart. Patients with evidence of acid–base abnormalities, end-organ dysfunction, or who require urinary alkalinization should be admitted to a high-dependency or intensive care unit. Transfer to a tertiary referral centre with facilities for HD should be considered if criteria for severe toxicity are present.

CONTROVERSIES

- The threshold for initiating urinary alkalinization is not well defined. Many toxicologists recommend commencing urinary alkalinization in any symptomatic patient with a view to minimizing the duration of medical admission.
- Although there is minimal case-controlled evidence supporting the use of continuous veno-venous haemodialysis (CVVHD) in severe salicylate poisoning, newer high-flow veno-venous haemodialysis units, such as SLED, may remove significant amounts of salicylate and provide an alternative to intermittent high-flow dialysis in cases where this is not easily accessible.

25.8 Antidiabetic drugs

Jason Armstrong

ESSENTIALS

1 **Deliberate self-poisoning with insulin or sulphonylureas may lead to life-threatening hypoglycaemia requiring prolonged observation and treatment over several days.**

2 **Octreotide blocks endogenous insulin secretion and is indicated in the management of symptomatic sulphonylurea toxicity.**

3 **Central venous access is often required following deliberate insulin overdose to facilitate treatment with concentrated glucose solutions.**

4 **Metformin is associated with life-threatening lactic acidosis. It does not cause significant hypoglycaemia in overdose.**

Introduction

Diabetes mellitus (DM) is a chronic metabolic condition caused by an absolute (type I) or relative (type II) lack of insulin. In Australia, more than 1 million people have diabetes and 100,000 people are diagnosed every year with the condition. Indigenous and Māori populations in Australasia have some of the highest rates of type II diabetes in the world.[1] For these reasons, antidiabetic medications are readily available and frequently taken in overdose both by diabetic and non-diabetic individuals.

The three major groups of antidiabetic medications are insulin, sulphonylureas and biguanides, all of which have been used for more than 50 years. Toxicity can result from intentional overdose, but also from decreased clearance of the medication at therapeutic dosing, due to underlying hepatic or renal disease.

A number of new agents for type II DM have been developed recently, including dipeptidyl peptidase-IV (DPP-IV) inhibitors, incretin mimetics, thiazolidinediones, alpha-glucosidase inhibitors, glinides and sodium–glucose cotransporter 2 (SGLT2) inhibitors. Overdose with these medications is less likely to cause significant clinical effects.

INSULIN

Pharmacology and pathophysiology

Insulin is synthesized by the pancreatic β islet cells as a pro-hormone packaged inside secretory vesicles. It is secreted primarily in response to elevated serum glucose levels and becomes metabolically active when pro-insulin is cleaved by serum proteases to form insulin and C-peptide. Exogenous insulin, administered therapeutically in the management of type I and II DM, does not contain C-peptide.

Insulin is eliminated by hepatic metabolism (60%) and renal clearance (40%). A number of preparations are available, and these have varying durations of action. However, following overdose, the usual pharmacokinetic properties of insulin may be altered because the injected dose forms a subcutaneous or intramuscular depot. Slow and erratic release of insulin from the depot can result in a markedly extended duration of action (up to several days), even with short-acting preparations.[2]

Insulin promotes the intracellular movement of glucose, potassium, magnesium and phosphate, as well as decreasing ketone production from the breakdown of fatty acids. It inhibits gluconeogenesis (the breakdown of fat and protein to release glucose) and stimulates the synthesis of glycogen, protein and triglycerides.

In overdose, the principal effect of clinical significance is hypoglycaemia, which may be profound and prolonged following self-administration of large doses subcutaneously or intramuscularly. Hypoglycaemia tends to be more profound and prolonged in non-diabetic patients.[3] Insulin toxicity also causes electrolyte abnormalities, the most important of which is hypokalaemia, secondary to intracellular shift of potassium. Hypophosphataemia and hypomagnesaemia are also reported.

Clinical features

The clinical features of insulin toxicity are the neuropsychiatric and autonomic manifestations of hypoglycaemia. Autonomic symptoms and signs include diaphoresis, tremor, nausea, palpitations and tachycardia; neuropsychiatric features are confusion, agitation, seizures, coma and focal neurological deficits. These manifestations are usually evident within hours of self-administration of an insulin overdose and the patient frequently presents in coma. The suspicion of deliberate overdose is entertained when recurrent profound hypoglycaemia occurs following an initial response to dextrose administration. If the history of deliberate overdose is known at the time of presentation, then profound, prolonged hypoglycaemia should be anticipated.

The reported dose of self-administered insulin should be compared to the daily therapeutic dose prescribed for the patient, if this is known or relevant. This will inform the risk assessment for the likely severity and duration of toxicity. Prolonged severe hypoglycaemia can cause permanent neurological sequelae or death.

Clinical investigations

Serial measurement of blood glucose concentrations, usually at the bedside, allows titration of dextrose administration. Serial measurements of electrolytes are necessary to monitor hypokalaemia and potassium replacement. Serum magnesium and phosphate levels may also be affected.

If surreptitious or malicious administration is suspected, assays of insulin and C-peptide levels can be useful to provide objective evidence of the presence of exogenous insulin, as endogenous insulin levels should always be suppressed in the presence of hypoglycaemia unless an insulinoma is present.

Treatment

Management of insulin overdose is essentially supportive and requires the administration of sufficient concentrated dextrose solution to maintain euglycaemia until all the insulin is absorbed from the depot site and its hypoglycaemic action terminated. After initial resuscitation to correct hypoglycaemia with 50% dextrose, a 10% dextrose infusion should be commenced at 100 mL/h and blood sugar levels followed closely. Further boluses of dextrose and titration of the infusion rate are implemented as necessary.

Very large doses of dextrose may be required, sometimes over days.[2,3] Frequently, it is necessary to administer a 50% dextrose infusion to maintain euglycaemia, and this usually requires placement of a central venous or peripherally inserted central catheter (PICC) line, because concentrated dextrose solutions can cause sclerosing thrombophlebitis in peripheral veins.

Oral feeding with complex carbohydrates is an important aspect of management in addition to intravenous therapy—this provides more physiological stabilization of blood sugar levels than parenteral administration of dextrose.

Hypokalaemia due to intracellular shifts should be anticipated and supplemental K^+ administered (e.g. 10 to 40 mmol/h IV in adults), guided by serial monitoring. Excessive K^+ administration should be avoided. Hyponatraemia and volume overload are other complications of hypertonic dextrose therapy.

Disposition

Patients who report an overdose of insulin should be admitted and observed with bedside blood glucose assays for at least 8 hours after self-administration. They are medically fit for discharge if they remain asymptomatic and euglycaemic at this stage. Those who develop hypoglycaemia requiring dextrose therapy should be admitted to a high-dependency or intensive care unit for ongoing dextrose infusion, potassium supplementation, and close monitoring of blood sugar and electrolytes.

The duration of therapy required is variable. Dextrose therapy may be withdrawn by halving the rate of infusion every 2 to 4 hours once hyperglycaemia develops, guided by regular bedside assessments of serum glucose. This minimizes the risk of precipitous hypoglycaemia. It may be particularly difficult to wean dextrose infusions in non-diabetic patients, as the large load of infused dextrose stimulates endogenous insulin secretion after the effects of the initial overdose have worn off. In these cases, a slower weaning regimen may be required to prevent hypoglycaemia, and clinicians should attempt to minimize bolus intravenous dosing of concentrated dextrose solutions in response to transient, mild, asymptomatic hypoglycaemia. It is sensible to avoid withdrawing dextrose infusions overnight when clinical features of hypoglycaemia are less easily recognized.

Patients are medically fit for discharge if they remain asymptomatic and euglycaemic 6 hours after dextrose therapy is ceased. All intentional overdoses require psychiatric assessment once their medical condition has stabilized.

SULPHONYLUREAS

Pharmacology and pathophysiology

Sulphonylureas are the most commonly prescribed oral hypoglycaemics in Australasia. Currently available agents include glibenclamide, gliclazide, glimepiride and glipizide. These agents bind to and block outgoing K^+ channels on the pancreatic β cells, leading to depolarization of the cell membrane, which opens voltage-gated Ca^{2+} channels and causes insulin release secondary to Ca^{2+} influx.[4] The result is a hyperinsulinaemic state. Although in therapeutic doses the duration of action is usually from 12 to 24 hours, this can be markedly prolonged following overdose. Sulphonylureas undergo hepatic metabolism and have a combination of active and inactive metabolites, which are excreted renally. An exaggerated therapeutic effect can therefore occur when these agents accumulate in patients with coexistent hepatic or renal disease.

Clinical features

Sulphonylurea-induced hypoglycaemia may occur as a complication of therapy, inadvertent administration to a non-diabetic patient or as a consequence of deliberate self-poisoning. The hypoglycaemia after intentional ingestion is likely to be particularly profound and prolonged.

Treatment

Hypoglycaemia should be corrected immediately once identified with bedside blood glucose testing or suspected on clinical grounds. An initial bolus of 50 mL 50% dextrose followed by an infusion of 10% dextrose at 100 mL/h is appropriate for hypoglycaemia secondary to deliberate self-poisoning with sulphonylureas. However, hypoglycaemia is frequently refractory to dextrose supplementation in this setting and early use of octreotide is then indicated to maintain euglycaemia (discussed later).

Activated charcoal can be administered to patients who present within a few hours of intentional ingestion of sulphonylureas (especially with extended-release preparations) but does not take precedence over resuscitation and correction of hypoglycaemia.

Elderly patients with sulphonylurea-induced hypoglycaemia often have intercurrent medical illnesses that require treatment. Euglycaemia may be relatively easy to maintain with intravenous or oral dextrose supplementation, but octreotide may also have a role in therapeutic management (discussed later).

OCTREOTIDE

Octreotide is a synthetic octapeptide analogue of the naturally occurring foregut hormone somatostatin. It suppresses insulin release from pancreatic β cells by binding to Ca^{2+} channels on the cell membrane, inhibiting Ca^{2+} influx and subsequent insulin release.

Octreotide is now seen as first-line antidotal therapy in patients with hypoglycaemia secondary to sulphonylurea overdose. Early administration of octreotide may greatly reduce or abolish the dextrose requirement, obviate the need for central venous access, and greatly simplify subsequent management and disposition. Therapy can be initiated with an initial bolus of 50 μg IV followed by an infusion of 25 μg/h. An alternative dosing regimen is 100 μg by intramuscular or subcutaneous injection every 6 hours. Once initiated, octreotide therapy should be continued for at least 24 hours before withdrawal is attempted. Octreotide is well tolerated, with nausea and vomiting only occasionally reported.[4,5]

For the treatment of hypoglycaemia due to therapeutic accumulation of sulphonylurea agents, a single dose of octreotide 25 to 50 μg subcutaneously may be adequate to prevent recurrent hypoglycaemia during in-patient management.

Disposition

Patients with a history of sulphonylurea overdose should be admitted and observed with bedside blood glucose assays for at least 8 hours after ingestion or up to 12 hours if a slow-release preparation. They are medically fit for discharge if they remain asymptomatic and euglycaemic at this stage.

Patients who require treatment for hypoglycaemia need admission, often for several days. Discharge can occur once they are tolerating a normal diet and their blood glucose level remains normal 6 hours after cessation of glucose and/or octreotide therapy.

Patients who develop hypoglycaemia on therapeutic doses of sulphonylureas should be admitted for at least 24 hours to monitor serum glucose and to review their medication regimen.

In all cases of sulphonylurea overdose or toxicity, discharge should not occur at night, due to the increased risk of occult hypoglycaemia.

METFORMIN

Pharmacology and pathophysiology

Metformin is the only biguanide currently available in Australasia. It is rapidly absorbed from the gastrointestinal tract, minimally metabolized and excreted almost entirely by the kidneys. The major antidiabetic effect is to inhibit gluconeogenesis, as well as to increase tissue sensitivity to insulin, thereby improving HbA1c control. It does not cause hypoglycaemia at therapeutic doses and, even following massive overdose, clinically significant hypoglycaemia is rarely

observed. However, metformin is associated with life-threatening lactic acidosis because it blocks intracellular oxidative pathways leading to increased anaerobic metabolism. Metformin-associated lactic acidosis can occur during therapeutic dosing when impaired renal function leads to drug accumulation or when intercurrent illness leads to tissue hypoperfusion. It is also reported after massive overdose, even in non-diabetic patients. The threshold for this effect is not well established but is probably over 10 g.[6] The risk of toxicity from an acute ingestion will be exacerbated by other agents that cause hypotension or decreased renal perfusion.

Clinical features

The majority of metformin overdoses are associated with only minor symptoms. In particular, hypoglycaemia is not a feature of the presentation. Paediatric ingestions are unlikely to cause significant toxicity, provided that co-ingestion of sulphonylureas can confidently be excluded.[7] Where the clinical course is complicated by lactic acidosis, the insidious onset of non-specific symptoms, such as nausea, malaise and lethargy, may be observed. As lactate levels rise, the patient's condition will deteriorate with progressive tachypnoea, cardiovascular instability and altered mental state.[8] Patients who develop progressive lactic acidosis while on therapeutic metformin may present severely unwell.

Metformin-associated lactic acidosis carries a significant mortality risk if it is not recognized and treated effectively.[9]

Clinical investigation

Urgent electrolytes, renal function and lactate levels are indicated in any patient on metformin therapy who presents unwell or in any patient who becomes symptomatic while being observed following deliberate self-poisoning with metformin.

Treatment

Most cases of metformin overdose can be managed supportively. Maintenance of euvolaemia is imperative, and IV crystalloid should be given to ensure effective renal perfusion and clearance. If lactate levels are elevated, serial estimations of pH and lactate must be performed until they return to the normal range. If lactate rises above 10 mmol/L or worsening acidosis, renal dysfunction and clinical deterioration occur, immediate treatment with lactate-free haemodialysis is indicated. This not only corrects the acid–base disturbance, but also rapidly removes metformin from the circulation. Either intermittent or continuous dialysis techniques can be used, as long as flow rates are adequate to ensure effective clearance.[8]

Temporary improvement in acidosis can be achieved by infusion of $NaHCO_3$ while organizing dialysis, but this does not address ongoing metformin toxicity, and progressive deterioration may occur without definitive therapy.

Disposition

Patients can be discharged following metformin overdose if they remain clinically well with normal haemodynamic parameters and acid–base status. Those who develop significant lactic acidosis require intensive care admission and consideration for haemodialysis. All patients on therapeutic metformin who develop lactic acidosis require admission for close clinical and biochemical monitoring and consideration for haemodialysis.

OTHER AGENTS

DPP-IV inhibitors ('gliptins', e.g. sitagliptin) prevent hydrolysis of the endogenous foregut incretin hormones, glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP). This results in increased insulin release and a decrease in endogenous glucagon activity. There is a possibility of gliptin-induced hypoglycaemia as a consequence of therapy or overdose, but this is unlikely to be prolonged or significant.[10]

Exanetide, an incretin analogue, is a synthetic, long-acting polypeptide derived from the saliva of the Gila monster *(Heloderma suspectum)*. It is administered by subcutaneous injection and adverse effects include significant vomiting. As with gliptin toxicity, drug-induced hypoglycaemia is likely to be mild, transient and readily responsive to supplemental dextrose.[11]

Thiazolidinediones ('glitazones', e.g. pioglitazone) are used in type II DM. They improve insulin sensitivity in skeletal muscle and adipose tissue via the receptor peroxisome proliferator-activated receptor gamma (PPAR-γ) and also inhibit hepatic gluconeogenesis. They improve insulin resistance and thereby act to decrease circulating insulin levels. They do not stimulate insulin secretion and are not associated with hypoglycaemia.

α-Glucosidase inhibitors (acarbose) are oligosaccharide agents that inhibit the activity of enzymes in the GI endoluminal brush border. Their action decreases the breakdown of complex sugars to monosaccharides, thereby decreasing the postprandial rise in blood glucose levels. They are not absorbed to any significant degree and do not cause hypoglycaemia or other systemic effects in overdose.

Glinides (e.g. repaglinide) are not commonly available in Australasia, but are prescribed more frequently in other countries. Their mode of action is to stimulate insulin secretion from the pancreas, but via a different part of the membrane receptor than sulphonylurea agents.[12] There are limited data available on overdose presentations, but there is potential for hypoglycaemia requiring therapy with IV dextrose. Because of the short half-life of glinides in comparison to sulphonylureas, prolonged toxicity is unlikely to result.

SGLT2 inhibitors (e.g. dapagliflozin) block resorption of glucose in the renal tubules, and promote glycosuria. There is a small risk of euglycaemic ketoacidosis with therapeutic dosing, but acute overdose does not cause hypoglycaemia or other significant toxicity.

CONTROVERSIES

- Glucagon is sometimes given pre-hospital for symptomatic hypoglycaemia. It can raise serum glucose due to enhanced breakdown of hepatic glycogen stores, but this effect is short lived and unreliable. It does not have a role in the in-patient management of deliberate self-poisoning with insulin or sulphonylureas.
- Surgical excision of insulin depot stores has been attempted but is not indicated as medical management is effective in dealing with all clinical manifestations of insulin overdose.
- The optimal dose and route of administration of octreotide in sulphonylurea overdose is not well defined. Recommendations are empiric. Greater doses than those quoted above might be necessary following massive overdose of sulphonylureas in non-diabetic patients.
- The role of insulin assays in determining ongoing requirement for octreotide therapy in sulphonylurea toxicity could be explored. Currently, insulin levels are not routinely monitored in this setting.

25.9 Colchicine

Dushan Jayaweera • Mark Salter

ESSENTIALS

1 **All deliberate self-poisonings with colchicine should be regarded as potentially life threatening.**

2 **Poisoning may present asymptomatically or with gastrointestinal symptoms only.**

3 **Consider the diagnosis in patients presenting with gastrointestinal symptoms followed by the development of multi-organ failure, especially bone marrow failure.**

4 **Key management points include early recognition of the potential severity of this poisoning, early gastrointestinal decontamination and aggressive supportive care.**

Introduction

Colchicine is an alkaloid extracted from the plants, *Colchicum autumnale* (Autumn Crocus) or *Gloriosa superba* (Glory Lily). It is used in the treatment of acute gout, familial Mediterranean fever, scleroderma, primary biliary cirrhosis and recurrent pericarditis.

Colchicine poisoning is rare, usually occurring in the context of deliberate self-poisoning or therapeutic overdose. Severe toxicity from therapeutic administration of oral colchicine is unusual but can occur in the elderly or patients with renal or hepatic disease. In this situation, the appearance of gastrointestinal symptoms usually acts as a safety mechanism and results in the discontinuation of the drug before the appearance of more severe symptoms. Poisoning is also reported from ingestion of various parts of the plants of *Colchicum autumnale* and *Gloriosa superba*.

Colchicine poisoning is potentially serious with a relatively high mortality, and is often underestimated or misdiagnosed at initial presentation.

Toxicokinetics

Colchicine is a substrate for efflux pump P-glycoprotein (P-gp) and is rapidly absorbed in the small intestine following oral administration, with peak levels occurring from 0.5 to 2 hours post-ingestion. Oral bioavailability ranges from 25% to 40% because of extensive first-pass hepatic metabolism. It is highly lipid soluble and has 50% protein binding.[1] Colchicine rapidly distributes from plasma to tissues, where it binds with high affinity to intracellular-binding sites. The distribution half-life is from 45 to 90 minutes, with a volume of distribution of 2 L/kg, which may increase to 21 L/kg in patients with toxicity.[2] Elimination is mainly by metabolism in the liver by de-acetylation via CYP3A4 enzymes. Colchicine and its metabolites also have significant biliary excretion and undergo enterohepatic circulation. Renal excretion accounts for 20% of elimination with terminal elimination half-lives in toxic patients ranging from 10.6 to 31.7 hours. Drug clearance is significantly reduced in patients with renal and hepatic insufficiency, and drugs that inhibit CYP3A4 or P-gp can increase colchicine levels, leading to toxicity.

Pathophysiology

Colchicine binds to tubulin and prevents its polymerization to form microtubules.[3] Microtubules are essential components of the cell cytoskeleton during mitosis and are integral to other cellular processes, including endocytosis, exocytosis, phagocytosis, cell motility and protein assembly. In toxic doses, colchicine causes mitosis to arrest in metaphase with serious consequences for the rapidly dividing cells of the gut mucosa and bone marrow. As colchicine-induced microtubular disruption continues, it affects cell shape, intracellular transport and the secretion of hormones, enzymes and neurotransmitters, resulting in toxicity to virtually every cell in the body.[4]

Clinical features

Severe colchicine poisoning presents as a distinct clinical syndrome characterized by early onset of gastrointestinal symptoms followed by delayed onset of multi-organ toxicity and a high incidence of mortality.

In the largest reported case series of colchicine poisoning, ingestions estimated at <0.5 mg/kg were associated with gastrointestinal symptoms and coagulation disturbances and a mortality of 0%. Ingestions of 0.5 to 0.8 mg/kg were associated with bone-marrow aplasia and a mortality of 10% while ingestions >0.8 mg/kg had cardiovascular collapse and 100% mortality at 72 hours.[5] However, a number of fatalities have been reported following ingestions of doses <0.5 mg/kg, including a death at 7.5 mg.[6] Therefore any overdose of colchicine should be regarded as potentially serious. The highest reported overdose that survived with aggressive supportive care is 1.38 mg/kg.[7]

The clinical course of colchicine toxicity can be divided into three sequential (and usually overlapping) stages (Table 25.9.1). Less severe cases may not progress beyond the first stage, whereas the most severe cases die during the second stage.

Following a significant acute oral overdose, the patient may remain asymptomatic for 2 to 24 hours. The toxic patient then develops severe nausea, vomiting, diarrhoea and abdominal pain.

Table 25.9.1 Clinical stages of significant colchicine toxicity

Stage 1: Gastrointestinal phase Time of onset: 2–24 h post-ingestion	Nausea, vomiting, diarrhoea, abdominal pain Intravascular volume depletion with hypotension Peripheral leucocytosis
Stage 2: Multi-organ failure phase Time of onset: 24–72 h post-ingestion	Adult respiratory distress syndrome Bone marrow suppression Cardiac arrhythmias, failure, arrest Disseminated intravascular coagulation (DIC) Fever Hypomagnesaemia Hyponatraemia Hypocalcaemia Hypophosphataemia Ileus Metabolic acidosis Mental status changes Neuromuscular abnormalities Oliguric renal failure Secondary sepsis Seizures
Stage 3: Recovery phase Time of onset: 6–8 days post-ingestion	Resolution of organ system derangements Rebound leucocytosis Alopecia

This corresponds to gastrointestinal mucosal damage and impairment of secretion of normal mucosal enzymes.[8] During this stage, fluid losses from vomiting and diarrhoea may be significant enough to result in hypovolaemic shock.

Multisystem organ failure is characteristic of the second stage, with onset from 24 to 72 hours following ingestion. Respiratory, haematological, cardiovascular, renal and neurological involvement is typical. Acute adult respiratory distress syndrome may be a consequence of hypovolaemic shock or sepsis or occur as a result of direct damage to the pulmonary vasculature. Bone marrow suppression is heralded by lymphopaenia, followed by granulocytopaenia, reticulocytopaenia and thrombocytopaenia, reaching a nadir at 4 to 8 days following ingestion. Sepsis may complicate this stage of toxicity.[2,5] Disseminated intravascular coagulopathy was noted to be a frequent complication in one large series of patients with colchicine toxicity.[5] Fever occurs commonly and may be a direct drug effect or a sign of complicating infection. Shock is cardiogenic and/or hypovolaemic in origin and is strongly associated with death.[9] Tachy-brady arrhythmias and sudden cardiac arrest have been reported. Renal failure is multifactorial and related to prolonged hypotension, hypoxia, sepsis and rhabdomyolysis. Metabolic derangements include metabolic acidosis, hyperglycaemia, hypokalaemia, hypocalcaemia, hypophosphataemia and hypomagnesaemia.[1] Neurological disturbances include delirium, coma, seizures, transverse myelitis and ascending paralysis. Death is common during this period and usually occurs as a result of profound cardiogenic shock, sudden cardiac arrest or sepsis. Cardiac arrest has been observed as early as 36 hours following acute colchicine ingestion.

In those who survive stage two, a rebound leucocytosis occurs at 7 or more days after initial symptoms and corresponds to the recovery of bone-marrow function. Alopecia commonly occurs around this time. Complete recovery is the rule in patients surviving stage 2.

Differential diagnosis

The diagnosis of colchicine poisoning is usually evident when the history and clinical features are considered. Difficulties and delayed diagnosis occur when the history of ingestion is not obtained or where colchicine poisoning has been misdiagnosed as gastroenteritis, sepsis or an acute abdomen. Colchicine poisoning should be considered whenever progressive multiple organ dysfunction occurs after gastrointestinal symptoms, especially in conjunction with bone marrow depression.

Clinical investigations

Given the potential for severe multisystem organ failure, baseline investigations including electrolytes, full blood count, coagulation profile, creatinine kinase, renal and liver function tests, electrocardiography and chest radiography should be performed upon presentation. Initial leucocytosis can commonly be seen in the early phase of toxicity.[2] These studies should be repeated, at intervals dictated by the patient's clinical course. Although colchicine concentrations in biological fluids can be measured, they are not readily available and not useful in the management of colchicine poisoning.

Treatment

The key points in the management of acute colchicine toxicity are early recognition of the potential severity of this poisoning, early gastrointestinal decontamination and aggressive supportive care.

Gut decontamination using single dose activated charcoal is the management priority for the patient presenting in the first (asymptomatic) stage of colchicine poisoning; prevention of absorption of even small amounts may favourably affect the severity of the poisoning and the ultimate outcome.[7,10] In patients who present later (during the second stage), resuscitative efforts take precedence over gastrointestinal decontamination.

Maintaining a good urine output with intravenous crystalloids is important. Further supportive therapy is dictated by the clinical status and may include plasma expansion, inotropes, artificial ventilation, correction of electrolyte and acid–base disturbances, correction of coagulation disorders, and antibiotic treatment of infectious complications.

Because of colchicine's large volume of distribution and high affinity to intracellular-binding sites, attempts to enhance elimination by haemodialysis or haemoperfusion are ineffective. However, in poisoning of less than 24 hours, multi-dose activated charcoal may provide some benefit given the enterohepatic circulation of colchicine, especially in patients with hepatic or renal failure or if drug interactions are expected to increase toxicity.[2] There is limited evidence for G-CSF in those with bone marrow suppression.[2,11] Anti-colchicine Fab fragments are not commercially available but may be considered.[2,12]

Disposition

All patients with suspected colchicine overdose require admission to hospital for a minimum of 24 hours for monitoring of clinical signs, laboratory investigations and cardiac rhythm as outlined previously. If there are no symptoms of poisoning (diarrhoea, vomiting or abdominal pain) at the end of this time, colchicine toxicity may be confidently excluded and the patient discharged. The symptomatic patient should be admitted to an intensive care unit for careful monitoring and supportive care.

Prognosis

Colchicine poisoning has a relatively high mortality. The prognosis is to a large extent but not entirely determined by the dose ingested. Early resuscitation and provision of appropriate

supportive care may improve prognosis. Patients who present late, in whom the diagnosis is delayed or where the potential seriousness of the presentation is underestimated, initially do worse. In patients who survive stage two, a complete recovery can be anticipated. The alopecia observed during the recovery phase is not permanent, with hair growth commencing after the first month.

CONTROVERSIES

- The bone-marrow suppression associated with colchicine toxicity has been reported to respond to the administration of G-CSF.[11] However, it is unclear whether these reports represent a true therapeutic response or the natural course of recovery.
- In animal laboratory research, anti-colchicine Fab fragments has effectively reversed colchicine toxicity,[13] and there is one case where administered to a patient with severe colchicine toxicity resulted in survival.[12] This may lead to further human studies, as anti-colchicine Fab fragments are not commercially available.

25.10 Theophylline and caffeine

Gopi Mann • Satish Mitter • Naren Gunja

ESSENTIALS

1 **Methylxanthine toxicity can be associated with life-threatening seizures and cardiac arrhythmias.**

2 **Predictors of toxicity include hypokalaemia, lactic acidosis and serum theophylline concentration.**

3 **Early identification of high-risk patients allows the institution of enhanced elimination techniques before life-threatening complications develop.**

Introduction

Theophylline, a methylxanthine derivative related to caffeine, can result in potentially life-threatening overdose presentations to the emergency department (ED). The decline in theophylline use has closely mirrored the emergence of caffeine overdose.

Therapeutic blood concentrations of theophylline are generally regarded as being between 10 and 20 mg/L. A single ingestion of more than 10 mg/kg of theophylline by an adult is capable of producing a blood concentration above this range.

Pharmacokinetics

Theophylline is well absorbed orally, with a bioavailability of almost 100%. The rate of absorption depends on the pharmaceutical formulation. The most commonly prescribed preparations are sustained-release, and following overdose of these preparations, peak absorption may be delayed up to 15 hours.

Once absorbed, theophylline is rapidly distributed. It is metabolized via the cytochrome P450 system to produce active and inactive metabolites. The rate of metabolism is extremely variable and exhibits saturable kinetics. At higher doses of theophylline, relatively small increments in dose are associated with disproportionate increases in serum concentration. In cases of severe intoxication, endogenous elimination of theophylline is very slow. Only about 10% of absorbed theophylline is excreted unchanged in the urine.

Pathophysiology

The precise mechanisms of toxicity of theophylline are unknown. Proposed mechanisms include inhibition of phosphodiesterase leading to elevated concentrations of intracellular cyclic adenosine monophosphate (cAMP), augmented plasma catecholamine activity, competitive antagonism of adenosine and changes in intracellular calcium transport.

Clinical features

Two different clinical syndromes of theophylline poisoning are recognized: acute and chronic. Both are potentially life threatening, although the chronic form is associated with greater morbidity and mortality.

Chronic toxicity is the most common clinical presentation and occurs with repeated

supratherapeutic ingestion, intercurrent illness or where drug interaction interferes with hepatic metabolism. Theophylline has a narrow therapeutic index, and up to 15% of patients with a serum theophylline concentration in the therapeutic range may have clinical manifestations of toxicity.

Acute intoxication is usually the result of deliberate overdose with suicidal intent but is occasionally observed following inadvertent iatrogenic overdose. Toxicity is anticipated following a single acute ingestion of >10 mg/kg, and life-threatening toxicity is anticipated with >50 mg/kg.

The clinical manifestations of theophylline intoxication are numerous and principally affect the gastrointestinal, cardiovascular, central nervous, musculoskeletal and metabolic systems.

The gastrointestinal tract is particularly sensitive to theophylline toxicity, the most prominent symptom being vomiting. This is usually severe and frequently refractory to treatment with antiemetics.

Sinus tachycardia is an almost universal manifestation of theophylline toxicity. However, severe intoxication is also associated with more unstable rhythms, including various supra-ventricular tachycardias such as atrial fibrillation and ventricular tachycardia.[1] Refractory hypotension may occur in severe toxicity as a result of β_2-mediated peripheral vasodilatation.

Central nervous system manifestations most commonly consist of anxiety and insomnia. With severe intoxication, tachypnoea from respiratory centre stimulation and seizures occur. Seizures can develop suddenly, may be recurrent and refractory to treatment, and are associated with poor outcome.

Metabolic complications of theophylline poisoning include hypokalaemia, hypophosphataemia, hypomagnesaemia, hyperglycaemia and lactic acidosis.[2] Hypokalaemia is frequent following acute overdose, occurs early and is a consequence of intracellular shift of potassium secondary to catecholamine excess.[3,4] Musculoskeletal manifestations include muscle aches, increased muscle tone and myoclonus.

Chronic toxicity usually occurs in elderly patients and is associated with vomiting and tachycardia. The metabolic abnormalities are less frequently observed. Seizures and cardiac arrhythmias occur more frequently and at much lower serum theophylline concentrations than in acute overdose.[5,6]

With ingestion of sustained-release preparations, the clinical manifestations of severe toxicity may be delayed up to 12 hours. These patients usually present with severe vomiting before the onset of seizures and arrhythmias.

Clinical investigations

The diagnosis of theophylline toxicity is suspected on history and clinical presentation and confirmed by documentation of a significantly elevated serum theophylline concentration. The serum theophylline concentration is also valuable in monitoring toxicity and ongoing management. Although theophylline is readily measured in blood, it is not detected on routine drug screens.

Patients with acute theophylline overdose generally exhibit signs of minor toxicity at serum concentrations from 20 to 40 mg/L, moderate toxicity with concentrations from 40 to 80 mg/L and severe toxicity with concentrations greater than 80 mg/L. Serum theophylline concentration of greater than 100 mg/L is a predictor of potential lethality.[7,8] After an acute overdose, serum theophylline should be measured every 4 hours until a falling concentration is documented.

In chronic theophylline poisoning, serious toxicity is observed at lower serum concentrations and the measured concentration is not predictive of the severity of poisoning.[9] Seizures, arrhythmias and fatalities can occur at concentrations as low as 20 to 30 mg/L. In these patients, the best predictor of poor outcome is age over 60 years.[8]

Other useful laboratory studies include electrolytes and creatinine, glucose, liver function tests (LFTs) and electrocardiogram (ECG).

Treatment

The initial management of theophylline poisoning follows the principles of general supportive care. Specific attention may need to be directed toward control of the airway, hypotension, tachyarrhythmias and seizures.

Hypotension usually responds to intravenous fluid administration. A noradrenaline (norepinephrine) infusion may be necessary in refractory vasoplegic shock. Supraventricular arrhythmias can be treated with a β-blocker, such as metoprolol or esmolol, but this may induce bronchospasm in susceptible individuals. Seizures must be treated aggressively with high-dose benzodiazepines. If this fails, phenobarbitone, thiopentone or propofol may be required. Phenytoin is ineffective and contraindicated. Distributive hypokalaemia should be cautiously corrected with potassium supplementation.

Following acute overdose, oral-activated charcoal should be administered after antiemetics, even if presentation is delayed.

The pharmacokinetic properties of theophylline, including small volume of distribution (0.5 L/kg), small size (180 Da) and low protein binding (56%), makes it amenable to enhanced elimination. Theophylline is removed by haemodialysis (intermittent haemodialysis being the most effective, but often not available in an emergency setting) and administration of multiple-dose activated charcoal.[10–12]

Theophylline clearance rates of 100 mL/min have been reported with multiple-dose activated charcoal[10]—aggressive antiemetic therapy may be necessary if this method of enhancing drug elimination is to be effective.

Haemodialysis greatly increases the elimination of theophylline and is effective in achieving a good clinical outcome especially in potential life-threatening theophylline toxicity. Commonly accepted indications include acute poisoning, where the serum theophylline is greater than 100mg/L; chronic poisoning, where it is greater than 60mg/L or in any patient with intractable hypotension, ventricular ectopy or resistant seizures.[5,7,13] Ideally, patients at greatest risk of developing arrhythmias, hypotension or seizures should be identified early and haemodialysis instituted before these complications develop. Continuous venovenous haemofiltration has been successfully used as an alternative to standard intermittent haemodialysis in the treatment of severe theophylline poisoning, with a reduction in the elimination half-life to 5.87 hours.[14] Newer (sustained low-efficiency haemodialysis/SLED) and historical (charcoal haemoperfusion) modalities have also been trialed successfully.[12]

Disposition

All patients with symptomatic theophylline toxicity require admission to the hospital. Patients with acute overdose of sustained-release preparations should be admitted for monitoring and serial serum theophylline concentrations. Patients with moderate-to-severe theophylline toxicity require admission to a monitored bed.

Caffeine

Caffeine is universally consumed for its stimulant properties in over-the-counter preparations, caffeinated beverages, energy drinks and in dietary supplements. Clinical features of energy drink overdose resemble those of caffeine toxicity, with palpitations, tremor, insomnia and agitation predominating.[15] Large caffeine overdoses can lead to acute coronary syndrome and seizure activity. Oral bioavailability is nearly 100% with a peak plasma concentration within 60 minutes. Severe caffeine toxicity is rare, but the lethal oral dose has been estimated to be >150 to 200 mg/kg. The pathophysiology, clinical features and treatment are similar those of theophylline intoxication. Most laboratories do not routinely process timely caffeine levels,[16] though a detectable theophylline level (a known metabolite of caffeine) can be utilized as a qualitative marker of caffeine exposure.

CONTROVERSIES

- Although charcoal haemoperfusion has been historically recommended as the most effective way to enhance theophylline elimination, it has not yet been shown to be associated with any additional improvement in clinical outcome compared with haemodialysis.
- Continuous renal replacement therapies offer a number of advantages over standard intermittent dialysis as a method of enhancing theophylline elimination. They are easily set up and run in most intensive care units and can be run 24 hours a day. However, clearance rates are slower, and these techniques are not currently recommended, except where standard dialysis is not available or unfeasible because of haemodynamic instability.

25.11 Iron

Zeff Koutsogiannis • Yit Hung Leang

ESSENTIALS

1 **Acute iron poisoning is a potentially life-threatening condition.**

2 **The risk of severe toxicity is determined by the dose of elemental iron ingested, not the weight of the iron salt.**

3 **Iron poisoning has both local (gastrointestinal) and systemic effects.**

4 **Early effective gastrointestinal decontamination with whole-bowel irrigation is important in the management of high-risk cases.**

5 **Chelation therapy with intravenous desferrioxamine is the definitive treatment for severe poisoning and should not be withheld awaiting an iron concentration in an unwell patient.**

6 **Generally, most patients recover, although presence of shock or coma indicates a poor prognosis.**

7 **Long-term sequelae are gastrointestinal scarring and obstruction but this is uncommon.**

8 **The approach to the pregnant patient with iron poisoning is identical.**

Introduction

The majority of exposures to iron occur in preschool children, but significant iron ingestions also occur in adults as a result of deliberate self-poisoning. It is also one of the most commonly ingested agents in self-poisoning during pregnancy as a result of its ready availability to obstetric patients. Iron supplements are often considered by patients and parents to be innocuous dietary supplements, leading to careless storage and handling and delays in seeking medical care following ingestions.

Due to education, different packaging, smaller dosages and toxicovigilance by poisons centres, iron toxicity has declined in the past decade, but significant poisonings still occur.

Pathophysiology

Iron is an essential element in red blood cell production, haemoglobin and myoglobin oxygenation and cytochrome function. It must come from exogenous sources and as the body cannot directly excrete iron; body stores are finely regulated by the gastrointestinal (GI) tract. After absorption across the GI mucosa iron is reversibly bound and stored as ferritin, or transported across the cell membrane into the blood, where it binds to transferrin. Iron is extracted from transferrin in the bone marrow and used for haemoglobin synthesis. It is also removed from transferrin by the reticuloendothelial system and hepatocytes and stored as haemosiderin and ferritin. Total iron-binding capacity (TIBC) is a measurement of the total amount of iron that transferrin can bind and normally exceeds serum iron by two- to threefold.

When an iron deficit exists, iron is transported from ferritin and the GI tract. If the body's iron requirements have been met, iron remains stored in the intestinal cell rather than bound to transferrin. Eventually, the intestinal cell dies and sloughs off into the lumen for elimination. This is the main mechanism limiting excessive iron absorption and the mechanism by which the body regulates iron balance.

Iron rarely exists as an unbound or 'free' element, and it is the free iron that is toxic to cellular processes.

Local effects

Iron preparations, like other metal salts, have a direct corrosive effect on the GI mucosa. In overdose, this can lead to irritation, ulceration, bleeding, ischaemia, infarction and perforation. Associated profound fluid losses can result in hypotension, shock and lactate formation leading to metabolic acidosis. The long-term sequelae of this corrosive action include GI scarring and obstruction from stricture formation. As the mucosal surface is disrupted, iron is absorbed passively and more readily down concentration gradients.

Systemic effects

When the absorbed iron exceeds the protein-binding capacity, the free iron causes cellular dysfunction and death. Free iron is an intracellular toxin localizing to the mitochondria, forming free radicals and disrupting oxidative phosphorylation. The resultant mitochondrial dysfunction and destruction lead to cell death. As a result, systemic findings of iron poisoning include cardiovascular collapse, anion-gap metabolic acidosis, coagulopathy and encephalopathy.

Table 25.11.1 Risk assessment based on dose of elemental iron ingested

Risk assessment	*Dose ingested (mg/kg)*
Asymptomatic	<20
Local (GI) symptoms only	20–60
Risk of systemic toxicity	60–120
Potentially lethal	>120

GI, Gastrointestinal.

Metabolic acidosis persisting after correction of hypovolaemia and hypoperfusion is probably a result of mitochondrial toxicity. Coagulopathy developing early in iron poisoning results from inhibition of thrombin formation and other clotting factors while, in the later stages, it is due to hepatic dysfunction.

Toxic dose

In general, the risk of developing iron toxicity can be predicted from the dose of elemental iron ingested per kilogram body weight (Table 25.11.1). It is essential to calculate the dose of elemental iron rather than dose of iron salt. If the formulation of the iron salt is not known, then assume a worst-case scenario and calculate 105 mg of elemental iron per tablet.

Prevention

Iron poisoning is a major cause of unintentional poisoning death in young children, making up almost one-third of all toxicological deaths in that age group in the 1980s to 1990s. However, there has been a decrease in the incidence of nonintentional ingestion by young children and decreased mortality following the introduction of unit-dose packaging. This, together with education, may further decrease the incidence of toxicity and late presentations.

Clinical features

The clinical course of iron poisoning is traditionally described as comprising five stages. These stages are used as a guide to conceptualize the clinical course but not all patients will experience all stages; they can die at any stage, can present at any stage and the time frames for each stage are imprecise and may overlap.

A more practical approach is to consider iron poisoning as comprising two clinical stages with a pathophysiological basis: GI toxicity and systemic toxicity.

Stage 1 (0 to 6 hours)

This stage is dominated by symptoms and signs of GI injury, particularly vomiting, but also abdominal pain, diarrhoea and GI bleeding. This occurs almost universally following a significant iron ingestion. In severe cases, hypovolaemic shock and metabolic acidosis secondary to GI losses can develop. The absence of GI symptoms within 6 hours of ingestion effectively excludes significant iron poisoning.

Stage 2 (2 to 24 hours)

Also known as the 'latent' or 'quiescent' phase, this stage represents the period between resolution of GI symptoms and appearance of overt systemic toxicity. It is not a true quiescent phase as ongoing cellular toxicity occurs. Although clinicians should be wary of GI symptom resolution, most patients in fact recover and do not progress to stage 3. Those with significant poisoning remain clinically ill with subtle signs (but easily identifiable) and progress to stage 3.

Stage 3 (6 to 48 hours)

This stage represents severe and systemic toxicity characterized by shock and multiorgan system failure. Most deaths occur during this stage. The shock is multifactorial arising from hypovolaemia, vasodilation and poor cardiac output with evidence of poor peripheral perfusion, worsening acidosis and acute renal failure. Coagulopathy may develop and lead to recurrent GI bleeding. Central nervous system effects include lethargy, coma and convulsions.

Stage 4 (2 to 3 days)

This is the hepatic phase of iron toxicity. It is relatively uncommon but has a high mortality rate. It is characterized by acute hepatic failure with jaundice, hepatic coma, hypoglycaemia, coagulopathy, elevated transaminase and ammonia levels.

Stage 5 (2 to 6 weeks)

This stage is relatively rare and represents the delayed sequelae from the corrosive effects of iron resulting in GI scarring. This results in gastric outlet (pyloric stricture) and small bowel obstructions.

Clinical investigations

Acute iron poisoning is a clinical diagnosis. All significantly symptomatic patients require treatment regardless of the iron concentration or results of other tests. However, serum iron concentrations, abdominal x-rays and other tests do guide management.

Serum iron concentration

Peak iron concentrations usually occur between 2 and 6 hours after overdose, although they may sometimes be delayed due to sustained release preparation or bezoar formation. Obtain an iron concentration on presentation and repeat 2 to 4 hourly until downward trend. Although iron poisoning is a clinical diagnosis, iron concentrations have been used to determine toxicity and direct management. A serum iron concentration less than 90 μmol/L at 4 to 6 hours after an overdose is not associated with significant systemic iron toxicity. However, it is intracellular and not serum iron that is responsible for systemic toxicity and thus during stages 2 or 3, the iron concentration may be decreasing or even normal while the patient deteriorates. In the presence of desferrioxamine, the serum iron concentration is artificially lowered.

The TIBC is falsely elevated in the presence of high iron concentrations or desferrioxamine, and it is not useful in the assessment of iron poisoning.

Plain abdominal x-rays

Most iron preparations are radiopaque and an early abdominal x-ray is useful in confirming ingestion of iron and in subsequently guiding gastric decontamination. A negative x-ray does not exclude iron ingestion as the tablets may have disintegrated (if presents late) or not radiopaque (liquid preparations, iron-containing multivitamins or chewable tablets).

Other laboratory tests

Although leucocytosis and hyperglycaemia are frequently observed in iron poisoning, they are not useful in terms of diagnosis or management. The presence of an anion-gap metabolic acidosis with a high lactate is a useful marker of systemic iron poisoning and, as such, a low serum bicarbonate concentration is a good surrogate marker of systemic iron poisoning in places where serum iron concentrations are not readily available.

Other tests that are useful in managing patients with established iron poisoning include serum electrolytes, renal function, liver function, blood gases and clotting profile.

However, if the white cell count, blood glucose and radiographic findings are normal and there are no GI symptoms, serious toxicity is unlikely.

Differential diagnosis

Usually, the diagnosis is self-evident from the history of exposure, but iron poisoning needs consideration in the undifferentiated poisoning with an anion-gap metabolic acidosis and GI symptoms.

Treatment

The approach to management is based on the dose ingested and the presence or absence of GI and/or systemic features of iron poisoning. For most patients, a period of observation and good supportive care, often including intravenous fluids, will be sufficient. In those patients at risk of systemic poisoning or who present with established iron poisoning, aggressive decontamination measures and chelation therapy may be necessary to achieve a good outcome. The aim is to prevent the development of systemic toxicity.

Observation and supportive care

All patients demonstrating signs and symptoms consistent with iron toxicity warrant further treatment. Aggressive fluid replacement with isotonic fluid is essential. An initial bolus of 20 mL/kg should be given, followed by boluses as needed to replace fluid losses and maintain urine output. Patients with established iron poisoning may require more advanced supportive care, including inotropic support, blood transfusions, correction of coagulopathy with fresh frozen plasma and correction of acidosis.

Any lethargic patient who is likely to deteriorate should be promptly intubated to facilitate safe decontamination.

Gastrointestinal decontamination

Limiting the absorption of ingested iron is part of the initial management. Iron is not well adsorbed to activated charcoal. Gastric lavage has serious risks and is often technically difficult due to tablets clumping and forming pharmacobezoars that attach to the gastric mucosa. It should only be considered in life-threatening ingestions (>120 mg/kg) presenting within 1 hour. Thus alternative methods of GI decontamination must be considered in patients who present following ingestion of more than 60 mg/kg of elemental iron, especially where unabsorbed iron is evident on abdominal x-ray.

Whole-bowel irrigation (WBI) is widely advocated as the GI decontamination method of choice in the setting of iron poisoning, although there are no controlled trials. It should be initiated in any patient who has ingested more than 60 mg/kg of elemental iron and still has a large number of iron tablets present in the GI tract on x-ray. The procedure is continued until there is a clear rectal effluent and no visible iron tablets on repeat x-ray. As iron has a direct corrosive effect on the GI mucosa, caution is therefore advised with the use of WBI in late presenters who may have sustained mucosal damage.

Upper endoscopy or surgical removal of iron tablets has been reported. These techniques can be considered in patients with potentially lethal ingestion and suspected pharmacobezoar formation.

Chelation therapy

Desferrioxamine is the parenteral chelating agent of choice for iron poisoning. It binds Fe^{3+} (Ferric ion) to form ferrioxamine which is water soluble, red-to-orange in colour and renally excreted. Desferrioxamine binds free iron and iron in transit between transferrin and ferritin thus effecting a redistribution of iron from tissue sites back into plasma. It does not chelate iron bound to transferrin, haemoglobin, myoglobin or cytochrome enzymes.

Chelation therapy is indicated, and administered as early as possible, in any patient with established systemic iron toxicity or at risk of developing such toxicity. Thus the indications are:

- systemic toxicity (shock, metabolic acidosis, altered mental status) irrespective of iron concentrations
- serum iron concentrations greater than 60 μmol/L and symptomatic
- serum iron concentrations greater than 90 μmol/L 4 to 6 hours post-ingestion even if asymptomatic because it is predictive of subsequent systemic toxicity

Although the use of desferrioxamine is considered the standard of care, no controlled studies have shown any effect on outcome.

Ferrioxamine's red-to-orange colour is responsible for the classically described *vin rose* urine in patients given desferrioxamine but this colour change is an insensitive marker of the presence of free iron. Thus desferrioxamine challenge tests are no longer recommended.

Desferrioxamine is given as a continuous intravenous infusion starting slowly and aiming for a rate of 15 mg/kg/h. Administration rate may be limited by hypotension, the principal adverse effect. Intramuscular administration is not recommended as it is painful, requires multiple injections, has erratic absorption and a higher side-effect profile. The precise endpoints for chelation therapy are unclear but therapy can be safely discontinued once the serum iron concentration is normal or low, the patient is clinically well and the anion-gap metabolic acidosis has resolved. Except under exceptional circumstances, desferrioxamine should not be continued for longer than 24 hours or exceed 80 mg/kg/24 hours because of the risk of pulmonary toxicity and acute respiratory distress syndrome (ARDS). Treatment duration of 6 hours is usually sufficient.

The dose should be reduced by 50% in severe renal failure.

Expert advice from a clinical toxicologist should be sought if using desferrioxamine therapy.

The approach to iron poisoning is not altered in the pregnant patient. Symptomatic iron overdose in pregnancy is associated with preterm labour, spontaneous abortion and maternal death. Desferrioxamine does not cause perinatal complications or fetal toxicity and is potentially life-saving. It is therefore indicated in iron intoxication in pregnancy with clinical evidence of moderate to severe toxicity. The dose is based on the pre-pregnancy weight of the patient.

Enhanced elimination

Haemodialysis and haemoperfusion are not effective at removing iron but may be necessary to remove the ferrioxamine complex in patients with renal failure.

Exchange transfusion has been used in massive paediatric ingestions but it is of questionable value.

Disposition

Patients who have ingested less than 60 mg/kg of elemental iron and remain asymptomatic at 6 hours may be medically discharged. Those with GI symptoms or requiring WBI because of large ingestion require admission for supportive care and ongoing observation and monitoring for at least 24 hours. Those with systemic toxicity and/or requiring chelation therapy require intensive care admission. All patients who present with deliberate self-poisoning require psychosocial assessment.

Prognosis

Most patients with iron overdose remain asymptomatic or develop minor GI toxicity only and do well with supportive care. Those with large ingestions should have an excellent outcome if recognized early and appropriate and timely decontamination and/or chelation therapy is instituted. Patients presenting late with established severe systemic toxicity have a poorer prognosis. GI stricture formation is a potential long-term sequela.

CONTROVERSIES

- Whether administration of desferrioxamine at higher rates or for longer does have a deleterious effect.
- N-acetylcysteine may protect against iron-induced hepatotoxicity.
- New Food and Drug Administration (FDA)-approved oral chelating agent, deferasirox (used in patients with chronic iron overload) was studied for potential antidote in supratherapeutic iron ingestion, but further study is warranted.
- Diazepam has been shown in animal studies to reduce mortality without chelation.
- The role of desferrioxamine in parenteral iron infusion error.

25.12 Drugs of abuse

Kerry A. Hoggett

ESSENTIALS

1 **The diagnosis of intoxication with drugs of abuse is clinical. Good supportive care ensures optimal outcome in the majority of cases.**

2 **Predisposing factors for opioid-related deaths include co-ingestion of Central nervous system (CNS) depressant drugs, poor tolerance, high purity and reluctance to seek medical care. Naloxone is a useful adjunct in the management of airway and ventilation in opioid overdose.**

3 **Benzodiazepines are important in the management of the central nervous system and cardiovascular manifestations of amphetamine intoxication. Hyperthermia, decreased conscious state, headache, neurological signs or chest pain suggest life-threatening complications and warrant aggressive investigations and management.**

4 **Cocaine use is associated with both cardiac and noncardiac toxicity and may be life threatening. Toxicity may be difficult to distinguish clinically from amphetamines, although it tends to be of shorter duration. Aggressive investigation and management is required for hyperthermia, seizures, chest pain and ventricular arrhythmias.**

5 **Gamma-hydroxybutyric acid is a sedative-hypnotic drug causing CNS depression. Management is supportive.**

6 **Synthetic psychoactive agents are widely available, with evolving structural modifications and variable effects.**

7 **The illicit overuse of prescription medications is an increasing problem, especially in the older population.**

8 **Presentation to the emergency department following overdose provides an opportunity for intervention. Education and referral is recommended.**

Introduction

Illicit use of drugs currently accounts for 1.8% of the total burden of disease and injury in Australia. In 2016, 43% of people aged over 14 years reported using illicit drugs at least once during their lifetime and 15.6% reported use within the previous 12 months, most commonly cannabis (10.4%), prescription and over-the-counter (OTC) analgesics (3.6%), cocaine (2.5%), ecstasy (2.2%) and methamphetamine (1.4%). While most users of illicit drugs are adults aged 20 to 29 years, the average age of illicit drug users is increasing, with people aged over 50 years accounting for more than 20%. Nine percent of the population report being the victim of a drug-related incident within the past year.

In Victoria, annual opioid dispensing has increased by 78% since 2006, with hospital presentations for opioid toxicity increasing by 10% per year. Deliberate self-poisoning accounts for 56% of these admissions.

Misuse of pharmaceutical agents refers to the use of pharmaceutical medications supplied OTC or on prescription, either for non-medical purposes or in doses or frequencies greater than those prescribed, to induce or enhance the drug effect. Opioid and prescription analgesic misuse is most common (3.6%), with codeine and oxycodone accounting for the majority. Although misuse is common in young adults, users tend to be older on average (45 years) than other illicit drug users (34 years). New restrictions on OTC codeine-based products may help to reduce the misuse of these agents in the future.

In assessment and management planning, consider the primary toxic effect of the agent, complications of intoxication and complications of the administration/injection technique. Complications of poor injection technique include cellulitis, thrombophlebitis, intra-arterial injection and embolization, mycotic aneurysm, endocarditis, anaerobic infection and blood-borne virus infection. A high index of suspicion is required.

Presentation to an emergency department (ED) with acute intoxication or complications of drug use indicates ongoing hazard and provides an opportunity for intervention. Patients should be counselled regarding strategies to avoid future overdose and if willing, should be referred to rehabilitation agencies.

AMPHETAMINES

Pharmacology and pathophysiology

Amphetamines are structurally related to adrenaline and resemble catecholamines. Substitutions on the basic structure of phenylethylamine include methamphetamine ('ice', 'speed'), 3,4-methylenedioxymethamphetamine (MDMA, 'ecstasy', 'Adam' or 'E'), 3,4-methylenedioxyethamphetamine (MDEA, 'Eve') 3,4-methylenedioxyamphetamine (MDA, 'love drug') and para-methoxyamphetamine (PMA).

Amphetamines may be ingested, smoked, insufflated or injected. All are absorbed from the gastrointestinal (GI) system, with peak serum levels within 3 hours. They are weak bases, 20% bound to plasma proteins and have large volumes of distribution. Half-lives vary from 8 to 30 hours. Hepatic transformation is the major route of elimination; however, up to 30% of amphetamine and methamphetamine may be eliminated in the urine.

Amphetamines enhance the release of catecholamines and block their reuptake causing increased stimulation of central and peripheral adrenergic receptors leading to a sympathomimetic toxidrome. Higher doses cause central serotonin release. Substitutions alter the hallucinogenic, behavioural and cardiovascular effects of the drugs. In overdose, it may be impossible to distinguish the exact amphetamine derivative involved as effects are more uniform.

Epidemiology

In 2016, 6.3% of Australians over 14 years reported using amphetamine derivatives in their lifetime. MDMA use was also common, with 11.2% of people over age 14 years reporting lifetime use. Amphetamine use has been declining in younger age groups since 2001.

Clinical features

Predominant symptoms are CNS excitation and peripheral sympathomimetic response. Euphoria, apprehension and agitation are common. Tachypnoea, mydriasis, tremor, diaphoresis and hyperpyrexia may also occur. Psychosis may occur with visual and tactile hallucinations, severe agitation and paranoia resembling paranoid schizophrenia. Myocardial infarction, aortic dissection, rhabdomyolysis, acidosis, acute cardiomyopathy, shock, renal failure and coagulopathy are documented. Symptoms may persist for several days. Death is secondary to hyperthermia, arrhythmia, intracerebral haemorrhage or trauma.

Hyponatraemia with cerebral oedema presenting as altered consciousness and seizures is reported following MDMA use and may be fatal. Mechanisms contributing to hyponatraemia include psychogenic polydipsia and inappropriate secretion of antidiuretic hormone.

Chronic abuse of amphetamines may be complicated by a necrotizing vasculitis which may involve multiple organ systems and lead to renal failure, myocardial ischaemia and cerebrovascular disease.

Amphetamine dependence and withdrawal is recognized. Withdrawal is characterized by neurasthenic symptoms, including somnolence and intense cravings for amphetamines. Management is supportive.

Differential diagnosis

Intoxication by an amphetamine derivative may not be discernible clinically from cocaine, except for the increased psychotic features and longer duration of action. The differential diagnosis also includes anticholinergic delirium, serotonin syndrome, alcohol and benzodiazepine withdrawal, sepsis, thyrotoxicosis and phaeochromocytoma.

Clinical investigations

Physical examination and investigations should be directed at excluding complications and alternative diagnoses. Seizures or coma should prompt investigation for complications, such as intracerebral haemorrhage or electrolyte disturbance. All patients should have a blood glucose measurement.

Treatment

Resuscitation for immediate life threats should proceed along standard lines. Care in a quiet area away from excessive stimulation may be advantageous. Patients exhibiting psychomotor acceleration or psychosis should be managed with titrated intravenous sedation.

Hyperthermia and seizures should be managed aggressively. Hyperthermia is an important contributing factor to morbidity and mortality. Core temperature should be measured in all patients and continuous monitoring is recommended if the temperature is elevated. Mild-to-moderate hyperthermia (<39°C) usually responds to benzodiazepine sedation and fluid resuscitation. If temperature continues to rise, intubation and paralysis are indicated. The use of dantrolene is not indicated.

Benzodiazepines are first-line therapy for seizures, followed by barbiturates, then general anaesthesia. Seizures in the context of acute hyponatraemia require initial rapid sodium replacement. Patients with persistent psychotic features may respond to an antipsychotic agent.

Disposition

The duration of observation in the ED and the need for admission will depend on the severity of intoxication, the influence of co-ingested drugs, comorbidities and complications. Patients with mild intoxication may be observed in the ED and discharged when vital signs and mental status have returned to normal. The long half-lives of the amphetamines may dictate inpatient care if symptoms or abnormal vital signs do not resolve within a few hours.

COCAINE

Pharmacology and pathophysiology

Coca leaves have been chewed by the natives of the South American Andes for approximately 1200 years and were first exported to Europe in 1580. Cocaine hydrochloride, or benzoylmethylecgonine hydrochloride, is a powder prepared from the leaves of the *Erythroxylon* coca plant. 'Freebase' cocaine is an alkaloid prepared by mixing cocaine hydrochloride, water and baking soda and separating the precipitate. If the solvent is allowed to evaporate, pure cocaine crystals remain, known as 'rock' or 'crack'. Cocaine reaches the cerebral circulation within seconds after smoking or insufflation. After oral ingestion, gastrointestinal absorption may not peak for 90 minutes. Cocaine is hydrolysed by plasma and liver cholinesterase to an active metabolite. Five to ten percent of cocaine is excreted in the urine unchanged with a half-life of 60 to 90 minutes.

Cocaine is a CNS stimulant acting via enhanced release of noradrenaline, plus blockade of noradrenaline, dopamine and serotonin reuptake. With increasing doses, euphoria is followed by dysphoria, agitation, seizures and coma. Cocaine stimulates the medullary vasomotor centre resulting in hypertension and tachycardia. Small doses may produce transient bradycardia. At high levels, the medullary centre may be depressed, leading to respiratory depression.

Peripherally, cocaine inhibits the reuptake of adrenaline and noradrenaline and stimulates the presynaptic release of noradrenaline. This leads to a sympathomimetic response mediated through both α- and β-adrenoreceptors, leading to tachycardia, diaphoresis, vasoconstriction and hypertension. Increased psychomotor activity, vasoconstriction and direct hypothalamic toxicity, possibly mediated by dopamine receptors, contribute to hyperpyrexia.

Cocaine is an ester-type local anaesthetic that blocks fast sodium channels. In severe toxicity, hypotension may occur due to a direct toxic effect on the myocardium. Wide complex tachyarrhythmias are observed with cocaine toxicity. Sodium channel and potassium channel blockade occur, in addition to sympathomimetic, ischaemic and cardiomyopathic effects. Arrhythmias are multifactorial; factors include dose, co-exposures, acid–base and electrolyte imbalance and genetic variability. Transient arrhythmias may account for syncope not attributable to seizures.

Epidemiology

The prevalence of cocaine use is increasing in Australia, with 9% of the population aged over 14 years reporting cocaine use in their lifetime in 2016.

Clinical features

The predominant symptoms are those of Central nervous system (CNS) excitation and peripheral sympathomimetic response. CNS manifestations include agitation, altered mental state, seizures, dyspnoea, transient focal neurological signs, intracranial haemorrhage and coma. Cerebral infarction, transient ischaemic attacks, subarachnoid haemorrhage, cerebral vasculitis and migraine-like headache are described. Contributing mechanisms include hypertension, vasoconstriction, vasculitis, increased coagulability, altered cerebrovascular autoregulation and embolization of particulate matter.

Cardiovascular manifestations include tachycardia, hypertension, supraventricular or ventricular tachydysrhythmias and syncope. Chest pain may be due to musculoskeletal, pulmonary or cardiovascular causes. Cocaine-induced myocardial ischaemia is multifactorial; increased myocardial oxygen demand, immediate or delayed coronary artery vasospasm, increased platelet aggregation, impaired thrombolysis and accelerated atherosclerosis all contribute. Aortic dissection associated with cocaine use is reported. A retrospective study of patients intoxicated with cocaine presenting with chest pain consistent with ischaemia found 6% suffered acute myocardial infarction.

Smoking cocaine may lead to respiratory complications including thermal airway injury, pneumothorax, pneumomediastinum, noncardiac pulmonary oedema, interstitial pneumonitis and bronchiolitis obliterans. Tachypnoea, mydriasis, tremor, diaphoresis and hyperpyrexia may also be seen. Mesenteric vasoconstriction and vasculitis may lead to bowel ischaemia and infarction. Rhabdomyolysis complicated by renal failure and hyperkalaemia is reported.

Differential diagnosis

The differential diagnosis includes intoxication with other sympathomimetic agents, hallucinogenic agents, anticholinergic delirium, serotonin syndrome, alcohol and benzodiazepine withdrawal, sepsis, thyrotoxicosis and phaeochromocytoma.

Clinical investigations

The diagnosis is clinical, based on history, sympathomimetic symptoms and signs and the exclusion of other conditions. Physical examination and investigations are directed at excluding complications and alternative diagnoses. Patients with altered vital signs should have a blood glucose measurement, 12-lead ECG and continuous ECG monitoring.

Treatment

Patients exhibiting CNS agitation or sympathomimetic cardiovascular effects should receive an intravenous benzodiazepine titrated to achieve sedation. Hyperthermia and seizures require aggressive resuscitation (as for amphetamines) to prevent a poor outcome. Seizures should be managed with benzodiazepines and barbiturates, escalating to general anaesthesia if required.

Benzodiazepines, nitrates and calcium channel blockers reduce hypertension and cocaine-induced vasoconstriction causing chest pain/myocardial ischaemia. The use of β-adrenergic receptor blockers in cocaine intoxication is controversial due to the theoretical risk of unopposed alpha-stimulation worsening hypertension. Agents with combined beta and alpha blockade (e.g. labetalol) are associated with fewer complications. Primary angioplasty is the treatment of choice for cocaine-induced ST-elevation myocardial infarction. Ventricular arrhythmias should be treated according to Advanced Coronary Life Support (ACLS) guidelines. In addition to defibrillation or cardioversion, intravenous bolus bicarbonate (1 to 2 mEq/kg) and titrated benzodiazepines are used. Lignocaine is an acceptable alternative. Ventricular arrhythmias occurring after the acute phase of intoxication are presumed to be secondary to myocardial ischaemia and should therefore be treated in a standard manner. In patients with nondiagnostic ECG, investigation should proceed as for non-toxicological chest pain.

Disposition

Disposition depends on the severity of toxicity, co-ingested drugs, comorbidities and complications. Patients with mild intoxication may be observed in the ED and discharged when the patient is asymptomatic with normal vital signs and mental status.

GAMMA-HYDROXYBUTYRIC ACID

Pharmacology and pathophysiology

Gamma-hydroxybutyric acid (GHB) (4-hydroxybutanoate; sodium oxybate) is a sedative-hypnotic agent causing sedation and psychotropic effects. GHB is a short-chain fatty acid that acts as a neurotransmitter. It is a metabolite of gamma-aminobutyric acid (GABA). The mechanism by which GHB causes its effects is unclear, but is probably mediated by specific GHB and GABA-B receptors. It also has dopaminergic activity, increases acetylcholine and serotonin levels and may interact with endogenous opioids. GHB was developed as a short-acting anaesthetic agent, but lost favour due to poor analgesic properties and a propensity to cause seizure-like activity at the onset of coma.

GHB is ingested as a liquid and is rapidly absorbed, peaking within 15 to 45 minutes. It is metabolized by alcohol dehydrogenase. The average half-life is 20 to 50 minutes.

Epidemiology

GHB ('grievous bodily harm', 'fantasy', 'scoop', 'liquid X', 'liquid E') and its congeners gamma-butyrolactone (GBL) and 1,4-butanediol have been advocated for body building, euphoria, sleep enhancement and sexual stimulation. In 2016, 0.1% of the population aged over 14 years reported using GHB in their lifetime.

Clinical features

CNS effects with increasing dose include euphoria, then agitation followed rapidly by sedation and coma. Profound coma may occur, but the patient may resist instrumentation of the airway or rouse when stimulated. Altered conscious state is associated with mild bradycardia and/or hypotension which rarely requires intervention. Agitation is common on emergence from coma and patients may rapidly change from unresponsive to agitated and combative. Abrupt resolution of coma within 2 to 3 hours of presentation is characteristic of GHB intoxication. However, co-ingested agents may cloud the clinical picture. Respiratory depression and apnoea may occur in the context of co-ingestants.

Seizures commonly represent myoclonic movements or may be generalized due to hypoxia or a co-ingested agent. Chronic users may develop a withdrawal syndrome that mimics alcohol or sedative-hypnotic withdrawal.

Differential diagnosis

The differential diagnosis includes toxicological and metabolic causes, sepsis, neurotrauma, stroke and post-ictal state. Persistent CNS depression beyond 6 hours suggests an alternative cause.

Investigations

The diagnosis of GHB intoxication is clinical. Examination and investigations are directed at excluding alternative diagnoses and complications. All patients should have a blood glucose measurement.

Treatment

Management is supportive. Resuscitation for immediate life threats should proceed along standard lines. Patients with an altered level of consciousness should be closely monitored in a resuscitation area, positioned to minimize the probability of aspiration and moved frequently to prevent dependent injuries. Intubation may be required if the airway is threatened due to vomiting or prolonged coma. There is no specific antidote for GHB.

Disposition

The duration of observation will depend on the need for intubation, co-ingested agents or the presence of complications. Most patients recover within a few hours and may be safely discharged from the ED when they are ambulant and orientated.

EMERGING PSYCHOACTIVE SUBSTANCES

Introduction and epidemiology

Emerging psychoactive substances (EPS) also known as 'legal highs', are synthetic agents with structural similarity or similar effects to existing illicit agents, particularly cannabis, MDMA and hallucinogens. They are readily available from 'head/herb shops' and via internet sources. In 2016, 2.8% of the population aged over 14 reported using synthetic cannabinoid receptor agonists in their lifetime and 1% reported using other EPS agents.

There is a wide variety of agents and inconsistency in final product. Many products contain additional caffeine. In addition, agents sold legally may contain unlisted illegal ingredients. Continual emergence of structural analogues and new chemical agents mean clinical effects are unpredictable and avenues for supply control are limited. Clinical features may be indistinguishable from conventional agents. The most commonly available agents will be considered here.

Cathinones

Pharmacology and pathophysiology

Cathinone is a beta-ketone amphetamine analogue from leaves of *Catha edulis*. Khat leaf chewing causes sympathomimetic effects similar to amphetamines. Synthetic phenylalkylamine analogues include mephedrone ('meow-meow', 'MCAT'), methcathinone, methylone and methylenedioxypyrovalerone (MDPV; 'bath salts', 'ivory wave'). The mechanism of action is similar to amphetamines, inhibiting monoamine reuptake. They are presented as a powder or pill which is insufflated, ingested or injected. Onset of action after ingestion is 15 to 45 minutes with effects lasting 2 to 7 hours.

Clinical features

Increased energy from ingestion of cathinones is reported to be better and longer lasting than cocaine. Twenty percent develop adverse symptoms including palpitations, GI upset and mental disturbance. Agitation, sometimes severe and requiring restraint, is common. A sympathomimetic toxidrome with chest pain, diaphoresis, tachycardia and hypertension may occur. Psychosis, anxiety, hallucinations and delusions are common; abnormal liver and renal function, rhabdomyolysis and hyponatraemia with seizures and death have been reported.

Piperazines

Pharmacology and pathophysiology

Benzylpiperazine (BZP, 'herbal party pills', 'BenzoFury') is most well known; however, other agents, such as trifluoromethylphenylpiperazine (TFMPP), are commonly available. BZP is a dopamine reuptake inhibitor and increases dopamine release. BZP increases peripheral catecholamine release, and stimulates peripheral alpha-2 receptors causing sympathomimetic stimulation.

TFMPP is a direct serotonin agonist at 5HT-1 and 5HT-2 receptors and inhibits serotonin reuptake. Piperazines are metabolized by cytochrome P450 and may cause enzyme inhibition, leading to drug interactions.

Clinical features

BZP and TFMPP are combined to mimic the effects of MDMA. Stimulant effects are predominant at lower doses and hallucinogenic effects at higher doses; however, there is significant interindividual variability. A sympathomimetic toxidrome is common with sinus tachycardia, hypertension, agitation, anxiety, confusion and gastrointestinal upset being reported. More severe effects include seizures, hyperthermia, movement disorders, chest pain/myocardial toxicity and hyponatraemia (rare). Effects are reported to last 6 to 8 hours; however, lethargy, insomnia, anxiety, paranoia and mood disorders may persist for several days.

Synthetic cannabinoid receptor agonists

Pharmacology and pathophysiology

Synthetic cannabinoid receptor agonists ('kronic', 'spice', 'k2') act at cannabinoid receptors CB1 and CB2, as well as N-methyl-D-aspartate (NMDA) receptors. There are several structural groups of chemicals which are added to herbal mixes and smoked. These agents have a higher affinity for the cannabinoid receptors than tetrahydrocannabinol (THC). Sympathomimetic and hallucinogenic effects may be due to over-activation of cannabinoid receptors, mixed receptor effects, or herbal material effects.

Clinical features

Most cases result in mild clinical effects such as tachycardia, diaphoresis, nausea and agitation. Life-threatening effects are increasingly reported, including myocardial ischaemia, acute kidney injury, rhabdomyolysis, generalized seizures and psychiatric effects including paranoia, psychosis and self-harm. Death has been reported, both directly and indirectly through trauma.

NBOMe

Pharmacology and pathophysiology

N-methoxybenzyl compounds (NBOMe) are phenylethylamine derivatives, first synthesized in 2003, which mimic the effects of Lysergic Acid Diethylamide (LSD). The most commonly available is 25I-NBOMe but there are several analogues varying by a halogenated functional group. These agents have high affinity for alpha-adrenergic and serotonin receptors, especially 5-HT2a. Administration is sublingual, buccal, nasal, oral, injection and inhalation.

Clinical features

Effects such as tachycardia, agitation, hallucinations, hypertension and confusion are common. Agitation may be severe and violent, leading to traumatic injury. Serotonergic and sympathomimetic effects including hyperreflexia, increased muscle tone, clonus and hyperthermia may occur, leading to rhabdomyolysis, acute kidney injury and death.

Clinical investigations

Diagnosis of intoxication by EPS is clinical. Drug levels are not readily available clinically but may

be measured for forensic reasons. EPS are not reliably detected by routine bedside drug testing.

Treatment

Management is symptomatic and supportive. There are no specific antidotes. Resuscitation for immediate life threats should proceed along standard lines. Intravenous benzodiazepine sedation is first-line management for seizures, agitation, psychosis or generalized muscle rigidity. Hyperthermia should be treated aggressively with cooling measures and titrated benzodiazepines with escalation to intubation and paralysis if necessary. Treatment of hyponatraemia follows standard protocols.

OPIATES

Opiates are derivatives of the opium poppy, *Papaver somniferum*, which contains approximately 20 alkaloids, including morphine and codeine. Opioids are one of the commonest causes of drug related deaths in Australia. The rate of accidental opioid deaths has more than doubled among Australians aged 35 to 44 since 2007, with greater than two-thirds of these deaths due to pharmaceutical opioids rather than heroin. Refer to Chapter 25.23 on opioids.

Opioid withdrawal syndrome

Symptoms of opioid withdrawal include anxiety, insomnia, apprehension, hyperventilation, mydriasis, nausea, vomiting, diarrhoea and abdominal pain. Symptoms usually occur 12 hours after the last dose of morphine or heroin, peak at 2 days and abate after 5 days. Seizures do not occur and the prognosis is good, even without medical intervention.

After exclusion of concomitant pathology, management should include treatment of dehydration, symptomatic care and referral to drug and alcohol services. Clonidine, an α_2-receptor adrenergic agonist, is used to decrease autonomic symptoms. An initial dose of 1 to 2 μg/kg, 2 to 3 times per day can be increased depending on side effects.

'BODY-PACKERS', 'BODY-STUFFERS', 'BODY-PUSHERS'

Body-packers and body-stuffers conceal illicit drugs inside the body. A body-packer swallows a large quantity of an illicit drug in an attempt to smuggle it across international borders. Up to 1 kg of drugs may be carefully packaged in 50 to 150 packages and layered with wax. Patients are usually asymptomatic at presentation. A body-stuffer ingests smaller quantities of drugs before apprehension by authorities. The package is usually poor and is more likely to leak. Symptoms of drug intoxication often onset within 1 to 2 hours of ingestion. Body pushers conceal drug packets in the rectum or vagina.

Ideally, a detailed history should be obtained noting the type and amount of drug ingested, the method of packaging, symptoms of drug intoxication and any factors that may increase the likelihood of bowel obstruction or ileus. History may be misleading, especially if taken in the presence of law enforcement officers. Physical examination should include vagina and rectum and assessment for signs of drug intoxication.

Clinical investigations

Imaging of the potential body-packer is controversial. With any imaging modality, an increased number of packets increases the sensitivity of imaging. Abdominal radiographs are often positive in body-packers. The sensitivity and specificity of plain abdominal films in large series is reported to be 85% to 90%. Negative plain radiographs do not exclude swallowed packets.

Abdominopelvic multidetector computed tomography (CT) scanning without contrast is now recommended with recent studies showing sensitivity and specificity 95% to 100% irrespective of number of packets, type of drug or wrapping material. Packet counts on CT are only accurate if less than 15 packets are swallowed. While packets may be visible on bedside ultrasound, sensitivity is much lower than plain films. Qualitative urine drug screens are not routinely indicated. In the presence of signs of intoxication, investigation for complications and co-morbidities is appropriate.

Treatment

In view of the potential sudden lethality of these practices, patients should receive a high triage priority and be managed in a resuscitation setting with secure intravenous access regardless of presenting symptoms or signs. Evidence of drug intoxication represents a medical emergency and requires aggressive management. Resuscitation for immediate life threats should proceed along standard lines. Optimal gastrointestinal decontamination of body-packers and body-stuffers is controversial and should be considered on a case-by-case basis. Cooperative patients should receive activated charcoal to adsorb intraluminal drug. Conservative management of asymptomatic patients is now advocated with observation, laxatives and light diet until all packets are retrieved. The risk of late-onset drug intoxication, bowel obstruction, laparotomy or death is less than 5% with this approach. The use of whole bowel irrigation with polyethylene glycol to accelerate passage of packages has previously been advocated. Surgical exploration is indicated if there is gastric outflow or bowel obstruction, concretion formation, ileus or perforation. If a cocaine or amphetamine body-packer exhibits toxicity, surgical exploration to remove all packages has been advocated following initial resuscitation. In the symptomatic opiate body-packer, adequate resuscitation, supportive care and antidote therapy should ensure a favourable outcome. Body-stuffers with a single package located in the stomach may be amenable to endoscopic removal, especially if there is failure to pass the pylorus, but it carries the risk of packet rupture.

All body-packers should remain in a closely monitored environment until all packages have been retrieved. Staff should be aware of potential signs of intoxication and be available to intervene in the event of complications. Patients are observed until all packages have been accounted for. Repeat radiology is performed to confirm clearance before discharge.

CONTROVERSIES

- Optimal sedation regimen for cocaine and amphetamine-intoxicated patients.
- Intubation vs. expectant management for patients with GHB intoxication.
- Optimal management of patients using synthetic agents or 'legal highs'.
- Optimal imaging and gastrointestinal decontamination in body-packers.

25.13 Cyanide

George Braitberg

ESSENTIALS

1 **Cyanide is a metabolic poison associated with a high mortality.**

2 **Cyanide toxicity is characterized by rapid onset of central nervous, respiratory and cardiovascular effects and by metabolic acidosis.**

3 **Cyanide exposure correlates well with serum lactate levels.**

4 **Prompt resuscitative efforts with high-flow oxygen and administration of antidotes may be life saving; a number of alternative agents are available.**

5 **Cyanide poisoning from smoke inhalation is often overlooked and treatment is complicated by the potential coexistence of carboxy- and methaemoglobinaemia.**

Introduction and epidemiology

Cyanide refers to any substance that contains the cyano (CN) group. It is used in a variety of commercial processes including metal extraction (especially gold) and recovery, metal hardening and in the production of agricultural and horticultural pest control compounds. A list of potential sources of cyanide exposure is found in Box 25.13.1.

Organic salts such as hydrogen cyanide (HCN) are highly toxic and can occur in a liquid or gaseous form. HCN has a distinctive odour of bitter almonds; however, 20% to 40% of people are genetically unable to detect this. Cyanide gas production from house fires is well documented. In one study, blood cyanide concentrations greater than 40 μmol/L (toxic level) were measured in 74% of victims found dead at the scenes of fires.

Box 25.13.1 Potential sources of cyanide exposure

Industrial sources
- Insecticides
- Photographic solutions
- Metal polishing materials
- Jewellery cleaners
- Acetonitrile
- Electroplating materials
- Synthetic products such as rayon, nylon, polyurethane foam, insulation, and adhesive resins

Natural sources
- Seeds and fruit pits of *Prunus* species (e.g. apple seeds and cherry and apricot pits)

Environmental sources
- Smoke inhalation in closed-space fires

Iatrogenic sources
Sodium nitroprusside infusion

(From Hamel J. A review of acute cyanide poisoning with a treatment update. *Crit Care Nurse*. 2011;31(1):72–82.)

In another study 11 of 138 patients with fire-related deaths had potentially fatal blood cyanide levels (greater than 100 μmol/L). It is suggested that in patients with severe burns, elevated lactate and/or carboxyhaemoglobin greater than 10%, the use of a safe cyanide antidote should be considered. It should be noted, however, although blood cyanide concentration can be measured, it is not of use for diagnosis in the acute setting as few laboratories perform the assay and results cannot be obtained rapidly. Diagnosis is therefore clinical.

Death from cyanide poisoning is one of the most rapid and dramatic seen in medicine and appropriate resuscitation with antidotal therapy must be given early to alter outcome. A dose of 200 mg of ingested cyanide, or a 3-minute exposure to HCN gas, is potentially lethal. Historically cyanide has been used in mass homicides (Zyklon B gas used by the Nazis during the Second World War) and suicide. Cyanide is considered a likely agent of terrorism because it possesses attributes of the ideal chemical weapon. It is readily available and, because of its use in industry and research laboratories, is widely distributed making it susceptible to theft, hijacking attempts and other terrorist acts and is capable of causing mass incapacitation and casualties. It can be released in the atmosphere as a gaseous weapon or introduced into pharmaceuticals, the food supply and is considered a primary threat to water supplies.

Toxicokinetics and pathophysiology

The uptake of cyanide into cells is rapid and follows a first-order kinetic simple diffusion process. The half-life of cyanide is from 2 to 3 hours.

While the precise in vivo action of cyanide is yet to be determined, it is believed that its major effect is due to binding with the ferric ion (Fe^{3+}) of cytochrome oxidase, the last cytochrome in the respiratory chain (Fig 25.13.1). This results in inhibition of oxidative phosphorylation, halting electron transport, oxygen consumption and adenosine triphosphate (ATP) formation. This leads to a net accumulation of hydrogen ions, a change in the NAD:NADH ratio and greatly increased lactic acid production. Other enzymatic processes, involving antioxidant enzymes, catalase, superoxide dismutase and glutathione, may contribute to toxicity. Cyanide is also a potent stimulator of neurotransmitter release in both the central and the peripheral nervous systems. Humans detoxify cyanide by sulphur transfer to form thiocyanate (SCN). The availability of the enzymes that sequester cyanide as thiocyanate, rhodanase and 3-mercaptopyruvate sulphurtransferase is the rate-limiting step.

Clinical features (Fig. 25.13.2)

Any acute cyanide exposure is potentially lethal. Onset of symptoms is usually rapid and can be within seconds to minutes for inhalation and within an hour for oral exposure. The 'classical' presentation is rapid onset of coma, seizures, shock and profound lactic acidosis.

Cyanide toxicity is characterized by effects on the central nervous system (CNS), respiratory and cardiovascular systems and by a marked metabolic acidosis.

CNS manifestations, in order of increasing severity of cyanide exposure, are headache, anxiety, disorientation, lethargy, seizures, respiratory depression, CNS depression and cerebral death. An initial tachypnoea gives way to respiratory depression as CNS depression develops.

Cardiovascular manifestations include hypertension followed by hypotension, tachycardia followed by bradycardia, arrhythmias, atrioventricular block and increased cardiac output followed by myocardial depression and cardiovascular collapse. Cyanide poisoning can shorten the QT interval to the point of 'T on R' phenomenon. The classic finding of bright red skin due to poor tissue oxygen usage (secondary to a decreased arteriovenous oxygen gradient) is not observed if significant myocardial, respiratory or CNS depression has already occurred, in which case the patient may appear cyanotic.

Clinical investigations

There is no reliable commercially available cyanide diagnostic that will provide a cyanide level in a clinically significant time frame. Arterial blood gas analysis and serum lactate measurements reveal metabolic acidosis with a raised

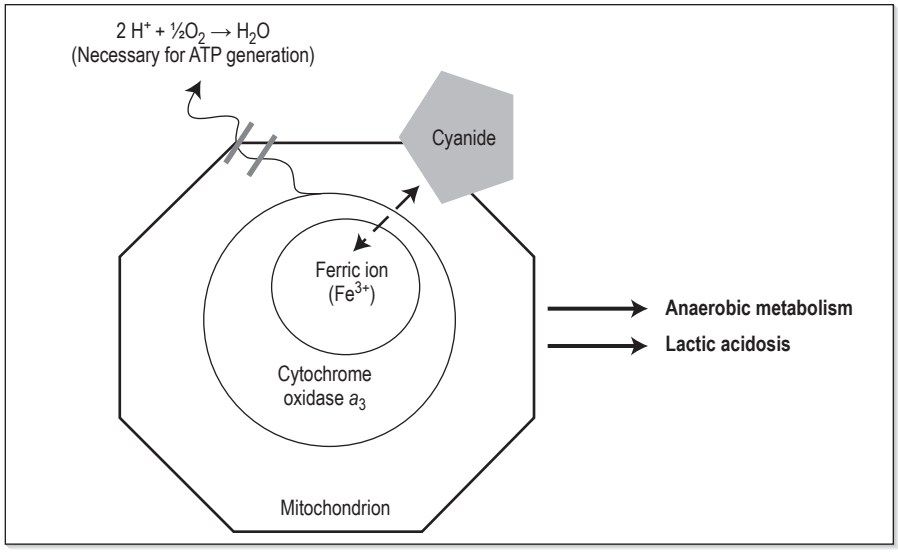

FIG. 25.13.1 Cellular Effect of Cyanide Toxicity. *ATP,* adenosine triphosphate. (Reproduced with permission from Hamel J. A review of acute cyanide poisoning with a treatment update. *Crit Care Nurse.* 2011;31[1]:72–82.)

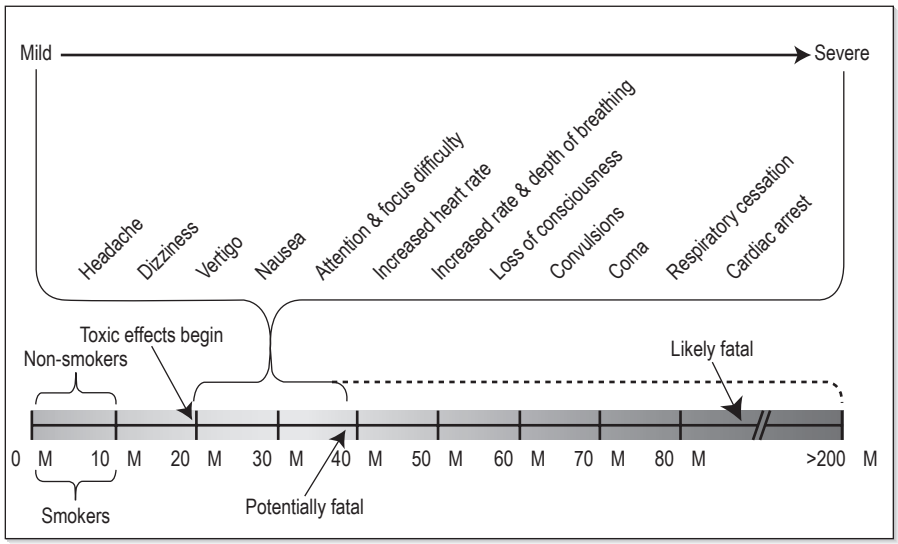

FIG. 25.13.2 Clinical signs and symptoms of cyanide toxicity correlated to blood cyanide concentrations. The darker colour indicated higher cyanide concentrations. (Reproduced with permission from Jackson R, Logue BA. A review of rapid and field-portable analytical techniques for the diagnosis of cyanide exposure. *Anal Chim Acta.* 2017;960:18–39.)

lactate. Concentration decay curves suggest that serum lactate concentration is closely correlated to blood cyanide concentration. In smoke-inhalation victims without severe burns, plasma lactate concentrations above 10 mmol/L correlate with blood cyanide concentrations above 40 μmol/L, with a sensitivity of 87%, a specificity of 94% and a positive predictive value of 95%.

Cyanide is concentrated 10-fold by erythrocytes and whole-blood cyanide concentrations are used as the benchmark when comparing levels. Symptomatic intoxication starts at levels of 20 μmol/L, toxicity at 40 μmol/L, and 100 μmol/L is considered potentially lethal. Environmental detectors that detect airborne toxic industrial chemicals such as cyanide are available to some first responder organizations and may provide the clinician with useful prehospital information.

Treatment

Resuscitation

Attention to airway, breathing, circulation and other resuscitative measures must be instituted immediately. Patients should be ventilated with 100% O_2. Patients must be removed from enclosed or confined spaces with high airborne concentrations of cyanide. Rescuers, likewise, must not enter such areas without full protective clothing and proper respirators or self-contained breathing apparatus. Mouth-to-mouth breathing should never be done.

Decontamination

Exposed skin and eyes should be copiously flushed with water or normal saline in an attempt to decontaminate the patient. All clothes should be removed and bagged. Activated charcoal is given only after the airway is secured.

Antidote treatment principles

Resuscitation bodies such as the Australian Resuscitation Council and the European Society for Emergency Medicine have recommended empirical antidotal treatment where there is clinical evidence of cyanide poisoning or a high index of suspicion of significant exposure from smoke inhalation. Where there is doubt it is logical to avoid the more toxic antidotes such as dicobalt edetate.

Table 25.13.1 Cyanide antidotes

Antidote	*Mechanism of action*	*Dose and route*	*Side effects*
Hydroxycobalamin	Binds cyanide directly	5 g IV over 15 min	Transient hypertension, headache, bradycardia, skin and urine discolouration
Sodium thiosulphate	Upregulates body's natural excretion mechanism of forming thiocyanate	12.5 g IV over 10 min (and repeat)	Nausea and vomiting, headache
Nitrites	Convert haemoglobin to methaemoglobin which binds cyanide	Sodium nitrite: 300 mg IV over 5–20 min Amyl nitrite: 0.3 mL ampoules crushed 4DMAP: 250 mg IV over 1 min	Reduction in oxygen carrying capacity of blood, vasodilation, hypotension
Dicobalt edetate	Binds cyanide directly	300 mg IV over 1 min	Anaphylaxis, hypotension, cardiac arrhythmias; more severe in absence of cyanide toxicity

4DMAP, 4-Dimethylaminopyridine, (Modified from MacLennan L, Moiemen N. Management of cyanide toxicity in patients with burns. *Burns.* 2015;41:18–24.)

Hydroxocobalamin and sodium thiosulphate, both with few adverse effects, would be safer in this setting.

Therapeutic endpoints in treatment are improvement in conscious state, haemodynamic stability and improvement in metabolic acidosis.

Importantly, there are case reports of early and aggressive supportive care resulting in good outcome without the use of antidotes.

Specific cyanide antidotes (Table 25.13.1)

Hydroxocobalamin (Cyanokit)

A systematic review of cyanide poisoning management for the Australian Resuscitation Council has recommended this as the initial antidote for the management of adults with suspected severe cyanide poisoning. It is the cyanide antidote most widely used in Europe. It complexes with cyanide, on a mole-for-mole ratio, to form cyanocobalamin. Antidotal doses of hydroxocobalamin are approximately 5000 times the physiological dose. In Australian it is approved for use under the Special Access Scheme.

Hydroxocobalamin and cyanocobalamin are excreted by the kidney. The half-life of hydroxocobalamin in cyanide-exposed patients is 26.2 hours. As the half-life of cyanide in smoke inhalation victims is calculated to be between 1.2 and 3.0 hours, it is suggested that hydroxocobalamin can be satisfactorily used as single-dose therapy. The amount of cyanocobalamin formed after a dose of 5 g hydroxocobalamin correlates linearly until a blood cyanide level of 40 µmol/L is reached. At higher blood cyanide concentrations, there is little further rise in plasma cyanocobalamin and it is suggested that the rate-limiting step in the formation of cyanocobalamin is the availability of antidote, not the absence of cyanide ions. In cases of ingestion of cyanide with suicidal intent (where blood cyanide levels may be >150 µmol/L or plasma lactate concentrations >20 µmol/L), the usual dose of 5–10 g may be insufficient. Initial dose is usually 2.5 g. Based on the limited efficacy data available, as well as the more widely documented safety data, hydroxocobalamin is a safe and effective first-line antidote for cyanide toxicity and has been demonstrated to be efficacious in patients with cyanide poisoning with whole blood cyanide levels up to 150 µmol/L.

Side effects are minimal. In healthy adult smokers, 5 g of IV hydroxocobalamin is associated with a transient reddish discoloration of the skin, mucous membranes and urine and a mean elevation in systolic blood pressure of 14%, with a concomitant 16% decrease in heart rate. No other clinical adverse effects are noted and allergic reactions are rare.

Hydroxocobalamin is a strong red chromophore with absorption maxima at 274 nm and 351 nm and no absorption above 600 nm. These physical properties may interfere with colourmetric measurements resulting in a falsely lowered carboxyhaemoglobin, a falsely elevated lactate and depending on the pathology system used a positive bias on methaemoglobin measurements may occur.

Hydroxocobalamin has a reasonably long shelf life, but is expensive. Hydroxocobalamin has also been recommended as the treatment of choice for mass casualty chemical disasters where cyanide poisoning is suspected.

Cyanide antidote kit

The cyanide antidote kit (CAK) has been discontinued but is still used overseas and held in stock in parts of Australia. It is composed of:

- amyl nitrite perles[1]
- sodium nitrite 10 mL (30 mg/mL)
- sodium thiosulphate 50 mL (250 mg/mL).

The mechanism of action is the conversion of haemoglobin to methaemoglobin promoting the movement of cyanide out of the cytochrome system; 4 mg/kg of sodium nitrite takes 30 minutes to achieve 7% to 10.5% methaemoglobin. Under usual circumstances humans tolerate up to 30% methaemoglobin levels. The formation of sodium thiocyanate allows for the reformation of Hb^{2+} (Ferrous haemoglobin), restoring the oxygen-carrying capacity of haemoglobin. Cellular respiration can continue as normal with cyanide removed from the respiratory chain. The observation that dramatic improvements in symptoms have occurred well before methaemoglobin levels have peaked has led many authors to suggest different mechanisms of action, such as vasodilatation and extracellular redistribution of cyanide. In smoke inhalation victims with suspected combined carbon monoxide and cyanide poisoning, the addition of 10% methaemoglobin may have clinically significant synergistic detrimental effects on the oxyhaemoglobin dissociation curve; in this setting, methaemoglobin inducers should be avoided.

Amyl nitrite alone in the management of per-hospital mass casualty cyanide poisoning has been reviewed recently. Evidence for its use is limited to animal studies and its role in the management of human case reports relative to the other treatments administered (e.g. life support, sodium nitrite and sodium thiosulphate) is unclear. Amyl nitrite has significant adverse effects (hypotension, syncope, excessive methaemoglobinaemia and haemolysis in glucose-6-phosphate dehydrogenase [G6PD] deficient patients). On balance, its use is not recommended in the prehospital or hospital setting. Novel antidotes for the use of mass casualty exposure based upon water soluble sulphagen salts are being investigated but none are commercially available.

Thiosulphate on its own can function as a slow sulphur donor, converting cyanide to thiocyanate. Thiosulphate is relatively non-toxic, although nausea and vomiting may occur following treatment. It should be given to all patients with suspected cyanide toxicity, including those with smoke inhalation if no other antidote is available.

Dicobalt edetate (Kelocyanor)

Dicobalt edetate had been discontinued but is used overseas and held in stock in parts of Australia. It complexes with extracellular cyanide to form cobalt cyanide, thus removing cyanide from the circulation and reducing toxicity.

Adverse effects are considerable and may be life threatening. Severe hypotension, cardiac arrhythmias, convulsions and gross oedema are reported. These effects are exacerbated when the drug is administered to an individual who is not cyanide poisoned. The use of this antidote is only for confirmed cyanide poisoning cases where the patient has lost consciousness and safer antidotes are not available.

The recommended initial dose of dicobalt edetate is 300 mg IV. Further doses may be required.

[1]Commercial kits such as *Nithiodote* are now available that omit amyl nitrite (*Nithiodote* [sodium nitrite injection and sodium thiosulphate injection] package insert. Scottsdale, AZ: Hope Pharmaceuticals; 2011).

Other therapies

Hyperbaric oxygen (HBO) has been proposed as a treatment in cyanide poisoning but remains controversial with conflicting animal data. In most published human reports, HBO is offered after a combination of modalities and it is not possible to determine the treatment effect specific to each.

Recommended antidotal regimen (Table 25.13.1)

Consultation with a toxicologist is recommended for all suspected cases of cyanide poisoning.

CONTROVERSIES

- The effectiveness of any antidote to treat cyanide poisoning is based on case reports and animal data. Hydroxocobalamin is the most commonly recommended antidote in cyanide poisoning. Data on human exposure are limited.

25.14 Hydrofluoric acid

Andis Graudins • Sam Alfred

ESSENTIALS

1 **Patients and medical staff are often unaware of the presence of hydrofluoric acid (HF) in household cleaning products.**

2 **Topical HF exposures may result in the gradual onset of severe local pain out of proportion to objective clinical signs.**

3 **Dermal exposures should be irrigated immediately and copiously.**

4 **Symptomatic dermal exposures should be treated with topical calcium. If pain persists, escalation to local infiltration or intravenous or intra-arterial calcium administration is dependent on site of exposure.**

5 **Systemic toxicity may occur following dermal exposure to either a high concentration solution, exposure of more than 5% body surface areas to any concentration or following inhalation or ingestion.**

6 **Systemic toxicity is typically manifest as severe hypocalcaemia, hypomagnesaemia, hyperkalaemia, metabolic acidosis and cardiac arrhythmia.**

Introduction

Hydrofluoric acid (HF) is a moderately corrosive inorganic acid widely used industrially at concentrations between 50% and 100% in the etching of glass, metal, stone and silicon. HF is also a constituent of domestic rust and scale removers, car wheel cleaners, brick cleaners and solder flux mixtures, typically at concentrations below 10%.

The most common route of accidental exposure to HF is topical.[1–3] This may occur when high-concentration HF leaks through damaged gloves in the industrial setting or when domestic HF products are used without gloves. Inhalational exposure to HF may also occur in the industrial setting, while oral exposure may result from accidental or deliberate ingestion.

Pathophysiology

HF is a relatively weak acid with limited immediate corrosive effects related to a $pK_a = 3.8$, which limits the concentration of free hydrogen ions on the skin surface after dermal exposure.[2–4] Consequently low concentrations of HF (<20%) cause little or no pain immediately following exposure, whereas HF remains in an undissociated state that facilitates penetration through the skin into deeper tissues. As the concentration of HF increases, so does the potential for immediate corrosive injury, and immediate pain is expected at concentrations greater than 50%.[3,5]

The primary mechanism of tissue damage resulting from exposure to HF relates to fluoride toxicity following dissociation of the acid in exposed tissues.[2,3] Fluoride avidly binds divalent cations to form insoluble fluoride salts, with consequent hypocalcaemia and hypomagnesaemia, impairment of calcium-dependent clotting factors and coagulopathy. Fluoride interacts directly with numerous enzyme systems, interferes with cellular respiration,[6] and impairs Na^+/K^+ ATPase activity, resulting in the leak of potassium into the extracellular space and systemic

hyperkalaemia.[1,7] Tissue damage caused by these effects results in liquefactive necrosis rather than the coagulative necrosis more typical of acid burns, and the absence of coagulative eschar potentiates deep tissue penetration.

Clinical features

Exposure to HF in the industrial setting is usually recognized as such. Patients will often receive decontamination and topical calcium therapy prior to arrival at hospital. They are also likely to bring appropriate product information in the form of material safety data sheets. Acute dermal exposures in the domestic setting may present a more difficult diagnosis, given the temporal delay between exposure and symptom development seen after exposure to low-concentration domestic products. The patient may not recognize or report that the symptoms are related to a chemical exposure.[3]

Highly concentrated (>50%) HF contains enough free hydrogen ions to produce a near immediate burning sensation on the skin, providing some warning that acute exposure has occurred.[1,5] Lower-concentration (<10%) domestic HF products often produce no symptoms at the time of contact, and patients experience gradually increasing pain that develops 6 to 12 hours after exposure.[1]

The primary presenting complaint following topical HF injury is commonly pain out of proportion to physical signs. The pain is usually described as a tingling sensation that progresses to a burning pain and then to a severe deep, throbbing pain.[1,5,8]

Initially the exposure site is typically erythematous and may develop oedema. As tissue injury progresses, the site becomes pale and blanched, progressing to a classical silvery grey appearance.[2] Local vesiculation and frank tissue necrosis may ensue and progress over several days in untreated patients, resulting in the development of deep ulceration and extensive tissue loss.

Owing to the way in which HF is used, burns often involve exposure of relatively small areas of skin on the fingers, hands or feet to low-concentration solutions (<10%); systemic fluoride poisoning is rarely a problem under these circumstances. The risk of systemic toxicity increases where more than 5% of the body surface area (BSA) and higher concentration solutions (>20%) are involved; the risk is especially significant following oral or inhalational exposure.[3]

Systemic fluoride toxicity causes severe electrolyte abnormalities and metabolic acidaemia due to direct fluoride chelation of cations and the interaction of fluoride with cell membranes and cellular enzyme systems.[3,4,6,7] Hypocalcaemia and hypomagnesaemia occur and result in paraesthesias, carpopedal spasm, hyperreflexia, tetany and coagulopathy. However the primary cause of cardiac arrhythmia is the development of hyperkalaemia.[4,7] Coma, seizures, shock and dysrhythmias herald impending death.

Ocular exposure may result in severe eye injury with corneal ulceration and anterior chamber reactions. Consequently an eye examination should be performed after all splash-type exposures.

Inhalation is associated with pulmonary injury, including the development of non-cardiogenic pulmonary oedema and acute respiratory distress syndrome. Ingestion may cause significant corrosive injury (although this is not universally experienced).

Clinical investigations

No investigations are necessary following dermal exposures to dilute domestic preparations involving less than 5% of BSA. Following more significant dermal exposure, ingestion or inhalation, investigations including serum electrolytes, calcium, magnesium, coagulation studies and a 12-lead electrocardiogram (ECG) are indicated. A chest radiograph should be performed in any patient with respiratory symptoms or severe systemic toxicity.

Treatment

All patients at risk of systemic toxicity (>5% BSA or exposure to a concentrated preparation, ingestion or inhalation) should have continuous cardiac monitoring and intravenous access established on arrival at hospital.

The initial management of topical HF exposure is thorough skin decontamination via generous irrigation with water. This should ideally be performed as soon as possible following the exposure. Despite experimental evidence of enhanced decontamination with hexafluorine preparations,[9] clinical experience suggests that these offer no benefit in terms of local burn minimization or prevention of systemic toxicity as compared with water irrigation of exposed surfaces. Other first-aid measures in the workplace for known or suspected HF burns include topical treatments such as calcium gluconate gel (2.5% to 10%) or soaks with quaternary ammonium salts such as benzalkonium or benzethonium chloride. Topical therapies form insoluble complexes with any surface fluoride ions, thus preventing tissue penetration and minimizing deeper injury and the risk of systemic fluorosis. Topical therapy is probably of little value once fluoride ions penetrate deeper tissues, but it should be initiated on presentation to the emergency department (ED). If calcium gluconate gel is not readily available, a preparation can be rapidly prepared by mixing 10 mL of injectable calcium gluconate in 10 to 30 g of water-based lubricant jelly.

Failure to respond to topical therapy requires the administration of calcium gluconate into the tissues affected by the exposure.[1–3,5,8] This may be achieved by direct tissue infiltration, regional intravenous infusion using a Bier block–like technique, or intra-arterial infusion.[1–3,5,8] The choice of method depends on the site and concentration of HF involved.

Direct injection of approximately 0.5 mL/cm^2 of 10% calcium gluconate solution at the burn site can be considered in areas with little skin tension (such as the trunk, forearm and limbs), with care taken to infiltrate into, around and beneath the burn area as completely as possible. Calcium chloride produces direct injury when injected into tissues and should not be used.[3]

Hand and foot exposures may be complicated by the lack of loose tissues in the digits, which may cause direct injection to be painful and limit the injectable volumes. Regional calcium delivery should be considered in patients who do not respond to or cannot be given locally injected calcium gluconate. Regional calcium delivery may be achieved intravenously or intra-arterially.

Arterial calcium delivery requires insertion of a cannula into the radial artery (for burns of the thumb, index and middle fingers) or brachial artery (for more extensive hand involvement) and infusion of 1 g calcium gluconate in 40 mL of saline over 4 hours. This may be repeated as required and allows the calcium to be delivered to the affected tissues directly through the vascular supply. The end point for therapy is the absence of pain, and there is case report–level evidence for the use of continuous infusions.[10] As HF may also penetrate beneath the fingernails and toenails, these may occasionally have to be removed to allow administration of calcium gluconate to the nail bed if intra-arterial or intravenous therapies are unsuccessful.

Intravenous calcium delivery is achieved using the Bier block technique.[5] The exsanguination technique is as described by Bier for regional limb anaesthesia, and it has the advantage of relative simplicity without arterial cannulation. Calcium gluconate (1 g) is added to 40 mL of 0.9% saline and injected into the ischaemic limb. The tourniquet is released after 20 minutes. The end point for therapy is the absence of pain. Repeat doses may be attempted if pain persists; however, intra-arterial infusion may be a better option in this situation.

There have been no controlled studies comparing these techniques in the treatment of HF burns. However, intra-arterial calcium infusion may be a better technique for distal

digital exposures, particularly following high-concentration exposure or where multiple digits are involved.[5] If the intravenous route is selected as the initial therapy and is unsuccessful, intra-arterial calcium infusion should be attempted. The use of intra-arterial magnesium in a small case series resulted in tissue necrosis and is not recommended.

Ongoing pain at the exposure site may be due to either continued tissue destruction, reflecting persisting fluoride ions in the tissues, or to established tissue damage. This may result in confusion regarding patients in whom repeated infusions of intra-arterial calcium have not produced further pain relief. A complete lack of response to repeated infusion of calcium gluconate suggests that the pain may be related to established tissue damage rather than ongoing tissue destruction. Repeated infusions should be terminated in this situation.

Ocular HF exposures should be treated with copious 0.9% saline irrigation and local anaesthetic drops for pain relief. Calcium gluconate solution (1 to 2 g/L) may be added to saline irrigation fluid. Animal studies suggest that calcium gluconate eye drops are no better than copious irrigation with normal saline and that their use may result in delayed corneal healing. In contrast, clinical case reports using calcium gluconate eye drops suggest that the treatment is not harmful, but conclusive evidence of benefit is lacking.

HF ingestion should prompt consideration of gastrointestinal decontamination. HF is not charcoal-bound, but aspiration of HF through a small-bore nasogastric tube may limit absorption if the patient presents within an hour of ingestion. Calcium- or magnesium-containing antacids can complex intra-gastric HF and prevent some systemic absorption of fluoride ions, although any benefit is likely to be marginal. Symptomatic patients should undergo endoscopy or thoracoabdominal computed tomography (CT) to assess the extent of corrosive injury. Nebulized calcium gluconate has been administered acutely to patients following HF inhalation, but its benefit is unclear.

Systemic toxicity should be anticipated on risk assessment and intravenous calcium and magnesium replacement should be commenced based on this prior to any fall in serum concentrations. Replacement doses can be guided by the calculated dose of fluoride ingested, and large amounts of calcium (200 to 300 mmol) have been administered in cases of severe poisoning.[3,4] Hyperkalaemia should be anticipated and aggressively managed. Hyperkalaemia in systemic fluoride poisoning may be resistant to standard potassium reduction measures such as insulin, glucose and bicarbonate infusions. Ventricular arrhythmias may be refractory to cardioversion and defibrillation and may not respond to antiarrhythmic agents.[7] Haemodialysis is indicated for severe or refractory hypocalcaemia, hyperkalaemia or clinical toxicity (e.g. arrhythmias) and may be useful for the removal of fluoride ions.[3]

Disposition

Patients with minor dermal exposures in whom ED treatment produces complete resolution of symptoms may be discharged home with follow-up arranged within 24 hours. Patients with evidence of tissue damage require surgical or burns unit referral.

Patients at risk of systemic fluoride poisoning (exposure to high-concentration solutions, >5% BSA burns, inhalational exposure and ingestion) require admission to an intensive care unit for ongoing observation and electrolyte monitoring and management.

All patients with eye exposures require ophthalmological referral.

CONTROVERSIES

- Relative value of intra-arterial versus regional intravenous calcium gluconate administration
- Role of hexafluorine preparations in decontamination

25.15 Pesticides

Darren M. Roberts • Matthew Bode

ESSENTIALS

1 Acute pesticide poisoning is an important cause of morbidity and mortality worldwide, in particular in the Asia-Pacific region.

2 Existing systems for classifying the toxicity of pesticides are imperfect, whereby the toxicity of even 'slightly hazardous' pesticides is sometimes significant. Moderate-to-highly toxic pesticides may have a case-fatality rate of between 5% and 70% in patients with self-poisoning.

3 In addition to the pesticide constituent, other components of the formulation can also contribute to its toxicity. For example, concentrated formulations, or certain salts, solvents or surfactants can lead to worse outcomes. So, different formulations of the same pesticide component can have differing toxicity.

4 Diagnosis is based on a history of exposure and clinical features. In the absence of a history, a high index of suspicion for pesticide poisoning is required.

5 Many pesticides have a delayed onset of clinical manifestations. All patients with oral exposure should be monitored for a minimum of 6 to 48 hours post-ingestion depending on the pesticide involved.

6 Resuscitation and supportive care are priorities in managing acute pesticide poisoning. Patients manifesting significant poisoning require prolonged admission, preferably in an intensive care unit.

7 The risk of secondary contamination to health care workers is low when universal precautions are used.

8 The specific antidote for anticholinesterase pesticide poisoning (organophosphates [OPs], carbamates) is atropine, which should be administered as soon as possible and titrated to effect. Data supporting the efficacy of pralidoxime have been used for acute OP poisoning but data supporting its efficacy are limited, and some studies have suggested harm.

Introduction

Pesticide self-poisonings account for 30% of completed suicides globally. As with pharmaceutical poisoning, the toxicity of pesticides varies between individual compounds. In general, however, pesticides are intrinsically more toxic than pharmaceuticals, although not all pesticide exposures lead to clinically significant poisoning. In Australia, most acute pesticide exposures are accidental and the majority of patients do not require admission to hospital.

Pesticide poisoning can occur due to either acute (intentional self-poisoning) or chronic (such as occupational) exposures. Acute poisoning is of more importance to the emergency physician and is the focus of this chapter.

A pesticide is any chemical used for the control of a plant or animal, and these products encompass hundreds of chemicals. They can be sub-classified in terms of their intended target, the most common being insecticides, herbicides (selective or non-selective, see chapter 25.16), fungicides, rodenticides and nematocides. Other methods for classification that have been used include toxicity to animal species (LD_{50}; dose that kills 50% of animal subjects), mechanism of action and chemical structure.

An accurate risk assessment is necessary in each patient with acute pesticide poisoning (see Chapter 25.1).

Owing to the low incidence of pesticide poisoning, clinicians do not always consider it in the differential diagnosis. Case reports from Australia describe delays in the diagnosis of pesticide poisoning because this possibility was not considered initially.

This chapter focuses on agricultural chemicals used in Australasia, in particular insecticides (OPs and carbamates) Table 25.15.3 summarises the clinical manifestations and management of selected pesticides.

Aetiology and pathophysiology

Acute intentional self-poisoning with pesticides commonly requires admission to hospital and ongoing care. However, significant poisoning may also occur with accidental (e.g. storage of a pesticide in a milk carton) or criminal exposures.

The pathophysiology of acute pesticide poisoning and therefore its clinical manifestations vary widely between individual compounds, see Table 25.15.3. Many pesticides induce multisystem toxicity due to interactions with a number of physiological systems. The mechanisms of toxicity in humans frequently bear little relation to that in the target pest. Frequently such mechanisms are poorly described; therefore less information is available to guide the management of these exposures.

It should be noted that proprietary pesticide products contain co-formulants, in particular hydrocarbon-based solvents. Herbicide products also contain surfactants to enhance herbicide penetration into the plant. These co-formulants can contribute to the toxicity of a pesticide product and in some cases are more toxic than the active pesiticide constituent.

Epidemiology

Acute pesticide poisoning is a major issue in developing countries of the Asia-Pacific region, and OPs are considered the most important cause of death from acute poisoning worldwide. In developed countries, however, the incidence of severe pesticide poisoning is relatively low. Nevertheless, it may be higher in rural areas because of greater access to concentrated formulations.

Prevention

Primary exposures

Regulatory restrictions to the availability of highly toxic pesticides may contribute to a decrease in mortality from self-poisoning. In Australia, for example, highly toxic pesticides such as paraquat, organochlorines and parathion are heavily regulated, so poisonings are increasingly rare. The proper storage, handling and use of pesticides can prevent accidental exposures and associated health consequences.

Secondary exposures or nosocomial poisoning

Secondary exposure refers to staff and family members being exposed to poisoned patients, predisposing them to nosocomial poisoning. These are exceptionally rare and occur in the setting of staff who are not taking universal precautions and not using decontamination (e.g. of the skin) if exposed to such an agent, usually via bodily fluids. Although mild symptoms—such as nausea, dizziness, weakness and headache—have been reported, these resolve after exposure to fresh air and are likely due to inhalation of the hydrocarbon solvent. Universal precautions including nitrile gloves are most likely to provide sufficient protection for staff members. Dermal decontamination is performed by washing spilt pesticide off the patient with soap and water while removing and discarding contaminated clothes. Staff with dermal exposure to a poisoned patient's bodily fluids should wash their skin with soap and water as soon as practicable.

ANTICHOLINESTERASE PESTICIDES

Anticholinesterase pesticides are among the most widely used pesticides and include organophosphate (OP, OGP) and carbamate compounds. The most commonly encountered anticholinesterase compounds in Australasia are listed in Table 25.15.1.

The relationship between exposure and clinical toxicity is poorly defined; therefore all exposures should be treated as significant. Deliberate self-poisoning by ingestion is the scenario most likely to result in severe toxicity, reflecting the larger exposure. Carbamates appear to be less toxic and induce poisoning of a shorter duration than OPs, although notable exceptions include carbofuran and carbosulfan, which are associated with severe toxicity and death.

Table 25.15.1 Anticholinesterase pesticides commonly associated with human poisoning

organophosphate compounds	*Carbamate compounds*
Chlorpyrifos	Aldicarb
Diazinon	Carbaryl
Dichlorvos	Carbofuran
Dimethoate	Carbosulfan
Fenthion	Fenobucarb
Malathion (maldison)	Methomyl
Methamidophos	Propoxur
Parathion	
Profenofos	
Prothiofos	

Mechanism of toxicity

The effects of anticholinesterase compounds on human physiology are multiple, complex and incompletely described, but inhibition of acetylcholinesterase (AChE) is considered the most important mechanism. This prevents the hydrolysis of acetylcholine, so it accumulates in cholinergic synapses, causing excessive stimulation of post-synaptic receptors. This interferes with systemic nervous function, producing a range of clinical manifestations known as the acute cholinergic crisis (Table 25.15.2).

OP-inhibited AChE is potentially reversible if an oxime is initiated early after exposure (Fig. 25.15.1). In the absence of reactivation, inhibited AChE undergoes irreversible inhibition ('ageing') and AChE resynthesis is required to restore nervous function (see Fig. 25.15.1). The rate of these competing inhibition, reactivation and ageing reactions varies between individual OPs and influences the response to oximes. Carbamates are structurally different from OPs such that there is spontaneous reactivation of carbamate-inhibited AChE and ageing does not occur.

Marked differences in the clinical manifestations of acute anticholinergic poisoning are observed between the different compounds in Table 25.15.1. This may reflect the variability in potency of enzyme inhibition, physiological adaptations following prolonged stimulation, pharmacokinetic factors, additional mechanisms of toxicity such as oxidative stress, inter-patient differences and/or other unknown factors.

Clinical features

The initial and prominent manifestation of acute anticholinesterase poisoning is the acute cholinergic crisis (see Table 25.15.2). The duration and manifestations of this crisis vary between individual anticholinesterase compounds, as mentioned earlier.

Gastrointestinal symptoms are most prevalent following oral exposures. Tachycardia does not consistently correlate with hypotension or pneumonitis but can be secondary to catecholamine release from the adrenal medulla under nicotinic stimulation.

Differential diagnosis

In situations where the history is not forthcoming, the differential diagnosis is broad and includes other drugs (clonidine, opioids, dopamine antagonists such as chlorpromazine or haloperidol), funnel web spider envenoming and pontine haemorrhage.

Clinical investigation

The diagnosis and management of acute anticholinesterase poisoning is primarily clinical, but measurement of cholinesterase activity can assist. The reference ranges are wide owing to the large inter-individual variability in baseline AChE and butyrylcholinesterase (BChE, plasma cholinesterase, pseudocholinesterase) activities. Cholinesterase inhibition is generally noted prior to clinical effects. AChE and BChE are generally depressed within 6 hours, although enzyme inhibition may progress until 12 to 24 hours post-ingestion. AChE or BChE activity that is below 80% of the lower reference range is consistent with significant anticholinesterase exposure. Patients in whom cholinesterase activity is higher than this might still have been exposed, but only to a minimal degree.

Erythrocyte AChE is structurally similar to synaptic AChE, and their activities decrease in a similar manner following exposure to anticholinesterase compounds. The degree of AChE inhibition is considered the most useful biomarker of severity because it correlates with the severity of OP poisoning. In severe poisoning, the erythrocyte AChE activity is less than 20% of normal. Serial measurements of erythrocyte AChE activity can be useful for confirming reactivation of the enzyme by an oxime. For example, if AChE activity normalizes following initiation of oxime therapy, then this suggests that ageing has not occurred (see Fig. 25.15.1) and that the dose of oximes is sufficient.

BChE inhibition is a sensitive biomarker of anticholinesterase exposure but has no relation to the *severity* of poisoning because the affinity of anticholinesterase compounds for BChE is highly variable and differs from that of AChE. Serial measurements of BChE cannot be used for measuring the effect of oximes because there is rapid ageing. Once BChE activity starts to increase (the rate of this depends on hepatic function and the kinetics and potency of the anticholinesterase compound), this suggests that the plasma concentration of the anticholinesterase compound is negligible.

Blood gases and routine blood laboratory analyses are recommended for measuring metabolic and respiratory derangements, for example, hypokalaemia secondary to vomiting and diarrhoea is not uncommon.

Criteria for diagnosis

Acute anticholinesterase poisoning is diagnosed on the basis of a history of exposure and the development of characteristic clinical features (see Table 25.15.2). Therefore a high index of

Table 25.15.2 Clinical manifestations and treatment of acute anticholinesterase poisoning

Clinical manifestations			
Acute cholinergic crisis	*Markers of significant poisoning*[a]	*Specific treatments*	*Endpoints for titration*
• *Muscarinic features:* diarrhoea, urinary frequency, miosis, bradycardia, bronchorrhoea and bronchoconstriction, emesis, lacrimation, salivation (DUMBELS) and hypotension. Cardiac arrhythmias have also been reported.	Bradycardia, bronchorrhoea or bronchospasm, hypotension	*Atropine*. Initially 1–3 mg IV for adults. If end points are not achieved by 3–5 min, double the dose. Continue to double the dose every 3–5 min until atropinization has been achieved. Large doses (hundreds of milligrams) may be required with massive poisoning. Maintain atropinization by infusion, commencing with 10%–20% of the loading dose every hour.	Clear chest on auscultation with resolution of bronchorrhea[b] and heart rate >80/min. Regular clinical observations are necessary to ensure that atropinization is achieved without toxicity (delirium, hyperthermia and/or ileus).
• *Nicotinic features:* fasciculations and muscle weakness which may progress to paralysis and respiratory failure,[c] mydriasis, tachycardia, and hypertension.	Muscle weakness (e.g. difficulty mobilizing or a decrease in forced vital capacity, progressing to respiratory failure requiring ventilatory support)	*Intubation and ventilation (avoid suxamethonium if possible).* *Oximes* (for OPs only). The oxime usually available in Australasia is pralidoxime and its indications and dosing regimen are controversial, see text for details.	If oximes are administered, continue until recovery (12 h after atropine ceased or once BChE is noted to increase).
• *Central nervous system:* altered level of consciousness, respiratory failure[c] and seizures.	Altered mental status, respiratory failure and seizures	*Intubation and ventilation (avoid suxamethonium if possible), and benzodiazepines*. Administer intravenously as required for agitation or seizures.	Termination of agitation and/or seizures.

[a]A guide for identifying patients with a significant exposure and to guide clinical management in terms of who requires close observation and specific treatments, rather than for prognostication.
[b]Focal crepitations and/or wheeze may be noted when there has been pulmonary aspiration.
[c]Respiratory failure occurs due to centrally and/or peripherally mediated mechanisms. It may manifest either during the acute cholinergic crisis (type I paralysis) or suddenly during an apparent recovery phase (intermediate syndrome, or type II paralysis). Weakness of neck flexors is an early sign of significant muscle weakness. Intermediate syndrome is noted in approximately 5% of patients in various series.
BChE, Butyrylcholinesterase; *OPs*, organophosphates.

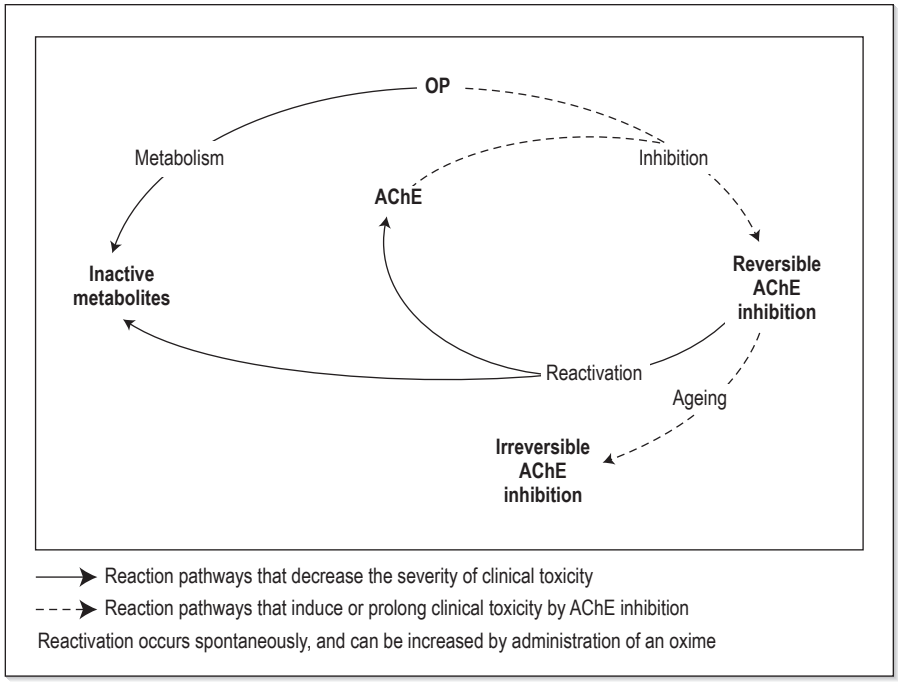

FIG. 25.15.1 Simplified scheme showing the interactions of organophosphates (OPs) in vivo. The relative rate of each reaction varies between individual OP compounds. *AChE*, Acetylcholinesterase.

clinical suspicion is necessary. Since the correlation between intent, dose and severity of toxicity appears to be poor and the clinical manifestations between individual compounds differ, each patient with an anticholinesterase exposure requires a thorough clinical review.

The onset of cholinergic toxicity is variable; however, the majority of patients who develop severe poisoning are symptomatic within 6 hours. Patients remaining asymptomatic for 12 hours after ingestion are unlikely to develop significant clinical toxicity. A possible exception is fenthion, which produces subtle cholinergic features initially, but then progressive muscle weakness develops over a number of days, including respiratory failure requiring ventilatory support.

Where there is doubt regarding the diagnosis or significance of an OP exposure, quantification of BChE or AChE activity, if available, is helpful. BChE is particularly useful because it is more widely available and a sensitive marker of exposure.

Table 25.15.3 Summary of clinical manifestations, investigations and treatment of acute pesticide poisoning

Pesticide	*Clinical manifestations*	*Investigations*	*Management*
• OP • Carbamates	Acute cholinergic crisis (see Table 25.15.1)	Blood gas Respiratory function testing AChE activity <80% of lower reference range is consistent with significant exposure BChE is a sensitive marker of exposure, but not severity of toxicity	Resuscitation and supportive care Gastrointestinal decontamination (see text) Dermal decontamination with soap and water Titrated atropine (see Table 25.15.2) Consideration of pralidoxime (see text)
• Paraquat	Severe gastrointestinal signs and symptoms and AKI, progressing to hypotension, pneumonitis, hepatitis and death	Dithionate urinary testing confirms exposure Serum electrolytes, kidney and liver function testing Serial blood gases Pulmonary imaging for diagnosis and progression of pneumonitis	Resuscitation (although if required then this suggests poor prognosis) and supportive care Intravenous rehydration to promote renal excretion Activated charcoal (or Fuller's earth if available) Early consideration of haemodialysis or haemoperfusion (initiated within 2–4 h of ingestion) Corticosteroids (see discussion in Chapter 25.16)
• Glyphosate	Abdominal pain, nausea, vomiting and diarrhoea progressing to multiorgan dysfunction including AKI and metabolic acidosis	Serial blood gases Serum electrolytes, kidney and liver function testing	Resuscitation and supportive care Observe symptomatic patients and those with intentional poisoning for minimum of 24 h. Intravenous fluids to replace gastrointestinal losses. Consider haemodialysis for metabolic acidosis and acute kidney injury, especially if there is progressive multisystem dysfunction.
• MCPA, 2,4-D and/or bromoxynil	Gastrointestinal symptoms, myalgia, rhabdomyolysis, hyperthermia, miosis, hypotension, agitation and confusion Respiratory alkalosis followed by metabolic acidosis	Serial blood gases Serum electrolytes, kidney and liver function testing	Resuscitation and supportive care. Observe symptomatic patients and those with intentional poisoning for a minimum of 24 h. Urinary alkalinization (urine pH >7.5) and urine output >1 mL/kg/h Gastrointestinal decontamination with activated charcoal. Urgent haemodialysis if progressive acid–base abnormalities.
• Propanil, metolachlor and other amide herbicides	Gastrointestinal signs and symptoms, agitation, seizures, coma, acidosis Propanil causes methaemoglobinaemia and haemolysis	Serial blood gases Serum electrolytes, kidney and liver function testing	Resuscitation and supportive care. Observe symptomatic patients and those following intentional poisoning for minimum of 12 h. Consider gastrointestinal decontamination with activated charcoal. Methylene blue (methylthioninium chloride) for methaemoglobinaemia.
• Glufosinate	Gastrointestinal signs and symptoms progressing to coma, seizures and respiratory failure	Serial blood gases and ammonia concentration Serum electrolytes, kidney and liver function testing	Resuscitation and supportive care. Observe symptomatic patients and those following intentional poisoning for minimum of 48 h. Consider gastrointestinal decontamination if airway protected. Treat seizures with benzodiazepines. Intravenous fluid for urine output >1 mL/kg/h. Consider early referral for haemodialysis, particularly with impaired kidney function.

2,4-D, 2,4-dichlorophenoxyacetic acid; *AChE*, acetylcholinesterase; *AKI*, acute kidney injury; *BChE*, butylcholinesterase; *LOC*, level of consciousness; *MCPA*, 4-chloro-2-methylphenoxyacetic acid; *OP*, organophosphate pesticide

Treatment

Resuscitation and early considerations

As with all acute poisonings, initial management begins with immediate assessment and management of disturbances in airway, breathing and circulation. Because suxamethonium is metabolized by BChE, it is avoided in patients with acute anticholinesterase poisoning because the duration of paralysis will be prolonged by many hours. Continuous non-invasive monitoring of vital signs is required. Hypotension not responding to intravenous fluid loading may be due in part to an OP-induced decrease in systemic vascular resistance, which requires intravenous vasopressors.

All patients with intentional poisoning who are symptomatic should be managed in a centre with access to intensive care facilities because of the potential for severe poisoning to develop. Gastrointestinal decontamination with oral activated charcoal can be given to patients presenting within 1 to 2 hours of ingestion if the airway is protected. However, the routine use of activated charcoal in this context is controversial.

During their immediate assessment and resuscitation, patients should have all their clothes removed and bagged and then undergo dermal decontamination with soap and water.

Subsequent interventions depend on changes to the clinical observations. Antidotal therapy when required should be initiated rapidly (see Table 25.15.2). Muscarinic features are reversed with atropine. Oximes such as pralidoxime are claimed to reverse muscle weakness if administered promptly, although clinical studies confirming this are lacking (discussed later).

Mild poisoning and dermal exposures

Patients with accidental oral or inhalational exposures who are asymptomatic or minimally symptomatic (with only mild gastrointestinal symptoms) often do not require hospital admission. Management priorities for these patients are rapid triage, a detailed risk assessment and consideration of forensic implications. If the exposure is trivial, the patient does not need medical review and can be observed at home or in the workplace. Other patients should be decontaminated and monitored clinically for a minimum of 6 hours except for those who have been poisoned with fenthion, who should be monitored for 12 hours. If available, testing of cholinesterase activity can exclude a significant exposure. A normal cholinesterase activity at 6 hours after exposure may be sufficient to

exclude a significant oral exposure, although more research is required to confirm this observation.

Patients with a brief acute dermal exposure rarely develop significant clinical effects and do not require medical assessment. Volunteer studies document that the risk of poisoning from a dermal exposure is far below that of an oral exposure. Although the rate of anticholinesterase absorption across the skin is slower than across the gut, patients who are asymptomatic at 12 hours are unlikely to develop significant poisoning. Such patients should be given instructions to present for medical review if there are signs or symptoms of clinical toxicity. Concern regarding a significant dermal exposure as a cause for symptoms prompts measurement of cholinesterase activity.

Moderate to severe poisoning

Patients with moderate to severe anticholinesterase poisoning experience prolonged and complicated hospital admissions. Close observation is required to monitor for a rapid clinical deterioration, even if there is an apparent recovery from the acute cholinergic crisis. Therefore, following resuscitation, these patients require ongoing management in an intensive care unit (ICU) for careful titration of antidotes and supportive care.

Antidotes

The most widely used antidotes for anticholinesterase poisoning are muscarinic antagonists (usually atropine) and oximes (usually pralidoxime in Australasia). Benzodiazepines are used for agitation or seizures. The indications and dosing regimen of atropine is described in Table 25.15.2.

Antimuscarinic agents

Atropine is the most widely used antimuscarinic agent. It is carefully titrated to reverse muscarinic effects and has no effect on the neuromuscular features.

Oximes

Oximes are used to reverse neuromuscular blockade by reactivating the inhibited AChE before ageing occurs and should therefore be administered as early as possible (see Fig. 25.15.1). In general, oximes are more effective in poisoning due to diethyl OPs (e.g. chlorpyrifos, diazinon) than dimethyl OPs (e.g. dimethoate, fenthion, malathion), due in part to slower ageing of inhibited AChE by diethyl OPs.

Evidence supporting the indications for oxime therapy, their efficacy and the optimal dosing regimen is lacking and controversial. The majority of the data are based on pralidoxime, and early clinical studies reported no effect or even harm. However, the design of these studies was suboptimal and the pralidoxime dosing regimen was usually 1 g q6h, which was less than that advocated by the World Health Organisation (WHO) at the time. This prompted further research.

Two subsequent randomized controlled trials (RCTs) are worthy of mention. One RCT (n = 200 patients in India) concluded efficacy from high doses of pralidoxime iodide: pralidoxime iodide 2 g loading dose in all patients, followed by either 24 g/day for 48 hours, then 1 g q4h until recovery (high dose) or the lower dose of 1 g q4h until recovery. AChE activity was not measured in this study. The other RCT (n = 235 patients in Sri Lanka) reported no benefit from pralidoxime dosed according to a WHO-recommended regimen of pralidoxime chloride 2 g loading dose, followed by a constant infusion of 0.5 g/h for up to 7 days; this was compared with saline. AChE was measured at multiple points in this study, confirming severe poisoning on arrival and an appropriate response to pralidoxime therapy. A concern in the latter study was the higher mortality in the intervention group, although this was not statistically significant. However, because the study was terminated early owing to slow recruitment, the importance of this observation is uncertain. Regarding dose equivalents, 1 g of pralidoxime iodide is equivalent to 650 mg of pralidoxime chloride. Both of these RCTs acknowledged limitations in their study designs and/or patient cohort and recommended further studies.

Because carbamate-inhibited AChE does not undergo ageing, the role for oximes appears limited.

In summary, the efficacy of oximes in anticholinesterase poisoning is not confirmed. Further studies exploring differing dosing regimens, types of oximes (obidoxime may be more effective) and selection criteria are required. Until that time, it is reasonable to conclude that oximes are not a standard of care in the treatment of anticholinesterase poisoning. However, it is reasonable to administer obidoxime or lower doses of pralidoxime (e.g. 1 g pralidoxime chloride q6h) to patients with significant anticholinesterase poisoning, in particular by diethyl OPs, and to monitor for the reactivation of AChE.

Prognosis

The mortality in patients with anticholinesterase poisoning is variable, which may reflect differences in exposure, reporting, resources, genetics or the types of compounds encountered. However, the overall mortality can exceed 10%, which is high, particularly compared with a mortality of less than 0.5% for pharmaceuticals.

Various tools are proposed to classify the severity of OP poisoning, but few have been widely adopted or validated. Generalized approaches to prognostication in OP poisoning are difficult given that individual compounds vary markedly in the onset, severity and manifestations of clinical toxicity. Further, these approaches are not often useful for guiding management.

In the case of dermal exposures, prognosis is very favourable, particularly following transient exposures.

CONTROVERSIES

1 Anticholinesterase pesticides.

- Significance of other potential mechanisms of toxicity.
- Role of oximes, including dose and indications, and the relative efficacy of individual oximes.
- Role of other proposed antidotes and treatments including α2-adrenergic receptor agonists (e.g. clonidine), BChE replacement therapy, gastric lavage, extracorporeal blood purification, magnesium sulphate, organophosphorus hydrolases and blood alkalinization with sodium bicarbonate.
- Importance of regulatory restrictions on 'highly toxic' anticholinesterase agents in decreasing mortality.
- Clinical and analytical predictors of the development of significant poisoning.

25.16 Herbicides

Katherine Isoardi • Geoffrey Isbister • Darren M. Roberts

ESSENTIALS

1 **The mortality from acute paraquat poisoning is high owing to rapid multi-organ failure or delayed progressive pulmonary fibrosis. Ingestion of as little as one mouthful of 20% w/v solution is sufficient to cause death. No satisfactory treatment exists.**

2 **The toxic component of glyphosate-containing herbicides appears to be the surfactant co-formulant or its salt. The mechanism of toxicity is not confirmed, but severe poisoning is associated with multi-organ toxicity and metabolic acidosis. Treatment is supportive.**

3 **Chlorphenoxy herbicides such as 2-methyl-4-chlorophenoxyacetic acid generally cause mild toxicity, but death from the uncoupling of oxidative phosphorylation can occur. Co-formulation with the herbicide bromoxynil appears to increase the toxicity significantly.**

Introduction

Acute poisonings with herbicides constitute a significant problem in developing countries; although uncommon in Australia, it can cause life-threatening toxicity. Herbicides encompass a broad group of poisons, with differing mechanisms and manifestations of toxicity.

PARAQUAT (BIPYRIDYL HERBICIDE)

Paraquat is a non-selective contact herbicide. It is extremely toxic when ingested and there are no effective treatments available. This is reflected in the very high mortality rate in poisoning, between 50% and 90%. Therefore access to paraquat is heavily regulated in Australia, but it continues to be an important cause of death in a number of countries throughout Asia. There is minimal absorption with inhalation or through intact skin, and systemic poisoning is not expected via these routes.

Diquat is another bipyridyl herbicide that is more widely available in Australasia. The clinical manifestations and management are summarised in Table 25.15.3.

Mechanism of toxicity

Paraquat is rapidly but incompletely absorbed. It is distributed to all tissues but concentrates in the lungs and kidneys owing to active uptake in type II pneumocytes and renal tubular cells. Paraquat toxicity results from the production of free oxygen radicals, which cause oxidative stress leading to lipid peroxidation of cell membranes, mitochondrial toxicity and cellular death.

Clinical features

Paraquat is corrosive, and gastrointestinal toxicity occurs with all oral exposures. Vomiting and diarrhoea occur initially, then ulceration of the oral mucosa follows about 12 hours after ingestion. In severe cases, oesophageal perforation can occur. Patients ingesting more than 20 mL are likely to develop severe toxicity with multi-system involvement and death within 48 hours. The sequelae manifest as pneumonitis, hypotension, hepatitis, acute kidney injury and severe gastrointestinal toxicity. Patients ingesting less than 20 mL are still at risk of death, but this is more likely to be delayed by weeks or months post-ingestion. The primary mechanism of death is respiratory failure due to pulmonary fibrosis, with varying degrees of hepatic and kidney impairment. Acute kidney injury usually recovers within 2 to 3 weeks in survivors.

Diquat does not concentrate in the pneumocytes as readily as paraquat and delayed pulmonary fibrosis is less likely to occur.

Clinical investigations

Exposure can be confirmed by a urinary dithionite test. This involves the addition of 1 g of sodium dithionite solution and 1 g of sodium bicarbonate (or 1 to 2 mL of 1% sodium dithionite in 1 to 2 M of sodium hydroxide) to 10 mL of urine. A blue colour change indicates paraquat ingestion and a green colour change indicates diquat ingestion. The darker the colour change, the higher the paraquat concentration. If the test is negative on urine passed 6 hours after ingestion, a significant exposure is unlikely. A commercial kit is now available for this test.

Further investigations should focus on specific organ injury, monitoring deterioration and recovery. These include serial measurements of electrolytes, kidney and liver function, as well as serial blood gases and chest x-ray to quantify pulmonary injury. Computed tomography (CT) of the chest can define pulmonary fibrosis. Paraquat concentrations can confirm exposure and estimate prognosis but are not widely available in a clinically useful time frame.

Differential diagnosis

Acute paraquat poisoning may resemble sepsis or poisoning with another cellular poison, such as phosphine (aluminium or zinc phosphides), colchicine or iron. Oropharyngeal necrosis is more marked in paraquat poisoning.

Treatment

All patients with paraquat ingestions should be observed in hospital for at least 12 hours post-ingestion because of the potential for severe toxicity. Standard resuscitative principles apply except that mild to moderate hypoxia should not be treated routinely with oxygen because it will exacerbate oxidative stress. Adequate hydration is important to optimize renal function and promote paraquat clearance.

Patients who present within 24 hours with severe systemic toxicity (e.g. hypotension, hypoxia, acidosis or low Glasgow Coma Scale [GCS] score) have no realistic chance of survival and early palliation should be instituted.

Current treatment options for paraquat poisoning include decontamination, immunosuppression, the provision of antioxidants and enhanced elimination.

Decontamination

A single dose of activated charcoal (or Fuller's earth) can be offered to patients presenting within 2 hours in an attempt to decrease absorption.

Immunosuppression

Immunosuppression aims to counter the acute inflammatory response induced by paraquat. Regimens including cyclophosphamide, methylprednisolone and dexamethasone are used on the basis of small positive clinical studies. A recent randomized controlled trial (RCT) comparing high-dose immunosuppression (intravenous

How to perform the urinary diothonite test

It is useful to confirm that an exposure to paraquat is significant because this will guide subsequent management. The easiest method to do this is by the dithionite urine test using the test that is distributed by Syngenta in Australia and many other countries free-of-charge. A blue colour change indicates paraquat ingestion and green colour change indicates diquat ingestion. The darker the colour change, the higher the concentration. If the test is negative on urine passed 6 h after ingestion, a significant exposure is unlikely.

cyclophosphamide and intravenous methylprednisone followed by oral dexamethasone) to standard care (fluids, charcoal and analgesia) found that immunosuppression did not improve survival. However, there was a potentially favourable effect of the 2-week course of dexamethasone, which requires further study. A reasonable regimen is methylprednisolone 1g/day for 3 days followed by a 5-week course of dexamethasone 8 mg tds.

Antioxidants

Antioxidants such as acetylcysteine, salicylic acid, vitamin C and vitamin E have been proposed to treat paraquat poisoning. They have theoretical promise to counter oxidative stress due to paraquat free radical production. The optimal dosing regimens are not known. For acetylcysteine, the same dosing regimen used for paracetamol overdose is employed, with a 200 mg/kg load over 4 hours followed by 150 mg/kg/day for 7 days.

Enhanced elimination

The benefit of haemodialysis or haemoperfusion to increase paraquat clearance is unclear. This is due to the rapid elimination of paraquat under normal conditions, in which 90% is excreted unchanged in the urine within 12 to 24 hours. Further elimination with extracorporeal methods is likely to be relatively modest. Additionally, the time frame within which it would affect distribution to the lungs is short. In an animal model it appeared that haemoperfusion had to be started within 2 hours following ingestion to be effective. Although some studies suggest a reduction in mortality with early haemodialysis or haemoperfusion, there are methodological limitations in most of these studies. If available, early dialysis should be considered, with the preferred modality being intermittent haemodialysis.

With the lack of effective treatment options in severe paraquat toxicity and the high mortality rate, it is important to balance the likelihood of benefit with the invasiveness of therapy. An aggressive regimen is probably reasonable in patients with small exposures and a faintly positive urinary dithionite test. However, any treatment is unlikely to be beneficial in patients with large exposures, a strongly positive test or evidence of evolving multi-organ toxicity.

Prognosis

Prognosis depends on the quantity of paraquat ingested. Ingestions of greater than 50 to 100 mL of concentrated liquid (>20% w/v) invariably result in fulminant organ failure. Smaller quantities result in acute kidney injury and lung injury over the first week with the development of progressive pulmonary fibrosis, which has a mortality rate of greater than 50% and which can be delayed for 6 weeks post-ingestion. The development of renal failure and chest x-ray changes are poor prognostic signs. Patients who complain of a burning sensation of the skin also have a poorer prognosis. Plasma paraquat concentrations can be used with nomograms or scoring systems to predict prognosis; however, they are not available in Australia.

GLYPHOSATE

Glyphosate is a broad-spectrum herbicide that comes in two common formulations: ready to use (1% to 5%) and concentrated (30% to 50%). Glyphosate is absorbed from the gastrointestinal tract and does not penetrate the skin to a significant extent, so ingestion is the most important poisoning. Respiratory, ocular and dermal symptoms may occur following exposure, but these are usually minor. The clinical manifestations and management are summarised in Table 25.15.3.

Mechanism of toxicity

Glyphosate itself appears to have minimal mammalian toxicity. Glyphosate salts are co-formulated with a surfactant to facilitate herbicide penetration, and toxicity is largely attributed to the surfactant co-formulant. The most common surfactant in use is polyoxyethylenamine (POEA). The exact mechanism of the surfactant toxicity is poorly understood. Proposed mechanisms include disruption of cellular membranes and uncoupling of oxidative phosphorylation. Severe hyperkalaemia may also occur with formulations using the potassium salt of glyphosate.

Clinical features

Features range from mild, self-resolving gastrointestinal upset following ingestions of dilute solutions to more severe poisoning with large ingestions of concentrated solution, which can be life threatening. Severe poisoning is characterized by corrosive gastrointestinal injury, electrolyte disturbance, metabolic acidosis, hypotension, renal failure and pneumonitis. This can progress over 12 to 72 hours to multi-organ failure, shock and death.

Clinical investigations

There are no specific clinical investigations to guide management. Targeted investigations should be performed in symptomatic patients. Serial blood gases and biochemistry are useful to detect acidosis, hyperkalaemia and acute kidney injury. Chest x-ray should be performed if there is suspicion of pneumonitis or pulmonary oedema. Although glyphosate concentrations appear to correlate with outcome, this assay is not available.

Criteria for diagnosis

The principal criterion for the diagnosis of acute poisoning with a glyphosate-containing herbicide is a history of exposure; therefore a high index of suspicion is necessary. Clinical criteria for the classification of severity based on degree of systemic toxicity have been suggested but none have been validated.

Treatment

Treatment of glyphosate poisoning is supportive. Intravenous fluids should be administered to replace gastrointestinal losses. Biochemical and acid–base abnormalities should be corrected as required. In severe poisoning, hypotension can occur for a number of reasons, including dehydration, decreased cardiac output and vasodilation; the reason for hypotension should be identified and treated. Dialysis should be considered early when there is severe acidosis, hyperkalaemia or renal failure.

All patients presenting following acute ingestion should be observed for a minimum of 6 hours. If they are asymptomatic and have normal blood gases, they can be discharged. Patients who develop gastrointestinal symptoms should be observed for at least 24 hours given that their symptoms may progress.

Prognosis

All intentional exposures, particularly of concentrated solutions, are potentially significant. Increasing age and the presence of metabolic acidosis, hyperkalaemia or end-organ dysfunction are associated with a poorer prognosis. Patients who develop renal failure, hypotension, pulmonary oedema, or arrhythmias are more likely to die. Mortality from acute poisoning with glyphosate-containing herbicides varies between studies but was found to be 3.2% in a prospective Sri Lankan study.

CHLORPHENOXY HERBICIDES

Chlorphenoxy herbicides are selective against broad leaf plants and include 2-methyl-4-chlorophenoxyacetic acid (MCPA), 2,4-dichlorophenoxyacetic acid (2,4-D), mecoprop and 2,4,5-trichlorophenoxyacetic acid (2,4,5-T). They are often co-formulated with other herbicides including bromoxynil, ioxynil and dicamba. The clinical manifestations and management are summarised in Table 25.15.3.

Mechanism of toxicity

The mechanism of toxicity is poorly understood and differs between agents. Chlorphenoxy herbicides appear to be directly irritating. In severe poisoning there is generalized cellular dysfunction. Co-formulations with herbicides such as bromoxynil are far more toxic due to the potential to uncouple oxidative phosphorylation.

Clinical features

Gastrointestinal effects predominate in the majority of exposures due to direct irritant effects. Severe toxicity is uncommon. A prospective series of 181 patients in Sri Lanka following MCPA ingestion found that 85% had minimal toxicity, which included mild gastrointestinal symptoms. Rhabdomyolysis, acute kidney injury and coma occurred uncommonly. The mortality rate in this series was 4.4%. Other chlorphenoxy herbicides are less well described in the literature.

Co-formulation of MCPA with bromoxynil requires special mention, as case reports describe severe toxicity, which can have a delayed onset. This combination appears to be much more dangerous in overdose due to mitochondrial uncoupling, which causes metabolic acidosis, hyperthermia and increasing CO_2 production that can rapidly progress to rhabdomyolysis, multi-organ failure and death.

Clinical investigations

Serial blood gases should be performed to assess acid–base disturbance and pCO_2. Tests of biochemistry, renal function and CK should be performed in symptomatic patients. Further investigations should be guided by clinical findings.

Treatment

Give activated charcoal early for decontamination. All patients following chlorphenoxy herbicide ingestion should be observed for at least 6 hours following ingestion. If they have no symptoms, a significant ingestion is unlikely.

Standard resuscitative principles apply in addition to good supportive care. It is important to maintain hydration, and it is possible that urinary alkalinization will increase the elimination of MCPA. This should therefore be considered in more severe or larger poisonings.

Patients who have ingested preparations containing bromoxynil should be closely observed for 24 hours due to the potential for delayed toxicity.

The development of hyperthermia, hypercarbia and acidosis must be aggressively managed with intubation and active cooling. There appears to be a role for early dialysis in these patients to correct metabolic acidosis and facilitate cooling, although MCPA and bromoxynil themselves are not significantly cleared by dialysis.

CONTROVERSIES

Paraquat

- Early palliation versus active treatment in large paraquat ingestions
- Efficacy and dosing of anti-inflammatories and antioxidants

Glyphosate

- The relative importance of glyphosate, its salt and other co-formulants on the severity of poisoning
- Clinical and analytical predictors of the development of significant poisoning

Chlorphenoxy herbicides

- Relative contribution to toxicity of MCPA and co-formulants such as bromoxynil

25.17 Ethanol and other 'toxic' alcohols

David McCoubrie • Mohan Raghavan

ESSENTIALS

1 **Ethanol is a major cause of morbidity, mortality and emergency department (ED) presentation in most Western societies. Presentations may result from acute intoxication, withdrawal or medical complications of chronic ethanol ingestion.**

2 **Ethanol causes central nervous system (CNS) depression that can be synergistic with other CNS depressants and can be life threatening without supportive care.**

3 **Ethanol withdrawal is commonly encountered in the ED and has a mortality of up to 5% without medical therapy.**

4 **Wernicke encephalopathy (WE) is under-diagnosed. The raised likelihood of WE in patients with altered mental status and a suspected history of prolonged alcohol abuse should prompt early treatment with parenteral thiamine.**

5 **Methanol and ethylene glycol, the toxic alcohols, are potentially lethal when ingested even in relatively small volumes.**

6 **They exert toxic effects through the production of organic acid metabolites; dialysis is the recommended treatment.**

7 **An elevated anion-gap metabolic acidosis and a raised osmolar gap are associated with increased mortality in toxic alcohol ingestions.**

8 **Osmolar gap has a poor sensitivity and is incapable of excluding toxic alcohol ingestion.**

Introduction

Alcohols are hydrocarbons that contain a hydroxyl (OH) group. Ethanol, a two-carbon primary alcohol, is the most commonly used recreational drug in Australasia and elsewhere in the western world. Ethanol misuse is a major cause of mortality and morbidity both directly and indirectly, and emergency departments (EDs) deal with the results on a daily basis. It was estimated that 3290 Australians died in 1997 from injury due to high-risk drinking, and that there were 72,302 hospitalizations. In a recent study it was noted that 1 in 10 presentations to EDs in Australia were related to alcohol.

The complications of chronic alcohol consumption contribute to the development of a number of medical and surgical emergencies, many of which are dealt with elsewhere in this text. This chapter confines its discussion to acute ethanol intoxication, ethanol withdrawal and two other important ethanol-specific emergency presentations—Wernicke encephalopathy (WE) and alcoholic ketoacidosis (AKA).

A number of other alcohols, though far less frequently implicated in ED presentation than ethanol, are metabolized to form toxic organic acids and produce life-threatening clinical syndromes. These alcohols include methanol and ethylene glycol and are termed 'toxic alcohols'. Early recognition of their ingestion and intervention can prevent significant morbidity and mortality due to these alcohols.

Ethanol

Pharmacology

Ethanol is a small molecule that is rapidly and almost completely absorbed from the stomach and small intestine. Ethanol is both water- and lipid-soluble and rapidly crosses lipid membranes to distribute uniformly throughout the total body water. Ethanol is principally eliminated by hepatic metabolism, with smaller amounts (5% to 10%) excreted unchanged via the kidneys, lungs and in sweat.

Ethanol is oxidized by cytosolic and microsomal cytochrome P450 (2E1 and 1A2) alcohol dehydrogenases (ADH) to acetaldehyde, which, in turn, is metabolized by aldehyde dehydrogenase to acetate. Acetate is converted to acetyl-CoA and enters the Krebs cycle to be finally metabolized to carbon dioxide and water. Entry of acetyl-CoA in the Krebs cycle is dependent on adequate thiamine stores. Importantly, the ADH system is saturated at relatively low blood ethanol concentrations, which results in blood ethanol elimination moving from first-order to zero-order kinetics. The rate of ethanol metabolism in non-tolerant adults is approximately 10 g/h and blood ethanol levels fall by about 0.02 g/dL/h. An alternative pathway for ethanol metabolism is via the microsomal ethanol oxidizing system, the activity of which increases in response to chronic alcohol exposure. Metabolism by this route is relatively important at very high blood ethanol concentrations and in chronic alcoholics.

The mechanism of action of ethanol is poorly understood. However, ethanol acts as a central nervous system (CNS) depressant, at least partially by enhancing the effect of γ-aminobutyric acid (GABA) at $GABA_A$ receptors. Tolerance to the CNS depressant effect develops with chronic exposure.

Clinical presentation

Acute ethanol intoxication

The clinical features associated with acute ethanol intoxication predominantly relate to the CNS and progress with increasing blood alcohol levels, although there is remarkable inter-individual variation, most commonly as a function of tolerance. Initial features include a sense of well-being, increased self-confidence and disinhibition. With increasing blood concentrations, impaired judgement, impaired coordination and emotional lability develop. At very high concentrations, ethanol can cause coma, respiratory depression, loss of airway protective reflexes and even death.

Presentation to the ED is usually a result of the social and behavioural consequences of the alteration in higher CNS functions. Ethanol is frequently implicated in trauma, drowning, violence, self-harm, domestic and sexual abuse and other acute social and psychiatric emergencies. Ethanol is a common co-ingestant in deliberate self-poisoning.

Many other important medical and surgical conditions that cause altered mental status may be incorrectly ascribed to ethanol intoxication or may coexist with ethanol intoxication. Box 25.17.1 lists an example of a differential diagnosis.

In the absence of a clear history, the diagnosis of ethanol intoxication is confirmed only on determination of a breath or blood ethanol concentration. Because ethanol consumption is so ubiquitous, a positive reading does not exclude coexisting pathology.

Ethanol withdrawal syndrome

A withdrawal syndrome usually develops within 6 to 24 hours of cessation or reduction in ethanol

consumption in dependent individuals. Symptoms can begin any time after the blood ethanol concentration begins to fall, and blood ethanol is frequently still measurable in withdrawing patients. The duration of the syndrome may be from 2 to 7 days. Although its pathophysiology is not well understood, the syndrome presents as unopposed sympathetic and CNS stimulation. It is associated with a mortality of 5%, and early clinical recognition of this syndrome is important.

Patients may present to the ED already in withdrawal after deliberately abstaining from alcohol or after stopping drinking due to intercurrent illness or lack of funds to buy alcohol. Alternatively, ethanol-dependent patients may begin to withdraw while being treated in the ED, particularly where their stay is prolonged.

Clinical features of mild ethanol withdrawal are those of mild autonomic hyperactivity and include nausea, anorexia, coarse tremor, tachycardia, hypertension, hyperreflexia, insomnia and anxiety. In more severe cases, the patient goes on to develop more pronounced anxiety, insomnia, irritability, tremor, tachycardia, hyperreflexia, hypertension, fever, visual hallucinations, seizures and delirium. Symptoms usually peak by 50 hours. Delirium tremens represents the extreme end of the spectrum of ethanol withdrawal. It is an uncommon but potentially lethal complication.

Wernicke encephalopathy

This is an acute neuropsychiatric syndrome that develops in certain alcohol-dependent individuals as a result of thiamine deficiency. It is a spectrum disorder that is classically described as a triad of
- oculomotor disturbance (usually nystagmus and ocular palsies)
- abnormal mentation (usually confusion)
- ataxia

In up to 20% of cases, the signs and symptoms of the classic triad are not evident at presentation. Less common presentations include stupor, hypothermia, cardiovascular instability, seizures, visual disturbances, hallucinations and alterations in behaviour. In extremis, the condition may present with hyperthermia, hypertonia, spastic paresis, dyskinesias and coma.

WE is a clinical diagnosis and constitutes a medical emergency with significant morbidity and a mortality of 10% to 20% if left untreated. For this reason, the emergency physician must maintain a high index of suspicion in any patient with altered mental status and suspected prolonged heavy ethanol intake.

Alcoholic ketoacidosis

AKA, also termed alcoholic acidosis, is an often unrecognized potentially life-threatening medical condition that develops in the alcoholic patient in response to starvation. The normal response to starvation is increased gluconeogenesis from pyruvate. In the alcoholic patient, pyruvate is preferentially converted to lactate. In response, fatty-acid metabolism is increased as an alternative source of energy, resulting in the production of acetyl-CoA and acetoacetate which, in turn, is reduced to β-hydroxybutyrate (BOHB), producing the ketoacidotic state.

Patients with AKA usually present with a history of prolonged heavy alcohol misuse preceding a bout of particularly excessive intake, which has been terminated several days earlier by nausea, severe vomiting and abdominal pain. There may be a history of previous episodes requiring brief admissions with labels of 'query pancreatitis' or 'alcoholic gastritis'. Examination usually reveals tachypnoea, tachycardia, hypotension and diffuse epigastric tenderness on palpation. In contrast to patients with diabetic ketoacidosis, mental status is usually normal. The presence of an altered mental state should prompt consideration of other causes, especially hypoglycaemia and acute ethanol intoxication.

Toxic alcohol poisoning is an important differential diagnosis. Toxic alcohol acidosis does not produce ketosis and, in contrast, does cause significant alteration to conscious state, visual symptoms (methanol) and renal failure/crystalluria (ethylene glycol).

Clinical investigations

The excretion of ethanol by the lungs, although relatively unimportant in terms of ethanol elimination, obeys the Henry law, that is, the ratio between the concentration of ethanol in the alveolar air and blood is constant. This allows breath sampling of ethanol to estimate reliably blood ethanol concentration.

Most non-tolerant adults would be expected to develop some impairment of higher functions at blood ethanol concentrations in the range of 0.025 to 0.05 mg/dL (5 to 11 mmol/L) and to develop significant CNS depression in the range of 0.25 to 0.4 mg/L (55 to 88 mmol/L).

In a patient presenting with acute intoxication, no investigations may be necessary; however, blood or breath ethanol levels (BALs) are frequently useful to confirm the diagnosis. A BAL of zero is highly significant in a patient with an altered level of consciousness, as ethanol intoxication is excluded and other diagnoses need to be considered. A positive blood ethanol level does not exclude alternative diagnoses.

Other investigations should be performed as clinically indicated in an effort to exclude coexisting pathologies and alternative diagnoses as detailed earlier.

In the patient with AKA, bedside investigations reveal a low/normal glucose, low or absent breath ethanol and urinary ketones (these may be low or absent due to the inability of bedside assays to detect all ketone moieties, especially BOHB). Laboratory investigation will reveal an anion-gap (AG) acidosis (this may be severe with AG >30) and mild hyperlactaemia insufficient to account for the AG.

Treatment

Acute ethanol intoxication

Severe ethanol intoxication with CNS depression is life threatening, but a good outcome is assured by the timely institution of supportive care. In particular, attention may have to be given to the airway and ventilation. Hypotension generally responds to intravenous crystalloid infusion. The blood sugar level must be checked and normoglycaemia maintained. Intravenous thiamine should be administered, particularly to those who chronically abuse ethanol. There is no specific antidote for ethanol intoxication.

Less severe ethanol intoxication presents a management challenge to the emergency physician when it results in a combative or violent patient threatening harm to self or staff or threatening to self-discharge against medical advice. Such patients frequently require chemical sedation with titrated doses of intravenous benzodiazepines or butyrophenones in order to facilitate assessment and observation, ensure the safety of patient and staff and prevent unsafe discharge.

Ethanol withdrawal

The key to management of this condition is early recognition and institution of adequate dosing of benzodiazepines. Large doses of benzodiazepines may be required to control symptoms. The risk and likely severity of ethanol withdrawal can usually be anticipated if an accurate history of alcohol intake and previous withdrawals is obtained. Coexisting conditions should be managed on their own merits. It is

important to exclude hypoglycaemia and correct it if present. Thiamine 200 mg (preferably given intravenously) should immediately be given to any chronically alcoholic patient who presents with or develops an altered mental status (see Wernicke encephalopathy later). Benzodiazepines are first-line therapy for seizures resulting from ethanol withdrawal. Phenytoin is not effective in treating or preventing withdrawal seizures.

The management of ethanol withdrawal in the ED or observation ward is greatly facilitated by the use of ethanol withdrawal charts. These charts facilitate recognition of the first signs of ethanol withdrawal and timely administration of benzodiazepines in adequate doses. An example of such a chart is shown in Fig. 25.17.1. Benzodiazepine, usually diazepam, administration is titrated to the clinical features of withdrawal. The total dose required to manage withdrawal is highly variable. Benzodiazepines are usually given orally but can be administered intravenously to the uncooperative or severely withdrawing patient. With extreme withdrawal refractory to benzodiazepines, small aliquots of ethanol may be effective in controlling severe symptoms.

Wernicke encephalopathy

Wernicke's encephalopathy is a clinical diagnosis with high mortality if untreated, any known or suspected alcoholic patient who presents with altered mental status should receive thiamine 200 mg IV during the initial assessment. Recommendations for thiamine dosing in patients with suspected WE vary between 200 and 500 mg tds, although there is less evidence supporting the 500-mg dose. These doses ought to be continued until the patient's consciousness clears or an alternative diagnosis is determined. Parenteral administration is vital, as thiamine is variably absorbed orally with low bioavailability. An example of an ED thiamine administration guideline is found in Fig. 25.17.2. If dextrose administration is required, it must follow thiamine replacement, as it may acutely worsen the neurological

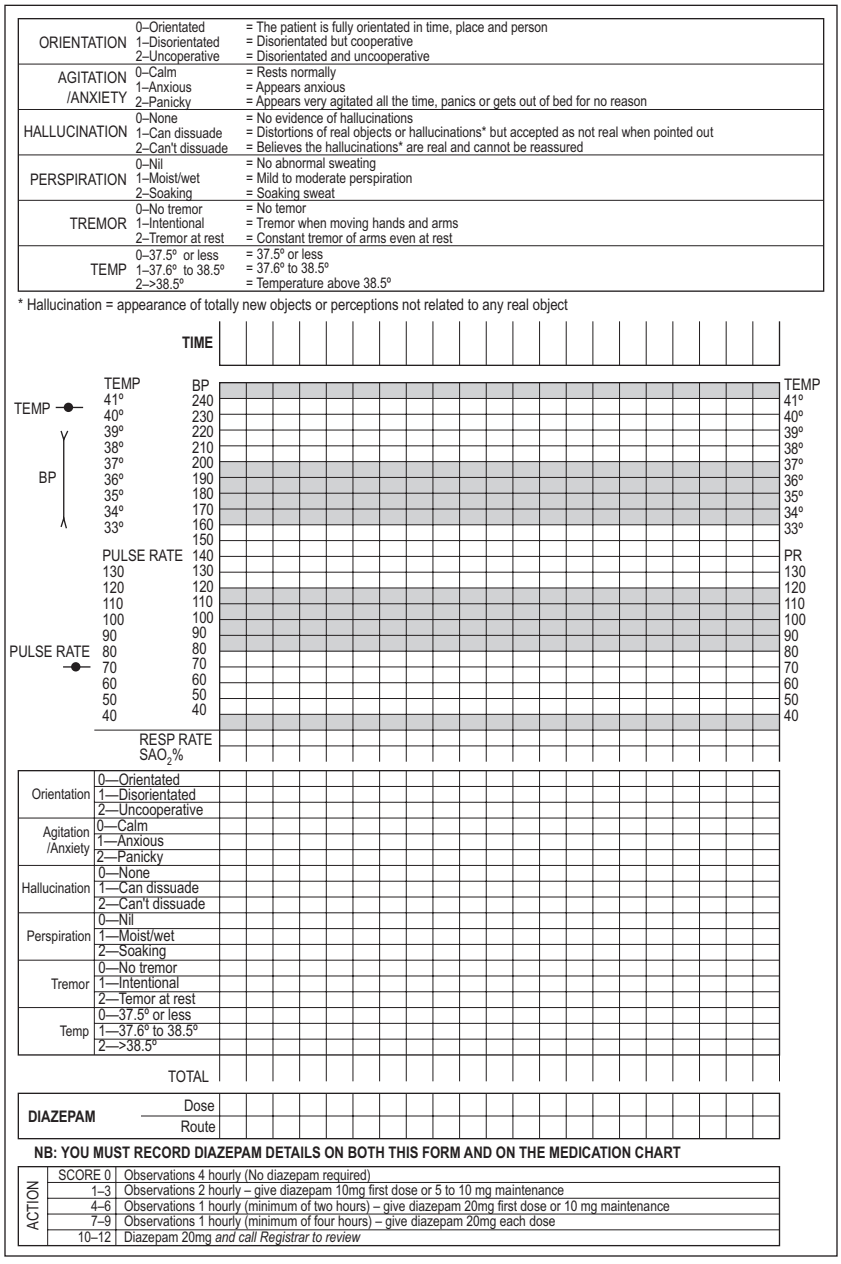

FIG. 25.17.1 An example of an alcohol withdrawal chart.

status of the thiamine-deficient patient. Magnesium is a co-factor for thiamine-dependent transketolase; therefore any magnesium deficiency should be corrected.

Alcoholic ketoacidosis

Initial resuscitation should include administration of adequate volumes of crystalloids to treat hypovolaemia, followed by parenteral thiamine and infusion of dextrose-containing fluids. Potassium and magnesium supplementation should be given according to serum electrolyte results. Administration of dextrose, usually an infusion of 5% dextrose, is essential, as it stimulates insulin release, inhibits glucagon release and so inhibits fatty-acid oxidation. Thiamine facilitates entry of pyruvate into the Krebs cycle. Administration of insulin or bicarbonate is not necessary.

Fluid, electrolyte and acid–base status should be closely monitored and further therapy tailored to the clinical response. Careful evaluation and treatment of the coexisting medical disorders is essential.

Disposition

The disposition of many ethanol-intoxicated patients presenting to the ED is determined by the associated medical, surgical, psychiatric or social issues. Ethanol-intoxicated patients should be discharged from the ED only when their subsequent safety can be ensured. Discharge into the

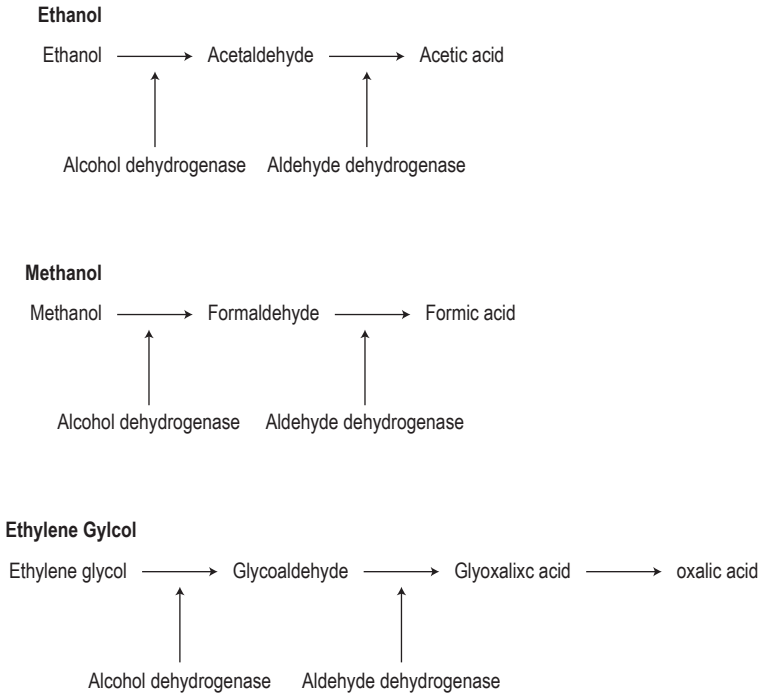

FIG. 25.17.3 Alcohol metabolism.

care of a competent relative or friend is sometimes appropriate. Other patients, particularly if they are aggressive or neurologically impaired, require admission to a safe environment until such time as the intoxication resolves and they can be reassessed. An observation ward attached to the ED may be the most appropriate place if available. More severely intoxicated patients requiring airway control and support of ventilation should be admitted to the intensive care unit.

Patients in ethanol withdrawal may require admission for management of the precipitating medical or surgical illness. For those who wish to complete withdrawal with a view to abstinence, the remainder of the withdrawal may be managed in a general medical ward, specialized medical or non-medical detoxification centre or at home. Medical detoxification is mandatory where a severe withdrawal syndrome is anticipated. In any case, ongoing psychosocial support will be required, and it is important for EDs to have a good knowledge of the locally available drug and alcohol services to ensure appropriate referral.

Patients with WE should be admitted for ongoing care and thiamine and magnesium supplementation. The ophthalmoplegia and nystagmus usually respond well to thiamine within hours to days. Ataxia and mental changes improve more slowly if at all and have a poorer prognosis. Up to 50% of cases will show no response despite thiamine therapy.

Patients with ethanol-induced ketoacidosis also require admission for ongoing dextrose and thiamine, monitoring of fluids and electrolytes and management of the precipitating medical condition. Mortality from ethanol-induced ketoacidosis per se is rare with early recognition and treatment, but death may occur as a result of the underlying medical condition, particularly if the latter is unrecognized.

Ideally any patient with an ethanol-related presentation should be offered referral to drug and alcohol rehabilitation services for counselling.

Toxic alcohols

Epidemiology

Both methanol and ethylene glycol poisoning are extremely rare in Australasia. This is due primarily to their limited availability.

Methanol is found in model aeroplane fuel and laboratory solvents. There is no methanol in 'methylated spirits' sold in Australia (this is, in fact, pure ethanol with bittering agents to minimize palatability). Methanol is more freely available in other countries, where it is found in household cleaning agents and windshield de-icers. Incorrect distillation of ethanol for human consumption, usually from home-made stills, has resulted in mass poisoning incidents with severe toxicity and fatalities.

Ethylene glycol is most commonly encountered as a constituent of radiator antifreeze or coolant. It is also found in hydraulic fluids and solvent preparations. Significant poisoning in Australasia almost always occurs following deliberate ingestion.

Toxicology

Methanol and ethylene glycol are both small molecules that are rapidly absorbed from the gastrointestinal (GI) tract, with a volume of distribution that approximates total body water (0.6 L/kg). Toxic alcohols are oxidized initially by hepatic cytosolic and microsomal ADHs and then further metabolized by aldehyde dehydrogenase into acidic moieties (Fig. 25.17.3). Methanol is metabolized initially to form formaldehyde and then to formic acid. Ethylene glycol is metabolized to glycoaldehyde and then to glycolate, glyoxylate and oxylate. The plasma half-lives of the toxic alcohols are appreciably increased in the presence of ethanol because ethanol has a much higher affinity for ADH: four times that of methanol and eight times that of ethylene glycol. As a result, the presence of ethanol greatly delays the onset of clinical and biochemical features of toxicity.

Methanol toxicity is mediated through the formation of formic acid, which binds to cytochrome oxidase, resulting in impairment of cellular respiration. Its half-life is prolonged (up to 20 hours) and its metabolism is dependent on the presence of tetrahydrofolate. The presence of systemic acidosis enhances the movement of formic acid intracellularly. The initial acidosis is secondary to formic acid. However, as cellular respiration is disturbed and toxicity progresses, a concurrent lactic acidosis usually becomes evident. The accumulation of formic acid manifests as increasing AG acidosis, GI and neurological toxicities.

Ethylene glycol itself is a direct irritant to the GI tract and has CNS depressant effects similar to those of ethanol. The major toxicity is mediated through the acid metabolites glycolate and oxylate. Oxalate complexes with calcium, leading to crystal deposition chiefly in the renal tubules

and the CNS. Myocardium and lungs can also be affected. In addition, these acids appear to be inherently toxic. Complexing with calcium produces systemic hypocalcaemia and may manifest with prolongation of the QT interval. A profound AG acidosis develops and is principally attributed to the accumulation of glycolic acid, although a concurrent lactic acidosis (type B) also contributes.

Predictors of toxicity

Toxic dose

The lethal dose of methanol is conservatively estimated as 0.5 to 1.0 mL/kg of a 100% solution. Clinical toxicity and visual sequelae may be seen with smaller doses, perhaps as little as 0.25 mL/kg.

The lethal dose of ethylene glycol is thought to be on the order of 1.0 mL/kg of a 100% solution.

Biochemical markers

Biochemical predictors of mortality in toxic alcohol ingestions are an elevated anion-gap metabolic acidosis and a raised osmolar gap (OG).

When available, serum levels of methanol and ethylene glycol greater than 50 mg/dL are associated with severe toxicity.

Clinical features

Methanol

Initially, mild CNS depression typical of ethanol intoxication is evident. A latent period (6 to 24 hours) is classically observed, during which time the patient may appear asymptomatic. Progressive ophthalmic, GI and CNS symptoms may then develop. Hyperpnoea is usually observed secondary to the metabolic acidosis. Progressive obtundation leading to coma and seizures heralds the onset of cerebral oedema and signifies a poorer prognosis. Those who recover from serious CNS toxicity can display extrapyramidal movement disorders. Retinal toxicity may be irreversible in up to one-third of cases.

Ethylene glycol

The progression of clinical features following ingestion of ethylene glycol is described in three stages: neurological, cardiopulmonary and renal. These stages are artificial and toxicity may progress in a rapid manner, with concurrent toxicities being observed. Initially, an intoxication syndrome analogous to that of ethanol occurs, along with nausea and vomiting due to mucosal irritation. A progressively severe AG acidosis with renal failure and hypocalcaemia is characteristic. Crystalluria may be observed. With severe poisoning, renal failure progresses rapidly. CNS depression is observed, with severe manifestations including seizures, coma and cerebral oedema. Hyperpnoea occurs secondary to the metabolic acidosis.

Clinical investigations

Direct assay of methanol or ethylene glycol concentrations in serum is rarely readily available. In the absence of direct assays, the ability to exclude a potentially lethal toxic alcohol ingestion at presentation is limited. The combination of an OG and a wide AG acidosis is highly suggestive of either methanol or ethylene glycol intoxication. However, a normal OG does not exclude toxic alcohol ingestion. In the presence of a profound acidotic state, it is possible that a toxic alcohol has been largely metabolized and thus is no longer sufficiently present to raise the OG. Additionally, baseline OGs may vary from −14 to +10 between individuals; therefore a 'normal' OG may mask a large occult increase representing a potentially lethal ingestion. Similarly, a normal AG at presentation is not sufficient to exclude toxic alcohol ingestion. Early in the clinical course an AG may be normal, only to develop rapidly as metabolism progresses. This is particularly so in the presence of ethanol, where the onset of an AG acidosis will be delayed until the ethanol itself has been preferentially metabolized.

Calculation for OG:

$$\text{Osmolargap} = \text{measured osmolality} - \text{Calculated osmolality:}$$

Osmolality is measured in the lab by suing freezing point depression.

$$\text{Calculated osmolality} - 2 \times \text{Na} + \text{glucose} + \text{urea} + \text{alcohol} + (\text{ethanol}) \times 1.25$$

Alcohol is usually measured and reported in terms of percent; the level acceptable as the legal driving limit is 0.05%, which is 50 mg/100 mL.

To convert alcohol from percent to millimoles per litre

$$\text{Alcohol in millimoles per litre} = \text{measured alcohol in per cent} \times 218$$

Alcohol is more osmotically active and hence requires a correction factor of 1.25.

Falls in serum bicarbonate and arterial pH correlate well with levels of toxic organic acid metabolites in the circulation; in the absence of direct assays, these are their chief surrogate markers. In this context, it is common practice to exclude toxic ingestion where there is a normal venous bicarbonate (>20) 8 hours after the serum or breath ethanol has been documented as undetectable.

When available in a clinically useful time frame, direct assays may shorten hospital assessment times, especially with accidental exposures. The interpretation of serum methanol and ethylene glycol concentrations requires a consideration of time since ingestion, ethanol co-ingestion and acid–base status.

Treatment

The definitive care for methanol and ethylene glycol ingestions is dialysis with concurrent ADH blockade therapy. All cases of deliberate self-poisonings with a toxic alcohol must be managed in a facility with easy access to dialysis if clinical intoxication becomes apparent. ADH blockade therapy can impede the progression of clinical toxicity and permit safe transfer to an appropriate facility.

Alcohol dehydrogenase blockade

Blockade of ADH can be achieved by the administration of either ethanol or the specific ADH antagonist fomepizole. These agents prevent the metabolism of toxic alcohols and the accumulation of their organic acid metabolites. ADH blockade significantly increases the half-life of parent toxic alcohols. In the presence of ethanol, the half-life may increase to about 50 hours for methanol and up to 20 hours for ethylene glycol. ADH blockade with ethanol, although an essential element of care, is not definitive in most circumstances owing to the practical difficulty maintaining a prolonged elevated blood ethanol concentration and obtaining serial toxic alcohol levels. However, where serial levels are available, there is evidence that fomepizole can be used in isolation to treat toxic alcohol ingestions. Fomepizole is currently available in Australia under Special Access Scheme (SAS).

Ethanol therapy can be initiated with a loading dose of 8 mL/kg of 10% ethanol intravenously or 1.8 mL/kg of 43% ethanol orally (equivalent to 3 × 40 mL shots of vodka in a 70-kg adult). Maintenance therapy requires an infusion of 1 to 2 mL/h of 10% ethanol or 0.2 to 0.4 mL/h of 43% ethanol orally (equivalent to one 40 mL shot of vodka each hour in a 70-kg adult). The ethanol concentration should be maintained in the range of 100 to 150 mg/dL (22 to 33 mmol/L) by careful titration of maintenance administration guided by frequent blood ethanol concentrations. The dose of alcohol will have to be adjusted once haemodialysis is commenced.

The dose of fomepizole is 15 mg/kg IV as a loading dose and then 10 mg/kg IV twice daily.

Haemodialysis

Haemodialysis represents definitive care for confirmed toxic alcohol ingestions. It effectively removes parent toxic alcohols and their acidic metabolites. Lactate-free and bicarbonate-buffered dialysates may assist the correction of acidaemia. Commonly accepted indications for haemodialysis are listed in Box 25.17.2. End points for haemodialysis are listed in Box 25.17.3. Ethanol is also rapidly cleared by dialysis and ethanol infusion rates must be increased (usually doubled) during haemodialysis.

Box 25.17.2 Indications for haemodialysis in toxic alcohol poisoning

Severe metabolic acidosis (pH < 7.25)
Renal failure (ethylene glycol)
History of a large toxic alcohol ingestion and osmolar gap >10 mmol/L
Visual symptoms (methanol)
Ethylene glycol or methanol levels >50 mg/dL (if available)

Box 25.17.3 End points for haemodialysis in toxic alcohol poisoning

Correction of acidosis
Osmolar gap <10 mmol/L
Ethylene glycol or methanol level <20 mg/dL (if available)

Supportive care and co-factor therapy

Folinic or folic acid administration is recommended in methanol poisoning (folinic acid 2 mg/kg IV qid) to aid in the endogenous metabolism of formic acid. Pyridoxine and thiamine supplementation is recommended in ethylene glycol poisoning when the patient is thought to be depleted (e.g. alcoholics), again to aid endogenous metabolism of the pathogenic acids.

In methanol poisoning, systemic acidaemia enhances the movement of formic acid into the intracellular compartment. Correction with intravenous bicarbonate if the pH is below 7.3 is recommended.

Calcium replacement in ethylene glycol poisoning is controversial given that it may promote calcium oxalate crystal formation. Consequentially calcium should be replaced only if there is symptomatic hypocalcaemia (including prolongation of the QT interval) or the patient has intractable seizures.

Prognosis

Prompt ADH blockade therapy and dialysis ensures an excellent outcome in toxic ingestions who present before the development of established end-organ toxicity. Delayed diagnosis and treatment is associated with death and permanent neurological and renal sequelae, including blindness in the case of methanol poisoning.

CONTROVERSIES

- It has been suggested that emergency departments could play a pivotal role in reducing ethanol-related morbidity by adopting procedures to detect and refer individuals who misuse ethanol. A number of centres have successfully done trial screening and brief intervention strategies for hazardous ethanol consumption.
- It is unclear whether fomezipole provides sufficient advantages over ethanol as an alcohol dehydrogenases blocker in toxic alcohol poisoning so as to justify the expense of importing and stocking it in Australasia.
- Co-factor therapy in toxic alcohol poisoning is of unproven efficacy; however, there are few contraindications to its use.

25.18 Carbon monoxide

Nicholas Buckley

ESSENTIALS

1 **Carbon monoxide is the commonest agent used in completed suicides by poisoning in Australia and the United Kingdom.**

2 **Carbon monoxide is produced by incomplete combustion and is found in car exhaust, faulty heaters, fires and in industrial settings.**

3 **Carbon monoxide poisoning may result in significant long-term neuropsychological sequelae.**

4 **Oxygen increases the elimination of carbon monoxide, and the extent of increase is proportional to the inspired oxygen pressure.**

5 **The optimal mode of oxygen delivery to improve clinical outcomes remains controversial.**

Introduction

Carbon monoxide (CO) poisoning is an important cause of mortality and morbidity from poisoning. Immediate resuscitation including 100% oxygen therapy is essential and the long-term results of most patients will be good with this simple intervention. It is unclear whether any additional intervention will reduce the low but important risk of serious long-term neurological damage.

Aetiology, pathophysiology and pathology

Carbon monoxide is a colourless, odourless, tasteless and non-irritant gas produced by

incomplete combustion of hydrocarbons.[1] Small amounts are also produced endogenously by normal metabolic processes. The most common sources of significant exposure are car exhausts, cigarette smoke, fires and faulty home heaters and barbecues. Catalytic converters reduce the production of CO and are in all cars manufactured in the last decade or two. Carboxyhaemoglobin (COHb) concentrations in cigarette smokers range as high as 10%.

The pathophysiology of CO exposure is complex and incompletely understood. Upon exposure, CO binds to haemoglobin with an affinity 210 times that of oxygen, thereby decreasing the oxygen-carrying capacity of blood. CO can also produce injury by several other mechanisms, including direct disruption of cellular oxidative processes, binding to myoglobin and cytochrome oxidases and causing peroxidation of brain lipids.[1] However, the end result in any case is tissue hypoxia, leading to varying degrees of end-organ damage and eventually death. The severity of poisoning is a function of the duration of exposure, the ambient concentration of CO and the underlying health status of the exposed individual. Although it is useful for diagnosis when detected, the COHb level on arrival correlates poorly with outcome.[2]

Epidemiology

Poisoning with CO is an important cause of unintentional and intentional injury worldwide. In the United States alone, an estimated 1000 to 2000 accidental deaths due to CO exposure occur each year, resulting from an estimated 40,000 exposures.[3] In Australia and the United Kingdom, it is the most common agent in completed suicide by poisoning. In East Asia, there is a recent epidemic of self-poisonings due to the burning of charcoal.[2]

Prevention

Prevention of environmental or occupational exposure is possible with CO air monitors. The threshold CO concentration of concern is reduced if exposed people are exercising or at high altitudes (increased breathing rate and pulmonary blood flow), as these increase uptake.

The introduction of catalytic converters has reduced CO production in vehicle exhaust; this may have contributed to fewer fatal suicidal poisonings in some countries.[4,5]

Clinical features

The signs and symptoms of acute CO poisoning are shown in Table 25.18.1,[6] and severity broadly correlates with maximal COHb concentration. Initial symptoms are non-specific (e.g. tachycardia, headache, dizziness, gastrointestinal symptoms) and probably predominantly due to compensatory mechanisms to maintain tissue oxygen delivery to vital organs. Signs with more severe toxicity directly reflect tissue hypoxia, with central nervous and cardiovascular toxicity being the most critical manifestations. Death results rapidly when impaired oxygenation of the heart prevents the compensatory increase in cardiac output. The skin is classically cherry pink, although severely ill patients are often pale or cyanosed. Pre-existing cerebral or cardiovascular disease, anaemia, and volume depletion or cardiac failure all increase toxicity (for a given COHb). These reduce the ability to compensate by increasing cardiac output or redistributing the blood supply to vital organs. Cardiac toxicity is common in moderate to severe poisoning. Screening with cardiac enzymes and further testing with echocardiography or single photon emission computed tomography (SPECT) have been suggested.[7,8] Abnormal troponin has also been linked with greater long-term mortality.[9]

Table 25.18.1 Typical clinical symptoms and signs relative to carboxyhaemoglobin (normal = 0.5%)

COHb (%)	*Symptoms and signs*
<10	Nil (commonly found in smokers)
10–20	Nil or vague non-descript symptoms
30–40	Headache, tachycardia, confusion, weakness, nausea, vomiting, collapse
50–60	Coma, convulsions, Cheyne-Stokes breathing, arrhythmias, ECG changes
70–80	Circulatory and ventilatory failure, cardiac arrest, death

COHb, Carboxyhaemoglobin; *ECG*, electrocardiogram.

Owing to low oxygen pressures, the high affinity of foetal haemoglobin for CO and the much longer half-life of CO in the foetal circulation, the foetus is particularly susceptible to CO poisoning. The outcome of significant CO poisoning in the mother is often foetal death or neurological damage.

Delayed or persistent neuropsychiatric sequelae occur, largely confined to those who have had a prolonged loss of consciousness at some stage.[10] Long-term follow-up is necessary, as more subtle defects can develop or become apparent over weeks to months. The most common problems encountered are depressed mood (even in those accidentally exposed) and difficulty with higher intellectual functions (especially short-term memory and concentration).[11,12] More severe problems include parkinsonism and speech problems. Neuropsychological testing may detect subtle defects not apparent on crude testing with the Mini-Mental State Examination. The incidence of sequelae depends on the definition used; major deficits are relatively uncommon, but neuropsychiatric complaints related to memory or concentration may occur in as many as 25% to 50% of patients with a loss of consciousness.[11,12]

Differential diagnosis

In suicide attempts, the diagnosis of CO poisoning is generally apparent from the circumstances when the person is found. The major diagnostic issue is whether there is some other deliberate self-poisoning, as this is extremely common. In unconscious patients, the electrocardiogram (ECG), paracetamol concentration and electrolytes should be reviewed with this possibility in mind.[6]

A large proportion of victims of accidental smoke inhalation also have cyanide poisoning. This rarely leads to a change in management (because of problems with administering the cyanide antidotes in this setting), but it should be suspected when CNS effects are out of proportion with COHb concentrations and there is a marked lactic acidosis.

Clinical investigations

Blood gases and oximetry

Most pulse oximeters do not attempt to measure COHb but merely the ratio of oxyhaemoglobin to deoxyhaemoglobin. Co-oximeters, where available, are not sufficiently accurate to use for either screening or quantification in a hospital setting.[13] Blood gases with a co-oximetry results are required to quantify COHb. COHb concentrations on arrival to hospital are a very poor guide to the extent of exposure. This is because it is impossible to estimate the prior half-life, which is dependent on inhaled oxygen as well as heart and respiratory rates. There is also substantial variability between individuals in the extent to which they can compensate for high COHb. Therefore the correlation of COHb with acute and long-term clinical effects is poor. COHb may confirm (or possibly exclude) the diagnosis, but it should not be used to estimate long-term prognosis.

Electrocardiogram

Patients should have a baseline ECG, another 6 hours later, and ECG monitoring for at least 24 hours; cardiac enzymes should be tested if the initial ECG is abnormal. The most important signs are those of cardiac ischaemia; these are identical to those seen in coronary artery disease.

Biochemistry

Cardiac enzymes should be measured when there is severe clinical toxicity or ECG changes are noted. Metabolic acidosis, predominantly due to lactate, will provide an indication of tissue hypoxia. Electrolytes (sodium, potassium, magnesium) should be measured, as low concentrations of any of these may exacerbate cardiac toxicity. S100B concentrations (an astroglial structural protein), indicating acute neurological injury, have the potential to be useful in estimating neurological damage, as early elevation correlates with long-term morbidity.[14–16]

All women of childbearing age should have a beta HCG test performed.

Criteria for diagnosis

A high COHb (>15%) with typical symptoms or signs confirms the diagnosis of acute CO poisoning.

In some parts of the world, it is common to attribute many non-specific presentations to chronic CO exposure, often despite COHb concentrations that are normal or within the range of those seen in 'healthy' smokers. There are no universally accepted criteria for making a diagnosis of chronic CO poisoning, but the diagnosis should not be seriously entertained without confirmation of high ambient CO concentrations in the person's environment.

Treatment

Initial management is directed toward securing the airway and stabilizing respiration and circulation. If there is impaired consciousness, make sure that if necessary, the airway is maintained with intubation. The comatose patient should be placed on a cardiac monitor, a 12-lead ECG should be performed, an intravenous line inserted and blood drawn for full blood count, electrolytes, lactate, COHb, blood sugar and troponin. If awake, the patient should be reassured and discouraged from activity, for muscle activity will increase oxygen demand.[6]

Metabolic acidosis should not be treated directly unless the acidosis itself contributes to toxicity (pH < 7.0). It should respond to improved oxygenation and ventilation and the net effect of acidosis on oxygen delivery is probably beneficial.

Oxygen

Oxygen decreases the biological half-life substantially from 4 hours in ambient air to approximately 40 minutes in a 100% oxygen atmosphere (Fig. 25.18.1).[6] Oxygen (100%) should be administered with mechanically assisted ventilation if necessary. In patients able to tolerate it, continuous positive airway pressure by mask may allow 100% oxygen delivery without intubation. Four to 6 hours of 100% normobaric oxygen will remove over 90% of the CO. If the only available oxygen delivery device is a Hudson mask, it should be remembered that at a flow rate of 15 L/min, no more than 60% oxygen is delivered. At these concentrations the half-life of CO may be as long as 90 minutes and a longer period of oxygen may be required for severe poisonings (see Fig. 25.18.1). Oxygen toxicity is unlikely with less than 24 hours of treatment, but the risk increases with increasing exposure.

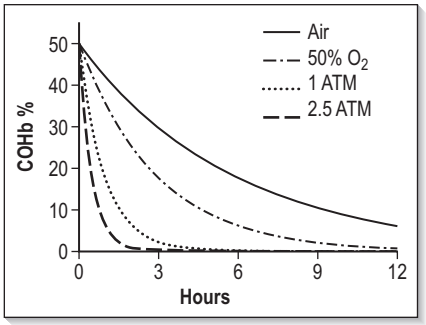

FIG. 25.18.1 Approximate decline in carboxyhaemoglobin *(COHb)* from 50% according to the inspired oxygen concentration and pressure. ATM is short for atmosphere (a unit for air pressure).

When immediately available, hyperbaric oxygen (HBO) should be considered for patients with serious CO poisoning. Oxygen at 2 to 3 atmospheres will further reduce the half-life of COHb to about 20 minutes (see Fig. 25.18.1); more importantly, it causes very rapid reversal of tissue hypoxia due to oxygenation of tissue from oxygen dissolved in the plasma.

Controversy exists on the benefits, risks and indications for HBO (see Controversies, further on). Indications for HBO commonly used by hyperbaric facilities are simply those factors that indicate a higher risk of long-term neuropsychiatric sequelae.[11,12] These include

- a prolonged decreased consciousness after removal from exposure
- abnormal neuropsychiatric testing or neurological signs
- pregnancy

Complications of HBO therapy[11,12] include

- decompression sickness
- rupture of tympanic membranes
- damaged sinuses
- oxygen toxicity
- problems due to lack of monitoring

Follow-up

As well as psychiatric follow-up for all patients who have been poisoned with CO due to self-harm, patients should have a neuropsychiatric follow-up at 1 to 2 months to evaluate any long-term neuropsychiatric injury.

Other treatments

Various pharmacological treatments have been proposed to reduce hypoxic/reperfusion injury.[2] The most promising is erythropoietin, which was shown to be effective in animals and in a small clinical trial. However, further clinical trials are required. Isocapneic hyperventilation is another experimental method that is more efficient than HBO in hastening the elimination of COHb.[2]

CONTROVERSIES

- The major controversy is about the benefits, risks and indications for HBO, and resolving this 'clinical uncertainty' with further trials will likely be frustrated by some extremely certain HBO clinicians.[17] There have been eight HBO randomized clinical trials (RCTs) reporting very conflicting outcomes. Some have concluded that HBO is harmful[18,19] and others that it is beneficial.[20] Systematic reviews have found no evidence for benefit from combined analysis of the trials.[11,12] They also find empiric evidence of multiple biases that operated to inflate the benefit of HBO in two positive trials. In contrast, the interpretation of negative trials was hampered by low rates of follow-up, unusual interventions for control patients and inclusion of less severely poisoned patients.
- In centres with a chamber, the use of HBO, when it can be given rapidly and safely, may be justifiable based on the biological rationale that it is the most efficient means of rapidly increasing oxygen delivery and removing carbon monoxide. However, transferring patients between hospitals for delayed use of HBO, particularly over long distances, is not justifiable on current evidence from RCTs, animal studies[21,22] or the known pathophysiology of CO.
- The use of measuring S100B protein in the assessment of prognosis of these patients.

25.19 Anticonvulsants

Joe-Anthony Rotella • Anselm Wong

ESSENTIALS

1 **Anticonvulsant overdose typically causes central nervous system effects, but other effects such as cardiotoxicity may be exhibited after the ingestion of certain agents.**

2 **Multiple doses of activated charcoal can reduce the duration of toxicity in carbamazepine and phenytoin toxicity.**

3 **Serum concentrations correlate with clinical toxicity in carbamazepine and phenytoin toxicity, guiding management in severe cases.**

4 **Depending on the agent, extracorporeal elimination may be required in severe cases of toxicity.**

5 **Paradoxical seizures can occur with any anticonvulsant, although they are rare in phenytoin toxicity.**

Introduction

Although traditionally used for the management of seizure disorders, the clinical scope of anticonvulsant medications has extended in recent years to the management of pain and mood disorders. As a result, the number of presentations with poisoning secondary to these agents has increased. This chapter covers some of the more common anticonvulsant poisonings.

Carbamazepine

Pathophysiology

Carbamazepine is a tetracyclic compound that bears a structural similarity to tricyclic antidepressants, which accounts for some of its clinical features in overdose. It blocks pre-synaptic voltage-gated sodium channels in the central nervous system (CNS) as well as blocking N-methyl D-aspartate (NMDA) and adenosine receptors. It has a slow rate of dissolution and thus is erratically and incompletely absorbed. Its metabolism is further complicated by the fact that carbamazepine induces its own metabolism with therapeutic use; therefore individuals who are on carbamazepine therapy tend to have less toxic symptoms that those who are naive. With continual therapeutic dosing, the half-life of carbamazepine is 12 to 17 hours; however, in overdose, much longer half-lives are reported. This is likely due to ongoing absorption, impaired elimination or a combination of the two.

Clinical features

The clinical features are neurological, cardiovascular and anticholinergic. Vomiting is a common feature with acute overdose. Clinical features may include altered mental status, dysarthria, ataxia and seizures. Coma with respiratory depression can occur with severe toxicity. Cardiovascular toxicity includes sinus tachycardia, hypotension, myocardial depression and conduction disturbances such as atrioventricular block and QRS complex prolongation. Carbamazepine has anti-cholinergic properties in high concentrations and can impair gut motility, leading to prolonged absorption over many hours. This is further compounded in the treatment of overdose with sustained-release formulations of carbamazepine.

Investigations

Patients presenting following carbamazepine overdose should have a blood sugar level, paracetamol level and electrocardiogram (ECG) performed as part of routine management. Furthermore, serum carbamazepine levels can be utilized both to confirm diagnosis as well as for therapeutic and prognostic applications. Carbamazepine concentrations offer guidance as to resolution of toxicity as well as indication for other therapies such as dialysis or haemoperfusion. Neurological effects start to occur above 10 mg/L (50 μmol/L). Significant toxicity including cardiac arrhythmias/conduction abnormalities usually occurs above 45 mg/L (200 μmol/L).

Patients should have 6-hourly carbamazepine concentrations tested in order to monitor the clinical course. Furthermore, ingestions of more than 50 mg/kg require close monitoring in a resuscitation bay, as such patients are at risk of developing coma calling for intubation; however, they rarely develop cardiac conduction abnormalities.

Treatment

Supportive care with particular attention to the airway is essential to the appropriate management of patients with significant carbamazepine toxicity. Appropriate lines and monitoring should be utilized, as would be expected with other unwell patients.

With regard to specific treatments,

1. Management of CNS effects: Seizures and agitation secondary to anti-cholinergic effects should be managed with benzodiazepines.
2. Decontamination: Activated charcoal should be considered for patients who have taken a significant overdose (20 mg/kg) who present early and without symptoms. If patient is drowsy and ingestion is significant, activated charcoal (50 g) should be given only in an intubated patient with a radiologically confirmed nasogastric tube.

3. Enhancement of elimination: Carbamazepine undergoes enterohepatic circulation; therefore multiple-dose activated charcoal (MDAC) (50 g initially, then 25–50 g q4h) is recommended for patients with coma. This should be continued until the development of ileus, evidence of obstruction or clinical improvement (resolution of coma). Usually two to four doses are given before ileus occurs.
4. Cardiovascular effects: In the event of a ventricular dysrhythmia secondary to sodium channel blockade, though rare, a bolus of 1 mmol/kg sodium bicarbonate 8.4% is recommended.
5. Extracorporeal elimination may have a role in severe toxicity. Intermittent haemodialysis is the preferred method; however, if that is not available, intermittent haemoperfusion or continuous renal replacement therapy is a suitable alternative. Extracorporeal elimination is recommended in the following circumstances[1]:
   - Multiple seizures refractory to other treatments
   - Life-threatening dysrhythmias or hypotension requiring inotropic support
   - Prolonged coma greater than 48 hours
   - Severe toxicity with rising or persistently elevated carbamazepine levels despite MDAC and supportive care

A suspected paediatric ingestions of 20 mg/kg or greater should be observed in hospital for at least 8 hours or longer if presenting at night. Adult patients who are clinically well at 8 hours following ingestion do not require any further monitoring or sedation.

Patients with evidence of toxicity should be admitted to hospital, with those presenting with coma managed in a high-dependency or intensive care unit.

Phenytoin

Pathophysiology

Phenytoin blocks voltage-dependent sodium channels and reduces neuronal hyper-excitability; thus it is indicated in seizure disorders. It is slowly and erratically absorbed after oral overdose and, as a result, clinical toxicity and peak serum concentrations may be delayed by 1 to 2 days. Furthermore, its elimination half-life is also prolonged in overdose, as phenytoin undergoes hepatic metabolism via zero-order kinetics, which is saturable. Individuals with genetic polymorphism at cytochrome P450 2C9 are known to have particularly prolonged elimination half-lives and may require additional treatment to achieve resolution of toxicity.

Phenytoin toxicity can be either acute (i.e. intentional overdose) or chronic. The latter presentation is often one of gradual onset of symptoms in patients taking therapeutic phenytoin where there may have been a dosing error or drug interaction.

Clinical features

The clinical features are predominantly neurological. At greater than 20 mg/kg, mild gastrointestinal symptoms may occur early after acute overdose. However, the onset of neurological toxicity develops slowly, over hours. CNS effects are predominantly cerebellar, such as dysarthria, ataxia and nystagmus.

Seizures in phenytoin overdose, unlike the case with other anti-convulsants, are rare except in massive overdoses (>100 mg/kg). Similarly, at this level, coma can also occur. As serum concentrations fall, neurological signs will improve.

Less common features include hypernatraemia, hyperglycaemia and hyperosmotic non-ketotic coma.

Rapid intravenous administration of phenytoin has been associated with the development of bradycardia, hypotension, ventricular arrhythmias and asystole; this, however, is not due to the drug but rather to the diluent (propylene glycol).

Investigations

Patients presenting following phenytoin overdose should have a blood sugar level, paracetamol level and ECG performed as part of routine management.

Serum phenytoin levels correlate with clinical toxicity as discussed earlier; these levels can be used to confirm diagnosis. Mild to moderate toxicity can be managed on clinical features alone. However if toxicity is severe, phenytoin levels offer guidance as to the resolution of toxicity as well as an indication for other therapies, such as haemodialysis. Severe ataxia and coma are associated with concentrations greater than 50 mg/L (200 μmol/L).

Treatment

Supportive care is the mainstay of treatment, with particular attention to the airway when there is significant phenytoin toxicity. Appropriate lines and monitoring should be utilized as would be expected with other unwell patients. ECG monitoring is not necessary for patients who have taken an oral overdose of phenytoin or have chronic phenytoin toxicity.

Those with mild to moderate toxicity are at risk of falls and should not be permitted to ambulate without supervision.

With regard to specific treatments,

1. Decontamination: Activated charcoal should be considered for patients who have taken a significant overdose who present within 4 hours of acute oral overdose as it may reduce toxicity and length of hospital stay.
2. Multiple-dose activated charcoal: Given the slow and erratic absorption of phenytoin, MDAC (50 g initially then 25 to 50 g q2–4h) may be useful for patients with ongoing significant toxicity. Patients with serial phenytoin levels that are not improving over time may benefit from MDAC, in particular, those with the cytochrome P450 2C9 gene polymorphism.[2] This should be continued until the development of ileus, evidence of obstruction or clinical improvement (resolution of coma).
3. Extracorporeal elimination: This may have a role in severe clinical toxicity. Intermittent haemodialysis is the preferred method; however, if it is not available, intermittent haemoperfusion is an acceptable alternative. Indications include prolonged coma or ataxia in the setting of severe toxicity or refractory seizures with end-point determined by the resolution of clinical toxicity.[3]

Patients are medically suitable for discharge once symptoms have resolved and they are able to walk safely. Patients with mild to moderate toxicity are suitable to be observed on a ward. Children can be observed at home unless there are symptoms or ingestion of more than 20 mg/kg.

Sodium valproate (valproic acid)

Pathophysiology

Sodium valproate exerts its anticonvulsant properties by increasing levels of gamma-aminobutyric acid (GABA); however, in toxic doses it can interfere with a number of mitochondrial metabolic pathways. Although it is normally well absorbed, sodium valproate can be slowly and erratically absorbed in overdose, so clinically significant overdoses can present asymptomatically prior to the delayed onset of toxicity. Peak serum concentrations can consequently be delayed up to 16 hours and toxicity may persist for days following massive overdose. Protein binding of sodium valproate is saturable; hence in overdose there is more free drug in the circulation, making the condition amenable to dialysis.

Toxicity can be predicted by ingested dose, with doses less than 200 mg/kg resulting in mild sedation and those between 200 and 400 mg/kg resulting in more profound CNS depression. Intubation is anticipated with ingested doses between 400 and 1000 mg/kg. Doses greater than 1000 mg/kg are potentially lethal, with multi-organ failure, coma, cerebral oedema and ultimately death.

Clinical features

The clinical features involve multiple organ systems including the gastrointestinal, CNS, cardiovascular and haematological systems as

well as metabolic pathways. CNS effects include decreased conscious state, with coma, ataxia, seizures and cerebral oedema. Gastrointestinal features include nausea, vomiting and abdominal pain. Tachycardia, hypotension and a prolonged QT interval are cardiovascular features that can be seen in sodium valproate toxicity. Symptoms of myelosuppression, in particular neutropaenia and thrombocytopaenia, are later haemological manifestations. Furthermore, hypernatraemia, hyperlactaemia, hyperammonaemia, hypocalcaemia, hypoglycaemia, metabolic acidosis and respiratory depression are also clinical features of toxicity.

Consider valproate poisoning in a comatose patient with access to valproate who has a high serum sodium level.

Investigations

Patients presenting following sodium valproate overdose should have a blood sugar level, paracetamol level and ECG performed as part of routine management.

Furthermore, serum valproate levels can be utilized both to confirm diagnosis and for therapeutic and prognostic applications. Concentrations greater than 3500 µmol/L (500 mg/L) have the potential for leading to coma or multi-organ injury. Concentrations greater than 6930 µmol/L (1000 mg/L) pose a high risk for multi-organ injury and death. Serum valproate levels should be checked every 4 to 6 hours until they begin to decrease.

Treatment

Supportive care is the mainstay of treatment. Particular attention to the airway is essential in the management of patients with significant sodium valproate toxicity. Appropriate lines and monitoring should be utilized as would be expected with other unwell patients.

Activated charcoal (50 g) should be given to all patients presenting with greater than 400 mg/kg ingestions within 4 hours or via a radiologically confirmed nasogastric tube after intubation. This can be repeated if the sodium valproate level is rising.

Whole bowel irrigation should be considered for potentially lethal ingestions (>1000 mg/kg). This should be discussed with a clinical toxicologist.

Extracorporeal elimination can have a life-saving role in severe toxicity. Consider haemodialysis if the sodium valproate concentration is greater than 6000 µmol/L (850 mg/L) or if cardiovascular instability, cerebral oedema or metabolic acidosis (pH <7.1) is present. Intermittent haemodialysis is the preferred method; however, if it is not available, high flux haemofiltration is an acceptable alternative.[4]

Patients with an overdose of less than 200 mg/kg should be observed for 6 hours with serial valproate levels (6 hours apart) that are lower than 3500 µmol/L and decreasing prior to medical clearance. Conversely, those ingesting greater than 200 mg/kg should be observed for at least 12 hours with serial concentrations that are less than 3500 µmol/L and decreasing prior to medical clearance owing to more erratic absorption in larger amounts.

Newer anticonvulsants

This chapter cannot cover all the newer anticonvulsants; however, these are two of the more common ingestions.

Lamotrigine

Pathophysiology

Lamotrigine is a novel phenyltriazine anticonvulsant and is chemically distinct from other classes of anticonvulsant. It enhances the actions of GABA and may also inhibit voltage-gated sodium channels. Serotonergic properties have also been observed, with the ability to cause serotonin toxicity in co-ingestion with other serotonergic agents.[5]

The toxic dose of lamotrigine is poorly defined; however, ingestions of greater than 20 mg/kg in adults are associated with moderate toxicity. Smaller ingestions have been associated cardiac arrest.[6] In children who are naive to lamotrigine, an ingestion of greater than 0.3 mg/kg can be toxic, whereas children on lamotrigine therapeutically may experience toxicity with greater than twice their usual dose.

Clinical features

The clinical features are predominantly neurological, but cardiovascular features and serotonin toxicity have also been reported. Neurological features include nystagmus, ataxia, sedation, and involuntary movements. Similar to most other anti-convulsants, lamotrigine can paradoxically cause seizures in overdose.

Cardiovascular toxicity manifests as hypotension with a prolonged QRS interval secondary to sodium channel blockade. As a consequence of the latter, refractory ventricular arrhythmias can also occur.

Investigations

Patients presenting following lamotrigine overdose should have a blood sugar level, paracetamol level and ECG performed as part of routine management. Laboratory serum concentrations are not routinely measured or available.

Treatment

Supportive care is the mainstay of treatment. Particular attention to the airway is essential in the management of patients with significant lamotrigine toxicity. Appropriate lines and monitoring should be utilized, as would be expected with other unwell patients. ECG monitoring is recommended for patients presenting with clinical toxicity, particularly those with ECG features consistent with sodium channel blockade.

With regard to specific treatments,

1. Decontamination: Activated charcoal should be considered up to 1 hour after ingestion for patients who have taken more than 20 mg/kg.
2. Seizures should be managed with benzodiazepines such as diazepam as necessary.
3. Ventricular arrhythmias and sodium channel blockage may not respond to sodium bicarbonate and therefore should prompt discussion with a clinical toxicologist. Beta blockers and amiodarone are not recommended.
4. MDAC may increase clearance of lamotrigine and is given as 50 g initially then 25 to 50 g every 2 to 4 hours until the development of ileus, evidence of obstruction or clinical improvement (resolution of coma).
5. Extracorporeal elimination may have a role in increasing lamotrigine clearance; however, evidence is limited. Possible indications include QRS prolongation, arrhythmias, and hypotension, but the decision to initiate therapy should be discussed with a clinical toxicologist first.

Patients are medically suitable for discharge if they are asymptomatic at 6 hours after ingestion.

Levetiracetam

Pathophysiology

Levetiracetam is a novel anticonvulsant whose exact mechanism of action is not clearly elucidated, but essentially it potentiates GABA neurotransmission. Of interest, a role as a second-line agent for the treatment of benzodiazepine-refractory, toxin-induced seizures has been postulated, but this requires further evaluation.[7]

Overdose with levetiracetam, as with other newer anticonvulsants, is relatively benign, with mild CNS symptoms only. Supportive care alone is likely to result in complete recovery in virtually all ingestions.

Clinical features

The clinical features are predominantly neurological. These features include altered conscious state ranging from agitation to coma, respiratory depression and seizures (albeit rare). Large doses of levetiracetam have been associated with hypoglycaemia, bradycardia and hypotension thought to be mediated via interaction with muscarinic receptors.[8]

Investigations

Patients presenting following levetiracetam overdose should have a blood sugar level, paracetamol level and ECG performed as part of routine management. Levetiracetam concentrations are not routinely measured or available.

Treatment

Supportive care is the mainstay of treatment. Particular attention to airway is essential in the appropriate management of patients with significant levetiracetam toxicity. Appropriate lines and monitoring should be utilized as would be expected with other unwell patients. ECG monitoring is not required if the initial ECG is normal.

With regard to specific treatments,

1. Decontamination: Activated charcoal should be considered for patients up to 1 hour after ingestion if the patient is alert and compliant.
2. Seizures should be managed with benzodiazepines such as diazepam as necessary.

Patients are medically suitable for discharge if they are asymptomatic at 6 hours after ingestion.

25.20 Hymenoptera stings

Annabel Somerville

ESSENTIALS

1 **Hymenoptera strings are responsible for one or two deaths annually in Australia.**

2 **Hymenoptera venom is a common cause of allergy and anaphylaxis (~3% of population).**

3 **Anaphylaxis is an absolute indication for venom immunotherapy.**

4 **Massive envenomation by bees and wasps can cause multi-organ involvement and death, although this is rare.**

5 **Mass envenomation does not appear to result from ant stings.**

Introduction

Hymenoptera, an order of insects, comprise some 35,000 species. Clinical effects occur from exposure to stings from the families Apidae (bees), Vespidae (wasps, yellowjackets/European wasps) and Formicidae (ants).[1]

Local irritation, allergy and anaphylaxis are common to all members of the group, with stinging events accounting for up to 35% of all cases of anaphylaxis reported annually. About 3% of people stung develop anaphylaxis.

Hymenoptera constitute a major threat to public health. In Australia they are responsible for as many deaths (average 2 yearly) and twice as many hospital presentations as our much more feared snakes.[2] Despite this, most species of bees and wasps are solitary creatures and rarely sting humans.

Bee stings

The European honeybee *(Apis mellifera)* is the most common cause of stings in Australia. Female bees sting only once, leaving their stings in place. The venom is complex, its main constituent being melittin (major cause of pain).

Clinical effects

These depend on the type of bee, prior exposure and the sensitivity of the victim.

- Local pain and irritation
  - Usually minor, usually subsides after 1 to 2 hours, but may last up to 48 hours.
  - Approximately 10% of those stung will develop a large local reaction, peaking at 48 hours and lasting 5 to 10 days.
- Anaphylaxis
  - IgE-mediated.
  - Almost always occurs within 30 minutes of the sting, with life-threatening anaphylaxis manifesting within minutes.
  - The reaction may be prolonged or recurrent, lasting up to 24 hours.
  - This is the most common cause of death from Hymenoptera stings.
- Serum sickness (see Chapter 2.8).
- Mass envenomation (see further on).
- Death.

Wasp stings

Wasps are responsible for the majority of single stings to humans, and the majority of Hymenoptera-related deaths in the United States and Europe. In Australia they cause fewer fatalities than bees.[2,3]

They are often aggressive and can sting multiple times. Swarming occurs due to the release of chemical attractants, resulting in tens to thousands of stings and life-threatening mass envenomation. Clinical effects are similar to those from bee stings.

Mass envenomation

Few species live in large enough colonies to be able to cause mass envenomation. Most reported cases are due to the African honeybee, or 'killer bee' (found in South America and the southern United States), although the more common and commercially used European honeybee and several wasp species may be involved. This typically occurs when a colony is disturbed.

Mass envenomation must be considered if more than 50 bee stings (one to four stings per kilogram in children) or more than 20 wasp stings.[4]

The characteristic clinical features are as follows:

- Initially, headache, weakness, lethargy, oedema, diarrhoea and vomiting.
- Systemic damage usually presents within 24 hours; it may include intravascular haemolysis, acute kidney injury, hepatic injury, rhabdomyolysis.
- Less commonly, acute respiratory distress syndrome (ARDS), myocardial injury, thrombocytopaenia, disseminated intravascular coagulopathy (DIC), shock and coma.

The mortality rate approximates 15% and is reported with more than 150 bee stings or more than 20 wasp stings.[4] Time to death is hours to days. If it occurs more rapidly, it is likely due to anaphylaxis.

Treatment

Single/few stings

- Venom sacs are emptied within 2 minutes of sting, so rapid removal is essential—the longer it is left in place, the greater the wheal.[5]
- Symptomatic relief—cold compresses, analgesia, antihistamines.
- Consider a short period of observation for hypersensitivity.
- Management of allergy/anaphylaxis is addressed in Chapter 2.8.

Mass envenomation

- All stings should be removed rapidly, as the time to removal as well as the number of stings relate to increasing severity.
- Hospital admission with meticulous supportive care is required, as there is no specific treatment.
- Monitoring is required for electrolytes, renal/liver function, creatinine kinase and coagulation profile as well as serial urinalysis for myoglobin.

Discharge advice

- Approximately 30% to 60% of those stung will have a recurrent allergic reaction if stung again by a bee or wasp; therefore all patients who have had moderate to severe allergic reaction should carry an Epipen.
- Consider referral for venom immunotherapy—anaphylaxis is an absolute indication, with 80% to 90% success in the prevention of future severe reactions.

Ant stings

Ants, like bees and wasps, sting and may do so repeatedly. They may also cause a noxious bite. Many groups of ants can cause pain; however, only a few families are medically significant[6]:

Bull ants *(Myrmecia)* are widely distributed throughout southern Australia. *Myrmecia pilosula*, often known as 'Jack Jumper ants', cause a painful local swelling at the bite site lasting several days. They also cause systemic allergic reactions in some 3% of Australians, 50% of which can be life-threatening.[7] Bull ants are the most common cause of anaphylaxis in parts of Tasmania. Approximately 70% of those stung will have another allergic reaction if stung again. At least four deaths have been reported.

Fire ants *(Solenopsis invicta)*, originally from South America, had entered southern parts of the United States by the 1930s and appeared in Australia in 2001, presumably having been introduced by cargo ship. Colonies have been found in southeastern and central Queensland and Port Botany NSW.[8]

The species is very aggressive and swarming is common, frequently resulting in multiple stings. The stings cause a painful, burning, itching sensation and can cause immediate hypersensitivity reactions,[9] which are managed by the usual means. Multiple stings result in feeling that the body is on fire. Sterile pustules may form following stings due to the alkaloid content of the venom; these should be left intact to prevent secondary infection. At least 85 deaths have resulted from fire ant stings in the United States alone.

Green ants *(Rhytidoponera metallica)*, found in Queensland, can also cause severe allergic reactions.

Venom immunotherapy

Commercial venom extracts are available for the diagnosis and treatment of allergic reactions to honeybees, paper wasps, European wasps and Jack Jumper ants. Venom-specific immunotherapy is considered the standard of care for patients with a history of anaphylaxis to one of these species.

Whole-body extract immunotherapy is used to treat fire ant allergy, although its efficacy remains subject to debate.

Venom therapy does not prevent local reactions.

25.21 Toxidromes

Nazila Jamshidi • Andrew H. Dawson

ESSENTIALS

Anticholinergic (anti-muscarinic) toxic syndrome

Anticholinergic toxic syndrome (ACTS) occurs as a result of the blockade of post-synaptic muscarinic receptors and/or a reduction or inhibition of cholinergic transmission at muscarinic receptor sites by drugs.

Serotonin toxicity

Clonus (spontaneous, inducible and ocular) can be diagnostic of serotonin toxicity (ST) once a serotonergic agent ingestion/toxicity has been identified.

1 **The interaction of selective serotonin reuptake inhibitors (SSRIs) with monoamine oxidase inhibitors can be lethal and may require aggressive treatment.**

2 **Dopamine agonists (e.g. bromocriptine, used to treat neuroleptic malignant syndrome [NMS]) can have dual receptor action (5-HT and dopamine agonist) and can worsen ST.[1]**

3 **In combination with other serotonergic drugs, fluoxetine can cause ST up to 5 weeks after its cessation.**

4 **Patients should be monitored for ST, which is based on clinical findings of particular clonus and hyperreflexia**

Sympathomimetic toxicity

1 **The salient features of a sympathomimetic toxidrome include agitation, repetitive movements, delirium, pressured speech, hypertension, tachycardia and hyperthermia. Complications can result in end-organ toxicity in almost all organ system in the body.**

2 **Tachycardia accompanied by diaphoresis or increased bowel sounds points to adrenergic toxicity, whereas tachycardia accompanied by decreased sweating, absent bowel sounds and urinary retention is likely to be a sign of anticholinergic toxicity.**

3 **Patients on monoamine oxidase inhibitors (MAOIs) or bupropion are at greater risk of adrenergic toxicity with lower doses of stimulants.**

4 **Management is based on supportive care, benzodiazepines, and the exclusion of end-organ injury. Hyperthermia must be identified and managed.**

Cholinergic toxicity

1 **Cholinergic toxicity can result from overstimulation of the acetylcholine (ACh) receptors nicotinic and muscarinic receptors or from a total increase in cholinergic transmission.**

2 **Clinical manifestations of nicotine toxicity are those of nicotinic cholinergic excess, most commonly including vomiting and agitation. Severe poisoning may cause seizures, cardiac arrhythmias, hypotension, neuromuscular over-excitation and subsequent neurotransmitter depletion, with muscular paralysis leading to respiratory failure.**

3 **Muscarinic agonists produce bradycardia, miosis, salivation, lacrimation, vomiting, diarrhoea, bronchospasm, bronchorrhea and micturition. However, central muscarinic agonists produce sedation, extrapyramidal dystonias, rigidity, coma and convulsions.**

4 **Management is mainly supportive, including advanced life support. Atropine, fluids and acetylcholinesterase (AChE) reactivator may be used for significant organophosphate toxicity.**

Anticholinergic (anti-muscarinic) toxic syndrome

General notes

Anticholinergic toxic syndrome (ACTS) occurs owing to the blockade of post-synaptic muscarinic receptors and/or the reduction or inhibition of cholinergic transmission at muscarinic receptor sites by drugs. ACTS can occur as a part of alkaloid-containing plant ingestion or associated with multiple classes of medication in both acute overdose or chronic ingestion in special populations. The result is central and peripheral clinical effects that are a consequence of relative cholinergic deficiency at the muscarinic receptors.

Mechanism and associated clinical signs

Symptoms of ACTS have classically been described as 'mad as a hatter, blind as a bat, red as a beet, hot as a hare, dry as a bone'. The most commonly observed peripheral effects in clinical practice include dry mucous membranes, tachycardia, urinary retention, blurred vision, reduced gastrointestinal (GI) motility (ileus) and fever. However great pharmacodynamic variation can be observed among the peripheral signs. Mechanisms for fever include decreased heat loss (due to absent sweating), increased heat production (due to agitation and activity) and central nervous system (CNS) dopamine mediated temperature dysregulation.[2]

Central symptoms are predominantly agitation, confusion and hallucinations.

High-risk populations

- Those with co-ingestion of other agents or agents with multiple receptor actions (e.g. antipsychotics, antihistamines)
- Geriatric populations, due to altered kinetics, but also due to decreased central cholinergic capacity
- Infants and children with trisomy 21,who have an increased sensitivity to anticholinergic drugs
- Individuals with any organic CNS disease (e.g. Parkinson disease, dementia, psychiatric illnesses)

Compounds

Over 600 compounds, most of which are medications, have anticholinergic properties. See Box 25.21.1.

Box 25.21.1 List of agents with anticholinergic properties (not comprehensive)

Antipsychotics
Olanzapine
Acepromazine
Acepromeţazine
Fluphenazine
Levomepromazine
Periciazine
Thioproperazine
Thioridazine
Clozapine
Chlorpromazine
Quetiapine

Gastrointestinal/urinary antispasmodics
Aconite
Belladonna alkaloids
Buzepide metiodide
Solifenacin
Clidinium bromide
Homatropine methylbromide
Hyoscyamine
Isopropamide iodide
Oxybutynin
Prozapine
Tiemonium

H1-antihistamines
Chlorpheniramine
Clocinizine
Cyproheptadine
Dexchlorpheniramine
Diphenhydramine
Doxylamine
Hydroxyzine
Meclozine
Mequitazine
Oxomemazine
Phenyltoloxamine
Promethazine
Dimenhydrinate
Pizotifene

Bronchodilators
Ipratropium bromide
Oxitropium bromide
Antiemetics
Metopimazine

Tricyclic antidepressants
Amitriptyline—single and combination products
Amoxapine
Clomipramine
Desipramine
Dosulepin
Imipramine
Maprotiline
Nortriptyline
Opipramol
Trimipramine
Doxepin
Nortriptyline

Antiparkinsonian anticholinergics
Orphenadrine
Trihexyphenidyl
Benztropine

Plants
Angel trumpet *(Brugmansia)*

Dose relationship

There is a dose/response relationship between toxicity and the severity of symptoms at presentation. Patients may present to medical attention without peripheral symptoms (these having resolved early after ingestion) and have predominant persistent central symptoms such as delirium or agitation.

Prognostic indicators

Outcomes associated with pure ACTS are favourable, with mortality being extremely unusual. However, this toxidrome is seldom seen in isolation. Complications may be observed as a result of the associated cardiac or central nervous system ion channel effects, or the presence of co-ingestants. For example in tricyclic antidepressant toxicity mortality is as a result of cardiovascular toxicity rather than anticholingeric effects.

The presence of fever, which correlates with larger ingestions, has been shown to be a poor prognostic indicator.

The CNS symptoms and delirium associated with anticholinergic drugs have been graded based on a severity score (Table 25.21.1).[3]

Management

In the case of large-dose toxic ingestions where there is a high probability of delirium developing (e.g. with sedating antihistamines), early administration of charcoal (within 2 hours) has been shown to reduce the risk of secondary delirium.[4]

CNS symptoms of agitation and delirium often require pharmacological intervention. AchE inhibitors increase acetylcholine (ACh) concentrations at both muscarinic and nicotinic receptors, leading to the reversal of muscarinic blockade. In ACTS, AchE inhibitors are used to reverse agitation and delirium with the benefit of restoring GI motility. The risk of seizures with AChE administration is less than 1%.[2] Despite the large clinical variation in the use and dosing of AchE inhibitors in anticholinergic delirium, there is now well-documented evidence for their role in moderate to severe ACTS delirium.[4] Although most studies describe the use of physostigmine, there have also been case reports of other AChEs (such as donepezil and galantamine) demonstrating efficacy in the management of delirium.

Mild (severity score 0–1)

- Benzodiazepines: limited use for agitation only
- Monitoring required for respiratory depression/worsening of delirium

Moderate to severe (severity score 2–4)

- Droperidol
  - 10 to 20 mg for severe agitated delirium
- Reversal of toxicity is achieved by increasing ACh levels with
  - Physostigmine
    - Dose: 0.5 to 1 mg IV titrated to response (i.e. observe for reversal of delirium every 15 minutes).[2] The most effective approach is to start with low doses and increase incrementally to response (slowly). Higher doses will start to cause nicotinic stimulation and lead to unwanted effects.
    - The best response (83% to 100%) is seen with drugs that have pure anticholinergic action.
    - Half-life of duration of response is 100 minutes.
    - Potential complications include proconvulsant effects (seizures ~1%), cholinergic toxicity due to excessive treatment and cardiotoxicity (brady/tachycardia).
    - ***Contraindications***: ***(relative)*** asthma, cardiotoxicity (wide QRS complex or bradycardia on electrocardiogram [ECG], asthma and pulmonary disease) underlying seizure disorder (if uncontrolled) ***(absolute):*** none
  - Rivastigmine oral
    - Dose: 2 to 4 mg orally titrated to effect when prolonged delirium is expected. The onset of effect is slower for both oral dosing and transdermal patches than for intravenous agents. Other AChE agents include donepezil and galantamine.

Peripheral symptoms are managed expectantly depending on the severity of symptoms. In cases where ileus develops, peripheral cholinesterase inhibitors such as neostigmine are effective in reversing colonic pseudo -obstructions. Neostigmine can induce both smooth muscle contraction and propulsion.

- Neostigmine intravenous
  - Dose: 2.5 mg over 10 to 20 minutes
  - Side effects: salivation, nausea, vomiting, abdominal pain, bradycardia, hypotension and bronchospasm

Monitoring

Cardiac monitoring is required (both for toxidrome and with AChE administration).

Table 25.21.1 Scale for grading the severity of central nervous system stimulation

Severity score	*Clinical findings*
0	Relaxed, cooperative
1	Anxious, irritable, tremulous
2	Intermittently or mildly disoriented, confused, and hallucinating; moderate agitation and motor hyperactivity
3	Incomprehensible speech, marked agitation and motor hyperactivity (requiring restraints)
4	Seizures, deep coma (unresponsive to voice or pain)

CNS, Central nervous system
(From Burns MJ, Linden CH, Graudins A, et al. A comparison of physostigmine and benzodiazepines for the treatment of anticholinergic poisoning. *Ann Emerg Med.* 2000;35(4): 374–381, with permission.)

Visual and/or auditory hallucinations are hard to identify.

- Patients may have visual perceptual abnormalities and be seen to be picking at objects on their bed sheets. This may be precipitated by asking the patient to pick up small pieces of white tissue. They will either be unable to distinguish the tissue or continue to pick at non-existent tissue.[2]
  - The presence of peripheral signs can help to diagnose a central cause of delirium when organic causes have been ruled out and ACTS is suspected.
  - Cholinergic symptoms such as salivation, diaphoresis, bradycardia, lacrimation, urination, or defecation are signs of too much AChE inhibition.
  - Sinus tachycardia and delirium can persist for days.
  - Antipsychotics with anticholinergic activity (e.g. olanzapine and quetiapine) should be avoided in the treatment of ACTS delirium as they exacerbate the delirium.
  - Treatment may be difficult in a profoundly delirious patient. Benzodiazepines and an AChE agent, such as physostigmine, can be used.

Serotonin toxicity

General notes

Serotonin syndrome (ST or serotonin toxicity) is a spectrum disorder with symptoms ranging from mild to severe (Fig 25.21.1). ST is normally apparent within 6 hours of exposure. Resolution of symptoms usually occurs within 24 to 72 hours of cessation of the implicated agent. ST is usually not severe with the ingestion of a single serotonergic drug but is more severe when a combination of serotonergic agents is ingested.

Severe ST is a medical emergency and is characterized by the following triad:

1. Neuromuscular excitation (manifesting as ankle or ocular clonus [or non-directional nystagmus], hyperreflexia, myoclonus, and rigidity)
2. Autonomic excitation (tachycardia, hyperthermia)
3. Altered mental state (e.g. agitation, confusion)[5]

Secondary complications of ST include severe hyperthermia, rhabdomyolysis and disseminated intravascular coagulation leading to multi-organ failure and acute respiratory distress syndrome.

Mechanism and associated clinical signs

The main symptoms of ST are due to an excess of CNS serotonin.

Drug classes implicated in ST (see Box 25.21.2) are largely restricted to serotonin precursors, serotonin agonists, drugs causing serotonin release, serotonin reuptake inhibitors, and MAOIs (inhibition of serotonin metabolism). They include opioids and over-the-counter (OTC) medications.

High-risk populations

- Patients who are genetically deficient in the cytochrome P450(CYP) 2D6 enzyme (8% of Caucasians) are more susceptible to ST if they are taking drugs such as venlafaxine, paroxetine, tricyclics, dextromethorphan and methadone.
- Patients on multiple agents with serotonergic activity (e.g. fentanyl, lithium, selective serotonin reuptake inhibitors [SSRIs]).
- Patients on drugs that inhibit CYP2D6 or CYP3A4, which lead to increased SSRI levels.

Compounds (Box 25.21.2)

Dose relationship

ST is a toxic reaction due to overstimulation of 5-HT2a receptors (directly or indirectly) in the CNS. Increasing doses of drug either in therapeutic use, combination agents or in overdose are correlated with increased severity and toxicity.

Prognostic indicators

- With adequate supportive care, recovery is good and mortality rates are very low (<1%). The Hunter ST criteria are validated to determine whether patients with overdose have serotonin toxicity[6] (Fig. 25.21.1) and should be used to guide treatment.
- Presence of a temperature of 38.5°C and/or marked hypertonia or rigidity (truncal) is suggestive of a high risk of progression to respiratory compromise and requires active measures to reduce fever as well as elective neuromuscular paralysis and intubation.
- Duration of the ankle clonus as well as the presence of non-convulsive seizures correlate with the severity of ST.[6]
- The presence of one or more agents with synergistic serotonergic activity (such as an MAOI).

Management

- Management is largely supportive, as most symptoms of ST subside based on the elimination half-life of the offending agent or agents.
- In severe cases of toxicity, management consists of sedation as well as paralysis to reduce muscle activity and allow adequate cooling. These must be instigated prior to patient deterioration. Hydration, thromboembolic prophylaxis and careful monitoring of temperature (to prevent hyperthermia) with active cooling should be emphasized. Pulse, blood pressure, and urine output must also be monitored. Decontamination with charcoal should be considered up to 4 hours after overdose.

Mild ST:

- Supportive care with or without decontamination with charcoal

Moderate ST (agitation the main concern):

- Sedation
  - Midazolam infusion should be used instead of a morphine infusion for sedation, post intubation.
- Diazepam: 5 to 10 mg orally twice daily.
- Olanzapine: 5 mg orally (or risperidone).
- Cyproheptadine (serotonin antagonist) has shown benefit in some studies: 8 to 16 mg daily, maximum 32 mg.

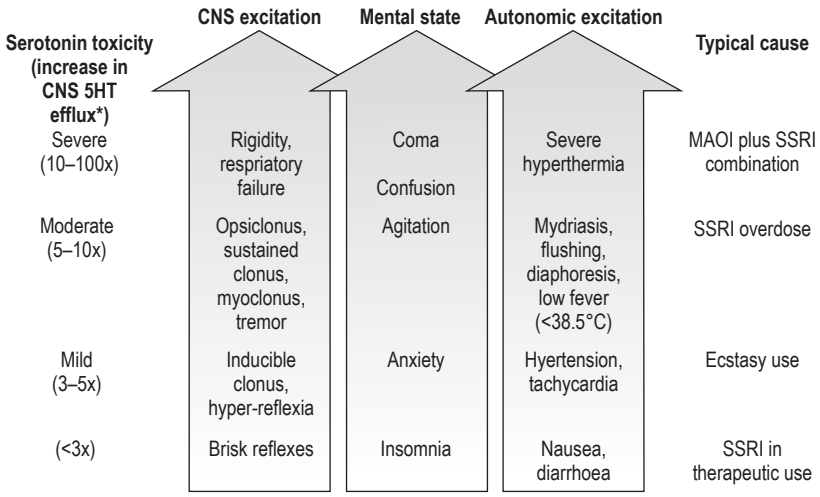
Severe ST:

- Intubation, ventilation, active cooling.
- Monitor for complication of ST, such as rhabdomyolysis and subsequent renal failure.
- Intravenous chlorpromazine (serotonin antagonist) in 25-mg i.v. over 1 hour.
- Intravenous fluid loading is needed to prevent hypotension.

Monitoring

Cardiac monitoring is not required in mild cases of ST unless the specific agent is known to have cardiotoxic effects (e.g. citalopram). Moderate to severe cases of ST will require observation in an intensive care or high-dependency unit if poor prognostic signs are present.

- Resolution of tachycardia is useful in determining improvement and response to treatment.[6]



CNS = central nervous system; 5HT = 5-hydroxytryptamine; MAOI = monoamine oxidase inhibitor; SSRI = selective serotonin reuptake inhibitor
*Approximate extent of increase in CNS 5HT efflux seen with animal models

FIG. 25.21.1 Spectrum of clinical presentations with serotonin syndrome, where inducible clonus is greater than three beats and sustained clonus is greater than 15 seconds. (From Buckley NA, Dawson AH, Isbister GK. Serotonin syndrome. *BMJ.* 2014;348:g1626, with permission.)

Sympathomimetic toxicity

General notes

Adrenergic or sympathomimetic toxicity results either from medications that bind directly to an α-adrenergic or β-adrenergic (e.g. salbutamol) receptors or indirectly cause the release of noradrenaline (e.g. mostly illicit drugs such as amphetamine related derivatives and analogues; see Box 25.21.5). However, potential toxicity problems can be as a result of both excessive catecholamines such as noradrenaline, adrenaline, dopamine and/or serotonin.

The salient features of a sympathomimetic toxidrome include agitation, repetitive movements, delirium, pressured speech, hypertension, tachycardia and hyperthermia. Additional sympathomimetic findings include mydriasis, diaphoresis and neuropsychiatric manifestations such as paranoid psychosis.

Complications can result in end-organ toxicity in almost all organ systems (see Box 25.21.4).

High-risk population

- Depressive symptoms can occur in mental health patients in the days following stimulant use and may progress to overt depressive illness warranting psychiatric assessment. Suicidal ideation and suicide attempts are not uncommon in patients with underlying mental health concerns or recurrent sympathomimetic abuse.

Compounds

See Box 25.21.5. Imidazolines are potent central and peripheral α2 adrenergic agents but also act on imidazoline receptors (stimulation of which leads to bradycardia and hypotension and the CNS actions of these compounds).

Dose/response relationship

Increase on dose are correlated with increase in severity and toxicity of the compound.

Prognostic indicators

Hyperthermia has been associated with increased mortality, especially in association with cocaine toxicity.

Monitoring

Toxic effects usually resolve within 8 to 16 hours. However, they may persist for more than 24 hours if a sustained-release product is ingested. Cardiac monitoring is recommended in cases of severe toxicity with haemodynamic instability.

Investigations

- ECG
- Serum electrolytes
- Liver function tests
- Creatine kinase concentration

Discharge criteria: when patients are normotensive and asymptomatic.

Management

Management is mainly supportive, with the judicious titration of benzodiazepines to control manifestation of adrenergic toxicity and reduce muscle activity and metabolic demands as well as to decrease the severity of hyperthermia, rhabdomyolysis and behavioural signs (agitation and psychosis) (Table 25.21.2).

Box 25.21.2 Drugs associated with moderate to severe serotonin toxicity

Monoamine oxidase inhibitors

- Irreversible inhibitors: Phenelzine, tranylcypromine, iproniazid, isocarboxazid
- Reversible inhibitors of monoamine oxidase A: Moclobemide[a]
- Non-psychotropic drugs: Linezolid, methylene blue (methylthioninium chloride)

Serotonin-releasing agents

- Fenfluramine, sibutramine
- Amphetamine, methamphetamine, methylphenidate, phentermine
- Synthetic stimulants: Ecstasy, 'bath salts' (cathinones, phenylethylamines)
- Serotonin reuptake inhibitors
- Selective serotonin reuptake inhibitors: Fluoxetine, fluvoxamine, paroxetine, citalopram, sertraline, escitalopram
- Serotonin-noradrenaline reuptake inhibitors: Venlafaxine, desvenlafaxine, duloxetine
- Tricyclic antidepressants: Clomipramine, imipramine
- Opioid analgesics: Pethidine, tramadol, fentanyl, dexmethorphan
- St John's wort *(Hypericum perforatum)*

Miscellaneous

- Lithium
- Tryptophan
- Buspirone

[a]Severe serotonin toxicity generally involves a combination of agents from different drug classes.
(From Buckley NA, Dawson AH, Isbister GK. Serotonin syndrome. *BMJ.* 2014;348:g1626.)

Box 25.21.3 Hunter criteria for predicting serotonin toxicity: decision rules

In the presence of a serotonergic agent:

1. IF (spontaneous clonus = yes) THEN serotonin toxicity = YES
2. ELSE IF (inducible clonus = yes) AND (agitation = yes) OR (diaphoresis = yes) THEN serotonin toxicity = YES
3. ELSE IF (ocular clonus = yes) AND (agitation = yes) OR (diaphoresis = yes) THEN serotonin toxicity = YES
4. ELSE IF (tremor = yes) AND (hyperreflexia = yes) THEN serotonin toxicity = YES
5. ELSE IF (hypertonic = yes) AND (temperature >38°C) AND (ocular clonus = yes) OR (inducible clonus = yes) THEN serotonin toxicity = YES
6. ELSE serotonin toxicity = NO

(From Dunkley EJ, Isbister GK, Sibbritt D, et al. The hunter serotonin toxicity criteria: simple and accurate diagnostic decision rules for serotonin toxicity. *QJM.* 2003;96(9):635–642.)

Tachycardia/hypertension

- Persistent tachycardia and hypertension after benzodiazapine use and fluid resuscitation

may require bedside transthoracic echocardiography to rule out global myocardial dysfunction.

Rhabdomyolysis

- Aggressive intravenous fluids
- Correction of hyperthermia

Neurological complications

- Seizures, and psychosis: intravenous benzodiazepines titrated to effect.
- Antipsychotics such as haloperidol may be useful in severe psychosis.
- Persisting headache and/or focal neurological deficits require investigation with non-contrast computed tomography (CT) of the brain to exclude cerebral and subarachnoid haemorrhage.

Box 25.21.4 Complications of sympathomimetic toxicity

Cardiovascular

- Aortic dissection
- Arrhythmias
- Vasospasm
- Myocardial ischemia and coronary artery syndromes (due to increased myocardial demand, coronary vasoconstriction, increased thromboxane A2 activity and thrombus formation)
- Large ingestions or chronic use can lead to cardiomyopathy with apical ballooning (Takotsubo) as a result of adrenergic overdrive (excess catecholamine release)

Central nervous system

- Anorexia
- Bruxism and jaw clenching
- Choreoathetoid movements
- Euphoria
- Headache
- Hyperreflexia
- Haemorrhagic and non-haemorrhagic cerebral infarction
- Seizures

Gastrointestinal

- Diarrhoea
- Mesenteric ischaemia
- Hepatotoxicity

Other

- Metabolic acidosis
- Rhabdomyolysis and acute kidney
- Nausea
- Tachypnoea
- Serotonin toxicity

Cholinergic toxicity

General notes

Cholinergic toxicity can result from overstimulation of the ACh nicotinic and muscarinic receptors or from a total increase in cholinergic transmission (such as that seen with AChE inhibitors). Anticholinesterase toxicity results in stimulation of both muscarinic and nicotinic receptors.

Knowledge of the distribution and actions of the pre- and post-ganglionic receptors is a useful guide for clinical presentations involving toxicity (Fig. 25.21.2).

The clinical syndrome therefore depends on the receptor stimulated and can include a range of symptoms and signs with many overlapping features. Clinical manifestations of nicotine toxicity are those of nicotinic cholinergic excess, most commonly including vomiting and agitation. Severe poisoning may cause seizures, cardiac arrhythmias, hypotension, and neuromuscular over-excitation and subsequent neurotransmitter depletion, with muscular paralysis leading to respiratory failure. Muscarinic agonists produce bradycardia, miosis, salivation, lacrimation, vomiting, diarrhoea, bronchospasm, bronchorrhea and micturition. On the other hand, central muscarinic agonists produce sedation, extrapyramidal dystonias, rigidity, coma and convulsions.

Box 25.21.5 Substances that can cause sympathomimetic toxicity

- Methamphetamines (ice [crystals]); speed: (powder), pills, base (oily powder)
- 3, 4-methylenedioxymethamphetamine (MDMA or Ecstasy)
- Phenylethylamines 'Bath salts'
- Cocaine
- Ma Huang (herbal ecstasy)
- Paramethoxyamphetamine (PMA or 'death')
- Mephedrone (4-MMC)
- Pseudoephedrine
- Methylphenidate
- Imidazolines: decongestants naphazoline, oxymetazoline, tetrahydrozoline
- Clonidine withdrawal[a]
- Dexamphetamine
- Caffeine
- Yohimbe containing supplements (used in combinations with stimulants)

[a]Clonidine is a central α2 agonist, it does not cause acute sympathomimetic syndrome except in abrupt withdrawals.

Table 25.21.2 Clinical features of serotonin toxicity, neuroleptic malignant syndrome and anticholinergic syndrome

	Anticholinergic toxicity	*Neuroleptic malignant syndrome*	*Serotonin syndrome*	*Adrenergic toxicity*
Tempo	*Rapid onset*	*Slow onset (1–3 days)*	*Rapid onset (minutes–hours)*	
Mental state:				
1. Confusion	+++	+++	+ (late stage)	+
2. Agitation/restlessness	+++	Akathisia	+++	+++
3. Coma	+	++ (severe)		
Motor system:				
1. Bradykinesia		++	---	---
2. Tremor		+	+++	+++
3. Rigidity		++ (lead pipe)	+	---
4. Hypertonia	+		++	---
5. Hyperreflexia	+	o	+++	+++
6. Clonus (ankle/eye)		--	+++ (LL > UL)	++
7. Myoclonus		--	+	---
8. Seizures		--	+ (rare)	++
Autonomic system[a,b]:				
1. Instability	---	+++	+	---
2. Hypertension	++	Labile (systolic blood pressure >30 mm Hg above baseline)	+	++
3. Tachycardia	++	Labile (>30 beats/min above baseline)	+++	+++
4. Diaphoresis	---	+++	++	++
5. Hyperthermia	+++[c]	+++	++	++
Others:				
1. Rhabdomyolysis	---	+++	++	++
2. Mydriasis	++	---	+++	++

[a]These features are non-specific and do not assist in differentiating between syndromes.
[b]Mechanism is excess serotonin.
[c]Mechanism is inability to sweat and unopposed dopamine centrally, leading to dysregulation. +: mild, ++: moderate, +++: severe, ---: not affected. UL: upper limbs, LL: lower limbs.

Mechanism and associated clinical signs

The nicotinic ACh receptors function as ACh-gated cation channels, whereas the muscarinic ACh receptors are members of the superfamily of G protein–coupled receptors.

Nicotinic receptors reside in the CNS, on preganglionic autonomic neurons mainly in the spinal cord and in both the sympathetic and parasympathetic nervous systems, in the adrenal medulla, and at skeletal neuromuscular junctions, where they mediate muscle contraction. There are five subtypes of muscarinic receptors; M1 to M5. These are mainly in the brain and on end organs innervated by postganglionic parasympathetic nerve endings and in most postganglionic sympathetically innervated sweat glands (Fig. 25.21.2).

High-risk population

Paediatric: children who ingest three or more cigarette butts require evaluation for nicotine toxicity, and ingestions of 0.1 mg/kg have been suggested to require medical attention.[7]

Compounds (Box 25.21.6)

Dose/response relationship

Cholinergic toxicity and cardiac effects present in a dose-dependent manner, with the onset of symptoms correlating with increased quantities ingested or from dermal exposure.

Prognostic indicators

Deaths associated with nicotine toxicity are rare; however, they are more common with AchE inhibitor toxicity.

Monitoring

Cholinergic toxicity requires cardiac monitoring as well as consultation with a clinical toxicologist.

Management

Nicotine toxicity

- The toxic dose of oral nicotine is debated in the literature,[7] and most fatal cases are cited in animal studies. Vomiting and hypotension are the most common adverse events and require supportive management with fluid resuscitation and treatment according to the biochemical imbalance.
- Dermal exposures require decontamination of the skin by washing it thoroughly with soap and copious amounts of water. Personal protective gear should be worn by the medical staff.
- Severe toxicity can cause cardiac arrhythmia, respiratory depression and convulsions, which require supportive management accordingly.

Muscarinic toxicity

- Toxicity as a result of pure muscarinics such as pilocarpine are rare and case reports have been published. Symptomatic patients with bradycardia and hypotension may require the administration of small doses of intravenous atropine.

25.22 Chloroquine

Michael A. Downes

ESSENTIALS

1 **In overdose, chloroquine is a highly toxic drug with a high mortality rate.**

2 **Cardiac toxicity occurs early and may manifest before arrival at hospital.**

3 **Good supportive care and the use of adrenaline are the principles of management.**

4 **Expert advice on management from a toxicologist should be sought at an early stage.**

5 **All deliberate self-poisonings require hospital admission and cardiac monitoring regardless of the patient's clinical state.**

Introduction

Chloroquine is a medication used to treat malaria as well as certain rheumatological conditions; it has a 4-amino-quinoline chemical structure similar to that of quinidine. Hydroxy chloroquine is another structurally similar agent that is often used therapeutically instead of chloroquine as it is believed to be modestly less toxic. The clinical profile of both drugs in overdose is similar; thus the same approach to the management of poisoning can be used for both substances. Chloroquine is by and large an ingestant specific to low- and middle-income countries where malaria is endemic. France, however, is an exception to this rule; thus the French literature on chloroquine poisoning has made a substantial contribution to our understanding of this life-threatening condition. This fact has been attributed to the publication of a French book in 1982 entitled *Suicide Mode de Emploi*, which advocated chloroquine as a means of taking one's life.[1]

At the cellular level chloroquine, like quinidine, has membrane-stabilizing effects on the myocardium. Chloroquine is postulated to block voltage-gated myocardial ion channels involving Ca^{2+}, Na^{+} and K^{+}. This subsequently leads to negative inotropy, slowed conduction and a higher electrical threshold for depolarization within the myocardium. Chloroquine is also believed to have some vasodilatory action; however, it is the effects on cardiac electrophysiology that make it a potentially lethal ingestion and one of the classic 'drugs that kill' when ingested in overdose.[2]

Kinetics

Most of the pharmacokinetic details regarding chloroquine have been extrapolated from therapeutic knowledge rather than kinetic studies of poisoning cases; however, it is thought to be well absorbed after oral ingestion, so that the myocardium is exposed to peak serum levels within several hours of ingestion. Blood levels have been shown to correlate with clinical toxicity and mortality rate.[3] Chloroquine has a large volume of distribution and is consequently distributed to extravascular tissues. Despite its long elimination half-life of 6 to 14 days, the biggest risks occur within the early hours post-ingestion.

Clinical manifestations

When chloroquine is ingested in overdose, it is its cardiac toxicity that is of most concern. Cardiac toxicity is likely to occur early, within the first few hours post ingestion, when blood levels are at their peak. Important clinical features are cardiac arrhythmias such as ventricular tachycardia and torsades de pointes, which not uncommonly lead to cardiac arrest.[3] Electrocardiographic (ECG) manifestations of toxicity, such as a QRS complex greater than 120 ms, may be seen, and prolongation of the QT interval can also occur. Hypotension is due to myocardial depression and can become refractory to treatment.[4]

Central nervous system (CNS) effects such as seizures can also occur but are less common than cardiac effects. A decreased level of consciousness may be seen with large ingestions, but this is more commonly attributed to coingestants such as ethanol or sedative hypnotic agents.

Chloroquine ingestion causes hypokalaemia, which can be severe and, moreover, is a potential marker of toxicity. This is thought to be due to a redistribution effect of potassium across cellular membranes rather than a total-body deficit.[5]

Deaths may occur early due to cardiac arrest, with later deaths often due to refractory shock states as well as complications of prolonged resuscitative measures where vital organs have been subjected to suboptimal perfusion for prolonged periods of time. Variable mortality rates are reported for chloroquine poisoning; however, a large case series in a high-income country with good supportive care and prompt access to critical services suggested an overall mortality rate just under 10%.

Generic management

As with all self-poisonings, a risk assessment is pivotal at an early stage of management. Ingestions of greater than 5 g have been asserted to be predictable of death or severe toxicity. However, it should be noted that deaths have occurred where a smaller dose was ingested.[3] Thus all chloroquine deliberate self-poisonings presenting to an emergency department (ED) should be presumed to be potentially lethal and all cases

should be given a minimal triage category of 2 as per the Australasian triage scale. Cardiac monitoring should be instituted immediately on arrival in the ED and observation and assessment carried out in the resuscitation room or an acute area with a high nurse/patient ratio. Sudden cardiovascular collapse, arrhythmia or cardiac arrest should be anticipated by the treating ED staff.

Awake patients should be given a dose of activated charcoal 50 g if presenting within 1 hour of ingestion. Beyond 1 hour, charcoal should still be considered if there are no contraindications to administration, particularly in larger ingestions. However, the efficacy of this intervention would be expected to decrease with increasing time post-ingestion. An important point of note is that there is little published experience on the use of charcoal, as the larger series in the literature were carried out in environments where the preferred decontamination technique was gastric lavage without the use of activated charcoal.[3] Although gastric lavage is a safe technique in an intubated patient, it has fallen out of favour in many places, such that most clinicians would have little to no experience with it.

Venous access and a serum potassium level should be obtained to look for hypokalaemia, which is an important measure of exposure and toxicity. A venous blood gas done at the point of care is usually the most prompt way to get this done. A 12-lead ECG should be performed looking for signs of chloroquine toxicity such as a prolonged QT interval, using the QT nomogram as a risk-assessment tool, and a QRS complex of greater than 120 ms. Vital signs should be monitored regularly and often, with particular attention to the occurrence of hypotension. The treating clinical team should consider expert toxicology consultation early in the course of management. The best marker of mortality is a blood level, but unfortunately this is rarely if ever available within a time frame that would be clinically useful.

Specific management

As with most poisonings, good supportive care is the cornerstone of management, with intubation and ventilation being considered at an early stage to facilitate management in a deteriorating patient. The choice of sedative for intubation has been a subject of controversy in the past, with one study detailing 11 patients who had intubation facilitated with a relatively large dose of sodium thiopentone 5 mg/kg and only one subsequent death.[1] Another later study details the development of profound shock in 7 patients given a bolus of thiopentone to facilitate intubation, which the authors attribute to this agent's negative inotropic and vasodilatory effects.[3] The author of the latter study thus recommends that thiopentone be avoided in this context. Although the issue of sedative agent for intubation has not been extensively studied, anecdotally ketamine would appear to be a reasonable choice based on its cardiac-stable properties.

The use of diazepam has been associated historically with a better outcome when it is taken as a coingestant in chloroquine poisoning. As a result, this has been proposed as a therapeutic agent for management.[1] Animal studies appeared to support its efficacy, as did the clinical data comparing the efficacy of diazepam use in a prospective cohort with that of a historical control. There are, however, several considerations to bear in mind in this context, namely that diazepam was administered as part of a treatment protocol involving the early initiation of adrenaline infusion, intubation and ventilation by a pre-hospital critical care team if greater than 5 g of chloroquine had been ingested. There were 11 patients in each group with 1 death in the diazepam cohort and 10 deaths in the historical control. A subsequent randomized controlled study of 32 patients who had ingested 2 to 4 g of chloroquine showed no benefit for diazepam bolus and infusion over placebo with regard to death, systolic blood pressure or ECG parameters indicative of chloroquine toxicity.[6]

Management of the circulation in chloroquine ingestion involves regular 12-lead ECGs looking for QRS prolongation of greater than 120 ms as well as prolongation of the QT interval. Continuous cardiac monitoring serves to look for arrhythmias, which should be managed as per the International Liaison Committee on Resuscitation (ILCOR) Advanced Cardiac Life Support (ACLS) guidelines. Likewise, blood pressure (BP) should be closely monitored, with a systolic BP of less than 80 mm Hg being a known significant risk factor for death.[1] If hypotension develops, a targeted approach is advised.

Although a 20-mL/kg bolus of crystalloid may be administered if the patient is thought to be hypovolaemic, the most likely cause of hypotension is toxin-induced cardiogenic shock due to the negative inotropic effect of chloroquine. A bedside echocardiogram, if available, will be of value to help confirm this. Adrenaline is the inotrope of choice and should be administered at an early stage.[3] Whereas it is often stated that central venous access is required to administer adrenaline, it can safely be given via a peripheral cannula provided that the size of the cannula is at least 18 gauge, a large vein is accessed and the adrenaline is diluted down to at least a 1:100,000 ratio. An adrenaline infusion should be instituted at an early stage, with one regimen described in the literature being a dose of 0.25 µg/kg/min followed by subsequent increments of 0.25 µg/kg/min until an adequate perfusing blood pressure is obtained.[1]

Management of hypokalaemia in chloroquine poisoning is somewhat controversial. The hypokalaemia itself is thought to be due to a redistribution rather than a total body deficit. Use of adrenaline or similar treatments may exacerbate this hypokalaemia even further. Aggressive maintenance of a normal serum potassium can theoretically lead to a significant increase in total body potassium stores, with the potential for rebound hyperkalaemia when chloroquine toxicity resolves.[7] Provided that the patient is receiving ongoing care in a critical care environment with regular serum potassium measurements, replacement of daily maintenance amounts titrated to a low normal serum level would seem to be a reasonable course of action.

Other therapies

In patients who have a less than adequate response to the measures outlined earlier, other interventions can be considered. Further intervention should ideally occur in discussion with a clinical toxicologist. Hypertonic sodium bicarbonate has been recommended as being of possible utility in chloroquine poisoning to overcome blockade of fast sodium channels. It may be considered as an adjunct in scenarios where the patient is ventilated and the QRS is prolonged beyond 120 ms, which may exacerbate hypokalaemia.

As with many cardiotoxic poisonings, lipid emulsions have been proposed as a potential treatment for chloroquine toxicity. The evidence for this is based on case reports where a lipid emulsion has been used as part of a multi-therapeutic approach; however, it is somewhat difficult to definitively attribute therapeutic benefit to lipid therapy per se. Significant doubt has recently been cast on the efficacy of lipid emulsions and caution is urged with regard to the somewhat indiscriminate use in different toxin exposures.[8]

Extra-corporeal membrane oxygenation (ECMO) is an intervention that may salvage a good outcome in cases of refractory shock.[4] If available, this would be the most logical intervention in profoundly shocked individuals who do not have an adequate response to supportive care and the initiation of inotropes. The main current disadvantage of ECMO is that it is difficult to access outside of large centres. However, the emerging concept of ECMO retrieval teams who can travel to regional sites is an exciting possibility for future of chloroquine and other cardiotoxic poisonings. Lipid emulsion therapy has been suspected of interfering with extracorporeal circuits in ECMO and should thus be avoided if this intervention is being considered.[9]

Due to their large volumes of distribution, neither chloroquine nor hydroxychloroquine are amenable to removal by any form of dialysis.

Disposition

Patients who develop cardiotoxicity within the ED phase of care will require transfer to an intensive care unit to manage ventilation and inotrope infusions. Patients who do not develop systemic toxicity in the ED should be admitted to hospital and continued on cardiac monitoring until 24 hours post ingestion.

25.23 Opioids

Angela L. Chiew • Therese Becker

ESSENTIALS

1 **Opioid toxicity is characterized by respiratory depression, decreased level of consciousness and miosis.**

2 **The mainstay of treatment of opioid toxicity is naloxone and good supportive care.**

3 **Many opioid agents can have other toxic effects; for example, tramadol may cause seizures, methadone causes QT prolongation and dextropropoxyphene causes QRS widening.**

4 **Opioid exposure in children can result in significant morbidity and mortality.**

Introduction

Opioids, a diverse group of substances, are typified by morphine. They include a number of prescription and illicit drugs and are often prescribed for both acute and chronic pain. They can be short- or long-acting and can be administered by many different routes, including oral, intravenous, subcutaneous, buccal, inhaled and transcutaneous. Opioids are among the commonest causes of drug-related deaths in Australia. The rate of accidental opioid deaths has more than doubled among Australians aged 35 to 44 since 2007, with greater than two-thirds of these deaths due to pharmaceutical opioids rather than heroin. Death from opioids is usually due to severe respiratory depression resulting in hypoxia. Death may occur many hours after ingestion, particularly from long-acting preparations, if patients are not carefully monitored. Furthermore, it is important to note than many opioid agents can have other toxic effects (Table 25.23.1).

Pharmacology

Opioid drugs act both in the central and peripheral nervous systems. They act as agonists on various types of opioid receptors, but it is the mu opioid receptor that is responsible for the preponderance of clinical effects. These receptors are widespread and are found not only within the nervous system but also in other tissues, including the gastrointestinal tract, cardiovascular and immune systems. Some opioids act on non-opioid receptors, which can produce other toxic effects in overdose; for example, tramadol also inhibits both serotonin and noradrenaline reuptake, whereas methadone inhibits the hERG potassium channel.

The pharmacokinetics of opioids differ between agents. For example, there is varying bioavailability within the group, from low (10% oral bioavailability with buprenorphine) to high (70% with oxycodone) (see Table 25.23.1). The onset of toxicity is dependent on the route of administration. Opioids are in general rapidly absorbed, with peak concentrations within minutes of intravenous injection, 1 hour of intramuscular administration and 2 hours of oral ingestion. The metabolism of opioids occurs mainly in the liver via the cytochrome P450 system and conjugating enzymes. Metabolism can result in inactive and active metabolites. Duration of action varies between agents and formulations. Oral controlled-release formulations of morphine and oxycodone and topical preparations of fentanyl can have prolonged absorption with toxicity lasting for many hours. Table 25.23.1 gives an overview of the commonly prescribed and abused opioids and their pharmacokinetic properties.

Clinical effects

The main presenting features of opioid toxicity include miosis, central nervous system (CNS) and respiratory depression. The CNS effects can range from mild drowsiness to profound coma. Other common clinical effects are nausea and vomiting. It is important to note that many opioid agents can have other non-opioid effects specific to that particular agent (see Table 25.23.1). For example, tramadol in overdose commonly causes seizures, methadone results in a dose related-QT prolongation and dextropropoxyphene has sodium channel–blocking effects that can result in cardiac arrhythmias.

Opioid toxicity can also result in various complications secondary to a drug's sedative and respiratory depressive effects. These can commonly include aspiration, non-cardiogenic pulmonary oedema, rhabdomyolysis (long lie), compartment syndrome, acute renal injury and hypoxic brain injury.

Management

The mainstay of treatment is good supportive care and administration of the antidote naloxone. The patient's airway and breathing should be supported as required. The respiratory rate must be closely observed, as opioid-dependent patients may appear rousable but still have respiratory depression requiring treatment.

Table 25.23.1 Commonly prescribed prescription opioids

Opioid	*Bioavailability*	*Half-life (immediate release preparations)*	*Precautions/special features*
Buprenorphine	30% via sublingual route	24–37 h	Partial opiate agonist with a high affinity for mu receptors and slow dissociation kinetics, making it a suitable opiate substitute. Can precipitate withdrawal in those who are opiate-tolerant.
Codeine	60%	3 h	Liver metabolism, with a variable dose converted to morphine.
Dextropropoxyphene	30%–70%	6–12 h	Cardiac effects: QRS widening and arrhythmias (including heart block). Active metabolite has a half-life of 30–36 h.
Fentanyl	30%–50% via buccal route	3 h, but duration of action is 1 h	100 times more potent than morphine. Topical patches not suitable for opiate naive patients as even the lowest formulations can cause severe toxicity.
Hydromorphone	30%	2.5 h	Available in sustained-release 24-h oral formulation.
Methadone	40%–95%	15–60 h	Complex pharmacokinetics; can prolong the QT interval.
Morphine	30%	3 h	Active metabolites can accumulate, with renal impairment causing toxicity on repeat dosing.
Oxycodone	70%	2.5 h	Available in sustained-release 12-h oral formulation.
Tramadol	70%	6 h	In overdose has a high incidence of seizures. Has SNRI properties and in combination with other serotonergic medications can cause serotonin toxicity.
Tapentadol	32%	4–6 h	Similar to tramadol but has a lower incidence of seizures in overdose.

SNRI, serotonin and norepinephrine (noradrenaline) reuptake inhibitor.

Furthermore, oxygen should not be administered without ventilatory support.

Naloxone

Naloxone is an opioid receptor antagonist that may be administered by the intravenous, intramuscular or intranasal route. Administration of naloxone is often titrated to respiratory rate, oxygen saturation and level of consciousness. A rapid response to naloxone is usually anticipated with opioid toxicity provided that hypoxic brain injury, co-ingestion or another event has not occurred. The elimination half-life of naloxone is 60 to 90 minutes; however, it is redistributed from the brain more rapidly than this. Consequently the duration of action is often shorter than the half-life of most opioids, so repeat doses or an infusion of naloxone may be required.

The dose of naloxone utilized should take into account whether the patient is opioid-naive or dependent and the toxic agent. Naloxone administration in opioid-dependent patients can result in opioid withdrawal and agitation, especially if reversal is sudden or complete. In opioid-dependent patients, it is better to utilize small boluses of naloxone titrated to maintain a normal respiratory rate.

In the majority of overdoses with short-acting opioids (e.g. heroin), often only a single dose of naloxone is required. In contrast, long-acting opioids (e.g. methadone) or slow-release formulations may require a naloxone infusion after the initial boluses. The infusion is titrated to clinical effect, respiratory rate and level of consciousness.

Opioids in children

Exposure in children can result in severe morbidity and mortality, as children are more susceptible to opioid toxicity. Opioid overdose in children can have a delayed onset and can be unexpectedly severe and prolonged. This is because of pharmacokinetic differences in children compared with adults, since both have differing rates of drug absorption, distribution into the CNS and metabolism.

Data from the United States have demonstrated that nearly all paediatric opioid exposures occurred in the home and were caused by medications prescribed for adults. Furthermore, the number of opioid analgesic overdoses were proportional to the number of opioid prescriptions and the doses prescribed. There have been many reported paediatric deaths following accidental opioid exposures, which highlights the importance of medication safety education.

Specific opioid agents

Buprenorphine

Buprenorphine is a partial agonist at opioid receptors with a high affinity and long duration of action at the opioid mu receptor. At high doses its agonist effects plateau and it behaves more like an antagonist. This results in a 'ceiling effect', limiting the maximal analgesic effect and degree of respiratory depression, which is thought to make it safer. Despite this ceiling effect, it has been associated with severe toxicity and deaths, particularly if co-ingested with other sedative agents. Furthermore, much larger doses of naloxone may be required to reverse the effects of buprenorphine toxicity.

Buprenorphine exposure in children has been associated with significant toxicity. Sublingual or buccal absorption by placing a tablet or wafer in the mouth even just a lick, may lead to toxicity in small children. Furthermore, the 'ceiling effect' of buprenorphine, in which escalating doses do not cause additional respiratory depression, has not been observed in children. There have been multiple reports of children developing severe and prolonged symptoms of opioid toxicity following accidental exposure to buprenorphine.

Fentanyl

Fentanyl is a synthetic opiate commonly prescribed for acute and chronic pain. It is administered via parenteral, transmucosal or transdermal routes. It is 100 time more potent than morphine, therefore much lower doses can result in serious toxicity. It has a low oral bioavailability, but if large doses are ingested or exposed to the mucosa, it can cause significant toxicity. It has an elimination half-life of 3 hours, but the duration of action is much shorter, often less than 1 hour, as it redistributes from the plasma to other compartments.

It is important to recognize that the transdermal patch reservoirs contain massive doses of fentanyl "depending on the brand of transdermal patch a 12 microgram/ hour patch can contain between 2.1 to 2.55 mg of fentanyl" It has been demonstrated that even after the recommended 3 days of topical use, up to 84% of the fentanyl dose can remain

present in the patch. Patches can be broken down and injected, chewed or swallowed, resulting in severe prolonged toxicity and death.

Methadone

Methadone is a long-acting potent synthetic opioid agonist with complex pharmacokinetics. The pharmacokinetics of methadone varies greatly between individuals, making dose titration complicated. In general the time to onset of effect is 30 minutes; the effect peaks at up to 3 hours and has a variable half-life between 15 and 60 hours. It is used mainly in opiate substitution programs and it can take 3 to 10 days to stabilize a patient on methadone.

Methadone also blocks delayed rectifier potassium ion channels in the heart. This can result in QT interval prolongation and an increased risk of torsades de pointes in susceptible individuals. This risk increases with increasing doses and should be considered when methadone or other QT- prolonging medications are being prescribed. Methadone is metabolized by cytochrome P450 enzymes and many medications can interfere with its metabolism, potentially causing withdrawal or increased plasma concentrations.

Tramadol

Tramadol is a centrally acting synthetic opioid analgesic agent. It exerts its analgesic effect by inhibiting the re-uptake of norepinephrine and serotonin and also by weak opioid receptor agonism, mechanisms that are due to tramadol and its active metabolite O-desmethyltramadol. Tramadol also consists of two enantiomers, one that preferentially inhibits serotonin uptake and the other a potent inhibitor of nonepinephrine reuptake. Opioid and non-opioid components independently contribute to the mechanism of action of tramadol, an 'atypical' opioid analgesic.

Tramadol overdose is often associated with a significant risk of seizures; benzodiazepines are the mainstays of treatment for these. Respiratory depression can also occur. However, tramadol is unlikely to cause serotonin toxicity. Both seizures and respiratory depression effects appear to be related to the dose ingested.

Tapendatol

Tapentadol is a centrally acting synthetic opioid structurally similar to tramadol. It binds to the mu opioid receptor and inhibits the reuptake of monoamines, especially noradrenaline. Similarly to tramadol, it can interact with other serotonergic medications. Pharmacologically tapentadol has a much higher affinity for the opioid receptor than tramadol. In overdose, tapentadol causes more opioid toxicity, with respiratory depression and coma, than tramadol; it also has a lower incidence of seizures and vomiting. The effects of tapentadol can be life threatening in children, and any exposure requires admission for observation.

Conclusion

Opioid toxicity is a common toxicology presentation. It is characterized by respiratory depression, a decreased level of consciousness and miosis. The mainstay of treatment is good supportive care and naloxone. It is important to be aware of the non-opioid effects of many agents.

25.24 Oral anticoagulants

Robert Dowsett

ESSENTIALS

1 **In overdose, any of the oral anticoagulants will elevate the international normalized ratio (INR), although not always in a direct dose-dependent manner.**

2 **Activated charcoal decreases the absorption following the ingestion of apixaban and is probably also effective following the ingestion of warfarin, dabigatran and rivaroxaban.**

3 **There are clear guidelines for the management of warfarin anticoagulation and these should continue to be followed.**

4 **Prothrombinex-VF will reverse the effects of warfarin and rivaroxaban. It does not reverse those of dabigatran but may be effective in apixaban over-coagulation.**

5 **Idarucizumab is the reversal agent of choice for major bleeding due to dabigatran.**

6 **Limited data on acute rivaroxaban poisoning suggests that it may be relatively benign due to its rate-limited absorption.**

Introduction

The currently available oral anticoagulants are warfarin, dabigatran, apixaban, and rivaroxaban (Table 25.24.1). The direct thrombin inhibitors and factor Xa inhibitors have the advantage of standard dosing without the need for coagulation monitoring.

With experience in the practical use of novel oral anticoagulants (NOACs), also referred to as direct oral anticoagulants (DOACs), their risks and advantages compared with warfarin have been studied. In a meta-analysis of studies of patients with atrial fibrillation, the therapeutic effect of apixaban was marginally superior to that of warfarin for thromboembolic events but not for stroke risk.[3] Apixaban was non-inferior to dabigatran for a therapeutic effect but rivaroxaban was marginally superior for thromboembolic events. The risk of major bleeding was significantly lower for apixaban compared with warfarin, dabigatran, and rivaroxaban.[3,4]

Table 25.24.1 Oral anticoagulants

Anticoagulant class	*Specific drugs*	*Mechanism of action*	*Indications[a]: prevention of venous thromboembolism[1]*	*Kinetics[2]*
Vitamin K antagonist	Warfarin	Inhibits synthesis of vitamin K–dependent clotting factors Synthesis of proteins C and S	VTE Prosthetic heart valves Stroke in patients with previous MI and increased embolic risk AF and a high risk of systemic embolism	Elimination: hepatic T½: 36–48 h Onset: 3–5 days
Direct thrombin inhibitors	Dabigatran	Inhibits fibrin production and thrombin-induced platelet aggregation	VTE after THR or TKR Recurrent VTE AF and a high risk of systemic embolism	Onset: 0.5–2 h Elimination: • 80% renal • 20% bileT½: 12–14 h
Factor Xa inhibitors	Apixaban	Inhibits thrombin and fibrin production	VTE after THR or TKR AF and a high risk of systemic embolism	Onset: 1–3 h Elimination: • 25% renal • 75% hepaticT½: 8–15 h
	Rivaroxaban		VTE after THR or TKR Recurrent VTE AF and a high risk of systemic embolism	Onset: 2–4 h Elimination: • 75% renal • 25% hepaticT½: 7–13 h

[a]All agents are indicated for the treatment of thromboembolism.
ACS, Acute coronary syndrome; *AF*, atrial fibrillation; *MI*, myocardial infarction; *PCI*, percutaneous cardiac intervention; *THR*, total hip replacement; *TKR*, total knee replacement; *VTE*, venous thromboembolism

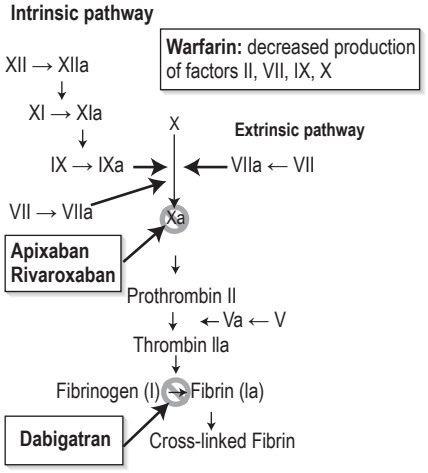

FIG. 25.24.1 The coagulation pathway and main effects of oral anticoagulants.

Pathophysiology

All the oral anticoagulants act on the final common pathway of the intrinsic and extrinsic coagulation pathway; this commences with the production of activated factor X towards a stabilized fibrin clot (Fig. 25.24.1). Additionally, warfarin affects the production of factors VII and IX of the intrinsic pathway.

Clinical features

Comparing the different NOACs, there does not appear to be a significantly increased risk of bleeding compared with warfarin when these agents are used therapeutically.[3,4] There are few reports of poisoning involving these agents.

Seven cases of deliberate self-poisoning with dabigatran have been reported.[5–7] The doses ingested ranged from 1,500 to 18,750 mg (maximal daily dose 300 mg). In a report on two patients, the INR and activated partial thromboplastin time (APTT) were closely correlated with plasma concentrations of dabigatran.[6] Peak INR levels greater than 6.5 were recorded in four patients, one of whom had an episode of haematemesis and another had a minor bleed from abrasions.[5,6]

In an observational study of 12 patients with deliberate self-poisoning with rivaroxaban, 5 patients had an elevated INR result but none developed bleeding.[8] Accidental paediatric ingestions did not result in bleeding, and coagulation studies, when measured, were normal.[8] Following a single ingestion of rivaroxaban, gastrointestinal absorption is limited to 40 mg (the maximal daily dose is 20 mg), explaining the benign effects of large ingestions.[9]

Two cases of deliberate self-poisoning with apixaban of doses of 200 and 300 mg (the maximal daily dose is 10 mg) have been reported, with peak INRs of 1.4 and 3.6 and only minor bleeding in one patient.[10,11] At the higher dose, apixaban appeared to exhibit saturable clearance.

Clinical investigation

The INR is elevated in poisoning by oral anticoagulants; this appears to be related to plasma anticoagulant levels.[6,10,11] Drug levels are not routinely available and do not appear to add to management. Following warfarin over-anticoagulation, an INR greater than 10, even in the absence of bleeding, is considered a threshold for the administration of a prothrombin complex in patients at high risk for major bleeding (Table 25.24.2). This guideline could be considered for managing over-anticoagulation by NOACs.

Treatment

Stabilization of active bleeding and fluid resuscitation are the initial priorities in the patient with over-anticoagulation. If the airway is not compromised or the patient is intubated, consideration can be given to gastrointestinal decontamination. There are limited data that activated charcoal significantly decreases the absorption of oral anticoagulants in overdose, but its use should be considered within 1 hour and up to 2 hours following apixaban poisoning.[14]

Established recommendations are in place for managing warfarin over-anticoagulation (see Table 25.24.2). Using currently recommended therapies, these could be extended to the NOACs, although no consensus recommendations currently exist (Table 25.24.3). The consensus guidelines for warfarin include consideration of treatment with a three-factor prothrombin complex concentrate (PCC) in the absence of bleeding if the INR is greater than 10 and the patient is at high risk for bleeding. This approach could also be extrapolated to the NOACs. Although unsupported by current studies, consideration could also be given to patients who are at increased risk for bleeding according to their HAS-BLED score (available on MedCalX from Apple App Store or Google Play).[15]

Warfarin

Human prothrombin complex (Prothrombinex-VF, CSL Behring Australia) is a PCC containing factors II, IX, X and unstated low levels of factors V and VII.[16] Retrospective observational studies

Table 25.24.2 Initial management of warfarin over-anticoagulation

No bleeding, but high INR	
INR >4.5	Withhold warfarin
INR 4.5–10	Withhold warfarin If bleeding risk is high, consider vitamin K[a]: 1–2 mg PO, 0.5–1 mg IV[b]
INR 10 or higher	Withhold warfarin Vitamin K oral or IV 3–5 mg[a] If bleeding risk is high,[b] consider adding Prothrombinex-VF
Bleeding	
Life-threatening bleeding	Withhold warfarin Vitamin K IV 5–10 mg[a] Prothrombinex-VF 50 U/kg Fresh frozen plasma 150–300 mL
Clinically significant bleeding (not life-threatening)	Withhold warfarin IV vitamin K IV 5–10 mg[a] Prothrombinex-VF 15–50 units/kg[c]
Minor bleeding with any INR	Withhold warfarin Consider vitamin K[a]: 1–2 mg orally, 0.5–1 mg IV[b]

[a]Administer vitamin K as phytomenadione (vitamin K1).
[b]Risk factors for major bleeding:
- Major bleed within the preceding 4 weeks
- Surgery within the preceding 2 weeks
- Platelet count <50 × 10⁹/L
- Liver disease
- Concurrent antiplatelet therapy

[c]Prothrombinex-VF dose is dependent on the initial and target INR. Consult specialist guidelines.[13]
INR, International normalized ratio.
See references 1, 12, 13.

Table 25.24.3 Suggested guidelines for over-anticoagulation with novel oral anticoagulants

NOAC	Treatment for significant bleeding or INR >10 and high risk
Dabigatran	Idarucizumab 5 g IV
Rivaroxaban	Human prothrombin complex (Prothrombinex-VF) 50 U/kg
Apixaban	Human prothrombin complex (Prothrombinex-VF) 50 U/kg

NOAC, Novel oral anticoagulant.

of the use of a PCC with significant amounts of factor VII (four-factor PCC) compared with a three-factor PCC have produced conflicting results of efficacy, with one study reporting that the four-factor PCC was more effective and another showing no difference.[12,17] Because of a lack of data, the Australian and New Zealand consensus guidelines continue to include the use of fresh frozen plasma (FFP) in addition to a PCC, but only in life-threatening bleeding or if a PCC is unavailable (Box 25.24.1).[18] Vitamin K will replete stores of factors II, VII, IX and X, although the onset of action can be up to 8 hours.[12]

Box 25.24.1 Risk factors for major bleeding

Major bleed within the preceding 4 weeks
Major surgery within the preceding 2 weeks
Platelet count <50 × 10⁹/L
Liver disease
Concurrent antiplatelet therapy
Consider patients with a HAS-BLED score of

Current local guidelines continue to include the use of FFP in addition to PCC, despite the seeming adequacy of a PCC (see Box 25.24.1).[18]

Dabigatran

Extra-corporeal removal of dabigatran has been used in the setting of life-threatening bleeding although there is a potential for redistribution and rebound anticoagulation.[19] Idarucizumab is a humanized monoclonal antibody fragment that binds to dabigatran with very high affinity. Since the availability of idarucizumab, extra-corporeal removal of dabigatran has not been required.[7] Administered as 5-g IV, it reverses the anticoagulant effect of dabigatran within 5 minutes.[20] Administration of a second 5-g dose may be required if there is a recurrence of clinically relevant bleeding or a second emergency surgery/procedure and a prolonged clotting time or residual anticoagulant activity is suspected.[20] Idarucizumab is registered by the Australian Therapeutic Goods Administration and PHARMAC New Zealand and is held in most major hospitals. In the reported management of deliberate self-poisoning with dabigatran, three patients were actively treated; one with FFP, one with haemodialysis and one with idarucizumab.[5,7] Dabigatran is not reversed by PCC.[18]

Rivaroxaban and apixaban

Rivaroxaban is reversed by a PCC.[18] Currently no data are available for the efficacy of a PCC in reversing apixaban, but it could be expected to do so. The role of FFP in the management of rivaroxaban and apixaban over-anticoagulation is uncertain.

Andexanet alfa is a recombinant, modified human factor Xa decoy protein that binds to rivaroxaban and apixaban, reversing their anticoagulant activity. It is currently being studied in ANNEXA-4, a phase IV study.[21]

Disposition

Following poisoning by oral anticoagulant medications, patients can be discharged once the INR and APTT are at therapeutic levels, bleeding has ceased and no further procedures are planned.

CONTROVERSIES

- The role of FFP in reversing over-anticoagulation from warfarin, rivaroxaban and apixaban where prothrombin complex concentrate is available is uncertain. Local guidelines or specialist advice should be followed.
- The reported benign course of rivaroxaban and apixaban poisoning should be balanced against the paucity of data currently available.
- The ceiling effects of the gastrointestinal absorption of rivaroxaban have not been assessed in cases of human poisoning.
- The future role of andexanet alfa for rivaroxaban and apixaban poisoning appears promising but awaits the results of phase 4 clinical trials.

SECTION 26

TOXINOLOGY EMERGENCIES

Edited by *Mark Little*

26.1 Snakebite

Geoffrey Isbister

ESSENTIALS

1 Australia has a number of medically important venomous snakes. All are elapids (front-fanged). New Zealand has no snakes of medical importance.

2 All patients giving a history of possible snakebite should be assessed and observed for at least 12 hours to rule out envenoming.

3 Most fatalities occur within hours of the bite from initial cardiac arrest and multiorgan failure. Delayed deaths are now uncommon and mainly due to major haemorrhage from the venom-induced consumption coagulopathy.

4 Pressure bandaging and immobilization is the recommended first aid.

5 Australian snakes are difficult to identify, and treatment should be guided by the possible snakes based on geography and the clinical syndrome, and expert snake identification if available.

6 Antivenom is indicated for all patients with clinical or laboratory evidence of envenoming. Sequris Ltd makes antivenoms against all important terrestrial snakes, as well as a polyvalent antivenom containing antivenoms to all five.

7 Antivenom should be given early and then sufficient time allowed for recovery, especially venom-induced consumption coagulopathy, which takes 6 to 18 hours to show recovery.

8 The dose of all snake antivenoms is one vial, and repeat doses are never required. Further laboratory testing is only required to determine when patients have recovered and can be discharged.

9 Sequris antivenom contains horse-derived $F(ab')_2$ antibodies and is associated with systemic hypersensitivity reactions in about 20% of cases, although severe anaphylaxis occurs in less than 5%. Premedication is not recommended, but adrenaline should be immediately available for treatment of anaphylaxis.

Introduction

Australia has a number of venomous snakes with some of the most potent venoms in the world. All the medically important snakes are elapids (front-fanged), although bites rarely occur from colubrids and non-venomous snakes. New Zealand has no snakes of medical importance. The risk of significant coagulopathy and uncommonly death, even after apparently trivial contact with Australian snakes, remains and must be appreciated by health care workers.[1]

Epidemiology

It is thought that approximately 3000 suspected snakebites occur annually in Australia, but this figure is difficult to estimate and depends on how many suspected bites, non-venomous bites and non-envenomed cases are included. The number of envenomed cases is far less and probably in the order of 100 to 200 each year; the majority of which occur in rural and regional areas.[2] Snakebite deaths continue to occur (about 1 to 5 per year) and are usually a result of early cardiac arrest in brown snakebites or major haemorrhage in coagulopathic patients.[1,2]

The commonest clinical manifestation is coagulopathy, which occurs in about three-quarters of envenomed cases (the majority in brown snake bites).[2] Neurotoxicity and myotoxicity are now uncommon, and mechanical ventilation is rarely required for treatment.[2] The types of snakes causing major envenoming differ across Australia. Bites in snake handlers remain an important problem, with about 10% of all bites being in snake handlers. However, they are almost all bites from Australian snakes, albeit the more uncommon and interesting snakes and exotic snakebite is very rare.[3] Although snake handlers often want to avoid antivenom, they should be treated like anyone else because there is little evidence to support they are at higher risk of antivenom reactions. Snake handlers and people working with snake venoms can develop systemic hypersensitivity reactions to venom itself, so venom anaphylaxis must be a differential diagnosis in these patients.[3]

Table 26.1.1 Clinical syndromes associated with the major venomous Australian snakes and the recommended antivenom

Snake	*Coagulopathy*	*Neurotoxicity*	*Myotoxicity*	*Systemic symptoms*	*Thrombotic microangiopathy*	*Cardiovascular effects*	*Antivenom*
Brown snake	VICC[a]	Rare and mild	–	<50%	10%	Collapse (37%) Cardiac arrest (5%)	Brown snake
Tiger snake group							
Tiger snake	VICC	Uncommon	Uncommon	Common	5%	Rare	Tiger snake
Rough-scale snake	VICC	Uncommon	Uncommon	Common	<5%	Rare	Tiger snake
Hoplocephalus spp.[b]	VICC	–	–	<50%	–	–	Tiger or brown snake
Black snakes							
Mulga snake	Anticoagulant	–	Common	Common	–	–	Black snake[c]
Red-bellied black snake	Anticoagulant	–	Uncommon	Common	–	–	Tiger snake[d]
Death adder	–	Common	–	Common	–	–	Death adder[c]
Taipan	VICC	Common	Rare	Common	5%	Uncommon	Taipan[c]

[a]The *Hoplocephalus* genus/group includes Stephen's banded snake *(H. stephensi)*, the broad headed snake *(H. bungaroides)* and the pale-headed snake *(H. bitorquatus)*.
[b]Polyvalent antivenom can be substituted for these large volume monovalent antivenom with no increase in risk or cost.
[c]Polyvalent or tiger snake antivenom cannot be used for sea snake envenoming.
VICC, Venom-induced consumption coagulopathy.

Prevention

Most snakebites are preventable and result from snake handling or interference with snakes in the wild, sometimes in the setting of alcohol consumption. Ideally, snakes should be left alone, and those working with or keeping snakes should have appropriate training and licences. Simple precautions, such as wearing thick long pants and boots when walking in the bush or when working with snakes, can prevent most bites due to the short length of Australian elapid fangs. Snake handlers should carry and maintain first-aid kits that include at least four broad elastic bandages (15 cm; e.g. ACE), and they should practise applying the bandage. If exotic snakes are being held, including Australasian snakes out of their geographical distribution, appropriate antivenoms should be available.

Clinical features

Systemic envenoming results when venom is injected subcutaneously and reaches the systemic circulation. Whether or not a snakebite results in systemic envenoming depends on a number of factors, including fang length, average venom yield of the snake, effectiveness of the bite and bite site. Recent studies have suggested that only a small amount of the injected venom actually reaches the systemic circulation.[1,4] Most snakebites do not result in envenoming because either insufficient venom reaches the systemic circulation or the snake is non-venomous.

Envenoming is characterized by local and systemic effects, although Australasian elapids rarely cause major local effects, such as necrosis and local haemorrhage. The clinical features of envenoming depend on the particular toxins present in each snake's venom, but non-specific systemic symptoms (nausea, vomiting, headache, abdominal pain, diarrhoea and diaphoresis) occur in many cases. The major clinical syndromes are coagulopathy, neurotoxicity, myotoxicity and acute kidney injury.[2] Severe envenoming can result in early collapse associated with dizziness, loss of consciousness, apnoea and hypotension.[1] In the majority of cases, there is spontaneous recovery over 5 to 15 minutes, but in some cases, this does not occur, and multiorgan failure and death ensue if resuscitation is delayed.[1,2]

The medically important Australian snakes and their associated clinical effects are listed in Table 26.1.1.

Coagulopathy

Venom-induced consumption coagulopathy

This is the commonest and most important clinical effect in Australian snake envenoming. Venom-induced consumption coagulopathy (VICC) results from a prothrombin activator in the snake venom converting prothrombin (factor II) to thrombin, which leads to consumption of factors V, VIII, and fibrinogen, associated with a massive increase in fibrinogen degradation products.[5] Most dangerous Australian snakes contain such a prothrombin activator, including brown snakes, snakes in the tiger snake group and taipans.[5] VICC develops rapidly within 15 to 60 minutes, and the onset may coincide with the initial collapse seen with major envenoming by brown snakes and taipans.[1] Recovery usually takes 12 to 18 hours.[5]

Anticoagulant coagulopathy

Anticoagulant coagulopathy occurs in black snake envenoming, including mulga and red-bellied black snakes, and is characterized by an abnormal activated partial thromboplastin time (aPTT).[6,7] It is unlikely to result in haemorrhage and of itself is rarely of clinical importance. However, anticoagulant coagulopathy is a useful marker of envenoming and is rapidly reversed with antivenom.[6] Unfortunately, the aPTT may not be abnormal in all cases because of the differing reagents used for the assay, so a normal aPTT does not exclude black snake envenoming.

Neurotoxicity

Paralysis is a classic effect of snakebite and is due to mainly presynaptic neurotoxins that occur in almost all Australian elapids. Presynaptic neurotoxins disrupt neurotransmitter release from the terminal axon and are associated with cellular damage. This type of neurotoxicity does not respond to antivenom treatment and may take days to weeks to resolve in severe cases. Neurotoxic envenoming manifests as a progressive descending flaccid paralysis. The first sign is usually ptosis, followed by facial and bulbar involvement, and progressing to paralysis of

the extraocular muscles, respiratory muscles and peripheral weakness in severe cases.

Myotoxicity

Some Australian snakes contain myotoxins that cause damage to skeletal muscles resulting in local and/or generalized muscle pain, tenderness and weakness, associated with a rapidly rising creatine kinase (CK) and myoglobinuria. In rare severe cases, secondary acute kidney injury can occur, or in rapidly developing systemic rhabdomyolysis, death can occur.

Renal toxicity

Acute kidney injury can occur in association with thrombotic microangiopathy or secondary to severe myolysis. Thrombotic microangiopathy occurs in snakebites associated with VICC and is characterized by severe thrombocytopaenia worse 3 to 4 days after the bite, acute renal failure that may last 2 to 8 weeks and require dialysis and microangiopathic haemolytic anaemia.[8] It is most common with brown snake envenoming, but also reported with all snakes that cause VICC.

Local effects

Local effects vary from minimal effects with brown snakebites to local pain, swelling and, occasionally, tissue injury following black and tiger snakebites.

Most fatalities occur within hours of the bite from initial cardiac arrest and multiorgan failure.[1] Delayed deaths are now uncommon and mainly due to major haemorrhage from VICC in brown snake, tiger snake group or taipan envenoming. Respiratory failure from neurotoxicity remains a problem in Papua New Guinea, where there continue to be large numbers of cases, mainly taipan bites, and a shortage of both antivenom and resources for mechanical ventilation.

Treatment

First aid

Australian snake venoms appear to be absorbed via the lymphatic system, so absorption is likely to be increased by movement and exercise. The aim of first aid is to minimize movement of venom to the systemic circulation. This is achieved by a pressure bandage (elastic bandage, such as ACE (ACE, BD, North Ryde, NSW, Australia)) being applied over the bite site and then covering the whole limb with a similar pressure to that used for a limb sprain. The bitten limb must be immobilized, as well as the whole patient, or the first aid will be ineffective. Immobilization consists of splinting and complete prevention of movement or exercise of the bitten part. It has been shown that movement of all limbs, not just the affected one, needs to be minimized for optimal effect.[9] Transport should be brought to the patient, and walking must be avoided. Pressure bandaging is clearly impractical for bites that are not on the limbs, but direct pressure with a pad and immobilization may be useful.

First aid must eventually be removed, but this should take place in a resuscitation area of a facility with the means definitively to treat envenoming. The first aid is removed when:

- thorough clinical and laboratory assessment fail to demonstrate any evidence of envenoming. In these patients, further clinical and laboratory evaluation for suspected envenoming is needed following removal of the bandage.
- there is definite clinical or laboratory evidence of envenoming. The bandage is removed after the completion of treatment with intravenous antivenom.

Initial assessment and treatment

Fig. 26.1.1 provides a simple approach to the management of suspected and envenomed snakebite patients. The patient is managed in an area with full resuscitation facilities. Assessment and management proceed simultaneously. The airway, breathing and circulation are assessed and stabilized. The majority of patients are not critically unwell and can have a focused neurological examination for early signs of paralysis (e.g. ptosis, drooling), examination of draining lymph nodes and general examination for signs of bleeding (oozing from the bite site, gum bleeds). Intravenous access should be established and intravenous fluids commenced.

Further management

Two major diagnostic and risk assessment issues exist for snakebite:

- whether or not the patient is envenomed
- in patients with envenoming, which snake is responsible and therefore which antivenom should be administered

The majority of patients are not envenomed, but all patients must initially be assessed as if they are potentially envenomed. Asymptomatic patients, particularly those seen early after a brown snakebite, may still be severely envenomed with VICC. The diagnosis of envenoming is made on history, examination and the clinical investigations listed as follows. Although systemic envenoming can be ambiguous in patients with mild envenoming, the following definitions are useful for determining whether patients require antivenom:

- VICC is defined as an elevated international normalized ratio (INR) or prothrombin time (PT) associated with an elevated D-dimer. A low or unrecordable fibrinogen will also occur but is not required for the diagnosis. In the majority of cases, there is complete consumption with unrecordable PT/INR, aPTT and undetectable fibrinogen, and the decision to give antivenom is straightforward. Milder forms of coagulopathy may occur with elevated D-dimer, decreased fibrinogen and only minimally elevated or even normal INR. Antivenom is still indicated in most cases, but these can be discussed with a clinical toxicologist.
- Neurotoxicity is defined as at least ptosis, but may progress without antivenom to include bulbar palsy, extraocular ophthalmoplegia, respiratory muscle paralysis and limb paralysis.
- Myotoxicity is defined as local or generalized myalgia and/or muscle weakness in association with an elevated CK (>1000 IU).
- Non-specific symptoms include nausea, vomiting, headache, abdominal pain, diarrhoea and diaphoresis, and may, in some cases, be the only early indication for antivenom, depending on the type of snake.

Box 26.1.1 provides a list of relative and absolute contraindications for antivenom which can be discussed with a clinical toxicologist if there is any doubt, and also depend on the timing of these effects. If there is no evidence of envenoming after clinical assessment and initial laboratory testing, the first-aid bandage can be removed. The patient requires ongoing close observation, including repeated investigations 1 hour after bandage removal and at 6 and 12 hours after the bite (see Fig. 26.1.1).

If the patient is envenomed, then management must proceed with antivenom. A small number of patients present in extremis, usually following collapse and in cardiac arrest, and should have antivenom administered immediately as part of advanced life support.

The next step is to determine the snake group responsible for envenoming in order to allow the administration of the appropriate monovalent antivenom. This is done taking into account:

- local geographical information on the potential snake species that could be responsible
- clinical syndrome (see Table 26.1.1)

In the majority of cases, a combination of these two factors allows determination of the correct monovalent snake antivenom required. In some cases, an expert may be available to identify the snake. The snake venom detection kit (sVDK) has been used in the past, but has recently been shown to provide confusing diagnostic information[2] and is no longer recommended. If it is unclear which snake is involved, then one vial of polyvalent antivenom should be administered or brown and tiger snake antivenoms (e.g. Victoria and most of coastal NSW), where this will cover all medically important snakes In Tasmania, only tiger snake antivenom is required, and in Northern Queensland, polyvalent should be used to cover taipan and brown snake.

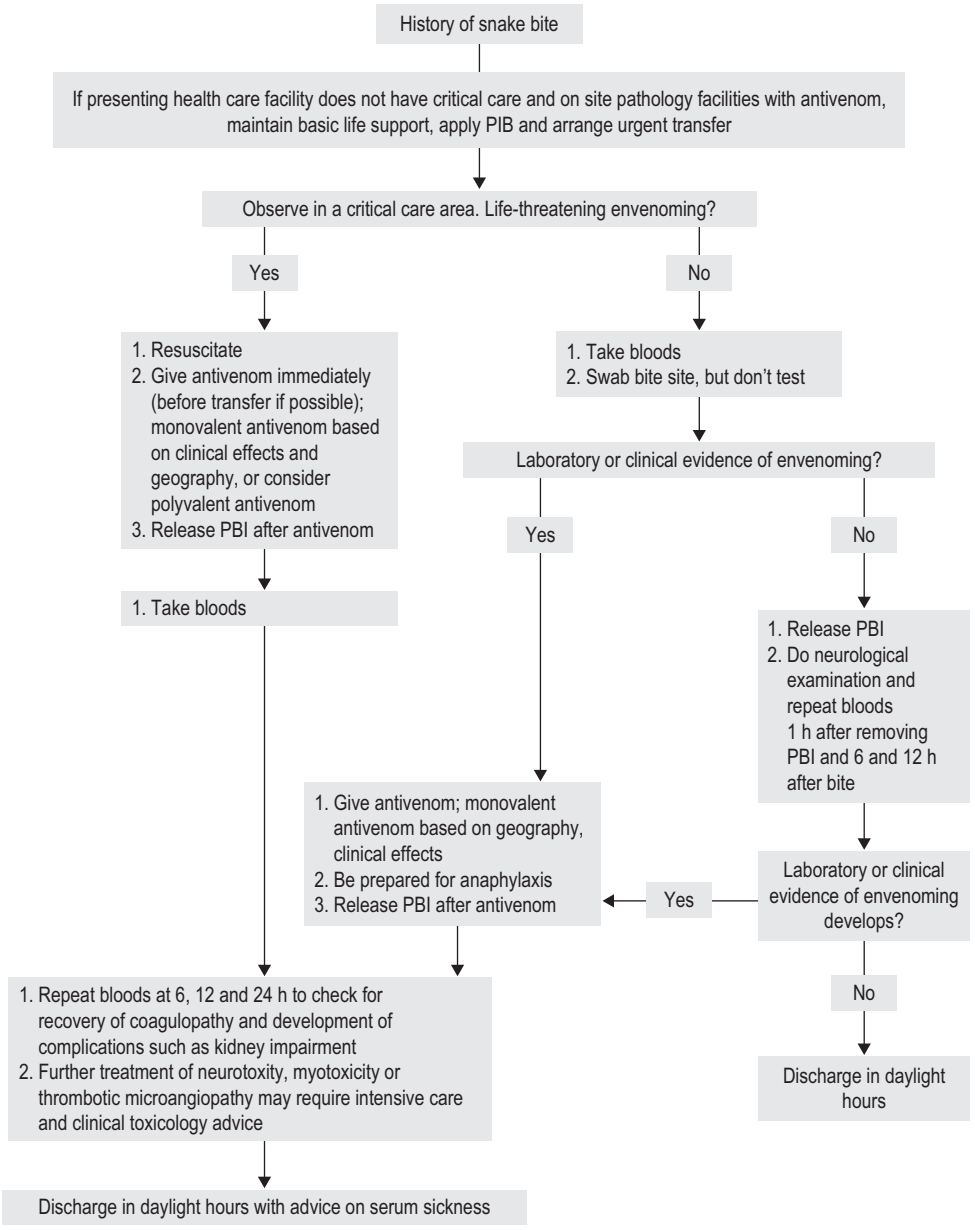

FIG. 26.1.1 Early management of snakebite. A toxicologist can be contacted at anytime via the Poison Information Centre 131126. Cardiac arrest, respiratory failure secondary to paralysis or major haemorrhage (intracranial, major gastrointestinal or other life-threatening bleeding). Blood tests include coagulation tests (INR/PT, aPTT, D-dimer, fibrinogen), FBC and blood film for fragments red cells, EUC, CK and LDH. Any improvement in coagulation studies, such as measurable but still abnormal aPTT or PT after 6 hours, is sufficient evidence of resolving coagulopathy. Neurotoxicity and myotoxicity are usually irreversible and further antivenom is unlikely to help. Any patient given antivenom needs advice on discharge about possibility of serum sickness occurring 4 to 14 days later. *aPTT,* Activated partial thromboplastin time; *CK,* creatine kinase; *EUC,* electrolytes, urea and creatinine; *FBC,* full blood count; *INR,* international normalized ratio; *LDH,* lactate dehydrogenase; *PBI,* pressure bandaging immobilization; *PT,* prothrombin time. (Modified from Therapeutic Guidelines Emergency Medicine, July 2012, with permission.)

Polyvalent antivenom should also be available in large regional hospitals or key centres for the treatment of death adder, mulga snake and taipan envenoming, which are rare.

Administration of antivenom

Snake antivenom should be administered by the intravenous route after being diluted 1 in 10 with normal saline and administered over 15 minutes. In patients with cardiac arrest or life-threatening effects, undiluted antivenom may be administered as a slow intravenous bolus. The dose of antivenom is one vial for all Australian snakes, and the dose for children is the same as adults. Recovery is determined by the reversibility of effects and the time it takes for recovery once venom is neutralized. Repeat doses of antivenom are never required. Although there has been controversy over the dose of antivenom, recent studies have demonstrated that previously recommended large doses are not required.[1,2,10]

Premedication for snake antivenom administration has previously been controversial but is no longer recommended in Australia. A recent randomized controlled trial has suggested that adrenaline is an effective premedication for snake antivenom,[11] but this is more appropriate in resource-poor settings where the risk of reactions is much higher. Systemic hypersensitivity reactions occur in about one-fifth of antivenom administrations in Australia, but are only severe (mainly hypotension) in less than 5% of

Box 26.1.1 Absolute and relative indications for antivenom

Absolute indications
History of sudden collapse, cardiac arrest or seizure
An abnormal INR
Evidence of paralysis with ptosis and/or ophthalmoplegia being the earliest signs
Relative indications: (suggest consultation with clinical toxicologist)
Systemic symptoms (vomiting, headache, abdominal pain)
Abnormal aPTT
Creatinine kinase >1000 U/L
Leucocytosis/lymphopaenia

aPTT, Activated partial thromboplastin time; *INR*, international normalized ratio.

administrations.[2,3] Reactions are more common with tiger snake antivenom and polyvalent antivenom compared with brown snake antivenom.[3] Antivenom should always be administered in a critical care area with readily available adrenaline, intravenous fluids and resuscitation equipment.

Delayed-type reactions to antivenom or serum sickness occur in just over a third of administration and appear to depend on the amount of horse protein administered.[12] All patients given antivenom should be warned of serum sickness. There is no evidence for the prophylactic use of a course of oral steroids, but they should be used for treatment in patients who present with serum sickness (prednisolone 30 to 50 mg/day for 5 to 7 days).

Other treatments

Tetanus prophylaxis should be given as appropriate, but local wound care is rarely required with Australasian snakes due to minimal local effects.

A recent randomized controlled trial has shown that the use of fresh frozen plasma (FFP) appears to speed the recovery of VICC,[13] but whether the decreased risk of bleeding is large enough to balance the risk of blood products remains unclear. The study also suggested that use of FFP within 6 hours of the bite may be associated with a poor response to FFP. Until larger studies are undertaken, FFP should be reserved for patients with coagulopathy and active bleeding.

Clinical investigations

Assessment of the potentially envenomed requires the following investigations to be performed, usually serially:

- Coagulation profile: PT or INR, aPTT, cross-linked fibrinogen degradation products or D-dimers and fibrinogen
- Full blood count, including a blood film looking for fragments, red cells and evidence of haemolysis
- Urea, creatinine, electrolytes, CK and lactate dehydrogenase
- Blood group and cross-match
- Urinalysis

Repeat laboratory testing, particularly coagulation studies, should not be used to determine if sufficient antivenom has been given because one vial is sufficient in all cases. Such serial testing should be used to determine when the patient has recovered and can be discharged.

Disposition

Patients with suspected snakebite but no evidence of envenoming 1 hour after the removal of first aid may be admitted to an observation area. Blood tests including coagulation studies and a CK should be repeated at 1 hour after first aid is removed, and 6 and 12 hours post-bite, and be observed for 12 hours or overnight (see Fig. 26.1.1). Envenomed patients requiring ventilatory support should have continued management in ICU, but patients with coagulopathy only are commonly managed in ED observation wards. All envenomed patients should have serial electrolytes, renal function, CK and full blood count to monitor for evidence of acute kidney injury, thrombotic microangiopathy and myotoxicity. Patients with VICC should be observed for any evidence of bleeding until the INR normalizes. Intracranial haemorrhage appears to mainly occur in older patients with a history of hypertension, and usually occur 6 or more hours after the bite.

CONTROVERSIES

- Indications for early antivenom therapy to prevent myotoxicity and neurotoxicity.
- Factor replacement appears to speed the recovery of VICC, but whether the decreased risk of bleeding is large enough to balance the risk of blood products remains unclear.

26.2 Exotic snakebite

Julian White

ESSENTIALS

1 Exotic snakebite is a growing issue worldwide, especially with the growth in illegally held snakes.

2 Symptoms and signs may be different to those seen in Australian snakebites.

3 As many non-Australian snakes, especially the vipers, cause local tissue destruction and damage, pressure bandage immobilization is not recommended.

4 Expert advice is available and recommended in managing these cases and helping locate antivenom.

5 Often there is a higher rate of allergic reaction due to overseas antivenom compared with Australian antivenom.

Introduction

Snakebite is a global phenomenon, with >2.5 million cases, >100,000 deaths and >400,000 amputations annually (this is greater than the annual amputation rate due to landmines). Australia accounts for a tiny fraction of all snakebite cases.

Exotic snakebite is a worldwide problem, with increasing seizures of illegally imported snakes and illegal collections by national authorities.

Exotic snakebite in Australia is either where an Australian snake species bites a person in a region where this snake is not usually found (e.g. a pet taipan bites its owner in Hobart), or where a snake not native to Australia bites someone in Australia. This chapter will focus on this second scenario.

Table 26.2.1 provides a list of selected genera/species, with distribution, clinical effects and major modes of treatment.

Bites by captive non-native (exotic) venomous snakes

There is an increasing number and diversity of exotic venomous snakes being kept in captivity, especially in private collections, either legally or often illegally (in Australia only registered zoos can legally keep exotic venomous snakes).

Exotic snakes may cause quite different patterns of envenoming compared with native snakes, and exotic antivenoms are required, which may be difficult to obtain. Doctors may not be trained in managing such bites. The person bitten may have limited knowledge of the risks, appropriate first aid, and if the snakes are illegally kept, may delay presentation with resultant more severe complications. Bites occurring in legal collections (zoos) present early, with correct first aid and appropriate antivenom immediately available.

Exotic venom activity

The mix of venom toxins and corresponding clinical effects varies with species of snake, including one or more of (1) paralytic neurotoxins (pre- and/or postsynaptic); (2) myotoxins (local or systemic); (3) toxins decreasing blood coagulability; (4) toxins promoting clotting; (5) haemorrhagins (damage vascular endothelium, promote bleeding); (6) nephrotoxins; (7) cardiotoxins and (8) local necrotoxins (cause severe local tissue injury/necrosis).

First aid

Many exotic venomous snakes can cause moderate to severe local effects around the bite site, including blistering, swelling, bleeding and skin necrosis (many vipers and pit vipers, some cobras, especially spitting species). For these, the Australian pressure bandage and immobilization (PBI) is not recommended, as it may worsen local tissue injury. Immobilize the bitten limb and ensure rings are removed from fingers for bites involving the hand.

For snakes which do not cause significant local tissue injury (sea snakes, kraits, some mambas, coral snakes, South American rattlesnakes, a few other pit vipers), the Australian PBI first aid is recommended.

Venom spit ophthalmia

Some African and Asian cobras can accurately spit venom over several meters and commonly aim for the eye, causing severe eye pain, corneal damage and potentially blindness, without systemic envenoming. Treatment is copious irrigation of the eye, slit-lamp examination for corneal injury, standard treatment for non-infective corneal ulceration (if present) and analgesia. Topical adrenaline drops may be effective analgesia if standard treatments prove inadequate. Antivenom is not recommended.

Approach to hospital management

Manage all cases as high priority with early expert clinical toxinologist advice (in Australia, the Toxinology Unit, Women's and Children's Hospital, Adelaide; 08-81617000). Provide early IV hydration, particularly in bites by necrosis-causing species where massive fluid shifts into the bitten limb can cause shock and secondary renal failure.

As done for Australian snakebites, urgently assess for flaccid paralysis (ptosis is a common early sign), haemodynamic status (beware hypovolaemic shock) and active major bleeding. Myolysis and local tissue injury may develop over some hours. Investigations include coagulation status, renal function, creatinine kinase and a full blood picture.

Antivenom use

The use of and dose of antivenom varies depending on snake species, extent of envenoming and patient-specific factors. Seek clinical toxinology advice on choice of antivenom (or consult www.toxinology.com) and where to source it from. All zoos legally holding exotic venomous snakes must carry appropriate antivenom. The earlier antivenom is given, once indicated, the more likely it will be effective.

Give antivenom IV, preferably diluted, with adrenaline and resuscitation immediately available in case of adverse reactions. If an adverse reaction occurs, stop the antivenom, control the reaction and then consider cautiously restarting the antivenom, as it is likely still needed.

A pretreatment skin sensitivity test should never be performed.

Table 26.2.1 Selected exotic snakes—overview of clinical effects and management

Snake	*Distribution*[a]	*Clinical effects*[b]	*Treatment*[c]

[a]Key to distribution: (Note: distribution is based on region and does not imply a given snake is either common or is found throughout the region; it may have limited distribution within the region.) *As*, Rest of Asia; *Aus*, Australia; *CeAm*, Central America; *EAs*, Eastern Asia (China, Japan, Korea, etc.); *Eur*, Europe; *Ind*, Indian region; *ME*, Middle East; *NtAf*, North Africa; *NtAm*, North America; *PNG*, New Guinea and adjacent Pacific; *SEAs*, South East Asia; *SSAf*, Sub-Saharan Africa; *StAm*, South America; *Was*, Western Asia.

[b]Key to clinical effects: (Note: listed clinical effects are based on best available information, but in some cases, very little information is available, and for these snakes, it should be considered a 'best guess' to guide care, not definitive.) *AC*, Anticoagulant coagulopathy; *BD*, haemorrhagin-based bleeding; *BH*, coagulopathy-based bleeding; *BS*, anterior pituitary infarction/hypopituitarism; *CC*, consumptive coagulopathy; *DV*, thrombosis & DVTs, etc.; *HF*, haemodynamic problems, shock; *LA*, local abscess formation; *LI*, local tissue injury/necrosis; *LS*, local swelling, not necrosis; *M*, myolysis; *NF*, renal damage/failure; *PD*, pre- and postsynaptic synergistic paralysis and fasciculation (mambas); *PN*, postsynaptic flaccid paralysis; *PP*, presynaptic flaccid paralysis; *PU*, flaccid paralysis, unspecified toxin types; *RF*, respiratory failure; *SO*, venom spit ophthalmia.

[c]Key to treatment: *AC*, Postsynaptic only flaccid paralysis may respond to neostigmine+atropine, if antivenom delayed or unavailable; *AV*, antivenom available (for details of available antivenoms see www.toxinology.com); *BP*, consider blood products as replacement in consumptive coagulopathy with major active bleeding—if antivenom available ensure adequate antivenom given first; *IV*, ensure adequate IV fluid hydration, watch for and treat shock (mostly hypovolaemic); *LC*, local wound care essential (necrosis or abscess potential); *NC*, particular risk of renal damage, ensure good hydration, renal output, strict fluid balance charting; *ST*, supportive treatment; may include intubation and ventilation for respiratory paralysis.

[d]No specific antivenom available, but some report South African Vaccine Producers polyvalent may be helpful in severe *Walterinnesia* bites.

[e]No specific antivenom available, but some report South African Vaccine Producers anti-*Echis* may be helpful in severe *Atheris* bites.

The Australian snake fauna is not listed here (see previous chapter).

Non-antivenom treatments

Some species capable of causing severe envenoming have no suitable antivenom available, so treatment must be supportive and secondary only (e.g. certain non-front-fanged-colubrid snakes [NFFC snakes; 'rear-fanged'] that can cause lethal consumptive coagulopathy, where haemodynamic support and, in selected cases, use of blood products may be required). In general, antivenom is preferred to blood products in treating major coagulopathy, but if there is active severe bleeding, then blood products may be appropriate once adequate antivenom has been given (where available); otherwise, blood product use is determined on a case-by-case basis based on clinical circumstances.

For some species causing postsynaptic-only flaccid paralysis, if antivenom is unavailable or delayed, consider using neostigmine (+atropine) to temper the severity of paralysis as a short-term measure (does not replace antivenom); this may be helpful in selected sea snake and cobra bites, but applicability to other neurotoxic species is less certain. This treatment will not work for predominantly presynaptic paralysis.

For species causing local tissue injury in the bitten limb, in addition to preventing shock and controlling bleeding, good wound care is important. Swelling and pain may be severe and suggest compartment syndrome, but beware of injudicious fasciotomy, as this can cause long-term loss of function, severe bleeding and a risk of secondary infection. Only perform fasciotomy as a last resort in cases where compartment syndrome is confirmed by pressure measurement (commonly for pressures exceeding 35 to 40 mm Hg). The role of limited-digit fasciotomy for bites to fingers is unclear, but some experts suggest it may reduce the incidence of later digit amputation; this is currently unproven.

26.3 Spider bite

Geoffrey Isbister

ESSENTIALS

1 **Australasia has a number of venomous spiders, but the majority of bites cause only minor problems.**

2 **Redback spider (a widow spider) bite is the most common cause of medically significant human envenoming in Australia. It can cause severe and persistent pain and, less often, systemic effects, but it is not life-threatening.**

3 **Australia appears to have the highest rate of widow spider envenoming (latrodectism) in the world.**

4 **Funnel-web spider (FWS) bite can cause life-threatening neurotoxic and cardiovascular envenoming.**

5 **A randomized controlled trial demonstrated that the addition of redback antivenom to standardized analgesia in patients with latrodectism did not significantly improve pain and systemic effects; and as such do not recommend using redback antivenom.**

6 **Antivenom to the FWS is rabbit serum based and so is less antigenic. No premedication is necessary and it is given intravenously.**

Introduction

Australasia is home to a large variety of arachnids including spiders, scorpions and ticks. Spiders are the most medically important arachnids in Australasia and include redback spiders and funnel-web spiders (FWSs). FWS envenoming occurs rarely in Eastern Australia and can cause severe and potentially life-threatening neurotoxicity. Redback spider envenoming (latrodectism) occurs throughout Australia and causes a local or regional pain syndrome associated with non-specific systemic symptoms and, less commonly, autonomic effects. Other spiders that commonly cause human bites are not associated with major medical effects and include huntsman spiders *(Sparassidae)*, orb-weaving spiders *(Araneidae)*, white-tail spiders (*Lampona* spp.), wolf spiders *(Lycosidae)* and jumping spiders *(Salticidae)*.[1] FWS envenoming has resulted in death prior to antivenom, but still remains a life-threatening condition.[2]

An approach to the patient with spider bite

Initially, a careful history should be taken to determine whether the patient has suffered a definite spider bite or only a suspected spider bite. The diagnosis of definite spider bite requires sighting of the spider at the time of the bite and usually some initial symptoms, such as local pain. If there is no history of bite or no spider was seen, then other diagnoses must be considered first. This is particularly important in persons presenting with ulcers or skin lesions with suspected spider bites (Box 26.3.1). It is important in these cases that appropriate investigations are done and the case treated as a necrotic ulcer of unknown aetiology. In the majority of these cases, an infective cause is found, although less commonly they are a result of pyoderma gangrenosum or a vasculitis.[3]

If the patient has a definite history of a spider bite and has either captured the spider or has a good description of the spider, a simple approach can be taken. Health professionals should not attempt to identify spiders beyond the following simple classification:

- redback spider
- moderate to large black spider that is potentially an FWS in Eastern Australia
- all other spiders.

The majority of redback spiders are likely to be identified correctly and, with supporting clinical features, this diagnosis is usually straightforward.

The second group is only important in regions where FWS are known to occur and cause significant effects (east coast of Australia from Southern Queensland to Southern New South Wales [NSW]). If the spider is large and black, then the patient should be managed as an FWS. A pressure bandage with immobilization (PBI) is the appropriate first-aid measure. The PBI should only be removed with FWS antivenom immediately available (i.e. antivenom present in the

Box 26.3.1 An approach to the investigation and diagnosis of necrotic skin ulcers presenting as suspected spider bites

A. Establish whether or not there is a history of spider bite

Clear history of spider bite (better if spider is caught):

- Refer to information on definite spider bites

No history of spider bite:

- Investigation should focus on the clinical findings: ulcer or skin lesion
- Provisional diagnosis of a suspected spider bite is inappropriate

B. Clinical history and examination

Important considerations:

- Features suggestive of infection, malignant processes or vasculitis
- Underlying disease processes: diabetes, vascular disease
- Environmental exposure: soil, chemical, infective
- Prescription medications
- History of minor trauma
- Specific historical information about the ulcer can assist in differentiating some conditions:
  - Painful or painless
  - Duration and time of progression
  - Preceding lesion

C. Investigations

Skin biopsy:

- Microbiology: contact microbiology laboratory prior to collecting specimens so that appropriate material and transport conditions are used for fungi, *Mycobacterium* spp. and unusual bacteria
- Histopathology

Laboratory investigations: may be important for underlying conditions (autoimmune conditions, vasculitis), including, but not be limited to:

- Biochemistry (including liver and renal function tests)
- Full blood count and coagulation studies
- Autoimmune screening tests, cryoglobulins

Imaging:

- Chest radiography
- Colonoscopy
- Vascular function studies of lower limbs

D. Treatment

Local wound management

Treatment based on definite diagnosis or established pathology

Investigation and treatment of underlying conditions may be important (e.g. pyoderma gangrenosum or diabetes mellitus)

E. Follow-up and monitoring

The diagnosis may take weeks or months to be established, so patients must have ongoing follow-up. Continuing management: coordinated with multiple specialties involved

(From Isbister GK. Spider bite. Australian Doctor 2004, with permission.)

emergency department [ED] but not opened). Once in the ED they should be observed for at least 2 hours after the pressure bandage has been released or after the bite in a patient without first aid. If the patient is asymptomatic at this time, they can be safely discharged. No attempt should be made to identify the spider because the distinction between some FWS and the less significant trapdoor spiders is impossible for non-experts.

The third group includes all other spiders. Despite previous concerns about particular spiders, such as the white-tail spiders, all other spiders are very unlikely to cause more than minor effects.[1] Patients can be reassured, their tetanus status confirmed and updated, if required, and symptomatic treatment with ice and analgesia can be offered. These patients do not need to be observed in hospital.

Redback spider *(Latrodectus hasselti)*

Distribution and taxonomy

The redback spider is a member of the widow group of spiders (*Latrodectus* spp.). The widow spider group is the single most medically important group of spiders worldwide[2] and belongs to the family of comb-footed spiders (Theridiidae). Widow spiders are distributed throughout the world and thrive in urban environments, ensuring that they frequently come into contact with humans. There are probably around 40 species, including the North American black widow *(Latrodectus mactans)*, the Australian redback *(L. hasselti)*, the New Zealand katipo *(L. katipo)* and the brown widow *(L. geometricus)*, which is found on most continents including Australia. All species produce venom with similar properties, although the clinical syndrome (latrodectism) appears to differ in some cases.[2] Australia probably has the highest rate of latrodectism in the world, with at least 2000 definite bites per annum. New Zealand reports few cases of envenoming by its widow spider, the katipo. There is at least one other important genus of spiders in this family, *Steatoda* spp., which is responsible for human envenoming. They are black spiders with the same body shape and size as widow spiders, but without the red markings.

Venom

The components toxic to humans in the venom of widow spiders are α-latrotoxins that cause massive release of neurotransmitters and deplete synaptic vesicles at nerve endings. Recent work based on *in vitro* effects suggests that all widow spiders have a similar toxin. However, although the effects of the toxin are well understood at the cellular level, it remains unclear how it produces the clinical syndrome.[4]

Epidemiology

Most bites occur when the spider is disturbed in human-made objects, such as clothes, shoes, gloves, furniture, building materials and sheds. Most bites are on extremities and occur during the warmer months of the year. Redback spider bites are not life-threatening, even to infants and young children, and no deaths have been reported since the mid-1950s. Reported deaths in other countries are likely to be overestimates due to reporting bias.[2]

Clinical features

The majority of patients bitten develop some effects from redback spider bites with pain being the most common and important symptom. Non-specific systemic symptoms occur in about one-third of cases. Initially, the bite may be painless or may feel like a pinprick or a burning sensation. The pain then increases over the first hour and may radiate proximally to the regional lymph nodes or the chest or abdomen. Localized sweating and, less commonly, piloerection may occur and are virtually pathognomonic of latrodectism. Regional and distant sweating

Box 26.3.2 Clinical features of redback spider bite

Local and regional effects

- Local pain: increasing pain at the bite site over minutes to hours, which can last for days
- Radiating pain: from the bite site to the proximal limb, trunk or local lymph nodes
- Local sweating
- Regional sweating: unusual distributions of diaphoresis (e.g. bilateral below-knee diaphoresis)

Less common effects: piloerection, local erythema, fang marks (5%)

Systemic effects

- Nausea, vomiting and headache
- Malaise and lethargy
- Remote or generalized pain
- Abdominal, back or chest pain

Less common effects: hypertension, irritability and agitation, fever, paraesthesia or patchy paralysis, muscle spasms, priapism

More common with paediatric cases. (Reproduced with permission from Therapeutic Guidelines Emergency Medicine 2008.)

can occur and bilateral below-knee sweating is characteristic. Non-specific systemic symptoms include malaise, lethargy, nausea and vomiting, abdominal pain and headache. A summary of the clinical effects is listed in Box 26.3.2, including the less common effects. Pain may persist for 1 to 4 days.[5] Delayed effects or effects persisting for days to weeks have been reported, but it is unclear in many cases whether the effects are a consequence of the spider bite.

Diagnosis

The diagnosis is clinical and based on history, which is typically one of persistent increasing pain that can radiate and may be associated with local sweating. There are no tests to confirm latrodectism. As the bite may not be felt, doctors should suspect the condition in circumstances where patients have been working in sheds, while potting plants or where contact with widow spiders is possible.

Treatment

First aid

Local application of ice has been recommended, although its effectiveness remains unproven. Warm compresses provide relief in some cases. Pressure bandaging is not appropriate.

Analgesia

Adequate analgesia is an important part of the treatment of redback spider bite. Paracetamol and/or non-steroidal anti-inflammatories and/or oral opioids should be used initially, although intravenous opioids may be required if the pain does not respond. Failure to respond to intravenous opioids is frequently reported and further research is required to define the most appropriate analgesia in redback spider bite.

Antivenom therapy

Although antivenom is still available for the treatment of redback spider bite, it is no longer recommended based on the RAVE-II study.[6] The RAVE-II study showed that antivenom did not provide any additional benefit to simple analgesia, for both pain and systemic effects. There continues to be controversy over the effectiveness of redback spider antivenom. A recent meta-analysis found a small overall benefit of intravenous antivenom over intramuscular antivenom or placebo, for pain in widow spider bites.[7] The analysis highlighted inherent bias in the small studies and a number needed to treat of five for minor benefits.[7]

Steatoda species (cupboard or button spiders)

There have been a number of reports of bites by *Steatoda* spp., mainly in Australia.[8] They appear to cause a similar syndrome to latrodectism with persistent local pain but fewer systemic features. *In vitro* studies of these spiders' venom demonstrate that they cause similar but far less potent effects compared to α-latrotoxin.[9] The majority of bites by this group of spiders cause only minor effects, although the patient may have annoying pain for a period of hours.[8] Uncommonly, they can cause more severe and persistent pain, similar to widow spiders.

Funnel-web spider (*Atrax* and *Hadronyche* species)

Distribution and taxonomy

At least 39 species of FWSs occur along the east coast of Australia, including Tasmania and Adelaide. However, only six species occurring from Southern NSW to Southern Queensland have been associated with significant envenoming: Sydney FWS *(Atrax robustus)*, the Southern Tree FWS *(Hadronyche cerberea)*, the Northern Tree FWS *(H. formidabilis)*, the Blue Mountains FWS *(H. versuta)*, the Toowoomba or Darling Downs FWS *(H. infensa)* and the Port Macquarie FWS (*H.* sp. 14).[10] Historical records suggest there is an increase in bites by other species in the last few decades compared to most bites being due to the Sydney FWS in the past. This may be due to increasing population density in the area of distribution of *Hadronyche* species. FWS are burrowing spiders and most encounters with humans occur when males are out looking for mates.

Venom

The males have a more potent venom than the females and only males have been reported to cause significant illness in humans.[4,10] The important toxins in human envenoming appears to be α-atracotoxins, which have been isolated from the venom of a number of species of FWS.[4] These are low-molecular-weight neurotoxins that prevent inactivation of sodium channels. The main effect of the neurotoxin is an autonomic storm that can be predominantly sympathetic or parasympathetic, or mixed in effect, associated with neuromuscular excitation.[4]

Epidemiology

Although there are a large number of suspected FWS bites each year, severe envenoming is rare and only 5 to 10 cases requiring antivenom occur annually.[10] Many definite bites by FWS do not result in envenoming (dry bites) and the frequency of non-envenoming varies between species.[10] In addition, many cases are a result of other big black spiders that appear to be FWS and are not collected or identified.

Clinical features

The initial bite is painful due to the size of the fangs, and the fang marks are usually present. Severe envenoming develops rapidly and usually occurs within 30 minutes.[10] Initial effects include paraesthesia (local, distal extremities and perioral), local fasciculations, tongue fasciculations and non-specific systemic effects (nausea, vomiting and abdominal pain). Autonomic features are typical of systemic envenoming with hypersalivation, lacrimation and generalized sweating. Other autonomic features can include miosis, mydriasis, tachycardia or bradycardia and hypertension. Initially, the patient is usually agitated and anxious with a decreased level of consciousness and coma developing as late signs associated with multiorgan failure.[10] The massive sympathetic stimulation can result in catecholamine induced cardiomyopathy, with hypotension and pulmonary oedema.[11]

Diagnosis

As with redback spider bite the diagnosis is clinical.

Treatment

First aid

Pressure bandaging with immobilization is the recommended first aid and, if not applied at the scene, it should be applied in hospital on arrival if antivenom is not available.

Supportive treatment

With the introduction of antivenom therapy, the requirement for intensive care therapy is

less common. Attention to basic resuscitation is essential, but usually does not require more than intravenous fluid therapy after assessment and stabilization of the airway and ventilation. Atropine can be used to treat cholinergic features, but this is not a substitute for antivenom. The use of inotropes and other pharmacological agents is only required in patients developing cardiomyopathy due to delayed presentation and/or severe envenoming not responding to antivenom. If pulmonary oedema occurs, this can be treated with continuous positive airways pressure ventilation in association with antivenom therapy.

Antivenom therapy

Definitive treatment is venom neutralization with specific FWS antivenom. The antivenom is derived from rabbit serum and appears to be less antigenic to humans than horse serum antivenoms with a low reaction rate (<2%).[10] Premedication is not recommended but antivenom must be administered in a critical care area with adrenaline available. Antivenom is indicated for systemic envenoming as defined above. Initially, two vials should be given intravenously, which can be repeated if there is no improvement after 15 to 30 minutes. Delayed serum sickness reactions have been reported in at least one case.[10]

Mouse spiders (*Missulena* spp.)

Another group of spiders, the mouse spiders (*Missulena* spp.), are rarely reported to cause similar effects to FWS.[12] These spiders belong to the family Actinopodidae and occur in most parts of Australia. Most bites are by wandering male spiders and do not cause any major effects. The initial bite causes pain and fang marks, due to the size of the fangs. There is one report of a bite by the Eastern mouse spider *(Missulena bradleyi)* that caused a syndrome similar to FWS envenoming in a 19-month-old child.[12] However, all other reported cases have caused only local effects and, less commonly, local neurotoxic effects and/or mild non-specific systemic effects.[12]

Other Australasian spiders

There are a number of other Australian spiders that cause human bites. In the majority of cases, they cause only minor effects and symptomatic treatment is all that is required. In a large study of definite spider bites, there were no cases of necrotic lesions or allergic reactions, suggesting these effects are either rare or do not occur.[1] The incidence of secondary infection is also low and occurred in less than 1% of cases in the same study.[1]

Necrotic arachnidism

Necrotic arachnidism is generally defined as necrotic lesions or ulcers that occur following a spider bite and are a result of venom effects. Significant skin necrosis following bites from recluse spiders (*Loxosceles* species) is well reported in many parts of the world.[2] However, excepting rare reports of *L. rufescens* in South Australia, this group of spiders is not endemic to the country and it has not been reported to cause necrotic ulcers from definite bites.

The white-tailed spider (*Lampona cylindrata/murina* group) has been implicated in the development of necrotic arachnidism. However, recent studies show that this is not the case with 130 definite bites by these spiders causing no cases of necrotic lesions.[13] Other spiders have been implicated in this condition, including wolf spiders, sac spiders and the black house spiders, but there is similarly little evidence to support this and prospective cases of definite bites by these groups of spiders have not demonstrated necrotic lesions.[1] Box 26.3.1 provides an approach to the patient with a skin ulcer attributed to a spider bite.

CONTROVERSIES

- There is ongoing controversy regarding the effectiveness of redback spider antivenom.

26.4 Marine injury, envenomation and poisoning

Jamie Seymour • Peter Pereira

ESSENTIALS

1 **The majority of marine-related presentations can be effectively managed with attention to basic life support (BLS) and the provision of supportive therapy. This includes aggressive analgesia and meticulous wound management.**

2 **Pain associated with barbed fish stings can sometimes be attenuated by immersion of the effected limb in warm water (up to 45°C).**

3 **Tropical jellyfish envenoming may be life threatening and require early diagnosis, prompt attention to BLS and liberal application of household vinegar to the sting site.**

4 **In life-threatening box jellyfish envenomation, six ampoules of intravenous antivenom are recommended, together with an extended period of advanced life support.**

Marine injuries

Wounds generated in the marine environment are particularly prone to infective complications in part because of the rich milieu of bacteria that rapidly contaminate. Additionally, penetrating wounds can masquerade as an innocuous laceration and hide imbedded foreign material. For these reasons all marine wounds require meticulous wound care, debridement and cleaning, followed by a low threshold for prophylactic antibiotics to primarily cover streptococci and vibrio for oceanic marine wounds. Delayed primary closure should be considered in all such potentially contaminated wounds.

Stingray

Stingrays possess a barbed spine with an enveloping integumentary sheath and associated venom glands on the tail. Injury usually occurs when the animal is trodden on, resulting in a wound on the distal half of the lower limb. Often a combined penetrative–lacerative injury, these wounds can appear deceptively minor. Part of the barb and its integumentary sheath is frequently left in the wound and as such, all wounds require exploration, meticulous debridement and cleaning, and then consider delayed primary closure and prophylactic antibiotics.

Although the majority of injuries are minor, three deaths have been documented in Australia, the last occurring in 2006. All died from penetrating cardiac wounds. All wounds to the chest and abdomen need to be treated as a penetrating injury. The patient should be admitted and appropriately investigated and observed.

Disproportionate pain lasting hours presumably occurs from the accompanying venom, and immersion in hot water may be of benefit in addition to parenteral narcotics and regional anaesthesia. Local injury occurs from both direct trauma and envenoming. Systemic envenomation is rare and usually minor with nausea, headaches and light-headedness, though there are reports of seizures and cardiovascular collapse. Treatment is symptomatic and no antivenom is available.

Envenomation

Cnidaria

Only *Chironex fleckeri* (box jellyfish) and *Carukia barnesi* ('classic' Irukandji jellyfish) have been documented to cause deaths in Australian waters, with the Australian Resuscitation Council (ARC) attributing 80 deaths to *C. fleckeri*, and 2 to Irukandji syndrome. Children are particularly prone to a fatal outcome and account for the last 10 *C. fleckeri* deaths in the Northern Territory.

Victims of *C. fleckeri* envenomation are readily identifiable from the characteristic cutaneous features. In comparison, stings from *C. barnesi* and other Irukandji syndrome-inducing jellyfish may have minimal or absent cutaneous manifestations. Other cnidaria may cause serious envenomation, although no deaths have been recorded in Australian waters from these species. In recent years *C. barnesi* have been found near Fraser Island and this appears consistent with models predicting southerly migration from rising ocean temperatures.

Chironex fleckeri

C. fleckeri, commonly referred to as the box jellyfish, is found in tropical coastal and estuarine waters of northern Australia, predominantly between November and April. It, or similarly deadly cubomedusae, are likely to be found in other tropical environments including those of Papua New Guinea (PNG), the Indonesian archipelago and South East Asia, based on similar case reports from these areas. The bodies of mature animals may be 40 cm in size with as many as 60 tentacles trailing for up to 3 m. These tentacles have a typical banded appearance, that impart the characteristic frosted ladder cutaneous lesions. Lethal envenomation has only been reported where more than 2.5 m of tentacles have been involved. The venom is a complex mixture of proteins ranging in size from 54 to 150 kDa; however, most of these proteins are yet to be researched and only some are demonstrably antigenic to CSL box jellyfish antivenom.

In a prospective study of jellyfish stings presenting to the Royal Darwin Hospital over a 12-month period, of 23 patients with nematocyst proven *C. fleckeri* stings, only 1 required parenteral analgesia and 0 received antivenom. Most victims experienced minor dermatological injuries, which were successfully treated as though they were burns. However, shock and loss of consciousness from cardiorespiratory depression may occur and victims, especially children, have died within minutes of being stung.

Chironex stings can be prevented by avoiding swimming in their known habitat during the dangerous months of the year, which varies according to region but is generally November to April, or swimming within netted areas on beaches (mainly in Queensland). The wearing of 'stinger' suits or pantyhose confers effective protection of the covered areas and is further assisted by the swimmer entering the water slowly and affording the jellyfish time to take evasive action.

First aid

The ARC recommends the liberal dousing of vinegar to the affected site(s) for at least 30 seconds, as it is effective in preventing further triggering of undischarged nematocysts. However, published *in vitro* research casts some doubt on its utility, as it has been demonstrated that triggered

nematocysts continue to contain residual venom, which is expelled after the application of vinegar, effectively increasing the volume of expressed venom by 60%.

Pressure immobilization bandages (PIB) are no longer recommended. Although previously advocated by the ARC, there is no evidence to support the application of ice packs to sting sites.

Treatment

The vast majority of *C. fleckeri* stings cause localized pain and discomfort.

- Remove the victim from the water.
- Liberally apply vinegar to the affected areas.
- Scrape off adherent tentacles.
- Apply analgesia as required.
- Treat the sting as a burn; watch for and treat any secondary infection.
- A delayed hypersensitivity rash may develop within 2 weeks of the sting and responds to corticosteroid cream.

In the event of a cardiac arrest (usually rapid progression at the beach) commence cardiopulmonary resuscitation (CPR) and continue until adequate doses of box jellyfish antivenom are administered. Some advocate prolonged CPR as there have been well-documented cases of return of spontaneous circulation and survival following the institution of CPR. This is further supported in animal models (unpublished) that suggest that the cardiotoxicity is temporary.

Box jellyfish antivenom is indicated if:

- severe pain is not relieved by parenteral opiates
- there is any cardiorespiratory compromise, including arrhythmias.

Box jellyfish antivenom is administered diluted 1:10 in normal saline by slow intravenous (IV) injection. In cardiac arrest, the use of up to six ampoules given consecutively undiluted is advocated. Premedication is not required.

- IV magnesium (0.2 mmol/kg up to 10 mmol) over 15 minutes may be administered as an adjunct. Animal work has suggested some benefit and this should be considered in unstable patients not responding to antivenom.
- The effectiveness of *C. fleckeri* antivenom is questionable given its apparent futility in cardiac arrest. This may be related to *C. fleckeri* venoms sampled from different parts of Northern Australia being measurably different in their toxin compositions. Despite this, antivenom is still recommended.

CARUKIA BARNESI

The Irukandji jellyfish *(C. barnesi)* consists of a bell measuring up to 3 cm across, and with tentacles up to 75 cm in length. It was first captured in 1961 in Cairns by Dr Jack Barnes, who demonstrated causation by stinging himself, his 9-year-old son and the local lifeguard. All three developed Irukandji syndrome and were taken to hospital for treatment. The syndrome is also caused by many other jellyfish, including blue bottles (*Physalia* spp.) and, as such, envenoming may occur in all Australian tropical waters. *C. barnesi* has been found in Australian waters north of Fraser Island, and cases have been reported in northern Australia around to Exmouth in Western Australia. Cases have also been reported internationally, including PNG, Hawaii, Florida, the Caribbean and Thailand.

Patients with Irukandji syndrome often have minimal symptoms at the time of the sting. After a latent period of up to 60 minutes the 'Irukandji syndrome' may develop, with clinical features of catecholamine excess that include restlessness, anxiety, diaphoresis, vomiting, abdominal, chest and back pain, blood pressure lability and tachycardia. It is reported that 20% of victims develop raised cardiac markers, 6% develop echocardiographic evidence of myocardial dysfunction and 2% develop clinical cardiac failure. Although most patients settle within 6 hours, all patients developing cardiac dysfunction have ongoing pain. There have now been two deaths associated with Irukandji syndrome, both succumbing from intracerebral haemorrhages. Recent in vitro research indicates that *C. barnesi* venom has no direct myocardial effect, strongly supporting the notion that the observed myocardial dysfunction may be due to catecholamine induced stress.

Treatment

Vinegar is indicated immediately on experiencing a sting even before the development of Irukandji syndrome. PIB is no longer recommended. Progressive, severe truncal pain traditionally requires large doses of opiates. In a review of 62 cases of Irukandji syndrome presenting to Cairns hospitals in 1 year, 38 (61%) required parenteral analgesia, while in a review of cases over a 10-year period, over 90% of patients required some type of pain relief. Often large doses of opioids are required. Fentanyl has been recommended solely because it is easily titratable and has an excellent cardiac profile. Patients should be observed in hospital for 6 hours after their last dose of opioid and, if asymptomatic, may then be discharged.

All patients require serial electrocardiogram and troponin (cTnI) levels measured (20% have elevated cTnI), especially those with ongoing pain or high opiate requirement. A small percentage (2%) of patients will develop pulmonary oedema, and will usually require ventilator and inotropic support. Following anecdotal success, IV magnesium has become a mainstay of treatment to control pain and other symptoms of catecholamine excess. However, the only randomized and blinded trial failed to demonstrate any superiority of magnesium over narcotics. It is likely that the reported variation in effectiveness of magnesium may reflect different species and different toxins. There is no antivenom. Similarly, recent anecdotal experience with clonidine has shown promising results.

Non-tropical jellyfish stings

This is by far the most common type of jellyfish sting in Australia and worldwide, with symptoms mainly comprised of painful welts.

First aid for all non-tropical Australian jellyfish stings consists of manually removing the tentacles, and the application of heat is recommended by the ARC, although the evidence for this is minimal. However, for known blue bottle (*Physalia* spp.) stings, hot water has been demonstrated to reduce pain, and should be applied as hot as can be tolerated (but no more than 45°C), ensuring the patients do not burn themselves. Vinegar is not recommended due to concerns that it triggers firing of undischarged nematocysts.

FISH

Scorpaenidae: stonefish, bullrout, lionfish, scorpionfish

The most clinically significant member of the Scorpaenidae family are the three species of stonefish (*Synanceia* spp.). Fatalities have been reported in other parts of the world; however, there are no confirmed Australian fatalities (although Sutherland reports the death of an Army doctor on Thursday Island in 1915). The stonefish possesses 13 dorsal fin spines, each with paired venom glands. These spines become erect when the fish is trodden on and venom is discharged deep into the wound. The venom has neurotoxic, myotoxic, vascular and myocardial effects. Because of their excellent camouflage, stonefish are rarely seen and the first indication of their presence may be the excruciating pain of a sting. The overwhelming clinical feature of the presentation is one of severe, unrelenting local pain out of proportion of the injury.

The other members of the Scorpaenidae family can produce similar clinical presentations, although the pain is more responsive to hot water and opiates. There are reports of stonefish antivenom being successful with severe, recalcitrant pain from these fish.

Treatment

- Immerse the limb in hot (up to 45°C) water. It is considered prudent to place the unaffected limb in the water as well particularly when regional anaesthesia has been employed.

- Parenteral analgesics often prove inadequate in managing severe pain, and regional anaesthesia with a long-acting local anaesthetic agent may be employed.
- PIB is not indicated as it is likely to exacerbate the intense pain.
- Stonefish antivenom, 1 ampoule (2000 units) per two puncture wounds via intramuscular or IV injection should be given if there is ongoing pain despite opiates. Although there is reliable symptomatic relief, there is no evidence that it is of benefit in reducing tissue injury.
- Wound exploration, debridement and toilet to minimize local tissue injury and loss. Consider radiography to exclude retained foreign bodies.
- Tetanus prophylaxis should be given if indicated.
- Appropriate broad-spectrum antibiotics may be considered.

Note that many other freshwater and oceanic barbed fish can produce similarly painful injuries. In the absence of research, it would seem prudent to apply the same first aid recommendations bar stonefish antivenom.

MOLLUSCS

Blue-ringed octopus

Seven species of this small octopus are found along the Australian coastline. Normally brown in colour, the characteristic small bright blue rings become vividly prominent when the animal is agitated. Humans are at risk of envenoming when they disturb the animal. There are two documented deaths from the blue-ringed octopus *(Hapalochlaena maculosa)* in Australia and several other cases of potentially fatal envenoming that were successfully managed. The active component of the venom is tetrodotoxin, which inhibits central and peripheral nerve conduction by changing the morphology of fast sodium channels. Death occurs from respiratory failure due to progressive paralysis. The bite is typically painless, but a small lesion with bleeding may occasionally be visible. There is a spectrum of envenoming, from minimal symptoms of localized neurology to rapid onset of generalized paralysis, during which time the patient remains conscious until succumbing to the effects of hypoxia.

Treatment

- Apply pressure-immobilization bandages after washing the bite site.
- Institute supportive management, which may include artificial ventilation with sedation and inotropes for up to 12 hours, as required.
- Antivenom is not available.
- Patients who are asymptomatic 6 hours after a bite may be discharged home safely.

Cone shell

Of the many species of cone shell, about 18 have been implicated in human envenoming. The sole Australian fatality reported was caused by *Conus geographus* in 1936.The cone shell snail injects venom from a radular tooth harpoon carried on a proboscis that protrudes from the narrow end of the shell. The venom consists of peptotoxins called conopeptides. Pain is usually felt at the site of the bite and, in serious envenoming, evidence of muscular weakness may rapidly develop and occasionally progress to respiratory paralysis.

Treatment

- Apply pressure-immobilization bandaging.
- Be prepared to commence expired air resuscitation.
- Supportive ventilation and sedation may be required.
- Antivenom is not available.
- Clinical recovery has been documented after 4 hours of assisted ventilation.

REPTILES

Snakes

Sea snakes are readily distinguished from terrestrial snakes by their flat oar-like tail.

It is important to remember that terrestrial snakes may also take to the water, but swim on the surface. Sea snakes, like terrestrial snakes, are air-breathing reptiles and, in Australia, are found in tropical or temperate waters.

In contrast to fish stings, the bite of a sea snake typically causes minimal local pain. Neuromuscular paralysis and rhabdomyolysis are common, but coagulopathy is rare. Fortunately, as for terrestrial snakes, most bitten victims are not envenomed.

Treatment

- Apply PIB.
- Antivenom and resuscitative facilities should be available before PIB is removed.
- Give antivenom if there is clinical or biochemical evidence of envenoming. Specific sea snake antivenom is available.
- One ampoule of sea snake antivenom (1000 units) is diluted 1 in 10 with crystalloid and infused over 30 minutes. Further doses may be required. Tiger snake antivenom or polyvalent antivenom could be used in desperate situations. Three ampoules of tiger snake antivenom used to be recommended but, due to changes in antivenom production, it is unclear if tiger snake antivenom would contain sea snake antivenom today.
- Supportive care including airway management, ventilatory assistance and treatment of rhabdomyolysis may be required.

Note: CSL venom detection kit does not detect sea snake antigens and the effectiveness of CSL polyvalent is unknown for these types of envenoming.

Poisonings

Ciguatera poisoning

Ciguatera poisoning is endemic in the tropics and is caused by ingesting tropical fish contaminated with ciguatoxins, a group of heat and acid stable, lipid-soluble toxins that bind and open voltage sensitive Na^+ channels. They originate in dinoflagellates often associated with algae on dead coral. These are consumed by herbivorous fish which, in turn, are consumed by carnivorous fish and so on, the toxins bioaccumulating up the food chain to humans. In Australia, ciguatoxic fish are particularly found between Mackay and Cairns and the syndrome is most commonly associated with the ingestion of Spanish mackerel, although a number of species are known to be ciguatoxic.

Poisoning is characterized by neurological dysfunction preceded or accompanied by an acute gastrointestinal illness. The symptoms usually begin within 1 and 6 hours of eating contaminated fish. Gastrointestinal symptoms include nausea, vomiting, abdominal pain and diarrhoea, and neurological symptoms include paraesthesia, particularly perioral, cold allodynia (a burning sensation on contact with cold), myalgias, mood disorders and autonomic and cerebellar disturbances. Cardiorespiratory complications, including respiratory depression, bradycardia or cardiovascular collapse, are rare and respond to standard resuscitation measures. In the absence of any diagnostic tests, the diagnosis is based on clinical suspicion and exclusion of other pathology. Treatment is primarily supportive with fluids and simple analgesics. A recent randomized controlled trial has demonstrated no benefit in using mannitol; however, it was a small study with many limitations. Alcohol classically exacerbates symptoms and should be avoided during the illness. The majority of victims are treated as outpatients and admission is reserved for those considered at risk for cardiorespiratory compromise. Most poisonings resolve within a week, though severe cases may have ongoing dysaesthesias for months or years. Commonly utilized pain modulators, such as gabapentin and amitriptyline, have been used to control dysaesthesias, although their effectiveness remains anecdotal and unproven. Recrudescence may occur with further ingestion of contaminated

fish and, as such, it is generally advised to avoid eating tropical fish for at least 6 months after symptoms have abated.

Scombroid poisoning

Scombroid poisoning is the manifestation of histamine toxicity following the ingestion of histamine-laden saltwater fish. Initially described after ingestion of the Scombridae species, such as tuna and mackerel, it has since been associated with non-Scombridae species, such as herrings and sardines. The toxic levels of histamine are by-products of bacterial action on histidine contained in the flesh of these fish during inadequate storage or improper thawing of frozen fish. Ingestion is soon followed by classic histamine-related symptoms mimicking allergic reactions. These include pruritus, urticaria, rhinorrhoea, bronchospasm, vomiting, diarrhoea and abdominal pain. Rarely, severe toxicity may present as an anaphylactoid reaction. Mild to moderate presentations respond to antihistamines (H1 and H2). Severe reactions require cardiorespiratory support and adrenaline.

Paralytic shellfish

Paralytic shellfish poisoning may occur following the ingestion of saxitoxin-contaminated shellfish, particularly during periods of algae bloom. Similar to ciguatoxin, saxitoxin is a heat- and acid-stable toxin produced by a dinoflagellate microorganism and is concentrated in the flesh of bivalve molluscs. Following ingestion, there may be rapid progression from vomiting and perioral paraesthesia, to generalized paraesthesia, muscular weakness, ataxia, to paralysis and death from type 2 respiratory failure. Unlike ciguatera poisoning, it would be prudent to admit all suspected cases, including those that initially only demonstrate gastrointestinal dysfunction, for at least 24 hours to observe for the development of weakness and deteriorating respiratory function. There is no antidote, and aggressive and prolonged respiratory support may be required. Gradual recovery occurs over 2 to 5 days with weakness persisting sometimes for weeks.

Tetrodotoxin poisoning

Tetrodotoxin (TTX) is a paralytic toxin that occurs in the flesh, skin and viscera of puffer fish. It acts by inhibiting voltage-sensitive fast sodium channels and thus preventing conduction centrally and in peripheral motor and sensory nerves. In Australia, TTX poisoning is rare and usually occurs in those ignorant of the danger of ingesting puffer fish. In Japan, where such fish are a delicacy called 'fugu', numerous cases and deaths occur every year. Toxicity usually manifests rapidly after ingestion, with paraesthesia starting periorally followed by facial numbness and weakness progressing to bulbar paralysis, respiratory paralysis and death. Unlike therapeutic neuromuscular blockade, the pupils are unresponsive. Management is supportive as there is no antidote. All cases should be admitted for observation until peak clinical effects have passed. It is extremely unlikely that life-threatening effects will occur after 24 hours in patients who have not already developed severe effects.

SECTION 27

ACADEMIC EMERGENCY MEDICINE

Edited by *Biswadev Mitra*

27.1 Research methodology

David McD. Taylor

ESSENTIALS

1. Research projects should be designed and undertaken in a structured, predetermined fashion.

2. During the study design phase, assistance from a statistician is highly recommended.

3. The study protocol should be written in advance of data collection and adhered to throughout the project.

4. Most research mistakes relate to inadequate sample size calculations and selection bias in subject recruitment.

5. Research ethics issues are becoming more important, especially since the introduction of new privacy legislation. Ethics committee authorization must be sought prior to study commencement.

Introduction

One important strategy in clinical research is to compare groups of human subjects. These might be different groups or the same group preintervention and postintervention. The methods used are mainly nonexperimental (i.e. observational). They are based on what we can observe and compare in groups of people within populations. By comparing the characteristics (such as behaviours and exposures) and the health experiences of these groups of people, it is possible to identify associations that might be responsible for the cause of a disease.

Initiating the research project

Research question

The research question forms the basis of every research study and is the reason that it is undertaken. It is the scientific, clinical, practical or hypothetical question that, when answered, will allow the researcher to apply newly found knowledge for some useful purpose.

The research question may be generated from many sources, including questions raised by clinical observations, the published medical literature, scientific conferences, seminars and discussions or the effectiveness of currently used or new treatment.

For example:

- Is drug A better than drug B?

Study hypothesis

A hypothesis is a bold statement of what we think the answer to the research question is. Essentially, it is our best guess of what the underlying reality is. As such, it has a pivotal role in any study. The purpose of a research study is to weigh the evidence for and against the study hypothesis. Accordingly, the hypothesis is directly related to the research question.

For example:

- 'directional' hypothesis: drug A is *better* than drug B
- 'null' hypothesis: drug A is as *good as* drug B.

In expressing a hypothesis, the researcher needs to be very specific about who or what is to be observed and under what conditions. A failure to define clearly the study groups and the study end points often leads to sloppy research.

Study aims

The aims of a study are a description of what the researcher hopes to do in order to weigh up the evidence for and against the study hypothesis.

For example:

- This study aims to determine which is the better drug, drug A or drug B.

Assembling the research team

Most research projects are undertaken as collaborative efforts with the co-investigators each contributing in their area of expertise. Co-investigators should meet the criteria for co-authorship of the publication reporting the study's findings.[1]

Usually, the person who has developed the research question takes the role of principal investigator (team leader) for the project. Among the first tasks is to assemble the research team. Ideally, the principal investigator determines the areas of expertise required for successful completion of the project (e.g. biostatistics) and

invites appropriately skilled personnel to join the team.[2] It is advisable to keep the numbers within the team to a minimum. In most cases, three or four people are adequate to provide a range of expertise without the team becoming cumbersome. It is recommended that nursing staff be invited to join the team, if this is appropriate. This may foster research interest among these staff, improve departmental morale and greatly assist patient enrolment and data collection.

All coinvestigators are expected to contribute time and effort to the project, although the extent of this contribution will vary. The temptation to include very senior staff or department heads simply to bolster the profile of the project should be avoided.

The importance of good communication within the research team cannot be overemphasized. This is usually the responsibility of the principal investigator and may involve regular meetings or reports. At the risk of flooding each coinvestigator with excessive or trivial communications (e.g. e-mail), selected important communications should be forwarded as they appear, for instance, notification of ethics committee approval and updates on enrolment.

Development of the study protocol

The protocol is the blue print or recipe of a research study. It is a document drawn up prior to commencement of data collection that is a complete description of the study to be undertaken.[3] Every member of the study team should be in possession of an up-to-date copy. Furthermore, an outside researcher should be able to pick up the protocol and successfully undertake the study without additional instruction. Care should be taken to appropriately number and track every version of the protocol.

Purpose of the study protocol

Research protocols are required:

- for the ethics committee application
- for applications for research funding
- to facilitate the smooth and efficient running of the study through the provision of well-researched and documented information
- for the basis of the Introduction and Methods sections of the final research report.

Protocol structure

The protocol should be structured largely in the style of a journal article's Introduction and Methods sections.[3] Hence the general structure is as follows:

Introduction

- Background, including a brief summary of the literature.
- Research question.
- Hypothesis.
- Aims.
- Need for the proposed research (i.e. the purpose of the study).

Methods

- Study design—a simple description of the design of the proposed study (e.g. randomized clinical trial, cohort study, cross-sectional survey).
- Study setting and period—a description of where and when the study will take place.
- Study subjects—inclusion and exclusion criteria and a description of how participants are to be recruited.
- Procedures and interventions—the nature of any interventions to be used, including information on safety, necessary precautions and rationale for the choice of dose(s).
- Study end points (outcome variables)—variables that are impacted upon by the factors under investigation (e.g. those that are affected by a study intervention).
- Data collection instruments (e.g. questionnaires, proformas, equipment).
- Data collection procedures including quality-control procedures to ensure integrity of data.
- Data management—including a description of how data will be handled, how privacy concerns will be addressed and how storage and backup of data will be undertaken.
- Bias and confounding control—sources of bias and variability and measures to be taken to address them.
- Ethical issues—subject confidentiality, safety, security and access to data.
- Statistical analysis:
  - sample size: a description of calculations used to determine sample size and assumptions included in this process should be included. This should include calculations, where appropriate, to ensure that it is clear that the study can recruit a sufficient number of patients to answer the research question
  - data analysis: this should include a description of the primary variables to be analysed, a specification of any a priori subgroup analyses and the statistical methods to be used. It is highly recommended that a statistician be consulted during protocol development and for data analysis.

This general plan should be followed in the preparation of any study protocol. However, the final protocol will vary from study to study.

Study design

Study design, in its broadest sense, is the method used to obtain data to weigh up the evidence for and against the study hypothesis. Many factors influence the decision to use a particular study design and each design has advantages and disadvantages. For a more extensive discussion on study design the reader is referred elsewhere.[2,4]

Observational studies

In general, research studies examine the relationship between an exposure or risk factor (e.g. smoking, obesity, vaccination) and an outcome of interest (e.g. lung cancer, cardiac disease, protection from infection).

In observational (non-experimental) studies, the principal challenge is to find a naturally occurring experiment (i.e. a comparison of two or more populations that enables the investigator to address a hypothesis about the outcome of interest).

Cross-sectional studies

Cross-sectional studies examine the present association between two variables. For example, within a population you could take a single random sample of all persons, measure some variable of interest (e.g. lung function) and then correlate that variable with the presence or absence of lung cancer. Data are often collected in surveys and the information on exposure and outcome of interest is collected from each subject at one point in time. The main outcome measure obtained from a cross-sectional study is prevalence.

Ecological studies

Ecological studies relate the rate of an outcome of interest to an average level of exposure that is presumed to apply to all persons in the population or group under investigation. So, for example, we could determine the association between the average amount smoked per capita in different countries and the incidence of lung cancer in each country.

Cohort studies

In a cohort study, a group of individuals in whom the personal exposures to a risk factor have been documented are followed over time. The rate of disease that subsequently occurs is examined in relation to the individuals' exposure levels. For example, within a population you could take a sample (cohort) of healthy individuals, document their personal past and ongoing smoking history and relate that to the subsequent occurrence of lung cancer in that same sample. Although not as powerful a study design as clinical trials (see later), cohort studies are able to provide valuable data relating to the causation of disease.

Case-control studies

Case-control studies are retrospective analyses that involve a comparison between a

representative sample of subjects with an outcome of interest (cases) and another sample of people without the outcome (controls). If an antecedent feature (exposure) is found to be more common in the cases than the controls, this suggests an association between that exposure and the development of the outcome. The frequencies of past exposures to risk factors of interest are compared in each group. Case-control studies provide only medium-level evidence of an association between exposure and outcome of interest.

Case reports and case series

This study design is often employed in emergency medicine research. The clinical details (history, management, outcome) of interesting or similar patients are described. This study design provides weak evidence for an association between exposure and outcome of interest and is best employed for hypothesis generation. For example, a series of patients who all developed skin necrosis after being bitten by a certain spider would reasonably lead to the hypothesis that the venom of the spider of interest contained a particular tissue necrosis factor. However, this hypothesis would need to be proven by the isolation of the factor and experimental demonstration of its effects.

Data for case reports/series are often extracted from medical record reviews or existing databases. This is one reason for the weakness of this study design insofar as the data were most likely collected for purposes other than the research study. Accordingly, such data are often of low quality and may suffer from inaccuracies, incompleteness and measurement bias.

Experimental or interventional studies

In an experimental study, the researcher is more than a mere observer and actively manipulates the exposure of study subjects to an exposure of interest (risk) and measures the effects (outcomes) of this manipulation.

The preferred form of experimental study is currently the randomized controlled trial, in which the intervention is randomly assigned at the level of the individual study subject. Although this is the most scientifically rigorous design, other study designs must often be used for a number of reasons including:

- the state of knowledge about a disease process
- real-world opportunities
- logistics and costs
- ethical considerations.

For ethical reasons, we cannot easily use experimental studies to study factors that are thought to increase the risk of disease in humans. For example, you could not do a study where you ask half of the group to smoke for 10 years and half of the group to remain non-smokers.

Main types of clinical trials

- Parallel group trials—these are the most common type of clinical trial and involve two or more groups of patients treated separately but concurrently.
- Two-period crossover trials—patients are treated for two periods using a different treatment in each period. Patients are randomly allocated to the two possible orders of treatment so that half the patients receive the treatments in the sequence AB and the other half in the sequence BA.
- Preintervention and postintervention trials—these trials measure the impact of an intervention when it is introduced into the management of a patient population. For example, the introduction of nurse-initiated analgesia may improve the pain management of emergency department patients.
- Cluster-randomized, crossover trials—institutions (e.g. emergency departments) are randomized to provide certain types of care (e.g. oxygen therapy or no oxygen therapy for patients following myocardial infarction). After a predetermined data collection period, the institutions crossover to the other form of care and data are again collected.
- Other types—factorial trials, N-of-one trials and sequential trials—are used much less frequently.

Key features of clinical trials

Randomization This is a process by which patients are allocated to one of two or more study groups, purely by chance. Randomization prevents any manipulation by the investigators or treating doctors in the creation of the treatment groups. This prevents a situation whereby a doctor can, for example, allocate the sicker (or not so sick) patients to a new treatment. Randomization also helps to produce study groups comparable with one another with respect to known, as well as unknown, confounding variables (e.g. risk factors). The most convenient methods of randomizing patients are random number tables in statistical textbooks or computerized random number–generating programs.

A fundamental aspect of randomization is that it must take place only after the commitment to participate has been made (enrolment has taken place). Another important principle is that randomized patients are irrevocably committed to follow up and must not be excluded from, or lost to, follow-up, regardless of their subsequent compliance or progress ('intention to treat analysis').

Blinding Blinding is the most effective method of minimizing systematic error (bias) in clinical trials. In single-blinded studies, patients participating in the trial are unaware which treatment they are receiving but the investigators do know. In double-blind studies, neither the subjects nor the investigators know which patient is receiving which treatment. This type of study is usually feasible only with drug studies where it is possible to provide identically appearing medication. This is often achieved using the double dummy approach in which patients receive two medications, one active and the other placebo. The alternative treatment involves a swap-over of the active and placebo medications. Even in apparently blinded studies, there may be various indicators that allow the patient or investigator to determine which treatment they are receiving. In this circumstance, additional methods of bias control may be needed.

Concepts of methodology

Validity and repeatability of the study methods

It is essential that the study uses valid and repeatable methods (i.e. measurements that measure what they purport to measure). Ideally, the validity of each of the measurements used in any study should be tested, during the design stage of the study, against another method of measuring the same thing that is known to be valid.

Two types of validity are described:

- Internal validity means that, within the confines of the study, the results appear to be accurate, the methods and analysis used bear scrutiny and the interpretation of the investigators appears supported.
- External validity is the extent to which the results of a study can be generalized to other samples or situations. Again, for all types of study, it is important that repeatable methods are used (e.g. measurements that are closely similar when repeated under the same circumstances). Thus, if someone is asked the same question twice about a characteristic that has not changed in the meantime (such as their height), it would be said to be repeatable if they always (or almost always) answered in the same way. Repeatability of the question should be tested during the design phase, although it is also useful to monitor it during the main study. A good example would be a haemoglobinometer that consistently measured the haemoglobin level 2 g/dL too low. Although the haemoglobin measurements would be repeatable, they would be wrong (invalid).

Response rate

Nonresponse is a problem for many types of observational study. Often, people who participate in a study (responders) have different characteristics from those who do not (non-responders). This can introduce substantial selection bias into the prevalence estimates of a cross-sectional study. In order to minimize this bias, as large a sample as possible is required. To this end, investigators undertaking cross-sectional surveys aim for at least 70% of invited participants actually to respond. Unfortunately, a target response rate of 70% is often not met and low response rates are likely to impact significantly upon bias and validity of the study.

Study variables

A variable is a property or parameter that may be similar or different among patients. The framework for the study hypothesis is the independent variable. This variable is often the factor that is thought to affect the measurable end points, or dependent variables, in the study. For example, cigarette smoking causes lung cancer. In this example, cigarette smoking is the independent variable and lung cancer is the dependent variable, because its incidence and nature depends upon cigarette smoking.

Study end points

Study end points are variables that are impacted upon by the factors under investigation. It is the extent to which the end points are affected, as measured statistically, that will allow us to weigh up the evidence for and against the hypothesis. For example, a researcher wishes to examine the effects of a new antihypertensive drug. It is known that this drug has minor side effects of impotence and nightmares. A study of this new drug would have a primary end point of blood pressure drop and secondary end points of the incidence of the known side effects.

Essentially, all forms of investigation involve counting or measuring to quantify the study end points. In doing so, there is always the opportunity for error, either in the measurement itself or in the observer who makes the measurement. Such errors (measurement bias) can invalidate the study findings and render the conclusions worthless.

Sampling study subjects

There are several important principles in sampling study subjects:

- The sample must be representative of the study population. If the study population comprises all people living in a certain area, the study sample should include a representative sample of all members of the population. Certain groups are frequently left out (e.g. the homeless, squatters, people in institutions or people with no telephone). Such groups must be thought of in advance and steps taken to ensure their inclusion. Otherwise, selection bias may be introduced.
- The sample must be derived from the population randomly. The way in which the sample is drawn from the study population is critical to how well the sample represents that population. This determines how 'generalizable' the results will be. Although there are many alternative ways to maximize sample representativeness, as a general rule, a random sample is preferred. A random sample is one in which each member of the population has an equal likelihood or probability of being selected.
- Loss to follow-up. The researcher must avoid loss of members from the sample once it has been taken, for two reasons. First, loss of subjects will effectively decrease the study sample size and may impact adversely on the power of the study to generate statistically meaningful results. Second, if subjects lost to follow-up differ in important ways from subjects who remain in the study, then the study results may be affected by selection bias.

Sampling frame

This is a list of all members (e.g. persons, households, businesses) of the target population that can be used as a basis for selecting a sample. For example, a sampling frame might be the electoral roll, the membership list of a club or a register of schools. It is important to ensure that the sampling frame is complete, that all known deficiencies are identified and that flaws have been considered (omissions, duplications, incorrect entries).

Sampling methodology

Probability sampling

When every member of the population has some known probability of inclusion in the sample, we have probability sampling. There are several varieties:

Simple random sampling: in this type of sampling, every element has an equal chance of being selected and every possible sample has an equal chance of being selected. This technique is simple and easy to apply when small numbers are involved but requires a complete list of members of the target population.

Systematic sampling: this employs a fixed interval to select members from a sampling frame. For example, every 20th member can be chosen from the sampling frame. It is often used as an alternative to simple random sampling as it is easier to apply and less likely to make mistakes. Furthermore, the cost is less, its process can be easily checked and it can increase the accuracy and decrease the standard errors of the estimate.

Stratified sampling

A stratified sample is obtained by separating the population into non-overlapping groups or strata (e.g. males and females) and then selecting a single random (or systematic) sample from each stratum. This may be done to:

- gain precision—this is possible by dividing a heterogeneous population into strata in such a way that each stratum is internally homogeneous
- accommodate administrative convenience—field work is organized by strata, which usually results in cost savings
- obtain separate estimates for each stratum
- accommodate different sampling plans in different strata (e.g. over-sampling).

However, the strata should be designed so that they collectively include all members of the target population, each member must appear in only one stratum and the definitions or boundaries of the strata should be precise and unambiguous.

Nonprobability sampling

Convenience sampling is an example of nonprobability sampling. This technique is used when patients are sampled during periods convenient for the investigators. For example, patients presenting to an emergency department after midnight are much less likely to be sampled if research staff are not present. This technique is less preferred than probability sampling because there is less confidence that a nonprobability sample will be representative of the population of interest or can be generalized to it. However, it does have its uses, such as in in-depth interviews for groups difficult to find and for pilot studies.

Data collection instruments

Surveys

Surveys are one of the most commonly used means of obtaining research data. While seemingly simple in concept, the execution of a well-designed, questionnaire-based survey can be difficult.

Designing a survey

From a practical point of view, the following points are suggested:

Before a survey
- Define the research question(s) to be answered.
- Determine the sampling strategy.
- Design, test and revise the questionnaire (validation).
- Train the data collectors.
- Determine the technique for cross-validation.
- Define the methods of data analysis.

During the survey
- Verify and cross-validate the questionnaire.
- Check timetables and budget.

After the survey
- Cross-check all the data again.
- Perform the main data analysis.
- Perform any other exploratory data analysis.
- Write the report.

If possible, incorporate commonly asked questions into your questionnaire. One good source of such questions is standard surveys (such as Australian Bureau of Statistics). There are many other sources of pre-validated questions (e.g. measures on quality of life, functional ability and disease-specific symptoms). The scientific literature, accessible through MEDLINE and other databases, is a good start. This is particularly important if you want to compare the sample with other surveys or, in general, if you want to be able to compare the sample's responses with previously completed work.

In addition, previously used questionnaires for similar topics are very helpful and often can be used directly. The advantage to doing this is that these questionnaires' reliability and validity are established.

The wording of a question can affect its interpretation. Attitude questions with slightly different wordings can elicit differing responses, so several questions on the same topic may be helpful to be certain that the 'true attitude' of the respondent is obtained. This technique can enhance internal validity and consistency.

Pretesting of a questionnaire is most important. Consider the following points:
- Assess face validity of all questions.
- Is the wording clear?
- Do different people have similar interpretations of questions?
- Do closed questions have appropriate possible answers?
- Does the questionnaire give a positive impression?
- Is there any bias in the questions?

It is always worth checking with your colleagues to determine whether the questionnaire will answer the study question. In addition, test the questionnaire on a cross-section of potential respondents of differing reading levels and background. There can be a few surprises, and several revisions may be required before the final questionnaire is determined.

Data collection proformas

These documents, also called case report forms, are generally used to record individual case data that are later transferred to electronic databases. These data may be obtained from the patient directly (e.g. vital sign measurements) or extracted from the medical records or similar source.

While simple in concept, careful design of a data collection proforma should be undertaken. First, a list of the data required should be drafted and translated into data fields on the proforma. These fields should be clearly laid out and well separated. Prior to data collection, the proforma should be trialled on a small selection of subjects. In such an exercise, it is commonly found that the data fields are not adequate for the collection of the required data. Hence revision of the proforma is often required.

Consideration should be given to the ease of data entry and extraction from the proforma. Data entry should progress logically from the top to the bottom of the document without interruption. This is particularly important for data extraction from medical records. Data extracted from the front of the record should be entered at the top of the proforma and so on. Consideration should also be given to later translation of the data to an electronic database. This should follow the same principles as described earlier. If possible, design a proforma that will allow data to be scanned directly into an electronic database.

Bias and confounding

Study design errors

In any study design, errors may occur. This is particularly so for observational studies. When interpreting findings from an observational study, it is essential to consider how much of the association between the exposure (risk factor) and the outcome may have resulted from errors in the design, conduct or analysis of the study.[4] The following questions should be addressed when considering the association between an exposure and outcome:
- Could the observed association be due to bias (systematic errors) in the way subjects were selected for the study or in the way information was obtained from them?
- Can the result be explained by confounding factors?
- Could the result be due to chance?

Systematic error (bias)

Bias resulting from the way a study is designed or carried out can result in an incorrect conclusion about the relationship between an exposure (risk factor) and an outcome (such as a disease) of interest.[4] Small degrees of systematic error may result in high degrees of inaccuracy. Many types of bias can be identified:
- Selection bias occurs when there is a difference between the people selected for a study (study sample) and those who are not, for instance employed versus unemployed. Only proportional representation of all groups can, in a way, indicate the absence of selection bias.
- Non-response bias is a function of two components: the non-response rate and the extent to which non-respondents systematically differ from respondents. We may need to ask why a survey question was not answered. Is it not clear? Is it too personal? Is there a negative interaction with the interviewer? Non-response bias may be a type of selection bias.
- Measurement bias may result from faulty methods to measure study end points. These may include poorly calibrated machines or stretched measuring tapes, for example. Strictly speaking, the following examples of bias are all types of measurement bias.
- Prevarication bias relates to subjects purposely giving incorrect answers and may result from threatening or insensitive questions.
- Interviewer bias results from the incorrect interpretations by the interviewer of the responses made by the interviewee. This is often an unconscious process but may result if the interviewer expects, or would like, certain responses.
- Interpretation bias may result from questions that are not clear enough or that the subject does not understand. Some subjects may 'interpret' the question differently from others; for instance, does 'teeth' include 'dentures'?
- Recall bias may result when asking about events that happened a long time ago. For example, 'Were you ever vaccinated against tetanus?' Every effort to avoid historical questions should be made.

Confounding

This is not the same as bias. A confounding factor can be described as one that is associated with the exposure under study and independently affects the risk of developing the outcome but not in the causal pathway between the exposure and outcome.[4] Thus it may offer an alternative explanation for an association that is found and, as such, must be taken into account when collecting and analysing the study results.

Confounding may be a very important problem in all study designs. Confounding factors themselves affect the risk of disease, and, if they are unequally distributed between the groups of people being compared, a wrong conclusion about an association between a risk factor and a disease may be made. A lot of the effort put into designing non-experimental studies is in addressing potential bias and confounding. For example, in an often-cited case-control study on the relationship between coffee drinking and pancreatic cancer, the association between exposure and disease was found to be confounded by smoking. Smoking is a risk factor for pancreatic cancer; it is also known that coffee drinkers are more likely to smoke than non-coffee drinkers. These two points create a situation in which the proportion of smokers will be higher in those who drink coffee than in those who do not. The uneven distribution of smokers then creates the impression that coffee drinking is associated with an increased rate of pancreatic cancer, whereas it is smoking (related to those who drink coffee and to pancreatic cancer) that underlies the apparent association.

Common confounders

Common confounders that need to be considered in almost every study include age, gender, ethnicity and socioeconomic status. Age is associated with increased rates of many diseases. If the age distribution in the exposure groups differs (such as where the exposed group is older than the non-exposed group), then the exposed group will appear to be at increased risk for the disease. However, this relationship would be confounded by age. Age would be the factor that underlies the apparent, observed, association between the exposure and disease. Although age is a common confounder, it is the biological and perhaps social changes that occur with age that may be the true causes that increase the rate of disease.

There are several ways to control for the effect of confounding. To control for confounding during the design of the study, there are several possible alternatives:

- Randomization—random assignment into treatment groups, the cornerstone of a randomized controlled trial, randomly distributes potential confounding factors between the control and intervention groups.
- Restriction—restricting the participants to one level of a potentially confounding variable helps to control for confounding, for instance only enrolling patients aged 60 years or older.
- Matching—matching subjects on potential confounding variables ensures that these variables are evenly distributed between cases and controls, especially in case-control studies.

In the analysis phase of a study, one can use:

- Stratification—during the analysis phase of a study, the effect of potential confounders can be assessed within separate strata of the confounding variable.
- Statistical modelling—regression models offer the benefit of controlling for multiple confounders simultaneously.

Principles of clinical research statistics

Sample size

The sample must be sufficiently large to give adequate precision in the prevalence estimates obtained by the study for the purposes required. The most common mistake made by inexperienced researchers is to underestimate the sample size required. As a result, the sample size may be too small and not representative of the population that the sample is meant to represent. This usually leads to outcome measures that have very wide 95% confidence intervals, and hence statistically significant differences between study groups may not be found.

To ensure that a study has adequate sample sizes to show statistically significant differences, if they are there, sample sizes should be calculated prior to the study commencement. In reality, sample size is often determined by logistic and financial considerations (i.e. a trade-off between sample size and costs).

Study power

The power of a study is the chance of correctly identifying, as statistically significant, an effect that truly exists. If we increase the sample size, we increase the power. As a general rule, the closer the power of a study is to 1.0, the better. This means that the type II error will be small, that is there will be only a small chance of not finding a statistical difference when there really is one. Usually, a power of 0.8 or more is sufficient.

Statistical versus clinical significance

To determine statistical significance, we can obtain a *P*-value, relative risk or some other statistical parameter that is indicative of a difference between study groups. However, a statistical difference (e.g. $P < .05$) between groups may be found if the study is highly powered (many subjects), even though the absolute difference between the groups is very small and not a clinically significant (meaningful) difference.

This difference is important for two reasons. First, it forms the basis of sample size calculations. These calculations include consideration of what is thought to be a clinically significant difference between study groups. The resulting sample sizes adequately power the study to demonstrate a statistically and clinically significant difference between the study groups, if one exists. Second, when reviewing a research report, the absolute differences between the study groups should be compared. Whether or not these differences are statistically significant is of little importance if the difference is not clinically relevant. For example, a study might find an absolute difference in blood pressure between two groups of 3 mm Hg. This difference may be statistically significant but too small to be clinically relevant.

Databases and principles of data management

The fundamental objective of any research project is to collect information (data) to analyse statistically and, eventually, produce a result. Data can come in many forms (laboratory results, personal details) and are the raw material from which information is generated. Therefore how data are managed is an essential part of any research project.[3]

Defining data to be collected

Many a study has foundered because the wrong data were collected or important data were not collected. In general, data fall into the following groups:

- identification data: personal information needed to link to an individual patient
- research data: provides the information that is analysed to answer the study question (i.e. end points)
- administrative data: initials of the data collector, the study centre if a multicentred trial.

Collect only the research data that are essential to answer the study question. Collection of data that will not be of use is time consuming and expensive and may detract from the quality of the remaining data. However, there will usually be a minimum of data that must be collected. If these data are not collected, then the remaining data may not be analysed adequately. This relates particularly to data on confounding factors.

Database design

A database is a specific collection of data that is organized in a structured fashion. In other words, database software provides us with a way of organizing the data we collect from a research project in a systematic way.

Good database design will:

- reduce repetitiveness (e.g. entering in an address or age for a patient many times)
- include validation
- have data in a convenient form for analysis
- be pilot tested.

Data entry

This refers to the entry of data into the electronic database (e.g. Access, Excel). Even if the study design and the data collection have been well done, the final dataset may contain inaccurate data if the data-entry process is inadequate. This relates particularly to manually entered data, where mistakes are bound to happen.

Data entry can be achieved in many ways:

- Manual data entry—this may be single entry undertaken by one person. Alternatively, double entry involves two independent people entering the same data. Any differences between the two are reconciled. This is a form of double checking but is clearly more time consuming and, therefore, expensive.
- Direct data entry—this can be achieved by having database forms (proformas) on a computer screen. Direct entry of data via an internet webpage is one form of direct data entry. Alternatively, scannable forms can be fed into a scanner, avoiding the need for manual transcription.

Data validation

Effectively, this is a quality assurance process that confirms the accuracy of the data and can be done in the following ways:

- Visual review: matching data on questionnaires with medical records (source data)
- Value range checks: cholesterol levels should be greater than 0 and less than 20 mmol/L (i.e. do the numbers in the database make sense?)
- Field type checks: text should not be entered into numerical fields
- Logical checks (if, then): if classed as a non-smoker, then cigarettes per day should be zero.

Research ethics

Participation in a clinical trial may involve a sacrifice by the participant of some of the privileges of normal medical care for the benefit of other individuals with the same illness. The privileges forgone might include:

- the right to have treatment decided entirely on the basis of the treating doctor's judgement rather than by random allocation
- the right to have concomitant therapy according to requirements, rather than be standardized for all trial participants.

Participation may also require the discomfort and inconvenience associated with additional investigations and the potential incursion on privacy. Without the willingness of some individuals to make these sacrifices, progress in clinical medicine would be greatly impaired. Most individuals who now expect to receive safe and effective medical care are benefiting by the sacrifices previously made by other individuals.

Some have argued, in contrast, that enrolment into clinical trials ensures the absolute best care currently available, with greater involvement and scrutiny by attending health care teams.

If one accepts that clinical trials are morally appropriate, then the ethical challenge is to ensure a proper balance between the degree of individual sacrifice and the extent of the community benefit. However, it is a widely accepted community standard that no individual should be asked to undergo any significant degree of risk regardless of the community benefit involved (i.e. the balance of risks and benefits must be firmly biased towards an individual participant).

Because of the trade-offs required and because of the spectrum of views about the degree of personal sacrifice that might be justified by a given community benefit, it is accepted that all clinical trials should be reviewed by an ethics committee that should have as a minimum:

- sufficient technical expertise to quantify the risks and benefits involved
- adequate community representation so that any decisions are in keeping with community standards.

Scientific value

It is unethical to request individuals to undergo the risks and inconvenience of a study that is unlikely to provide a scientifically worthwhile result. It is also unethical to request sacrifices from volunteers that are out of keeping with the value of the research being undertaken. In keeping with this principle, studies that suffer from substantial design errors or are susceptible to serious bias should not be approved until these deficiencies are remedied.

It is unethical to allow scientifically invalid studies to proceed. Sample-size calculations should be scrutinized because of the ethical undesirability of including too few subjects to provide an answer or many more than is needed to provide a convincing answer. Another safeguard to ensure that the research will be valuable is that the investigator should be qualified, experienced and competent, with a good knowledge of the area of study and have adequate resources to ensure its completion.

Benefits forgone

It is unethical to require any patient to forgo proven effective treatment during the course of a trial. It follows that clinical trials should be undertaken only when each of the treatments being compared is equally likely to have the more favourable outcome.

However, very commonly, there is an expectation before a trial is commenced that one or other treatment is the more beneficial. This may be based on results of uncontrolled studies or even on biochemical or physiological expectations. The large number of times such expectations have been proven wrong can still provide strong justification for a trial.

If such an expectation of benefits is held strongly by an individual, it is probably not ethical for that individual to participate in a study. Furthermore, it is the responsibility of an ethics committee to assess the strength of the presumptive evidence facing one or other treatment and consider whether any substantial imbalance in likely outcome exists. This must be considered in relation to the importance of the question being addressed.

Informed consent

Participants in clinical trials have a fundamental right to be fully informed about the nature of a clinical trial and to be free to choose whether or not to take part. Ethical principles also dictate that prospective participants be:

- told they are taking part in a clinical trial and have an unambiguous right to decline to participate or to withdraw at any time
- provided with a full explanation about the discomforts and inconvenience associated with the study and a description of all risks that may reasonably be considered likely to influence the decision whether or not to participate.[3]

It is usual practice to provide prospective participants with a participant information and consent form that provides a simple, easy to understand account of the purposes and risks and benefits associated with participation in the study. Ethics committees are required to review these statements and confirm that they provide a reasonable account.

In practice, the procedures involved in obtaining informed consent are often problematic. Considering the dependence of sick patients on the health system, their anxiety and their desire to cooperate with their physicians, it is doubtful whether informed consent is ever freely given. When ethics committees identify situations where this scenario is likely to be a particular problem, the involvement of an independent uninvolved person to explain the study may be useful.

CONTROVERSIES AND FUTURE DIRECTIONS

- The issue of consent of patients requiring resuscitation raises serious ethical issues. In this circumstance, the patient is clearly unable to give consent and some argue that this automatically precludes their enrolment. Others disagree and note that such a position would terminate much research in this difficult area.
- In response to perceived difficulties in the passage of research through the ethical approval process, ethics committee streamlining is occurring in most jurisdictions and standardization of application forms now exists at the national level.
- Substantial clinical research requires skilled personnel, time, funding and a supportive infrastructure. Emergency medicine in Australasia has established a respected clinical practice. However, among its present challenges is the establishment of a culture of research with the resources to support and promote it.

27.2 Writing for publication

Anne-Maree Kelly

ESSENTIALS

1 **Check and follow the journal's suggested format and length. Pay particular attention to the abstract, text and references.**

2 **Make sure that the objectives, methods, results and conclusions are logically consistent.**

3 **Be clear and concise.**

Introduction

Sharing of research findings through publication is an important way of improving clinical practice. Publication may be by an original research manuscript, systematic or narrative review, brief report, case report or letter to the editor. Each of these has different requirements in terms of content, format and length, and these requirements may vary between journals. It is useful to choose the intended journal for publication early. Choose a journal that has the appropriate target audience for the subject matter of your paper. The impact factor should be a secondary consideration. It is important to check the *Instructions for Authors* to ensure that your submission matches that journal's requirements. Failure to do so reduces the chances of acceptance considerably.

Journals prefer clear and concise communications. In particular, it is important for the content to be arranged logically so that clear relationships can be seen between the objective, the results/evidence and any conclusions drawn.

Important principles

Authorship, acknowledgement and competing interests

There are defined requirements for qualification as an author. The International Committee of Medical Journal Editors state that authorship credit should be based on:

- substantial contributions to conception and design, acquisition of data or analysis and interpretation of data
- drafting the article or revising it critically for important intellectual content
- approval of the final manuscript.

All three conditions must be met. Contributions that do not meet these criteria can be recognized in an Acknowledgement. To avoid misunderstandings, authorship should be decided as early as possible in the research process.

Journals require authors to disclose competing interests. This is to assist readers in deciding if those interests have a potential bearing on the conduct or reporting of the research. Competing interests may be financial (e.g. external research funding, support from a company for activities potentially related to the project) or personal (authorship of guidelines, editorship of the journal of submission). Further information and a template for reporting can be found at http://www.icmje.org/conflicts-of-interest/.

Duplicate publication

Duplicate submission and duplicate publication are unacceptable. An exception is secondary publication of material with the express approval of both editors of the relevant journals. This only occurs under special circumstances.

Sometimes studies generate large amounts of data that are difficult or unsuitable for reporting as a single paper. Authors should strike a balance between including data about a large number of secondary outcomes in a single paper (potentially causing confusion about the research question and distracting from the main messages) and splitting data into a large number of small papers. In principle, separation of data into meaningful groups for separate papers is acceptable but should be acknowledged in the submission process.

Readability

To get your message across, it must be accessible to the reader. This is best achieved by avoiding long sentences, using simple words and avoiding jargon. Abbreviations should be kept to a minimum and always defined in the paper at their first use.

Publication types

In the 'traditional' model of publishing, journals require transfer of copyright from authors, and the journal's revenue is through fees charged to readers to access journal content, most commonly subscription fees or pay-per-article charges. Open access publishing, in contrast, typically allows for authors to retain copyright, and is combined with a license that enables free and immediate access to published content. Some open access journals and many hybrid journals (i.e. those with some open access content and some non-open access content) rely on publication charges paid by the author or funder to permit immediate and free access.

In recent years there has been a proliferation of on-line 'junk' or 'predatory' medical journals. These typically actively solicit manuscripts and charge a publication fee without providing robust peer review and editorial services (such as licensing, indexing and perpetual content preservation). These journals should be avoided. Further information and a journal checking tool are available at http://thinkchecksubmit.org/.

Manuscript preparation

Original research manuscripts

Original research manuscripts aim to answer a specific research question. Defining that question, indicating why it is important, what methods were used to answer it, key findings and their interpretation is the purpose of this type of paper. An original research manuscript is usually divided into five sections: Abstract, Introduction (or Background), Methods, Results and Discussion. In addition, some journals prefer a separate concise Conclusion and/or limitations section. It is very important to check the journal's preferred format and ensure that your manuscript complies. Most manuscripts also require a key word list of up to five words or phrases to assist with indexing. The EQUATOR network (http://www.equator-network.org/) provides checklists to guide reporting of research studies. Some journals require submission of the relevant checklist at the time the manuscript is submitted.

Abstract

This is a key part of the paper as it is the part that will appear in on-line indexing services. There is considerable variation between journals about how the abstract section is set out, but they all include sections describing objectives, methods, results and interpretation/conclusion. Some prefer a single paragraph without subheadings, but many require structured abstracts with specific subheadings. These are detailed under *Instructions for Authors*.

The abstract should contain all key data. In particular, the specific aims, methods, outcomes of interest, main results (with numbers) and conclusions should be clear enough to be understood without the support of the text. It is important that no data or conclusions appear in the abstract that have not been presented in the main body of the paper.

Introduction

Shorter introductions are often more effective. The aim is to convince the reader why the area of study is important, what this study adds to the body of knowledge and the specific aims of the study. A lengthy review of the literature should be avoided unless it is imperative to put the study in context. A concise review of the literature is more appropriately reported in the Discussion. The last paragraph should explicitly state the aims of the study.

Methods

The Methods sections should describe the study in a way that it is easily understood and potentially replicated. Some journals like this under subheadings, while others are happy for it to be rolled into logical paragraphs.

- *Study design:* what type of study is it?
- *Setting:* where was it conducted? Are there special features of this setting?
- *Selection of patients:* what are the inclusion and exclusion criteria? How were patients identified? What was done to ensure that no patients were missed?
- *Data collected:* this should describe all the data collected.
- *Outcomes measures:* what was the primary outcome of interest? Were secondary outcomes also collected?
- *Sample size:* how was the number of subjects chosen? A power calculation is often helpful to justify the numbers.
- *Data analysis:* what types of analyses were used?
- *Ethics approval:* there should be a statement confirming that the study was approved by an appropriate research ethics review process.
- *Clinical trials registry registration:* many journals now require that prospective clinical studies are registered in a public trials register (e.g. www.anzctr.org.au, www.cct.cuhk.edu.hk, www.clinicaltrials.gov). The trial's registration number should be included in *Methods*.

Results

It is important for the results to be presented logically and for the relationships with the objectives and methods to be obvious. A useful structure is to start by describing the study population. This should include how it was derived (a summary figure may be helpful) and its demographic features.

This should be followed by descriptions of the results with respect to stated outcomes of interest: primary outcomes first then secondary outcomes. These should align with the stated objectives. Any subgroup or other analysis should follow this. All results should give the appropriate statistics with confidence intervals (if appropriate) and the type of test used. Avoid any comments on what the results might mean or why they might have occurred. Interpretation of the results belongs in the Discussion section.

Tables and figures can be very effective ways of communicating results. They should not repeat what can be described adequately in the text. All tables and figures should be self-explanatory, with clear descriptive headings. Tables should be constructed so that the main comparisons of interest are horizontal and left to right, with number of subjects clearly shown for each column. Graphs or figures should be used to convey patterns and details that cannot be succinctly conveyed in tables or text. Figures that show the distribution of data (scatterplots, box plots, etc.) are more effective than those simply summarizing data (bar graphs, pie charts, etc.). Axes must be clearly labelled. Tables and figures should be kept to the minimum number needed to convey the information, and should be numbered in the convention of the journal.

Discussion

The Discussion should be concise and to the point. This structure may assist:

- Summarize the principal findings.
- Comment on how it compares with other research. Where does it agree? Disagree?
- Taken together with the other available evidence, comment on possible explanations and implications, avoiding the temptation to overstate the significance of the findings.
- Discuss any other results that are worthy of comment.
- Describe any unanswered questions or directions for future research.
- Describe the limitations of the study. This is important as it is an opportunity to acknowledge limitations, and give the rationale for some of these. A good limitations section adds to the quality of the paper rather than detracting from it.
- Give a summary or conclusion. This should be a few sentences only, offer conclusions directly drawn from the results of the study and be consistent with the Conclusion given in the Abstract. Avoid overstating the findings. Some journals prefer this as a separate heading.

All statements throughout the Introduction, Methods and Discussion that make an assertion or refer to other evidence or methods must be referenced. Ensure that referencing is in the journal's preferred style.

In general, as long as the key elements are included, shorter is better than longer in manuscripts. If in doubt, shorten the Introduction and Discussion rather than the Methods or Results. As Stephen Lock, former Editor of the *British Medical Journal* states: 'A good paper has a definite structure, makes its point and then shuts up'.

An alternative to the full original research manuscript is the short report. This form has a word limit of 1000 to 1500 words and usually has some minor formatting differences. However, it is indexed the same as a full original research manuscript.

Case reports

Fewer journals are accepting case reports. Those accepted for publication tend to have an exceptional element or important clinical message, either in terms of an unusual diagnosis, an innovative use of tests or treatments, or an unusual adverse event. It is not enough for a case to simply be 'interesting'.

The usual structure for a case report is an abstract of about 100 to 150 words summarizing the case and the clinical messages, the case report itself and a discussion. The case should be described in sufficient detail for the reader to be confident of the evidence. The Discussion is the key element of a case report. It usually includes a concise review of the literature and uses the case to draw out important clinical messages.

Systematic reviews and meta-analyses

A systematic review is a summary of primary studies. It aims to answer a clinical or research question by using strategies that limit bias, and that critically appraise and synthesize relevant studies on a selected topic. A meta-analysis is a mathematical synthesis of the results of primary studies addressing the same question in a similar way.

A detailed description of the methods for systematic reviews and meta-analyses is beyond the scope of this chapter. That said, they share several aspects with original research including definition of a research question, development of a research protocol, literature search/review, data analysis and interpretation.

The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; www.prisma-statement.org) checklist is an evidence-based minimum set of items aimed at assisting authors improve the quality of systematic reviews and meta-analyses. Authors are being increasingly encouraged to register the protocol for systematic reviews in registries such as Prospero (https://www.crd.york.ac.uk/prospero/).

Letter to the editor

These are short communications, usually 500 to 800 words in length. Most often they comment on a recently published paper in the journal concerned, but they may also report a pilot study, a case or case series, make an observation or express an opinion.

Manuscript submission

Almost all journals require online submission of manuscripts. The sites vary in the way they want material entered, so it is important to check this. A manuscript must only be under consideration by one journal at a time.

The cover letter

Most journals require a cover letter, and its content is specified in *Instructions for Authors*. It is often quite short and includes a request for consideration for publication in the journal concerned, a statement that the paper has not been published and is not under consideration by another journal, a statement regarding ethics approvals and a note of the presence or absence of author conflicts of interest.

The cover letter is also an opportunity to alert the editor to other issues that may be important. For example, if the manuscript overlaps with previously published work or another manuscript such that there might be a possibility of duplicate publication, it allows the editors to assess any overlap for themselves.

Feedback from journals

It is quite rare for manuscripts to be accepted 'as is'. Usually, some revision is required and, in some cases, manuscripts are rejected. Neither of these necessarily implies that the study is not worth publication. It may simply be that the editors consider that their journal is not appropriate for the subject matter of the paper. Seriously consider the comments given, which are often detailed, and decide whether the issues can be addressed. If so, it is important to undertake a revision and re-submit as soon as practical. If the journal requested revisions and the concerns can be addressed, re-submit to that journal, otherwise submit to another journal after notifying the initial journal that the paper will not be re-submitted. Reformatting as a short report or letter to the editor are sometimes alternative ways to get your findings published.

Post-acceptance issues

These include completion of assignment of copyright forms and checking the proofs of the paper. The publisher will usually manage these processes.

Social media

The rise of social media has also had impacts on medical research, researchers and journals. One example is the increasing use of alternative means of quantifying journals' impact, notably using the Altmetric statistic, which conglomerates an article's social media presence through blogs, news outlets, Facebook and Twitter. While a detailed discussion of the use of social media with respect to research publications is outside the scope of this chapter, evidence suggests that Twitter is a potentially powerful way of promoting and disseminating research findings.

27.3 Principles of medical education

Debbie Paltridge

ESSENTIALS

1 **The emergency department (ED) provides a rich learning environment despite the constraints of service provision and time pressure.**

2 **Understanding individual learners by exploring their prior experience and learning goals, then tailoring teaching to address these goals will maximize learning in the ED.**

3 **Setting clear learning objectives at the beginning and summarizing the learning experience at its conclusion enhances any form of teaching.**

4 **A learner-centred approach allows the learner to determine learning objectives, actively engage in learning opportunities and participate in evaluation.**

5 **Characteristics of a 'good' ED teacher include providing a role model, tailoring teaching to the learner and situation, involving the learner in problem-solving, actively seeking opportunities to teach and giving timely feedback.**

Introduction

George Bernard Shaw famously quipped, 'He who can, does. He who cannot, teaches'. However, the emergency physician can rarely teach without doing. The tradition for doctors to teach their colleagues and students goes back to the Hippocratic Oath, where the duties of a doctor to students are outlined: '… to teach them this art, if they want to learn it, without fee or indenture'.[1]

Emergency physicians have been taking an increasing role in teaching and education, in part because of the need for all doctors to learn and refresh emergency skills, but also because emergency physicians are usually full-time and hospital-based and have access to students, patients and teaching resources. In addition, they have a unique opportunity of seeing students progress in their chosen specialty and may have multiple inputs vertically over several years in a younger doctor's career. This can be very satisfying and also very motivating.

The emergency environment is one of constant new learning experiences while, at the same time, being the location for patient care and critical decision making. Barriers to teaching in hospitals in general, but applicable to emergency departments (ED), have been summarized by Lake in her 'Teaching on the Run' series as lack of time, lack of knowledge, lack of training in teaching, criticism of teaching when given and lack of rewards, either materially or by recognition.[1]

In addition, teaching in the pressure cooker environment of an ED gives further layers of difficulty, both logistically and ethically. Challenges include:

- Patient acuity
- Shifts, requiring teaching at all hours of the day and night
- Junior medical staff from a variety of specialties and backgrounds with varying needs
- Numbers of junior medical staff and rostering affecting continuity for teacher and learner
- Huge variation in workloads from shift to shift
- Administration pressures to reduce waiting times and time-based access targets
- Physical restraints in many ED environments caused by overcrowding[2–4]

The ED is a teaching environment, not only for physicians at various levels, but also for nurses, allied health workers, paramedics and others. A significant component of ED teaching is procedural. It is suggested that most patients believe they should be informed if it is the first time a doctor is performing a procedure on them, but less than half of patients feel comfortable about themselves being the first patient ever for suturing (49%), intubation (29%) or lumbar puncture (15%) for a resident.[5] For non-procedural medicine, the evidence is that most patients enjoy being part of the teaching process, in outpatient and ambulatory settings at least, and that no extra negative effects on patients occur from teaching.[6,7]

An added component of complexity in teaching in the ED is the potential for slowing patient processing by having to stop and supervise a junior. It is often so much quicker just to do it yourself. Supervising a lumbar puncture, for example, may take both the teacher and the taught away from seeing new patients for half an hour. However, as far as it has been researched, teaching in academic EDs does not appear to slow down patient care but in fact improves quality of care.[8,9] Doctors who are seen by their juniors as good teachers are just as likely to see as many patients per shift as those who are not.[10]

All emergency physicians are teachers at some stage in their career at various levels and, as in Hippocrates' time, are mostly unpaid for it. Although most doctors become teachers, the majority of pre-vocational doctors in Australia have had no exposure to learning how to teach.[11] Here we present the principles of teaching and learning to assist emergency physicians, whether they are involved in teaching medical students, residents, registrars or other health professionals.

Adult learning principles

Contemporary medical education needs to be couched in terms of contemporary education theory. Adult learning principles should underpin educational practice from the bedside, through the clinical skills laboratory to the seminar room. In addition, these principles are relevant to the education of the undergraduate, prevocational (first 2 to 3 years' postgraduate) and vocational registrar years, as well as the continuing professional development of the mature medical practitioner.

Malcolm Knowles first introduced the notion of andragogy or adult learning in the early 1970s.[12] He described five assumptions regarding how adults learn:

- As mature people they move from being dependent to being self-directing. This transition allows them to determine their own learning needs.
- Adults bring a wide range of experiences accumulated over their lifetime to the learning situation. These experiences provide both a context and a resource for new learning.

- Adults' readiness to learn (or motivation) is linked to the applicability of the learning to their current life/employment.
- Adults are more problem-centred—that is, they want learning relating to a problem they may encounter in everyday life.
- Adults are motivated to learn by internal factors, such as desire to succeed, personal goals and so on, as compared with external factors, such as rewards.

Knowles and other authors have since developed principles of adult learning that can be used to guide education activities[13–17]:

- An effective educational climate is one that allows learners to feel safe. They should be encouraged to express themselves without fear of judgement.
- Establishment of learning needs requires learner participation so that their intrinsic motivation to learn is engaged. The process of developing learning needs helps to assist learners' self-reflection and establish relevancy for them.
- Once a need has been identified, learners should be involved in determining specific learning objectives for the educational intervention.
- Designing the educational intervention should be collaborative, ensuring communication between the learner and teacher/facilitator. This will ensure that the methodology chosen will be relevant to the learner's needs.
- Learners should be encouraged to identify appropriate resources to assist their achievement of learning objectives. This will ensure that activities are learner-centred and self-directed as required by adult learners.
- Facilitators should assist learners to implement their learning plans so that objectives are achieved.
- Learners should be involved in evaluating their learning.

However, these principles of adult learning are irrelevant to the emergency physician educator unless they are actively applied to the education of their postgraduate charges. The question remains of how these principles are put into practice. Table 27.3.1 outlines some examples of how these principles may be incorporated into education within the ED.

Table 27.3.1 Application of adult learning principles and assumptions in the emergency department environment

Adult learners	*Application to ED teaching*
Have prior learning and experience	Even the most junior doctors (e.g. interns) bring experiences with them to the ED. They may have specific experience relevant to the condition that they are treating (e.g. they saw similar patients in their undergraduate course) or it may be life experience (e.g. they had relatives with that experience). Open questioning techniques (requiring a more detailed answer from the learner as opposed to a closed question requiring a yes/no answer) can be used to promote reflection on past experiences and practices. A case study with short answer questions to facilitate this reflection could be used in a small group tutorial situation. Small group discussions can also provide opportunities for learners to draw on their own experiences and to learn from each other as well as the facilitator.
Are self-directed learners	Orientation at the commencement of a rotation in the ED, should include the identification of personal learning goals, establishment of. This is expectations of both learner and facilitator and ground rules for how education will be carried out within the ED rotation. Learners should also be offered a choice of learning activities. This will allow learners to choose activities which will address their individual learning objectives and which will address their specific learning requirements and styles. For example, one intern may want to watch a lumbar puncture before performing one under supervision, another may want to practise a lumbar puncture on a manikin first before performing one.
Learn most effectively when they perceive a need for learning	The ED educator needs to help learners recognize the relevance of a learning experience. This will significantly impact on their motivation to learn. Sharing of experiences (e.g. a case example from real life) can help establish relevancy for a learner. Additional methods may include documentation of ED presentations, participation in unit audit meetings or presentations of cases.
Prefer problem-centred approaches	ED presentations require sophisticated problem-solving techniques. The undifferentiated patient is the norm. Modelling of clinical reasoning from experienced practitioners can assist the novice to understand problem-solving approaches. Evidence suggests that the experienced practitioner does this subconsciously, however, verbalization is necessary to promote collaborative problem solving by the less experienced. Unit case-based discussions also encourage shared problem solving.
Practise self-evaluation	• Adults require an opportunity for 'reflection-on-action'[a] or self-evaluation. Self-evaluation opportunities can be incorporated formally by: use of case studies in a tutorial setting • end of shift review of cases • trolley-side reflection opportunities using open questions
Require feedback	Opportunities for feedback on performance should be incorporated into the ED term both formally (as part of a requirement of training, e.g. mid- and end of term feedback) and informally from supervisors or peers. Written and verbal feedback can be used.
Value experiential ('hands on') learning opportunities	There are numerous opportunities for hands on experience within the ED. Educators need to involve learners in case-based discussions and problem-solving activities. However, procedural skills may need to be practised away from patients until competence is determined. Then practice under supervision will be appropriate.

ED, Emergency department.

Learner-centred education

Many traditional medical education experiences are teacher centred. The teacher is the expert and determines what, how, when and where much is learnt. The teacher is the active participant and the learner is the passive recipient.[18] However, a more effective approach to education is the learner-centred approach. Learner-centred education refers to educational events that place the learner in the pivotal position, responsible for determining learning objectives, actively engaging in learning opportunities and participating in evaluation.[19] This is more in line with adult learning principles. Learner-centred education does not disregard the expertise of the teacher but rather directs the use of that expertise to learning that is relevant to the individual learner.

So how does the ED physician become a learner-centred educationalist? The following suggestions are provided to assist:

- Orientation—to the unit, to the department, to the rotation. Junior medical staff require an orientation for a number of practical workplace reasons, such as awareness of policies and procedures, occupational health and safety, rostering, pay and so on. However, this is an important opportunity from an educational perspective. The orientation can allow exploration of the junior doctor's learning goals and objectives, past experiences, confidence with procedural tasks, and expectations of their ED rotation. The orientation allows the educational supervisor the opportunity to establish their expectations and ground rules in terms of educational

interactions, when feedback will be given and how education with patients will occur. The ED supervisor can acknowledge barriers to learning which are more specific to the ED environment and discuss how these will be overcome.
- Ask the resident to select a patient to present rather than dictating which patient or topic will be discussed.
- Ask residents about past experiences to assist in determining their confidence in managing certain conditions independently. Obviously, supervision will be required until this is determined firsthand, but demonstrating insertion of an intravenous (IV) cannula to an intern who has previously inserted numerous IVs may not be the most appropriate use of your time, and you will not know unless you ask!
- Present junior medical staff with suggested topics for in-service education and ask them to prioritize.
- Ask junior medical staff to present a case to their peers. Let them determine the format they want to use and resources they require. Junior medical staff are not a homogeneous group. They differ in how they learn, what they need to learn and why they want to learn. By involving learners in the planning, implementation and evaluation of their learning experiences, both relevance and motivation to learn will be facilitated.

What makes a good emergency department teacher?

The challenges facing the emergency physician educator, including environmental constraints, patient characteristics, administrative imperatives and resource availability, cannot be overstated. However, despite this, there is a consistent commitment to education by emergency physicians. What then makes a good ED teacher? Bandiera and colleagues used a qualitative research design to investigate experienced ED teachers and establish the behaviours that made them good teachers.[2]

Twelve strategies were identified:
- Tailor teaching to the learner—Taking time to get to know the learner was seen to increase the efficacy of the teaching and learning interaction.
- Optimize the teacher–learner interaction—This refers to making the teaching more directed and efficient by listening to the learner and using what you know about them.
- Tailor teaching to the situation—This relies on being adaptable to the situation and changing strategies accordingly, for example by adjusting teaching amounts, types and timing to the time of day, workload and case mix.
- Actively involve the learner—Involve the junior doctor in problem solving; give them responsibility and some autonomy appropriate to their skill level.
- Actively seek opportunities to teach—Sometimes it is necessary to seek out learners. The junior doctor may be busy with an administrative task when an interesting teaching case arrives. The teacher needs to recognize the potential for learning and bring this to the junior doctor's attention.
- Agree on expectations—This can be done at the orientation, when learning objectives and ground rules for interactions are established.
- Demonstrate a good teacher attitude—This is about being an approachable supervisor/teacher. The teacher's affect influences the learner's willingness to engage in the learning activity, such as the teacher's positive approach to the learner, enthusiasm for teaching and openness to questioning.[20]
- Make additional teaching resources—This may involve collecting sample cardiographs, x-rays or blood gases for a resource file. It may be writing up some interesting case-generated problems for future review or development of evidence-based clinical guidelines.
- Use teaching methods beyond patient care—With the advent of interest in clinical skills training and simulation, there are opportunities to take the teaching away from the bedside on occasion. Use of standardized patients and role-plays may also be appropriate for practising some skills, such as communication and teamwork.
- Be a role model—This is about demonstrating and practising the principles that you are trying to teach. Don't underestimate the importance of role modelling appropriate professional behaviours. Junior doctor learning needs encompass aspects of professionalism that can be actively learnt through positive role models.
- Provide and encourage feedback—Adult learners require feedback for motivation and for learning.
- Improve the environment—The competing demands within an ED environment make this difficult, but the effective teacher identifies ways in which to enhance the learning environment (e.g. by creating space and time in a crowded ED) and providing feedback away from others.

These findings are supported further in the literature with what learners want. Additional suggestions include:
- Using teachable moments well
- Taking the time to teach
- Challenging the learner
- Treating the junior doctor as a colleague[4,21]

The factors reported by ED teachers and ED learners reflect what is required according to adult learning theory and reinforce the applicability within the ED environment. A commitment to evaluating the effectiveness of the instruction (e.g. by asking the learner) will also serve to enhance future teaching moments.

Types of teaching in the emergency department

There are a number of teaching and learning strategies available for use within the ED environment. These can include spot electronic searches on active clinical problems, formal quarantined tutorials, case discussions, demonstrations of procedures or techniques, audit meetings, self-directed learning opportunities, such as reading medical literature, online learning programmes and so on. This section deals with three strategies: 'trolley-side' teaching, teaching procedural skills which most ED physicians are familiar with and perform regularly, and simulation, which is developing an emergent role within teaching and learning in the ED.

'Trolley-side' teaching

Interactions with patients at the bedside are a crucial component for learning in medicine, the traditional apprenticeship model relying on this methodology. Bedside teaching can provide an opportunity for the experienced clinician to explain clinical reasoning, role model appropriate communication (e.g. listening, patient questioning and respect), directly observe and assess junior clinicians as they interact with patients, and provide feedback to them.[22,23] However, with the numerous environmental constraints within the ED, there is a need to look at bedside teaching and determine how best to conduct this activity. In addition, the care of the patient remains paramount, and ensuring that this is maintained and that the junior doctor–patient relationship is not undermined is an additional challenge.

The benefits of orientation have previously been mentioned in terms of adult learning principles and learner-centred instruction. However, they are crucial to establishing the expectations from both the learner and the teacher's perspectives in regard to bedside teaching. Establishing up-front how bedside teaching will be conducted, while remaining patient-centred, will enable the learner's needs to be met. Briefing the patients beforehand and getting them involved in the teaching process enhances patient comfort and participation and may provide enjoyment. Expectations of patient-based teaching may include:

- Number of bedside teaching opportunities per shift. The supervisor may want to ensure one bedside teaching interaction per shift, identified by either the supervisor or the learner. Alternatively, the supervisor may prefer to be less prescriptive and more opportunistic, identifying bedside opportunities as they arrive, accepting that some shifts may have none and others numerous.
- Type of bedside teaching. This involves discussing the types of teaching and learning the supervisor is prepared to undertake (e.g. a procedural skill or history taking or interaction with relatives).
- What will happen by the trolley-side? It is important to discuss what will and won't happen by the trolley-side. For example, the history and physical examination will be done at the bedside, but discussion of clinical reasoning may occur away from the patient. This is important to consider, especially if the junior doctor is to have an ongoing professional relationship with the patient. Feedback as to the resident's performance should also be conducted away from the patient.
- Outline specific teaching approaches. There are a number of models of bedside teaching that can be used.[24] Lake and Ryan[25] describe the use of set, dialogue and closure. This technique involves an introduction, outlining the objectives of the session (set), a discussion in which questioning techniques are used to elicit information from the learner and to discuss reasoning/rationales (dialogue) and a summation in which the main learning points are discussed and further learning required (closure). An alternative to this is the SNAPPS model described by Wolpaw et al.[26] in which the learner:
  - summarizes the case history and their findings
  - narrows the differential diagnosis usually to two or three possibilities
  - analyses the different diagnoses by comparing and contrasting them
  - probes the supervisor/teacher for opinions or any information on which they require clarification
  - plans the patient's management
  - selects an issue for self-directed learning later on

Procedural skill teaching

Management of patients in the ED often involves the practitioner performing procedural skills, some to assist in formulating diagnoses in the undifferentiated patient (e.g. performance of bedside ultrasound) and others for treatment of patient conditions (e.g. application of a plaster to a fracture). Ideally, in this day and age, procedural skills should be practised in a clinical skills setting prior to implementation on a 'real' patient.[27] However, observation by a junior doctor of an experienced clinician performing a task is also valuable and can sometimes be overlooked in the busy ED department. Sometimes it is done before you realize you could have shown a junior doctor.

The educational theories relevant to teaching clinical skills are drawn from psychomotor theories. There are seven basic principles of the psychomotor domain,[28] including:

- Conceptualization—where the learner needs to understand the background knowledge element of the skill (i.e. the cognitive components); this involves a knowledge of why the skill should be done, when to do it, precautions and contraindications, and so on
- Visualization—where the learner needs to see the skill demonstrated to get a clear picture of what the skill looks like in real time and as a whole '*in toto*'
- Verbalization—where the learner needs to hear the steps of the skill verbalized
- Practice—where the learner gets the chance to practise the skill
- Correction and reinforcement—where feedback is given to reinforce performance
- Skill mastery—where the learner can perform the skill independently in the learning environment
- Skill autonomy—where the learner can perform the skill independently in a variety of real life situations

Similarly, Gagne[29] describes three phases in instructional design relevant to teaching a technical skill, including a cognitive phase where the learner is developing cues from the facilitator, an associative phase where the learner is integrating the component parts and an autonomous phase where the skill has become automatic for the learner.

The issue of the relationship of the learner to the experienced clinician is further investigated within the cognitive apprenticeship model.[30,31] The emphasis in this model is on the requirement that the thinking of the expert be made visible and brought to the surface for the learner. Underpinning this model is the ability of the teacher to assess/recognize the skill level of the learner.

Another debate in the literature is around the issue of whole skill training versus part skill training. Evidence would suggest that the part skill training method be used for the more complex skills while whole skill training be used for the relatively straightforward skills. This requires the facilitator to analyse the skills to be taught and determine the level of complexity of that specific skill. In addition, what is the whole skill? It can be argued that procedural skills do not occur in isolation. Rather, communication skills are required along with the technical expertise and should be taught together rather than in isolation to reflect the requirement in reality.[32,33]

So what do these theories mean for the ED physician wanting to assist a learner in developing a procedural skill? The important requirements are:

- background knowledge is required—why, what, how?
- demonstration by, or observation of an experienced clinician is an important component of learning a psychomotor skill
- verbalization of steps—this requires breaking the skill down into steps by the teacher and then the learner
- feedback on performance by the expert
- opportunities for repeated practice under supervision (deliberate practice—tailored to the individual learner[34]), to allow for feedback and self-reflection
- teaching the skill in context not in isolation.

A dedicated skills area within the ED is most beneficial, as this can be used in quarantined or quieter times for supervised or independent practice (once the learner is deemed relatively competent in the skill, to avoid practising incorrect technique). Highlighting the need for practice and observation to all the experienced clinicians assists in identifying these opportunities for the learner within the ED environment.

Simulation

Simulation is well-established teaching methodology. In its broadest sense, it refers to any situation in which the real situation is emulated. It may involve actors playing the role of patients, who are often described as standardized patients, part task trainers for teaching procedural skills or manikins with computer-generated physiological responses.[35,36]

The underpinning educational theory behind simulation comes from a number of theories, including adult learning. However, experiential learning theory is probably of most relevance. Kolb[37] describes experiential learning activities as opportunities for learners to acquire and apply knowledge, skills and attitudes in an immediate and relevant setting. A four-point continuous learning cycle is described:

- Concrete experience
- Observation and reflection
- Forming abstract concepts
- Testing in new situations

Simulation in health care education is clearly an example of experiential learning. It provides the learners with a relevant and realistic patient problem to manage. Following this experience, the learners are able to observe their performance and reflect, while exploring with

a facilitator hypotheses and new concepts. They can then test this experience by repeat simulations.

There are a number of ways in which ED physicians can incorporate simulation opportunities into their teaching in ED. It may be that paper-based simulations are used to explore clinical reasoning. This involves developing case scenarios and structured questions. Role-playing, using peers or expert clinicians, can be used to practise difficult communication skills, such as breaking bad news. Simple part-task trainers can be incorporated into a more complex scenario involving the practice of the skill while interacting with a patient. Kneebone and colleagues[33] describe integrating a urinary catheter manikin with an actor to ensure that the technical and communication skills are taught concurrently.

Where higher level manikins are available, whole patient scenarios can be conducted. Teams of junior medical staff can practise rarer critical situations and explore not only technical skills but non-technical skills, such as teamwork. Use of audio-visual aids to capture performance is important for providing feedback after such activities. It also allows an opportunity for reflection and peer feedback.

Not all EDs have the luxury of the highly technical simulation 'gadgetry', but this should not put them off using simulation as a teaching methodology. Determining the content areas appropriate for using simulation and how this fits into the overall curriculum will be important to ensure that resources are used rationally.[38]

Feedback to learners

Feedback is a crucial requirement for learning, and the importance of positive feedback for learning has been well established.[39] Feedback should provide the learner with information that offers 'insight into what he or she did as well as the consequences of his or her actions'.[40] It should allow the learner to know what went well and what could be improved or changed next time. Feedback is part of the formative assessment process that occurs throughout the learning period, rather than as a summative assessment that is to determine a grade or make a final judgment.

Effective feedback has a number of characteristics.[41,42] Feedback should:

- be given in a suitable environment to allow privacy and confidentiality
- be given at a suitable time (e.g. as soon as possible after the performance, when there is adequate time for the learner and teacher to explore the performance, not directly after a critical incident when emotions may be high)
- be directly related to the pre-agreed learning goals
- come from direct observation of the learner

Providing learners with feedback is a specific skill in itself and requires practice to develop. A structured approach to giving feedback will assist the teacher/facilitator to provide effective and useful feedback. There are many models of feedback in the literature; however, one such model from Pendleton's[43] work is suggested here to assist the ED physician:

- Ask the learner how he or she felt.
- Ask the learner what went well and why.
- Ask the facilitator/teacher to say what went well and why.
- Ask the learner what could have been done better and why.
- Ask the facilitator/teacher to say what could have been done better and why.
- Ask the facilitator/teacher to summarize the strengths and up to three things to concentrate on.

Feedback, when delivered effectively, is a strong motivator to the adult learner and encourages ongoing performance review and reflection by the learner.

Conclusion

Juggling the demands of a being a busy emergency physician requires balancing clinical, administrative and teaching duties. Time is often limited and yet the rewards of being involved in teaching are obvious. Apart from personal satisfaction gained from interacting with junior colleagues, the ability to keep up to date and the opportunity to reflect on one's own performance are enhanced. Reviewing performance as a teacher and practising education techniques to improve the effectiveness of the facilitation motivate the teacher to continue to teach and improve the satisfaction from teaching. Structuring learning experiences, considering learner needs and providing effective feedback are essential for learners in the ED environment.

Likely developments over the next 5 to 10 years

- Increasing numbers of medical students and junior medical staff seeking learning in the ED may lead to the need for specific emergency physician educators to orientate and supervise them in the ED.
- Expansion of scenario-based simulation and skills centres may lead to more opportunities for ED team-based interdisciplinary education.
- Increasing patient participation in decision making will necessitate more detailed consent when procedures are performed by the inexperienced.

CONTROVERSIES

- Teaching procedural skills should no longer be 'see one, do one, teach one' on surprised patients, although some find it difficult to break out of this mould.
- What is the best way to teach clinical skills and ensure a patient centred approach?
- Should patients be informed of the level of experience of those providing care or performing a procedure?

27.4 Teaching medical students emergency medicine

Geoffrey A. Couser

ESSENTIALS

1 **Emergency medicine as an academic discipline has achieved maturity, with medical student teaching a core business of every emergency department in the country, with structured terms in emergency medicine now considered an essential part of any medical curriculum.**

2 **The specialty of emergency medicine has a unique and practical body of knowledge that can contribute much to the entire medical curriculum and it is essential that all emergency physicians 'own' and effectively teach this knowledge to students.**

3 **To become a truly effective discipline, emergency physicians need to adopt a strategic and comprehensive approach to curriculum development, delivery and assessment throughout all years of the medical course.**

4 **It is essential that goals and objectives of academic terms in emergency medicine be developed, clearly defined and then articulated to all clinical staff so that a consistent and integrated curriculum is delivered.**

5 **Emergency physicians are ideally placed to be able to introduce new and emerging topics in health care, and to embrace innovative teaching and assessment methods.**

Introduction

Emergency medicine now plays a central role in medical curricula in undergraduate and postgraduate medical schools in Australia and New Zealand. This is expected, as the principles and practice of the specialty have much in common with the desired features of contemporary medical education: it is problem focused, interdisciplinary and integrates many aspects of community-based and hospital-based clinical practice. The clinical practice of emergency medicine integrates and builds upon the foundation biomedical sciences. Much growth in academic emergency medicine has occurred in the last two decades, with the establishment of academic departments and salaried university positions. Nevertheless, the majority of medical student teaching is performed 'pro-bono' by clinical emergency physicians employed by public and an increasing number of private emergency departments. Put simply, emergency medicine has become a key part of academia, and academia has become a key part of emergency medicine.

Regardless of institutional affiliation or employment, it is essential for emergency physicians committed to teaching medical students to be aware of recent trends and developments in medical education. Medical education as a discipline is vast, and it is not the purpose of this chapter to delve into the many intricacies and emerging themes of medical education as a whole. As an example, in 2010 the US-based Carnegie Foundation (which published the landmark Flexner Report in 1910) published a comprehensive review of contemporary physician education and identified the need for reform in medical education.[1] The authors called for greater alignment between educational institutions and the workforce, and the requirement for medical schools to produce graduates more responsive to society's health care needs in the 21st century. These reforms are necessary and timely, and while emergency medicine does not specifically feature in the report, most emergency physicians would see a significant role for the specialty in delivering them. In Australia, some curriculum reform has occurred in parallel with significant changes in the health system. The shift to the home and community management of many conditions has altered the 'traditional' patient mix and numbers available for student teaching. At the same time, there has been an increasing number of medical students and medical schools, with 3853 domestic and international students commencing medical training in Australia in 2017.[2] It is in this changing environment that emergency medicine, with 7.8 million patients presenting to 287 public emergency departments in the 12 months of 2016 to 2017,[3] has established itself as a both a desirable and necessary part of the modern medical curriculum, and the specialty is poised to play an even greater role in the training of future doctors. Both the need and the opportunity exist for such expansion.

The importance of medical student teaching

Many departmental directors and clinicians feel that the provision of clinical care is the core business of an emergency department and hence may not be willing to allocate increasingly stretched resources and time for teaching students. Similarly, the 'old school' leadership teams at medical schools may not be aware of the growth of emergency medicine as a specialty and hence not aware of what it can offer students or, indeed, may not even be aware that emergency medicine is an independent specialty with its own unique body of knowledge. However, once established, a strong academic presence can contribute to departmental morale, recruitment and retention of staff, quality of care, performance, and the standing of the department within the hospital and community. For students, a positive exposure to a specialty in medical school has been shown to influence career choice and attitudes towards specialties.[4] Box 27.4.1 lists the benefits of emergency medicine teaching to students, emergency departments (EDs) and medical schools. These points may be used to argue for an increased presence and accompanying resources within a department, hospital or university curriculum. Resources and a formal place in the curriculum often come only after years of hard work in establishing the bona fides of emergency medicine. This may require much time and effort from a dedicated individual before sustainable resources will be allocated to emergency medicine as a discipline.

Curriculum and discipline development

Undergraduate emergency medicine in the past was ad hoc, unstructured and highly selective, in that clinical exposure was based around what the students themselves thought was interesting and useful in the department at the time. With the growth of the specialty as an academic discipline, departments have been able to take a more active role in education, control student entry to the department, ensure appropriate orientation, and harness the rich, broad and clinically relevant experiences on offer. As faculties have become

Box 27.4.1 Benefits of medical student teaching in emergency departments

Benefits to students

- An enjoyable term with unparalleled pathology and 'real life' clinical experience
- Integrates theoretical knowledge with the workplace—skills of diagnosis and management can be tested and applied in a safe real-life environment
- Learns acute care resuscitation and other practical skills
- Non-technical skills can be taught and practiced
- Communication with fellow health professionals can be practiced and refined prior to starting work as a junior doctor
- Demonstrates an equitable and accessible health care system

Benefits to the emergency department and hospital

- Students gain a positive view of the specialty and this may influence subsequent career choice
- May improve subsequent intern performance
- Improves the overall professionalism and reputation of the department
- Assists with recruitment and retention of staff with an interest in teaching
- Students can assist with procedures and may improve patient flow in some circumstances if recognized and utilized as junior members of the team

Benefits to the medical school

- Allows access to a large number of patients with a broad range of clinical conditions otherwise not available for teaching
- Allows access to a large pool of medical and nursing staff otherwise not available for teaching
- Emergency medicine can teach knowledge and skills not readily taught by other disciplines, such as resuscitation, non-technical skills, health systems and time management

aware of the learning opportunities on offer in emergency departments, as well as the teaching abilities of staff, emergency physicians have been able to negotiate a greater role in university affairs and integrate emergency medicine into the broader undergraduate curriculum. It may take years of hard work and negotiation to get to a point where emergency medicine becomes an established term in a medical school with consequent recognition and exposure throughout the course. With this comes a responsibility for emergency physicians to understand the function of universities and the requirements which come with running an academic term. Box 27.4.2 provides suggestions for developing such a presence.

Box 27.4.2 Minimum requirements for developing student placements in emergency departments

- Nominate one person to be the term coordinator and liaison with the university.
- Understand the rules and regulations which govern student placements in your hospital and at the affiliated university.
- Develop relationships with key individuals in the medical school leadership group who will ultimately understand and appreciate the value of emergency medicine as a discipline and will support you in your development.
- Develop a clear orientation package for students and make it clear that students will not be allowed into the department until they have received orientation.
- Develop a clear curriculum statement providing a broad overview of goals and objectives for the term.
- Define specific learning objectives for students (e.g. 'At the end of this placement, you will be able to describe the assessment of the patient presenting with chest pain.').
- Consider how students will be assessed and clearly describe this prior to the commencement of the term.
- Consider who will supervise the students; for this reason, it is essential to engage with all levels of staff within the department and to provide them with support, training and guidance.

It is essential that once a department has decided that medical student teaching should be a part of its function then a curriculum must be considered. Many national colleges and societies have, in past years, produced curriculum guidelines with varying degrees of detail.[5–8] Most core curriculum statements contain elements which reflect the clinical practice of emergency medicine and provide a framework around which specific topics can then be taught. It is not the intention or scope of this chapter to prescribe which content should or should not be included in any curriculum. However, an emergency medicine curriculum should focus on the elements which define the specialty rather than simply being an acute mimic of what students would be exposed to in other disciplines. These could include, as an example, a focus on the assessment and management of patients with undifferentiated conditions, recognition of the deteriorating patient, clinical diagnosis and presentation skills, the appropriate use of investigations, time management, nontechnical skills, and special skills such as toxicology and resuscitation.

Teaching programmes will need to be modified and adapted accordingly depending on the expertise of and time available to specialists within the department, as well as the local epidemiology and patient demographics. The challenge remains to pragmatically and effectively implement a teaching programme which meets the desired goals and objectives.

An often overlooked but essential component to consider in any curriculum development process is that of the 'hidden curriculum'. This is less well understood, but relates to what students learn by being exposed to the practice of medicine. It can cover aspects such as professionalism, ethics and physician behaviour. As the vanguard of a fair, accessible and equitable health system, emergency medicine can teach important attitudes to the next generation of doctors.

Methods of teaching emergency medicine

Until recently, undergraduate emergency medicine has largely been taught in the workplace, and no other teaching options have existed. However, with the growth of the specialty, the increased need for teachers, combined with a growing interest in the value of education and technological advances, the specialty has been able to develop and disseminate resources and play a greater role in all years of the medical course in some universities. Therefore, depending on available time and resources, different formats of teaching should be considered for different situations. For example, resuscitation skills are best taught using team-based simulation and practice to reflect the reality of the workplace, once basic concepts have been covered by lectures or online modules. There is much discussion surrounding methods of medical student training, but emergency medicine, by its very nature, is highly adaptable and capable of working within any number of teaching formats.

In all formats, teachers should consider the basic principles of adult learning and teach accordingly. When delivering material, teachers should remember that adults learn best when the topic is meaningful, linked to experience and pitched at the correct level, and the students are motivated, have clear goals, are actively involved, receive regular feedback and have time for reflection.[9] Utilizing a range of methods means that material can be delivered in a meaningful way, and optimal learning conditions can be achieved. It is essential that the physician taking responsibility for undergraduate teaching within a department takes a leadership role and provides ongoing training and support for both junior and senior colleagues in effective teaching methods.

Whichever teaching method is chosen, evaluation of the process by the participants is an essential part of the quality improvement cycle. Evaluation helps ensure teaching is meeting students' learning needs, identifies areas where teaching can be improved, and provides feedback and encouragement for teachers.

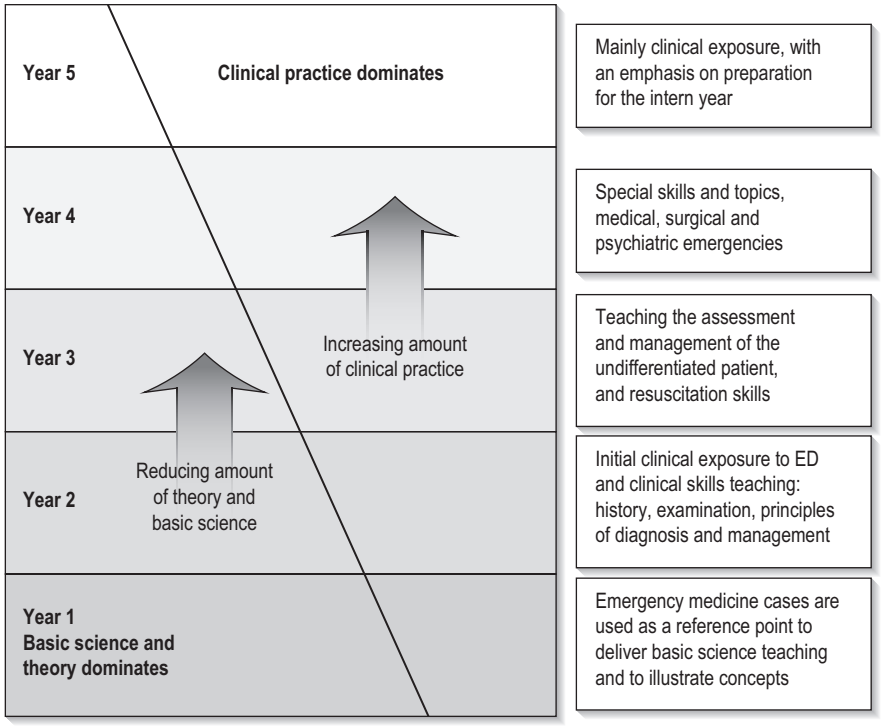

FIG. 27.4.1 A suggested overview of the progression of emergency medicine in an integrated 5-year curriculum.

Documenting evaluations can form part of a teaching portfolio, which can be used in academic job applications as tangible evidence of a clinician's and a department's commitment to and proficiency in teaching. Importantly, from a student's perspective, being asked to evaluate a teaching session and then seeing the comments acted on provides a strong sense that their participation is valued and, as a result, may improve the learning process overall.

Some basic pedagogical theory should be considered when choosing methods of teaching, and there is a wealth of material available to assist curriculum developers in this regard. Fig. 27.4.1 is a schematic representation of how emergency medicine as a subject can progress through a 5-year course utilizing contemporary theories of curriculum design. Most departments will only be in a position to offer clinical exposure in the final years of the course, but much progress has been made in penetrating all years. The following delivery methods could be used in this framework to deliver a comprehensive and effective emergency medicine curriculum.

Lecture based

Lectures can be delivered at any stage of the medical course, but to maximize their effectiveness, they need to be developed in an integrated fashion and linked to other components of the course. Emergency medicine can be used effectively as a vehicle to illustrate biomedical science concepts to junior medical students.[10] Case-based learning is a popular method to use in this setting, as learning objectives and concepts can be demonstrated in a 'real-world' setting. For example, rather than delivering a lecture on ischaemic heart disease, an emergency medicine lecture would be entitled 'I've got pain in my chest', and the lecturer would engage with students to create an authentic feel for this common emergency presentation. The content would need to be modified depending on the seniority of students: for example, junior medical students would use the case as a reference point to illustrate anatomy and physiology, while more senior students could use the same scenario to learn about clinical decision making and evidence-based medicine.

Lectures must not be boring, didactic and overloaded with content—a good lecture should be an efficient and entertaining means of effectively transmitting information to large groups. Put simply, lectures should add value. Prospective lecturers should remind themselves of the qualities of an effective educator: expertise in the subject area, enthusiasm for the topic and the task, and capacity to engage the learners. By utilizing these qualities, emergency physicians can turn a lecture into a valuable learning experience. Lecturers should have notes pre-prepared and available for students and be prepared for the fact that most will have mobile devices open while the lecture is taking place, will be busy annotating and linking to other resources, and may not appear to be giving the lecturer their undivided attention. These are the principles of blended learning, and they will be a key part of education in the 21st century. Recording lectures on the university's learning management system is now standard procedure and allows for later review and discussion.

Work based

The original method of medical education is at the bedside of the patient. Medicine has been taught this way for thousands of years and reinforces the point that medical students are essentially apprentices in a trade. Emergency medicine excels in this area because of the broad range of experiences on offer in any department any day of the week. Challenges exist, as not all students will be exposed to the same conditions during a rotation. Achieving a uniform experience for students is difficult, and so workbooks based on curriculum statements have been developed to guide students through their rotation, alerting them to the broad range of undifferentiated conditions which regularly present.

The key aspect of this form of education is to engage the medical students as junior members of the team, where they actively assess and develop management plans for patients under the close supervision of senior staff. This makes the term more enjoyable and provides the students with an authentic clinical experience where they get to put their skills into supervised practice. Implemented properly, the students adopt a 'physician assistant' role and potentially improve clinical productivity. This arrangement has met with great acceptance and enthusiasm by students.

Utilizing junior staff can be helpful in the education of medical students: pairing a student with a resident or registrar involves junior doctors in teaching at an early stage of their careers. It helps with rostering, in that students can be allocated to medical staff with a pre-existing timetable. Medical schools offer incentives such as clinical academic titles and subsidised courses to doctors involved in teaching and all staff should be encouraged to apply for such benefits. Teaching by the bedside remains a valued activity and abundant clinical teaching opportunities exist in emergency departments. It is essential that clinicians are aware of the curriculum, as it can be difficult to think on the spot when confronted with a 'teachable moment'. Many resources exist to guide clinical staff with teaching, from web-based guides, to textbooks, to formal units of study such as master's degrees in clinical education.

Tutorials and small-group learning

Tutorials are small group sessions, with opportunities for interaction and reflection. This model

of teaching is well suited to clinical emergency medicine, as individual cases and experiences can be discussed and reflected upon in a comfortable and safe environment. The learners can lead the discussion and take the topics into new and previously unconsidered areas. Nevertheless, providing a structure to the tutorial will help ensure that the time is spent wisely and learning opportunities are maximized. These are usually easily implemented in a department, as they can be integrated with other departmental activities and can run independently of any broader curriculum. This is often the only way that the specialty can deliver a curriculum in a school without a formal discipline of emergency medicine.

Simulation

Simulation is an established field which has been particularly embraced by emergency physicians at an undergraduate and postgraduate level. A large knowledge base has been developed, and as such, it will not be discussed at length here. Enhanced educational experiences can be achieved through the use of trained simulated patients. Universities have largely recognized the value of this method of teaching, with simulation utilizing human factors and the principles of interprofessional learning being integrated into curricula at all levels. Many institutions use advanced simulation techniques in short residential placements, such as popular 'wilderness weekends', which promote team-based learning in a non-hospital environment.

Web-based and mobile learning

This is growing in popularity as schools rely more on information technology to deliver content and this is occurring at the same time that emergency physicians worldwide are taking a leading role in developing resources and promoting the role of social media and other online resources for teaching and clinical care. At a basic level, bulletin boards, web logs (blogs), social media platforms and email are useful ways to maintain regular communication with students and to distribute journal articles, and policies and orientation manuals can be posted online.

However, with faster internet connections and a new generation of students predominantly utilizing mobile learning devices in informal learning environments, new opportunities are emerging with applications, podcasts, social media and e-books playing increasingly prominent roles in education at all levels. Most, if not all, students and doctors would be very familiar with the vast resources on offer through the explosion of Free Open Access Medical Education (better known as #FOAMEd). Students are extremely active in generating and curating resources themselves. Self-directed learning uses the principle of learners being able to make decisions about what information they want to access. In emergency medicine, self-direction is likely to speed learning in situations in which there is a large space of possible things to learn but the learner has a proper understanding or representation of this space. Such representation must be provided by emergency clinicians with the combination termed 'assisted learning'. Progress and on 'assisted learning' will require educators to relinquish the control they are accustomed to exerting over the learning process and let individuals freely explore and sample information in their environment.

Assessment

Assessment should be considered as a tool which drives learning and should be developed in parallel with the curriculum rather than considered as an 'add-on' at the end. Emergency physicians need to become intimately involved in examination processes throughout the course so that the specialty is taken seriously by students, and to ensure that appropriate and authentic emergency conditions and scenarios are presented. Schools are always in need for examination writers and examiners, so a keen and enthusiastic emergency physician can set an agenda relatively easily through being both creative and present for the process. Emergency physicians are very familiar with the Objective Structured Clinical Examination (OSCE) format and proficient at writing and examining in this format.

Assessment no longer occurs at the end of each term: as methods of assessment become more sophisticated and innovative, methods such as workplace-based assessments and the mini-CEX should be adopted and incorporated into assessment throughout the emergency medicine term.

Future directions

Emergency medicine will continue to play a significant role in medical student education and is poised to make greater contributions in coming years. Its presence and influence as a discipline is unquestioned. Emergency medicine has proven itself to be unique in the medical curriculum in that it is probably the only discipline (with the possible exception of general practice) which can offer students an authentic and safe opportunity to be involved in the diagnosis and management of undifferentiated patients in a supervised environment as junior members of the team. This is in contrast to most other terms where students are forced to adopt a passive 'medical tourist' role, with a corresponding lack of satisfaction and preparation for the workforce. Emergency departments are where students can finally apply their accumulated knowledge before completing their degrees. To this end, emergency medicine plays a critical role as both a key discipline and a 'finishing school' for students.

Nevertheless, a number of challenges and controversies remain to be addressed:

- EDs will struggle to handle increased numbers of students without additional dedicated support from universities and will need to strongly negotiate for additional resources, either from the hospital or the university.
- Emergency physicians still have much work to do in creating a coordinated undergraduate curriculum that is vertically integrated with prevocational and specialist training in the specialty.
- It is inevitable that academic departments of emergency medicine will continue to be created, but first the specialty must clearly define its core curriculum and its role in the university sector.
- Changes in the health workforce with a redefinition of the role of the doctor and evolution of other health professions will necessitate that the specialty apply its knowledge base to broader health science training, including that of evolving positions such as physician assistants.

The time has come for the specialty to move beyond just the provision of training in acute medicine as envisaged in past years. The specialty has developed its own body of knowledge and curriculum in important but underrepresented areas of medical education, such as clinical decision making, toxicology, pre-hospital care, medical error, resource stewardship, and health systems design and management. The management of elderly patients and end-of-life decision making is becoming a significant part of most emergency physicians' practice. Hence, emergency physicians need to take a leading role in the development and delivery of curricula in these areas. Emergency medicine as a specialty has the opportunity to take a prominent role in training doctors and other health professionals capable of understanding and addressing the key challenges facing the health system in the 21st century.

27.5 Postgraduate emergency medicine teaching and simulation

Victoria Brazil

ESSENTIALS

1 **Emergency medicine training programs need explicit curricular objectives, effective learning and teaching strategies, and valid and reliable assessment methods.**

2 **Technology, social media and online collaboration are affecting the way emergency medicine trainees and their supervisors learn and access information, and demand new skills in information retrieval and critique.**

3 **Simulation offers learning opportunities in clinical and procedural skills, teamwork and communication, and requires disciplined application for good educational outcomes.**

Introduction

Emergency departments (EDs) are fertile learning environments for postgraduate doctors. The varied clinical case mix, procedural practice and enthusiastic teaching by emergency physicians have made emergency medicine an important experience for new medical graduates. Many of these same factors attract doctors to vocational training in emergency medicine.

Postgraduate training in this field, like most other specialties, traditionally followed an apprenticeship model. However, contemporary emergency medicine practice demands new knowledge and skills, must meet different expectations from patients and health care systems, and needs contemporary educational approaches.

Oversight of training programs

The governance of emergency medicine training, certification and credentialing varies internationally. In Australasia, training and assessment is by the Australasian College for Emergency Medicine (ACEM),[1] in conjunction with hospitals and health services. Formal specialist recognition is granted by the Medical Boards of Australia (MBA) or New Zealand (MBNZ). 'Non-specialist' training in emergency medicine is provided by the both ACEM and Australian College of Rural and Remote Medicine (ACRRM).

Other governance models of specialist training exist internationally and include oversight by universities (Malaysia), professional societies (Sweden, USA) government organizations, cross-specialty professional associations (Royal College of Physicians and Surgeons of Canada) or combinations (UK). Organized training programs in low- and middle-income countries (LMICs) are now more common.

Curricular trends in emergency medicine

There has been a global trend in postgraduate medical education toward 'outcomes-based' curricular models. This has resulted in a shift from curricula defining a knowledge base to be acquired, to outcome concepts of roles and competencies for specialist physicians.

The CanMEDS model, developed in Canada and adopted by the ACEM, requires training to be orientated toward preparing emergency physicians (and other specialist trainees) for their roles as medical expert, communicator, collaborator, manager, health advocate, scholar and professional.[2]

Integral to this curricular trend has been increased recognition of teamwork, leadership, patient safety, quality improvement,[3] physician wellness, and communication with patients and peers as training goals. New domains of learning, such as medical informatics and evidence-based medicine, have become explicit curricular content.

Learning and teaching methods in emergency medicine

Bedside teaching, or 'teaching on the floor', remains the foundation of most ED trainees' educational experience. This supports reflection upon clinical and professional aspects of emergency medicine practice in an integrated manner, and should be facilitated by a graduated increase in patient care responsibility. However, the quality of this experience is dependent on the availability and skill of clinical supervisors and on time constraints in busy EDs. Clinical teaching can be 'education by random opportunity', and learners may not encounter important conditions or procedures and may not reflect usefully on the experiences they do have. The use of workplace-based assessments (WBAs) can help provide more structured feedback on performance in the clinical environment.

Didactic elements of specialist training vary in format, but most programs or institutions provide a structured element of training that consists of trainee- and supervisor-delivered presentations, procedural skill sessions, journal clubs and invited lectures. Following the trend towards competency-based curricular models, these teaching activities are becoming more structured and supported by online content. Advances in learning science suggest there may be more effective methods of learning than most programs employ, using retrieval practice, spaced repetition, deliberate practice and optimizing cognitive load.[4]

Reflective practice is an important learning skill for postgraduate trainees. Clinical audit and portfolios can facilitate this reflection, combined

with participation in critical incident review, trauma review meetings, and morbidity and mortality rounds.

There is a trend toward interprofessional and team-based learning, recognizing the team approach required for effective clinical practice.[5] This includes multidisciplinary formal educational sessions and team-based simulation experiences. These activities are focused on communication and professional domains of competence and provide trainees with a broader perspective on systems-based practice in emergency medicine.

Technology for learning in emergency medicine

Technology-enabled learning offers many teaching and learning applications in emergency medicine. Textbooks and other content repositories are now likely to be accessed online or in e-book formats, making published references more available, more easily updated and employing multimedia formats.

More significant is the change toward accessing online resources for emergency medicine training and for continuing medical education, including websites, podcasts and blogs on emergency medicine topics (Table 27.5.1). The use of social media such as Twitter (San Francisco, CA) and global collaboration to 'collate and curate' these resources[6] offers unparalleled access to educational materials and online discussions, as well as opportunities for informal peer review. As a result, the emergency medicine trainee requires effective information retrieval and critical appraisal skills for online sources,[7] and their supervisors need to reconcile online with 'traditional' sources of learning.

Procedural skill training has been enhanced by the use of manikins, part trainers and virtual or augmented reality systems, reducing the use of animal labs and cadavers. Video-based instruction of procedures allows demonstration of procedural performance under ideal conditions, with rehearsed teaching scripts. Many of these are now available on personal digital assistants for 'just-in-time learning'.

Clinical decision support software provides educational opportunities in conjunction with solutions to clinical problems. Many are in 'app' format (e.g. MDcalc) for mobile access and have extensive embedded resource materials that can be utilized in clinical practice or for primarily educational purposes.

Videoconferencing, webinars and tele-education have sought to answer the challenges of distance in emergency medicine education. Improvements in technology (including consumer platforms such as Skype [Luxembourg], Google Hangouts, etc.) and bandwidth continue to improve the learning experience.

Simulation-based learning

Simulation enables efficient and effective learning through practice and failure in a safe environment, without risk to patients, and through exposure to challenges which may be infrequent in clinical practice. Simulation debriefing supports habits of reflective practice and identification of performance gaps for individuals, teams and systems.

Effective simulation-based learning for emergency medicine requires clear educational objectives and robust strategies for translating simulation-based learning to clinical practice. Targeting knowledge acquisition, procedural skill proficiency, applied physiology and pharmacology, or complex teamwork skills and crisis resource management behaviours requires different equipment, scenario designs, levels of physical realism, and approaches to debriefing or feedback.

Simulators, equipment and fidelity

Simulations may employ simple part task trainers (e.g. an intravenous cannulation arm), simulated patients (SPs) or actors, mechanical manikin simulators, virtual-reality-based procedural skill trainers or combinations of these modalities.

The most technologically complex full-body manikin simulators operate via detailed physiological modelling software and can manifest pulses, breathing, blinking and vocalization, together with an ability to alter lung mechanics and compliance and cardiovascular parameters.

Improvements in materials science have enhanced physical resemblance of skin and facial features. Wireless technology allows simulator portability.

Learner perceptions of fidelity of the simulation experience depend on much more than physical resemblance. Individual learning styles, the authenticity of the scenario presented, the realism of the team composition and the physical environment all affect learners' perception of fidelity and the 'functional task alignment' educators seek to achieve.

'Hybrid' simulation—combining simple part task trainers with standardized patients—has been successfully used to integrate a procedural skill with communication performance (e.g. an actor wearing a synthetic skin pad with a laceration interacts with a doctor suturing the wound).

Video-assisted feedback may be used as a debriefing adjunct in health care simulation. Some programs provide simulation-based experience and group debriefing via videoconferencing and remote control of equipment.

Simulation training environments

Training may be delivered in dedicated simulation labs, on site or 'in-situ'. Advanced manikin and audiovisual technology, together with logistic expertise, mean that these learning experiences can be provided in situ—in clinicians' own EDs. The use of the authentic work environment allows high levels of fidelity to be achieved. The usual work team can engage in learning together and review their everyday systems and processes, without the cost and logistical barriers of travelling to a synthetic environment.[8]

An example of a typical emergency medicine simulation session is provided in Box 27.5.1.

Training for providers of simulation-based learning

Educators using simulation-based modalities require proficiency in technological issues, experiential learning principles and small group process. Short courses exist at many simulation centres, and most programs run their own 'in-house' training and quality assurance process to ensure a standardized approach to scenario design, delivery and group debriefing. In Australia, provider training is available through the National Health Education and Training in Simulation (NHET-Sim) program.

Box 27.5.1 Example—Teamwork and communication skills training using health care simulation

Crisis resource management (CRM) training in emergency medicine using human patient simulation draws on parallels between acute patient care and the aviation and military industries, where it has been recognized that human factors are crucial to team performance.[5]

A typical scenario might involve a team of medical and nursing participants managing a patient with chest pain, complicated by a life-threatening arrhythmia. The scenario is delivered in the providers own emergency department (ED), using a full body manikin. Participants would be expected to identify and manage clinical issues, while engaging in the communication, teamwork and leadership activities inherent in real clinical practice, as well as using their own ED equipment and systems. The scenario is then followed by video-assisted, expert debriefing to reflect upon individual and team performance, as well as latent safety threats in the environment. This experiential learning approach enables cross-domain training in which cognitive, procedural and affective domains of practice are authentically integrated. The interprofessional nature of the learning experience provides a unique opportunity for increased understanding of the role of other health care disciplines.

Outcomes and limitations of simulation-based training

There are significant costs in equipment and trained personnel to run programs. Clinical challenges, such as cardiac and airway emergencies, can be simulated with a high degree of fidelity, but many other emergency medicine clinical challenges are not suitable for this format. Negative training is a recognized risk (e.g. allowing participants not to wear gloves or lead aprons can inadvertently encourage poor habits in the real clinical environment). Simulations with overly positive clinical outcomes (e.g. successful resuscitation of the PEA cardiac arrest) may train learners to have unrealistic expectations.

Evidence for clinical practice improvement resulting from simulation-based learning is sparse, despite intuitive appeal. Features of simulations that lead to effective learning are better understood,[9] and increasingly simulation in health care is viewed as a strategy for directly targeting clinical outcomes.[10]

Assessment and performance appraisal for emergency medicine training

No single assessment format can adequately measure performance across all domains of emergency medicine practice. Within the specialty, there is considerable international variation in the domains of performance formally assessed, the definition of 'professional competence' required and in the standardization of assessment processes undertaken. Robust assessment strategies and programmatic approaches are especially important for moving from time-based models of training to hybrid, outcomes-based approaches such as the Canadian *Competence by Design*.[2]

In-training assessment by clinical supervisors is a core element in most programs. Although a valid tool (in that it measures the right thing), the potentially subjective nature of supervisor assessments and recall bias can decrease the reliability of in-training assessment. WBA formats such as mini-CEX (clinical evaluation exercise) and DOPS (direct observation of procedural skills), in which trainees are directly observed and assessed in a clinical encounter and given immediate feedback, are valid and reliable if sufficient assessments are undertaken, but resource-intensive and challenging to implement.

Most training programs have formal examination components, generally developed and administered externally by a national training body. Formats include multiple-choice questions, written tests, structured interviews and clinical examination vivas. Other contemporary assessment tools include clinical simulations, portfolios, standardized patients, patient outcomes and multisource '360 degree' feedback assessment. These formats support the trend toward specific assessment of communication and professionalism domains, which mirror contemporary shifts in curricular content. However, each format has unique validity, reliability and implementation challenges, and development and evaluation of Emergency Medicine assessment programs require specialist assessment expertise.

Faculty development in emergency medicine

Many emergency physicians are enthusiastic clinical teachers, but are more effective in their teaching role if their clinical expertise is combined with specific educational knowledge and skills. Training opportunities for educators in emergency medicine include master's level courses, short workshops or institution-based group professional development activities. These courses typically cover topics such as curriculum development, teaching and learning methods, and assessment and feedback skills.

Formal, longitudinal programs for clinician educators include Medical Education Registrar posts, such as those accredited by ACEM, and education fellowships in the United States and Canada.

These initiatives have been reinforced by the emergence of 'clinician educator tracks' in academic institutions to provide an academic career structure for clinical teachers.

Continuing professional development

There is a professional and societal expectation that physicians maintain their skills and competence to practice. Australasian emergency physicians are required by the MBA and New Zealand to demonstrate participation in a continuing professional development (CPD) program accredited by the Australian Medical Council. Internationally, the nature of CME requirements varies, but most require periodic assimilation of a portfolio of attendance at conferences and workshops, together with demonstration of participation in clinical practice, teaching, quality assurance activities, research and other special interests. Some jurisdictions require update examinations.

Providers of CPD include professional societies, commercial organizations and freely available online sources (e.g. #FOAMed blogs and podcasts). Many emergency medicine conferences have evolved to include more engaging talks, interactive formats and social media elements. There is limited evaluation of CPD activities in supporting practice change or maintenance of skills.

CONTROVERSIES AND FUTURE DIRECTIONS

- Technology and online collaboration challenges traditional learning and assessment methods for emergency medicine practitioners at all levels.
- The involvement of professional educators in postgraduate emergency medicine training brings evidence-informed approaches to curriculum design, teaching and assessment.
- Training programs need flexibility to match changes in contemporary health care delivery. Changing workforce roles and emergency physician scope of practice needs to be reflected in curricular objectives.
- An international medical workforce shortage, plus a doubling of medical graduate numbers in Australia, will increase pressure to produce qualified specialist practitioners, including emergency physicians, in a shorter time and with a more 'work-ready' focus.

SECTION 28

EMERGENCY MEDICINE AND THE LAW

Edited by *Biswadev Mitra*

28.1 Mental health and the law: the Australian, NZ and UK perspectives

Georgina Phillips • Matthew Warden

ESSENTIALS

1 **The emergency department is frequently the point of access to the mental health system.**

2 **Emergency physicians need to be able to distinguish between patients with physical and those with psychiatric illness.**

3 **Patients should only be committed involuntarily to an approved hospital if they have a mental illness requiring immediate treatment for their own health or safety or the protection of others and if adequate treatment cannot be obtained in a less restrictive manner.**

4 **Emergency physicians need to have a sound working knowledge of mental health legislation as it relates to their practice and to the jurisdiction in which they work.**

5 **Recent mental health legislative reform across Australia and NZ emphasizes autonomy and self-determination within a human rights framework and is moving towards minimizing restrictive practices, increasing safeguards and transparency, and enhancing independent oversight.**

Introduction

The emergency department (ED) is frequently the interface between the community and the mental health system. Health policy now prioritizes 'mainstreaming' of mental health services, so that stand-alone psychiatric facilities are uncommon and services are more likely to be provided in a general hospital setting. Linked to this has been a move away from managing long-term psychiatric patients in institutional settings, so that many of these former patients are now living in the community with or without support from mental health services.

Traditionally, by virtue of their accessibility, EDs have been a point of access to mental health services for persons with acute psychiatric illness, whether this be self- or family referral or by referral from ambulance, police or outside medical practitioners. An important function of an ED is to differentiate between those who require psychiatric care for a psychiatric illness and those who present with a psychiatric manifestation of a physical illness and who require medical care. Admission of a patient with a psychiatric manifestation of a physical illness to a psychiatric unit may result in further harm to or death of the patient.

In the UK, Australia and NZ, doctors in general are empowered by legislation to detain a mentally ill person who is in need of treatment. Mental illness, particularly its manifestation as self-harm, is a common ED presentation (in the UK, making up around 1% to 2% of new patient attendances and up to 5% of attendances in Australasia) and emergency physicians require not only the clinical skills to distinguish between those who require psychiatric or medical intervention, but also a sound working knowledge of the mental health legislation and services relevant to the state where they practice. This ensures that patients with psychiatric illness are managed in the most appropriate way, with optimal utilization of mental health resources and with the best interests and rights of the patient and the community taken into consideration.

While there are variations in mental health legislation between the UK, Australia and New Zealand, all legislation recognizes fundamental common principles that respect individual autonomy and employ least restrictive management practices. The World Health Organization (WHO) advises 10 basic principles of mental health care law, including enshrining geographical, cultural and economic equity of access to mental health care, acceptable standards of clinical assessment, facilitating self-determination, minimizing restrictive treatment and enshrining regular and impartial decision making and review of care.[1] These themes are all present in Australia, NZ and UK law, and awareness of such principles aids the clinician in delivering humane and ethical treatment for mentally unwell patients who seek emergency care.

Variations in practice

Mental health legislation in England and Wales

The National Service Framework for Mental Health

The report of the Mental Health Taskforce to the National Health Service (NHS) in 2016 created a 5-year plan for Mental Health in the NHS. One of the priority actions was the creation of a 7-day NHS with specific focus in creating 24-hour mental health services, including a mental health response for people attending the Accident and Emergency Department (A&E). In 2015 to 2016, 165,000 people attended A&E with mental health problems across the NHS.

Two pieces of legislation cover the care and treatment of patients with disorders of the brain or mind. The Mental Health Act (2007) deals with compulsory assessment and treatment of people with mental illnesses, while the Mental Capacity Act (2005) deals with people who are unable to make decisions about their medical treatment for themselves for various reasons.

Mental Health Act

Definition of mentally ill or mental illness According to the 2007 Mental Health Act, mental illness is defined as any disorder or disability of the mind. In practice, it includes conditions such as schizophrenia, bipolar disorder, depression, psychosis and organic brain syndromes.

Detention of patients with mental illness The Mental Health Act 2007 provides legislation with regard to the management of patients with a mental illness unwilling to be admitted or detained in hospital voluntarily, where this would be in the best interests of the health and safety of patients and others. For the purposes of the Act, patients in the ED are not considered inpatients until they are admitted to a ward. In order for legislation to be imposed, it is necessary for two conditions to be satisfied: the patient must be suffering from a mental illness, and emergency hospital admission is required because the patient is considered to be a danger to himself/herself or others.

Detention under the Mental Health Act does not permit treatment for psychiatric or physical illness. Treatment can be given under common law where the patient is considered to pose a serious threat to himself/herself or others. Otherwise all treatment must be with the patient's consent.

Section 2 of the Mental Health Act facilitates compulsory admission to hospital for assessment and treatment for up to 28 days. The application is usually made by an approved Mental Health Professional or the patient's nearest relative and requires two medical recommendations, usually from the patient's general practitioner and the duty senior psychiatrist (who is approved under Section 12 of the Mental Health Act). In the ED, the responsibility for coordinating the procedure often lies with the emergency physician.

Section 3 of the Mental Health Act covers compulsory admission for treatment. Once again, recommendations must be made by two doctors, one of whom is usually the general practitioner and the other a psychiatrist approved under Section 12 of the Act. The application is usually made by an approved mental health professional or the patient's nearest relative. Detention is for up to 6 months but can be renewed.

Section 4 of the Mental Health Act covers emergency admission for assessment and attempts to avoid delay in emergency situations when obtaining a second recommendation could be dangerous. It requires the recommendation of only one doctor, who may be any registered medical practitioner who must have seen the patient within the previous 24 hours. The order lasts for 72 hours. Application can be made by the patient's nearest relative or an approved social worker. In practice, the application of Section 4 of the Mental Health Act rarely happens. Usually Section 2 or 3 is the preferred option.

Section 5(2)—doctors holding power and Section 5(4)—nurses holding power of the Act allow the detention of patients who are already admitted to hospital until a more formal Mental Health Act assessment can take place. Unfortunately, presence in the ED is not considered to constitute admission to hospital, and this section is, therefore, not applicable to the ED.

Police powers

Section 136 of the Act authorizes the police to remove patients who are believed to be mentally disordered and causing a public disturbance to a place of safety. The place of safety referred to in the Act is defined in Section 135 as 'residential accommodation provided by a local authority under Part III of the National Assistance Act 1948, or under Paragraph 2, Schedule 8 of the National Health Service Act 1977, a hospital as defined by this Act, a police station, a mental nursing home or residential home for mentally disordered persons or any other suitable place, the occupier of which is willing temporarily to receive the patient'. In practice, the police often transport these patients to local EDs. The patient must be assessed by an approved social worker and a registered doctor. The order lasts for 72 hours.

Section 135 allows the police to enter premises to remove a patient believed to be suffering from a mental disorder to a place of safety for up to 72 hours. The patient is then assessed as noted previously.

Mental Capacity Act

The Mental Capacity Act relates to decision making, for those whose mental capacity is in doubt, on any issue from what to wear to the more difficult issues of medical treatment, personal finance and housing.

Lack of capacity can occur in two distinct ways. First, that capacity is never achieved—for example, someone with a severe learning difficulty. Second, capacity can be lost either as a result of long-term conditions, such as dementia, or for a short period because of a temporary factor, such as intoxication, shock, pain or emotional distress.

It is also important that decision making is task specific. An individual may be able to make decisions about simple matters, such as what to eat or wear, but may be unable to make more complex decisions, for example about medical care.

Assessment of capacity To have capacity about a decision, the patient should be able to comply with the following four steps:

- Understand the information relevant to the decision.
- Retain the information for the period of decision making.
- Use or weigh that information as part of the process of making a decision.
- Communicate their decisions.

Every effort needs to be made to enable people to make their own decisions.

The Act points out that people should be allowed to make 'eccentric' or 'unwise' decisions, as it is their ability to decide that is the issue not the decision itself.

Advance directives The Act makes provision for advance directives to be made at a time when the patient has capacity. These directives need to make specific reference to the medical treatments involved and include the statement 'even if life is at risk'. The validity of any advance decision needs to be clearly documented.

Advocates Although family and friends have no legal powers (unless specified in advance) to make decisions for the incapacitated patient, the Act recognizes their role in acting as an advocate. An independent mental capacity advocate is available to represent those with no close family or friends.

Emergency treatment Treatment can be given to patients who lack capacity, but several factors need to be considered:

- Any action must be in the best interest of the patient.
- Anything done must be the least restrictive of the patient's rights and freedoms.
- Where time can be afforded, every effort should be made to enable the patient to make his or her own decision.
- Treatment should not be delayed while attempts are made to establish the validity of any advance decision.
- Medical staff have a duty of care to the incapacitated patient.

Use of sedation or physical restraint This is covered in detail elsewhere (Chapters 20.6 – 21.5). From the perspective of the mental health legislation, there are occasions where physical or pharmacological restraint is needed. Sedation or restraint must be the minimum that is necessary to prevent the patient from self-harming or harming others. In general, a patient committed involuntarily is subject to treatment necessary for his or her care and control, and this may reasonably include the administration of sedative or antipsychotic medication as emergency treatment. Transporting these patients to a mental health service should be done by suitably trained medical or ambulance staff and not delegated to police officers or other persons acting alone.

Mental health legislation in Australia and NZ

In Australia, mental health legislation is a state jurisdiction, and among the various states and territories, there is considerable variation in the scope of mental health acts and between definitions and applications of the various sections. Since the National Mental Health Strategy in 1992, there has been an effort in Australia to adopt a consistent approach between jurisdictions, with an emphasis on ensuring legislated review mechanisms and a broad spectrum of treatment modalities.[2] In 2012, this national strategic approach was reaffirmed by all the States and Territories of Australia with the release of the Roadmap for National Mental Health Reform 2012–2022, focusing on promoting mental health and preventing mental disorders, minimizing the impact of mental illness across the whole community and protecting the rights of people with mental illness.[3]

Several Australian, states and territories and NZ have recently passed new Mental Health Acts, all within a human rights framework and consistent with the United Nations' Principles for the Protection of Persons with Mental Illness and the Improvement of Mental Health Care.[4] In general, there is an increased recognition of autonomous and supported decision making with a particular focus on enhancing informed consent through advance directives or involving a nominated support person. Increased transparency of and limitations around restrictive practices will affect activities within EDs. Community visitors and mental health tribunals are introduced to ensure frequent independent oversight and review, and it is now mandatory in several jurisdictions to give patients and caregivers written copies of involuntary orders made about them, as well as a statement of their rights. Despite these common themes, key differences apply between mental health acts, and therefore specific issues should be referred to the Act relevant to the emergency physician's practice location.

The Australian and New Zealand mental health acts and related documents referred to in this chapter are the following:

ACT—Mental Health Act 2015

New South Wales—Mental Health Act 2007 and the NSW Mental Health for Emergency Departments: Reference Guide 2009

New Zealand—Mental Health (Compulsory Assessment and Treatment) Act 1992, and Amendment Act 1999, the Second New Zealand Mental Health and Addiction Plan 2005 (Te Tahuhu, Improving Mental Health 2005–2015) and the discussion document; Mental Health Act and Human Rights 2016 (Ministry of Health, New Zealand)

Northern Territory—Mental Health and Related Services Act 2017

Queensland—Mental Health Act 2016

South Australia—Mental Health Act 2009, Clinicians Guide and Code of Practice (Mental Health Act 2009 SA), SA Mental Health and Emergency Services Memorandum of Understanding 2010

Tasmania—Mental Health Act 2013 with Amendments 2016

Victoria—Mental Health Act 2014

Western Australia—Mental Health Act 2014

Sections of the various mental health acts relevant to emergency medicine include those dealing with

- the definition of mentally ill
- indigenous and cultural acknowledgement
- the effects of drugs or alcohol
- criteria for detention and admission as an involuntary patient
- involuntary admission
- persons unable to recommend a patient for involuntary admission
- physical restraint and sedation
- emergency treatment
- powers of police
- prisoners with mental illness
- offences in relation to documents
- information and patient transfer between jurisdictions
- deaths

Definition of mentally ill or mental illness

For the purposes of their respective mental health acts, New Zealand and all the Australian states and territories define mental illness or disorder as follows.

Australian Capital Territory

The Australian Capital Territory (ACT) Act defines a psychiatric illness as a condition that seriously impairs (either temporarily or permanently) the mental functioning of a person and is characterized by the presence in the person of any of the following symptoms: delusions, hallucinations, serious disorder of thought form, a severe disturbance of mood, or sustained or repeated irrational behaviour indicating the presence of these symptoms.

The ACT Mental Health Act also defines 'mental dysfunction' as a 'disturbance or defect, to a substantially disabling degree, of perceptual interpretation, comprehension, reasoning, learning, judgement, memory, motivation or emotion'.

New South Wales

The New South Wales Act defines mental illness in the same way as the ACT but, in addition, distinguishes between a mentally ill person and a mentally disordered person, chiefly for the purposes of determining need for involuntary admission and treatment.

A person (whether or not the person is suffering from mental illness) is mentally disordered if the person's behaviour for the time being is so irrational as to justify conclusion on reasonable grounds that temporary care, treatment or control of the person is necessary for the person's own protection from serious physical harm or for the protection of others from serious physical harm.

New Zealand

In New Zealand, the Mental Health Act defines a mentally disordered person as possessing an abnormal state of mind, whether continuous or intermittent, characterized by delusions or by disorders of mood, perception, volition or cognition to such a degree that it poses a danger to the health or safety of the person or others, or

seriously diminishes the capacity of the person to take care of themselves.

Northern Territory

In the Northern Territory, mental illness means a condition that seriously impairs, either temporarily or permanently, the mental functioning of a person in one or more of the areas of thought, mood, volition, perception, orientation or memory, and is characterized by the presence of at least one of the following symptoms: delusions, hallucinations, serious disorders of the stream of thought, serious disorders of thought form or serious disturbances of mood. A mental illness is also characterized by sustained or repeated irrational behaviour that may be taken to indicate the presence of at least one of the symptoms mentioned above. The Northern Territory Act goes further to specify that the determination of mental illness is only to be made in accordance with internationally accepted clinical standards.

Similar to the New South Wales Act, there is a provision in the Northern Territory for those who are 'mentally disturbed', which means behaviour of a person that is so irrational as to justify the person being temporarily detained under the Act. The Northern Territory also has provisions for people with complex cognitive impairment who require involuntary treatment.

Queensland

The Queensland Act defines mental illness in a similar way to Victoria, in that it is a condition characterized by a clinically significant disturbance of thought, mood, perception or memory, in accordance with internationally acceptable standards.

South Australia

In the South Australian Act, mental illness means any illness or disorder of the mind.

Tasmania

A person is taken to have a mental illness if they experience temporarily, repeatedly or continuously, a serious impairment of thought (which may include delusions) or a serious impairment of mood, volition, perception or cognition.

Victoria

A person is mentally ill if they have a mental illness, being a medical condition characterized by a significant disturbance of thought, mood, perception or memory.

Western Australia

Persons have a mental illness if they suffer from a disturbance of thought, mood, volition, perception, orientation or memory that impairs judgement or behaviour to a significant extent.

Indigenous and cultural acknowledgement

Cultural differences in the understanding and experiences of mental illness can impact greatly on the ability to provide adequate care. While there are some cursory references to acknowledging special cultural and linguistic needs when interpreting the various mental health acts, only the Northern Territory, Victoria and South Australia in Australia, and the New Zealand Mental Health Acts make specific mention of indigenous people, who are known to be a particularly vulnerable group.[5] Recent legislative reform in some Australian states incorporates recognition of the needs of Aboriginal and Torres Strait Islander and other culturally diverse peoples within a general statement of principles.

The Northern Territory Act states that there are fundamental principles to be taken into account when caring for Aboriginal and Torres Strait Islander peoples. Treatment and care needs to be appropriate to the cultural beliefs and practices of the person, their family and community, and involuntary treatment for an Aboriginal person is to be provided in collaboration with an Aboriginal health worker.

New Zealand stipulates that powers are to be exercised in relation to the Mental Health Act with proper respect for cultural identity and personal beliefs, and with proper recognition of the importance and significance to the persons of their ties with family, whanau, hapu, iwi and family group. Interpreters are to be provided if the first or preferred language is not English, with special mention of Maori and New Zealand Sign Language.

Safeguards against prejudice

New Zealand and all Australian states include a number of criteria that, alone, cannot be used to determine that a person has a mental illness and requires involuntary admission. These generally include the expression of or refusal to express particular religious, political and philosophical beliefs; cultural or racial origin; sexual promiscuity or preference; intellectual disability; drug or alcohol taking; economic or social status; immoral or indecent conduct; illegal conduct; and antisocial behaviour. The Northern Territory, Western Australia and Queensland also include past treatment for mental illness and past involuntary admission under these criteria.

Effects of drugs or alcohol

In most Australian states and New Zealand, the taking of drugs or alcohol cannot, of itself, be taken as an indication of mental illness. However, the mental health acts of New South Wales, South Australia, Tasmania, Western Australia and Victoria specify that this does not prevent the serious temporary or permanent physiological, biochemical or psychological effects of alcohol or drug taking from being regarded as an indication that a person is mentally ill. The Queensland Act acknowledges that a person may have a mental illness caused by taking drugs or alcohol.

The remaining states do not specifically exclude the temporary or permanent effects of drugs or alcohol but use definitions of mental or psychiatric illness that are broad enough to cover this. In general, when a person is so mentally and behaviourally disordered as a result of drug or alcohol use that adequate assessment is impossible and risk of harm to self or others is high, then detaining them for the purposes of assessment and treatment is possible under all Australian and New Zealand mental health acts.

Criteria for admission and detention as an involuntary patient

All states require that an involuntary patient has a mental illness that requires urgent treatment while detained in an inpatient setting for the health (mental or physical) and safety of that patient or for the protection of others. Most states also require that the patient has refused or is unable to consent to voluntary admission. It is also emphasized that appropriate treatment must be available and cannot be given in a less restrictive setting. In New South Wales, the effects of chronicity and the likely deterioration of the person's condition should be taken into account when determining need for involuntary admission.

Tasmania, Western Australia, Queensland, South Australia and ACT have all included decision-making capacity as part of their criteria for admission and detention

In New Zealand, the doctor must have reasonable grounds for believing that the person may be mentally disordered and that it is desirable, in the interests of the person, or of any other person or of the public, that assessment, examination and treatment of the person are conducted as a matter of urgency.

Involuntary admission

The process of involuntary admission varies quite markedly across the states. It is variously known as recommendation, certification or committal. All jurisdictions require doctors to examine patients and carefully document on prescribed forms the date and time of examination as well as the particular reasons why the doctor believes that the person has a mental illness that requires involuntary treatment. In addition, patients or their advocates are to be informed of the decisions made about them and their rights under the law at all stages of the involuntary admission process. Increasingly, clinicians are required to give copies of formal

orders and printed information about their rights to patients and guardians.

ACT

In the ACT, a person may apply for an assessment order if a person who appears to be mentally ill is at risk to themselves or others. The assessment order requires the person to be taken for assessment at a hospital within 7 days, whereupon an application for a treatment order can be made (or an emergency apprehension and detention order if there are immediate concerns).

New South Wales

The Mental Health Act in New South Wales allows for a patient requiring involuntary admission to be detained in a declared mental health facility (which includes EDs) on the certificate of a doctor (or trained 'accredited person') who has personally examined the patient immediately or shortly before completing the certificate.

For a mentally ill patient, the certificate is valid for 5 days from the time of writing, whereas for a mentally disordered patient, the certificate is valid for 1 day. Mentally disordered patients cannot be detained on the grounds of being mentally disordered on more than three occasions in any 1 month.

Part of the certificate, if completed, directs the police to apprehend and bring the patient to hospital and also enables them to enter premises without a warrant.

An involuntary patient must be examined by an authorized medical officer (including emergency doctors) as soon as practicable, but within 12 hours of admission. The patient cannot be detained unless further certified mentally ill or disordered. This doctor cannot be the same doctor who requested admission or certified the patient. After their own examination, the medical officer must arrange for a second examination as soon as practicable, this time by a psychiatrist. If neither doctor thinks that the person is mentally ill or disordered, then the person must be released from the hospital.

A patient who has been certified as mentally disordered, but not subsequently found to be mentally ill, cannot be detained for more than 3 days and must be examined by an authorized medical officer at least once every 24 hours and discharged if no longer mentally ill or disordered, or if appropriate and less restrictive care is available. New South Wales legislation involves several checks and balances, including timely and regular Mental Health Review Tribunal assessment for all patients recommended for involuntary care.

New Zealand

In New Zealand, a person aged 18 years or older may request an assessment by the area mental health service if it has seen the person within the last 3 days and believes the person to be suffering from a mental disorder. The request may be accompanied by a certificate from a doctor who has examined the 'proposed patient' within the preceding 3 days and who believes that the person requires compulsory assessment and treatment. The medical certificate must state the reasons for the opinion and that the patient is not a relative. The area mental health service must then arrange an assessment examination by a psychiatrist or other suitable person forthwith. If the assessing doctor considers that the patient requires compulsory treatment, the patient may be detained in the 'first period' for up to 5 days. Subsequent assessment may result in detention for a 'second period' of up to 14 more days, after which a 'compulsory treatment order' must be issued by a family court judge.

Northern Territory

Any person with a genuine interest in or concern for the welfare of another person may request an assessment by any medical practitioner to determine if that person is in need of treatment under the Northern Territory Mental Health Act. The assessment must then occur as soon as practicable and a subsequent recommendation for psychiatric examination made if the doctor believes that the person fulfils the criteria for involuntary admission on the grounds of mental illness or mental disturbance. The person may then be detained by police, ambulance officers or the doctor making the recommendation and taken to an approved treatment facility, where the person may be held for up to 24 hours. The Northern Territory Act acknowledges that delays in this process are likely and enshrines a process to account for this, including the use of interactive videoconferencing. A psychiatrist must examine and assess the recommended person at the approved treatment facility, and must either admit as an involuntary patient or release the patient if the criteria for involuntary admission are not fulfilled.

A patient admitted on the grounds of mental illness may be detained for 24 hours or up to 14 days if the recommending doctor was also a psychiatrist. Patients admitted on the grounds of mental disturbance may be detained for 72 hours or have that extended by 7 days if two examining psychiatrists believe that the person still requires involuntary treatment and cannot or will not consent. Frequent psychiatric reassessment of detained and admitted patients is required to either extend admission or release patients who do not fulfil involuntary criteria, and patients and their caregivers must be notified of any decisions.

Queensland

In Queensland, the recommendation for involuntary assessment of a patient must be made by a doctor who has personally examined the patient within the preceding 7 days and is valid for 7 days from the time the recommendation was made. The recommendation enables the health practitioner, ambulance officer or police, if necessary, to take the patient to a mental health service or public hospital for assessment. Once there, or if the recommendation was made at a hospital, the assessment period lasts for no longer than 24 hours.

The patient must be assessed by a psychiatrist (who cannot be the recommending doctor) as soon as practicable and, if the treatment criteria apply, will have the involuntary status upheld through a treatment authority. The assessment period can be extended up to 72 hours by the psychiatrist after regular review.

South Australia

In South Australia, a doctor or trained authorized health professional (who may be a nurse, allied or aboriginal health worker) who considers that a patient requires involuntary admission authorizes a Level 1 Detention and Treatment Order, which is valid for 7 days. A psychiatrist or authorized medical practitioner (senior psychiatry registrar) must examine the person within 24 hours or as soon as practicable.

In recognition of the difficulties in accessing appropriate care for people in remote and rural environments, the South Australian Mental Health Act allows for audiovisual conferencing and a range of community and inpatient based treatment orders. A wider range of health professionals can authorize treatment orders so that early access to care in the least restrictive environment can occur.

Tasmania

In Tasmania, an application for an assessment order may be made by a close relative or guardians or a medical practitioner, nurse, mental health officer, police or ambulance officer; however, an assessment order can be made without an application. A medical practitioner must then assess the person and, if satisfied that the criteria are met, make an order for admission and detention as an involuntary patient in an approved hospital. This initial 'assessment order' is valid for 24 hours and gives authority for the patient to be taken to the hospital and detained, whereupon a psychiatric assessment must be carried out within 24 hours and the assessment order extended for up to 72 hours or discharged. A 'treatment order' for the continuing detention of a person as an involuntary patient can only be made by application (including an individualized treatment plan) through an independent tribunal.

Victoria

A person can be placed under an assessment order by a medical or mental health practitioner. This remains in force for up to 24 hours unless extended (up to a maximum of 72 hours). Once admitted, the patient must be seen by an authorized psychiatrist within 24 hours. The assessment can take place in the community or in a hospital. A temporary treatment order can be made following the assessment that can be either a community order or an inpatient order.

Western Australia

In Western Australia, a person who requires involuntary admission is referred for examination by a psychiatrist in an authorized hospital. The referring doctor or authorized mental health practitioner may also make a detention and/or transport order which allows safe transport involving the police or ambulance personnel if required. These orders are valid for up to 72 hours, although there are provisions for time extensions outside the metropolitan area.

The referral for assessment is valid for 72 hours (although this can also be extended); however, the patient must be examined by a psychiatrist within 24 hours of admission and cannot be detained further if not examined. The patient can be detained for further assessment for up to 72 hours after initial admission on the order of the psychiatrist, after which time the patient is formally admitted as an involuntary patient, discharged on a community treatment order or released.

Persons unable to recommend a patient for involuntary admission

New Zealand and most states, except for the ACT, specify that certain relationships prevent a doctor from requesting or recommending a patient for involuntary admission.

The recommending doctor cannot be a relative (by blood or marriage) or guardian of the patient and, in addition, in the Northern Territory, Queensland and Western Australia, the doctor cannot be a business partner or assistant of the patient.

In New South Wales, the doctor must declare, on the schedule, any direct or indirect pecuniary interest, or those of their relatives, partners or assistants, in a private mental health facility. In Western Australia, the doctor cannot hold a licence from or have a family or financial relationship with the licence holder of a private hospital in which the patient will be treated, nor can the doctor be a board member of a public hospital treating the patient.

In Victoria and Tasmania, anyone with a conflict of interest is prohibited from performing functions or duties under the Act.

Use of sedation or physical restraint

From time to time, a patient may need to be sedated or even restrained. The various mental health acts vary considerably in dealing with this issue and accepted clinical practice has evolved differently in each jurisdiction and does not necessarily reflect subtleties within the legislation.

In general, patients committed involuntarily are subject to treatment necessary for their care and control, and this may reasonably include the administration of sedative or antipsychotic medication as emergency treatment. In general, sedation or restraint must be the minimum that is necessary to prevent the patient from self-harming or harming others, and careful documentation of the reasons for restraint and the types of restraint is required. While restrained, access to clothing, sustenance, toilet facilities and other basic comforts must be assured.

Patients who are physically or pharmacologically restrained must be closely supervised and not left alone or in the care of persons not trained or equipped to deal with the potential complications of these procedures. Transporting these patients to a mental health service should be done by suitably trained medical or ambulance staff and not delegated to police officers or other persons acting alone.

The ACT allows treatment of persons held under emergency detention to prevent immediate and substantial risk of harm to self or others, whereas Western Australia specifies that emergency treatment can be given without consent and that the details must be recorded and a copy given to the patient and the chief psychiatrist. Queensland allows a doctor to administer medication for recommended patients without consent to ensure safety during transport to a health facility.

Victoria allows a health practitioner to treat a person without consent in urgent circumstances to save lives, prevent serious damage to health or prevent suffering. The South Australian law stipulates that medication can only be used for therapeutic purposes and that chemical, physical restraint and seclusion is to be used as a last resort for safety reasons and not as a punishment or for the convenience of others. NT allows emergency treatment when delay in seeking approval might be 'deleterious' to the person's health. Tasmania allows treatment of involuntary patients under urgent circumstances upon authorization from the chief civil psychiatrist or their delegate.

The legislation is more specific with regard to the use of physical restraint or seclusion. In the ACT, if a person is restrained or secluded, it must be recorded in the patient's notes, and the public advocate must be informed in writing and a register must be kept. Queensland requires that restraint used for the protection of the patient or others can only be done if authorized by an authorized doctor but is permissible for the purposes of treatment if it is clinically appropriate. Victoria permits the restraint of involuntary patients for the purposes of medical treatment and the prevention of injury. Victoria also allows the use of restraint by ambulance officers, police or doctors in order to safely transport the patient to a mental health service, but this must be documented in the recommendation schedule. Tasmania differentiates between chemical restraint and chemical treatment, and allows either when it is deemed reasonable.

The Northern Territory allows reasonable force to be used to restrain a person being treated under the act to prevent harm and maintain security of the unit. Western Australia permits the use of restraint for the purposes of medical treatment and for the protection of the patient, other persons or property, and this authorization must be in writing and the senior psychiatrist must be notified as soon as possible

The New Zealand Mental Health Act makes minimal specific reference to restraint or sedation but enables any urgent treatment to protect the patient or others, and allows hospitals and police to take all reasonable steps to detain patients for assessment and treatment. Authority is given to administer sedative drugs if necessary, but the Act mandates a record of this for the area mental health service.

New South Wales has a Reference Guide specifically for mental health issues in the ED which covers sedation and restraint issues. The law permits the use of involuntary sedation for acute behavioural disturbance in an emergency situation in order to prevent individual death or serious danger to the health of others under the common law principle of 'Duty of Care'. The same applies for children, although consent should be sought from both children or adolescents and their parents or guardians. For the use of physical restraints, although acknowledged as a clinical decision, four pre-conditions must be met:

- The person has a medical or psychiatric condition requiring care.
- The person is at the time incapable of responding to reasonable requests from health staff to cooperate, and other self-control measures are impractical or have failed.
- The person's behaviour is putting themselves or others at serious risk.
- Less restrictive alternatives are not appropriate.

Emergency treatment and surgery

On occasion, involuntary patients may require emergency medical or surgical treatment. New Zealand and most states, except for Queensland, make provision for this in their legislation, in that

patients can undergo emergency treatment without consent, but usually only with the approval of the relevant mental health authorities or treating psychiatrist. In New Zealand, treatment that is immediately necessary to save life, prevent serious damage to health or prevent injury to the person or others can be undertaken without consent.

Victoria has the most specific reference to this treatment by making special allowance for a patient requiring treatment that is life sustaining or preventing serious physical deterioration for whom no other decision maker is identified; then an authorized psychiatrist can give consent.

Apprehension of absent involuntary patients

Involuntary patients who escape from custody or who fail to return from 'leave' are considered in most state mental health acts to be 'absent without leave' (AWOL) or 'unlawfully at large'. Authorized persons, including ambulance officers, mental health workers and police, have the same powers of entry and apprehension as other persons to whom a recommendation or certificate relates.

In New Zealand, any compulsory patient who becomes AWOL may be 'retaken' by any person and taken to any hospital within 3 months of becoming absent. If not returned after 3 months, the patient is deemed to be released from compulsory status.

Powers of the police

The police in all states and New Zealand have powers in relation to mentally ill persons who may or may not have been assessed by a doctor. For someone who is not already an involuntary patient and who is reasonably believed to be mentally ill, a risk to self or others and requiring care, police are able to enter premises and apprehend, without a warrant, and to use reasonable force if necessary, in order to remove the person to a 'place of safety'. In general, this means taking the person to a medical practitioner or a mental health service for examination without undue delay.

South Australia, ACT and Queensland specifically include ambulance or other authorized officers within this legislation and acknowledge that they often work together with police to detain and transport people for mental health assessment. In Tasmania, people may only be held in protective custody for the purposes of medical assessment for no longer than 4 hours and then released if no involuntary assessment order has been made.

Some states (ACT, New South Wales and Victoria) make special mention of a threatened or actual suicide attempt as justification for police apprehension and transfer to a health facility. New South Wales allows police discretion after a person who appears mentally disordered has committed an offence (including attempted murder), to determine whether it is beneficial to their welfare to be detained under the mental health act rather than under other criminal law. The Victorian, Northern Territory and South Australian Acts, in contrast, acknowledge that police do not need clinical judgement about mental illness but may exercise their powers based on their own perception of a person's appearance and behaviour that may be suggestive of mental illness.

In New Zealand, detention by police is limited to 6 hours, by which time a medical examination should have taken place. Ideally, police should not enter premises without a warrant, if it is reasonably practicable to obtain one.

The same powers apply to involuntary patients who abscond or are AWOL, although some states have specific schedules or orders to complete for this to be done. In general, once police become aware of the patient, they are obliged to make attempts to find and return them to what can be viewed as lawful custody.

Prisoners with mental illness

Mental illness among people in prison is extremely prevalent, either as a cause or as a result of incarceration. New Zealand and most Australian states and territories include provisions for prisoners with mental illness within their mental health legislation. While the health care of prisoners is generally managed within regional forensic systems, EDs in rural and less-well-resourced areas can become a site of care for prisoners with acute psychiatric illness.

The New Zealand Act states that prisoners with mental illness who require acute care can be transferred to a general hospital for involuntary psychiatric treatment if the prison is unable to provide that care. Australian Acts in New South Wales, the ACT, the Northern Territory and Victoria all include similar specific provisions for mentally ill prisoners to be able to access involuntary care in public hospitals if needed. New South Wales has separate legislation specifically dealing with mental illness in the forensic setting (NSW Mental Health [Forensic Provisions] Act 1990), while the Tasmanian Act includes a large section involving the admission, custody, treatment and management of forensic patients within secure mental health units. The Victorian Act has some detail in this matter, although, in practice, rarely relies on public hospitals due to the development of a stand-alone forensic psychiatric hospital. Both Queensland and Western Australia enshrine the same principle of allowing prisoners access to general psychiatric treatment, although their legislation is less specific, while the South Australian Act does not mention prisoners at all. In all jurisdictions, there is significant overlap with other laws such as Crimes and Prisons Acts, which also mention health needs of prisoners.

Offences in relation to certificates

Most states and New Zealand specify in their respective mental health acts that it is an offence to willfully make a false or misleading statement in regard to the certification of an involuntary patient.

Some states (New South Wales and South Australia), except in certain circumstances, also regard failure to personally examine or observe the patient as an offence.

Protection from suit or liability

New Zealand and all Australian states specify in their Mental Health Acts that legal proceedings cannot be brought against doctors acting in good faith and with reasonable care within the provisions of the Mental Health Act relevant to their practice.

Information and patient transfer between jurisdictions

All Australian states and territories include special provisions for the apprehension, treatment and transfer of mentally ill patients from other jurisdictions. State governments can enter into agreements to recognize warrants or orders made under 'corresponding law' in other states or territories, as long as appropriate conditions are met within their own law. Thus a patient under an involuntary detention or community treatment order in another state can be apprehended and treated under the corresponding law in a different jurisdiction. Authority is given to police and doctors to detain such patients and information to facilitate assessment and treatment can be shared between states.

Deaths

Involuntary patients should be considered to be held in lawful custody, whether in an ED, as an inpatient in a general hospital or psychiatric hospital or as an AWOL. As such, the death of such a patient must be referred for a coroner's investigation.

CONTROVERSIES AND FUTURE DIRECTIONS

United Kingdom

- The provision of mental health services to EDs varies widely across the UK. Responsiveness of services remains an issue of contention, particularly in light of national 4 hours targets for treatment in EDs. 'Emergency Psychiatry' standards are required to ensure consistency of care.
- In the UK, the most commonly used places of safety for individuals deemed to be a danger to themselves or the public are EDs, police stations and psychiatric units. Concern exists about the suitability of EDs for acting as places of safety. The National Service Framework on Mental Health states that hospitals should be used in preference to police stations; however, there is no national consensus on the future use of the ED as a place of safety. Currently, individual departments are entering into local policy agreements with other agencies on their use.
- As the specialty of emergency medicine expands, health professionals, such as emergency nurse practitioners and paramedics, are increasingly making clinical decisions about patients. This presents a challenge to the specialty in ensuring that all are appropriately trained and informed of the law relating to patients with mental health problems. It is vital that training and education continue to be central to delivering an appropriate service in often difficult circumstances.
- In 2004, the National Institute for Health and Clinical Excellence (NICE) published a guideline on the treatment and prevention of self-harm focusing on care in the ED. It stressed the importance of staff attitudes towards these patients. Patients who have self-harmed reported frequently being treated not only with a lack of respect, as 'time wasters', but at times receiving punitive treatment at the hands of ED staff.
- A current review of the existing UK Mental Health Act will look at:
  - caregivers' and relatives' involvement in treatment choices, and the ability of patients to choose which of these people are involved
  - the possibility of detaining patients without necessarily treating them
  - a review of the effectiveness of community treatment orders
  - a review of safeguards available to patients

Australia and NZ

- Greater uniformity between the mental health legislation of Australian states and territories is desirable from both a patient's and a health care provider's perspective. While there has been some move towards commonality with recognition of 'corresponding laws', great disparity still exists in some areas between jurisdictions. These differences could be overcome without compromising the fundamental principles of mental health legislation in the Australia and NZ region.
- More legal recognition of cultural and language difference is required as Australia and New Zealand become home to increasingly diverse populations. In particular, refugees and people from areas exposed to warfare and torture have specific mental health needs that should be accounted for within progressive legislation. Better acknowledgement of indigenous mental health issues is also an area requiring legislative improvement.
- Police are given great powers within Australia and NZ laws to apprehend and detain mentally unwell people, yet lack a sophisticated knowledge of mental illness. Greater education and collaborative work between police and health care providers, especially those working in EDs, should lead to more humane and patient-focused provision of care.
- Governments and the community are taking increasing interest in what actually happens within EDs, particularly in regard to practices of chemical sedation and physical restraint for patients with mental illness and acute behavioural disturbance. Increased clarity, uniformity and transparency around criteria for the use of chemical and physical restraints will benefit clinicians, patients and external observers from a both a clinical quality and safety perspective. A human rights framework that enshrines least restrictive practices is recommended.
- With an increased legislative focus on recognition of individual human rights and elevation of autonomous decision making, recognition of advanced directives is shaping future emergency care for patients with mental illness and acute behavioural disturbance.

28.2 The coroner: the Australian, NZ and UK perspectives

Biswadev Mitra • Jane Terris

ESSENTIALS

1 **The Coroners Court is a specialist court established to investigate certain types of deaths and fires. The purpose of these investigations is to consider ways that similar events may be prevented in the future.**

2 **Preparation for a coronial investigation should start as soon as someone dies in reportable circumstances.**

3 **A coronial inquest is generally a public inquiry into a death to which a medical practitioner may be subpoenaed.**

4 **Coronial findings may be used constructively to effect positive change within a department, institution or system.**

Introduction

The function of the coroner is to investigate and report the circumstances surrounding a person's death or fires. A coronial inquest is generally a public inquiry into one or more deaths conducted by a coroner within a court of law. Legislation in each Australian state and territory defines the powers of this office and the obligations of medical practitioners and the public towards it. The process effectively puts details concerning a death on the public record and is being increasingly used to provide information and recommendations for future injury prevention.

As many people die each year either in an emergency department (ED) or having attended an ED during their last illness, it is almost inevitable that emergency physicians will become involved in the coronial process at some stage during their career. Such involvement may be brief, such as the discharge of a legal obligation by reporting a death, or may extend further to providing statements to the coroner regarding deaths of which they have some direct knowledge. Later, the coroner may require them to appear at an inquest to give evidence regarding the facts of the case and, possibly, their opinion. Occasionally, the coroner requires a suitably experienced emergency physician to provide an expert opinion regarding aspects of a patient's emergency care.

Although the inquisitorial nature of the coronial process is sometimes threatening to medical practitioners, their involvement is a valuable community service. In addition, they may obtain important information regarding aspects of a patient's clinical diagnoses and emergency care, which may improve the provision of emergency care to future patients.

Legislation

The office of the coroner and its functions, procedures and powers are created by state and territory legislation. The legislation also creates obligations for medical practitioners to notify the coroner of reportable deaths and to cooperate with the coroner by providing certain information in the course of an inquiry. The normal constraints of obtaining consent for the provision of clinical information to a third party do not apply in these circumstances.

The coroner is vested with wide-ranging powers to assist in obtaining information. In practice, the police are most commonly used to conduct the investigation. Under the various Coroners Acts they have the power to enter and inspect buildings or places, take possession of and copy documents or other articles, take statements and subpoena people to appear in court. The coroner has control of a body whose death has been reported and may direct that an autopsy be performed.

As each Australian state and territory legislation is different, emergency physicians must be familiar with the details in their particular jurisdiction. The current legislation in New Zealand and each state and territory is:

Australian Capital Territory—Coroners Act 1997
New South Wales—Coroners Act 2009
New Zealand—Coroners Act 2006
Northern Territory—Coroners Act 2011
Queensland—Coroners Act 2003
South Australia—Coroners Act 2003
Tasmania—Coroners Act 1995
Western Australia—Coroners Act 1996
Victoria—Coroners Act 2008.

As an example, under the Coroners Act 2008 (Victoria), when a death is reported, the coroner investigating a death must find, if possible, the identity of the deceased, how the death occurred, the cause of death and the details needed to register the death with the Registry of Births, Deaths and Marriages. Under the Coroners Act 2008, a coroner investigating a fire must find, if possible, the cause of the fire and the origin of the fire. In some cases, the coroner may comment and make recommendations about public health or safety or the administration of justice aimed at helping to prevent similar deaths and fires from happening.

Reportable deaths

Reportable deaths are a special category of death required to be reported to the court and investigated by a coroner. There doesn't have to be anything suspicious in order for a coroner to investigate a death. In fact, the majority of deaths investigated by coroners do not have any suspicious circumstances at all. Coroners investigate deaths that are directly or indirectly the result of an accident or injury. This may include, but is not limited to, road fatalities, public transport fatalities, accidental falls, workplace deaths, electrocutions, drownings and animal attacks. Coroners also investigate types of reportable deaths called unnatural deaths. This means that the cause of the person's death was not due to a natural disease or medical condition. This may include, but is not limited to suicides, poisonings, overdoses and homicides.

Most deaths that occur in the community are not reported to a coroner and, consequently, are not investigated. The coroner has no power to initiate an investigation unless a death is reported, but may choose to investigate the death at the request of a next of kin or a person who registers themselves as an interested party. If a medical practitioner is able to issue a medical certificate of the cause of death, the Registrars-General of that state or territory may issue a death certificate and the body of the deceased may be lawfully disposed of without coronial involvement.

In general, to issue a certificate of the cause of death, a doctor must have attended the deceased during the last illness, and the death must not be

encompassed by that jurisdiction's definition of a reportable death. It is essential that every medical practitioner has a precise knowledge of what constitutes a reportable death within the jurisdiction.

It is uncommon for a doctor who is working in an ED to have had prior contact with a patient during the last illness. Therefore, even if sure of the reason why the patient died, the doctor is often unable to complete a medical certificate of the cause of death. It is quite permissible, and even desirable, under these circumstances, to contact the patient's treating doctor to inquire as to whether that doctor is able to complete the certificate. This process reduces the number of deaths that must be reported and assists families who may be distressed about coronial involvement.

All Australian Coroners Acts contain a definition of the deaths that must be reported. Although the precise terminology varies, there are many similarities between them. In general, each Act has provisions for inquiring into deaths that are of unknown cause or that appear to have been caused by violent, unnatural or accidental means. Many acts also refer to deaths that occur in suspicious circumstances and some specifically mention killing, drowning, dependence on non-therapeutic drugs and deaths occurring while under anaesthesia. The Tasmanian Act goes further to specify deaths that occur under sedation.

Coroners do not hold criminal trials and cannot find a person guilty or innocent of a criminal offence. In circumstances where a coroner's investigation into a death involves a homicide, he or she examines the circumstances surrounding the death in order to establish whether it could have been prevented. In some circumstances, a coroner may need to make a specific decision about a matter reported to the court during the course of the investigation or during a court proceeding, such as an inquest. These decisions are called orders or rulings. Orders and rulings are not written findings. They can include, but are not limited to Non-Publication Orders restricting the release of some information, rulings on applications as to whether an inquest should be held, rulings on applications as to whether an investigation should be re-opened, rulings on applications as to whether a person or organization should be an interested party or rulings on whether the coroner has jurisdiction to investigate.

Despite the seemingly straightforward definitions given in the various acts, there are many instances where it may not be clear whether a death is reportable or not. Emergency physicians are often faced with situations where there is a paucity of information regarding the circumstances of an event and where the cause of death may be difficult to deduce. Correlation between the clinical diagnoses recorded on death certificates and subsequent autopsies has been consistently shown to be poor. What exactly constitutes unexpected, unnatural or unknown is open to debate and may require some judgment. In all cases, the coroner expects the doctor to act with common sense and integrity. If at all in doubt it is wise to discuss the circumstances with the coroner or assistant and to seek advice. This conversation and the advice given must be recorded in the medical notes.

The process of reporting a death is generally a matter of speaking to the coroner's assistants (often referred to as coroner's clerks), who will record pertinent details and, if necessary, investigate. The report should be made as soon as practicable after the death. A medical practitioner who does not report a reportable death is liable to a penalty.

Even though coroners' offices and the police work closely together, reporting a death to the coroner is not necessarily equivalent to reporting an event to the police. If it is possible that a person has died or been seriously injured in suspicious circumstances, then it is prudent to ensure that the police are also notified.

A coronial investigation

After a death has been reported, the coroner or designated assistant may initiate an investigation. This is most commonly conducted by the police assisting the coroner, with an autopsy conducted by a forensic pathologist.

The body, once certified dead, becomes part of that investigation and should be left as far as possible in the condition at death. If the body is to be viewed by relatives immediately, it is often necessary to make it presentable. This must be done carefully, so as to not remove or change anything that may be of importance to the coroner. If a resuscitation was attempted, all cannulae, endotracheal tubes and catheters should be left in situ. All clothing and objects that were on (or in) the deceased should be collected, bagged and labelled. All medical and nursing notes, radiographs, electrocardiographs and blood tests should accompany the body if it is to be transported to a place as directed by the coroner.

Medical notes taken during or soon after the activity of a busy resuscitation are often incomplete. It is not easy to recall accurately procedures, times and events when the main task is to prevent someone from dying. Similarly, after death there are many urgent tasks, such as talking to relatives, notifying treating or referring doctors and debriefing staff. However, it is essential that the documentation is completed as accurately and thoroughly as possible. The notes must contain a date and time and clearly specify the identity of the author. If points are recalled after completing the notes, these may be added at the end of the previous notes, again with a time and a date added. Do not under any circumstances change or add to the body of the previous notes.

In addition to completing the medical notes, a medical practitioner may be requested to provide a statement to the coroner regarding the doctor's involvement with the deceased and an opinion on certain matters. Such a statement should be carefully prepared from the original notes and written in a structured fashion, using non-medical terminology where possible. The statement often gives the opportunity for the medical practitioner to give further information to the coroner regarding medical qualifications and experience, the position fulfilled in the department at the time of the death and a more detailed interpretation of the events. If a statement is requested from junior ED staff, it is strongly advisable for these to be read by someone both clinically and medico-legally experienced.

Providing honest, accurate and expeditious information to relatives when a death occurs assists in preventing misunderstandings and serious issues arising in the course of a coronial investigation. Relatives vary enormously in the quantity and depth of medical information they request or can assimilate after an unexpected death. It is wise not only to talk to the relatives present at the death but also to offer to meet later with selected family members. Clarification with the family of what actually occurred, what diagnoses were entertained and what investigations and procedures were performed is not only good medical practice but can allay concerns regarding management. Such communication, as well as aiding in the grieving process for relatives of the deceased, may avert an unnecessary coronial investigation initiated by relatives seeking answers about the death by contacting the coroner.

If a significant diagnosis was missed or inappropriate or an inadequate treatment given, or a serious complication of an investigation or procedure occurred, assistance and advice from the hospital insurers and medical defence organizations should be sought before talking to the family. However difficult it may be, it is far better that the family is aware of any adverse occurrences before the inquest than for them to harbour suspicions or to get a feeling something is being covered up. Such a conversation should be part of an open disclosure approach to patient care, involving open communication with a patient or family following an adverse or unexpected event. The coroner is far more likely to be sympathetic to a genuine mistake or omission when it has been discussed with the family and the hospital has taken steps to prevent a recurrence.

A coronial inquest

A coronial inquest is a public inquiry into one or more deaths. Deaths may be grouped together if they occurred in the same instance or in apparently similar circumstances. The purpose of the inquest is to put findings on the public record. These may include the identity of the deceased, the circumstances surrounding the death, the medical cause of death and the identity of any

person who contributed to the death. The coroner may also make comments and recommendations concerning matters of health and safety. In some jurisdictions these are termed 'riders'. In addition, as His Honour BR Thorley pointed out, the inquest serves to:

…include the satisfaction of legitimate concerns of relatives, the concern of the public in the proper administration of institutions and matters of public and private interest…

The inquest does not serve to commit people for trial or to provide information for a subsequent criminal investigation.

With broad terms of reference and the ability to admit testimony that may not be allowed in criminal courts, inquests interest many people—not only those who may have been directly involved. They are often highly publicized media events and may provoke political comment, especially where government bodies are involved. A medical practitioner served a subpoena to attend should prepare carefully, both individually and in conjunction with the hospital, and should ensure that he or she has legal representation, either individually or through the hospital insurers. Where the doctor subpoenaed is being provided legal counsel by the hospital, it is vital to ensure that the hospital administrators support the actions of the doctor in relation to the death. It is advised that, in the event of being subpoenaed to a coronial inquest, the doctor seek advice immediately from the appropriate medical defence agency.

Preparation for an inquest begins at the time of the death. Complete and accurate medical notes, together with a carefully considered statement, provide a solid foundation for giving evidence and handling any subsequent issues. Statements containing complex medical terminology, ambiguities or omissions only serve to create confusion. Discuss the case with colleagues who are not directly involved and have the hospital lawyers read the statement before it is submitted.

Appearing at an inquest can be a stressful event, especially if, on a review of the circumstances, a doctor's actions or judgement may be called into question. Professional peer support, as well as legal advice, should be offered to all medical staff. Simple actions, such as a briefing on court procedures and some advice on how to deal with cross-examination, can be of immense value.

A coroner's court is conducted with a mix of 'inquisitorial' and 'adversarial' legal styles. It is inquisitorial in that the coroner may take part in direct proceedings and can question witnesses and appoint court advisers. It is adversarial in that parties with a legitimate interest can be represented in proceedings and can challenge and test witnesses' evidence, especially where it differs from what they would like presented. Interested parties generally attend court and can ask any questions of the doctor through their own legal representative or through the police counsel to the coroner. The 'rules of evidence' are more relaxed in the coroner's court than in a criminal court. Hearsay evidence—that is, evidence of what someone else said to a witness—is generally admissible. Despite these differences, it is important to remember that it is no less a court than a criminal court and demands the same degree of respect and professional conduct one would accord to the latter.

Coronial findings

At the conclusion of an inquest, the coroner makes a number of findings directed at satisfying the aims of that inquest. These findings are made public and are often of interest to those who are directly involved, as well as to a wider audience. For example, The Coroners Act 2008 (Victoria) requires that all inquest findings with recommendations be published on the internet, unless otherwise ordered by a coroner. This will identify all medical practitioners involved in the case including ones providing expert opinion.

The findings of an inquest in which the conduct of a particular emergency physician, ED or hospital has been scrutinized will be of particular interest. Although it is always pleasing to have either positive or a lack of negative comment delivered in the finding, criticism of some aspect of the conduct of an individual, department, hospital or the medical system in general is not uncommon. Unfortunately, it is often this criticism that attracts the most public attention and, somewhat unfairly, the public perception of our acute health care system is shaped by the media's attention to coronial findings.

In the recent past, coroners have commented on inadequate training, experience and supervision of junior doctors, inadequate systems of organization within departments and poor communication between doctors and family members.

Although adverse or critical findings have no legal weight or penalties attached to them, they are in many respects a considered community response to a situation in which the wider population has a vested interest. Used constructively, they can be extremely useful in convincing hospital management that a problem exists and beginning a process for effecting positive change within a department or institution.

THE UK

ESSENTIALS

1. **A coroner (or procurator fiscal in Scotland) is an independent judicial officer whose role is to enquire into the circumstances surrounding an unexplained death. The purpose of this enquiry is to establish the facts without considering liability, in order to minimize the risk of undetected homicide or other crime and to reduce public danger to life and health.**
2. **There are two types of post mortem examination (PME) in the UK, namely hospital and coronial. An inquest will be required by law if the death is found to be due to unnatural causes. Just under half of all deaths are reported to the coroner, and inquests numbered 17% of all reported deaths in 2016.[1]**
3. **Emergency physicians should be familiar with the types of death that require reporting to the coroner or procurator fiscal, including deaths potentially due to any trauma, poisoning, occupational hazards, as a result of medical procedures or the effects of an anaesthetic and deaths whose cause is unknown. Deaths that occur at work, and deaths while in custody should also be reported.[2]**
4. **The Coroners and Justice Act 2009 introduced changes to the coroner system in the UK, including reforms to the training, structure, appointment and governance of the coronial system. Death certification in the UK must now go through a medically qualified medical examiner for scrutiny and investigation if required.**
5. **Concise documentation of the clinical circumstances surrounding a death in hospital may direct the pathologist towards a detailed examination of the relevant organ or system plus review of any procedures performed in a hospital PME, and acts as a solid basis for the emergency physician to aid preparation of a subsequent statement and examination at inquest.[1]**
6. **Post-mortem imaging is increasingly used as an adjunct, or sometimes an alternative, to autopsy, and has been shown to be highly accurate in identifying the cause of death.[3,4]**
7. **Emergency physicians should seek senior assistance and may require legal advice when asked to prepare a statement for the coroner. A well-prepared statement may avoid the need for the doctor to be summoned to give evidence in court.**

Introduction

The investigation into the circumstances surrounding a death is an important part of a civilized society. Accurate recording of the cause of death serves many purposes, including accurate disease surveillance, the detection of secret homicide and potentially avoidable factors that have contributed to a death. By virtue of the patient population encountered by emergency physicians and the types of deaths that are subject to investigation, a working knowledge of coronial systems is important.

History of the coroner

The history of the coroner in the UK goes back over 700 years and is an interesting reflection of events that shaped our civilization. It is still constantly evolving. The Shipman Inquiry (2003) and the Fundamental review of Death Certification and Investigation (2003) identified problems within the services available to bereaved families and led to reforms under the Coroners and Justice Act 2009.[2]

The office of the coroner was first established in 1194 and its primary function was that of protection of the crown's pecuniary interests in criminal proceedings. The coroner was involved when a death was sudden or unexpected or a body was found in the open; however, aside from the duty to ensure the arrest of anyone involved in homicide, the coroner held a significant role in the collection of the deceased's chattels and collection of various fines.

Introduction of the Births and Deaths Registration Act in 1836 mandated registration of all deaths before burial could legally occur. This may have arisen out of need for accurate statistical information concerning deaths, but also concern about hidden homicide. Another act introduced the same year enabled coroners to order a medical practitioner to attend an inquest and perform an autopsy in equivocal cases. The Coroners Act of 1887 saw a shift of emphasis from protection of financial interests to the emphasis that remains today, namely the medical cause of death and its surrounding circumstances with eventual community benefit in mind.

The Broderick committee was appointed in 1965 to review and improve death certification in response to adverse publicity about inquests. Their report published in 1971 contained 114 recommendations, many of which were enacted. Box 28.2.1 lists the reasons the Broderick Committee considered the purpose of an inquest.

The Coroners Act (1988) states that a coroner shall hold an inquest into a death when there is:

'…reasonable cause to suspect that the deceased has died a violent or unnatural death, has died a sudden death of which the cause is unknown, or has died in prison or in such a place or circumstances as to require an inquest under any Act'.

Box 28.2.1 Reasons for an inquest (according to the Broderick Committee)

- To determine the medical cause of death
- To allay rumours or suspicion
- To draw attention to the existence of circumstances which, if unremedied, might lead to further deaths
- To advance medical knowledge
- To preserve the legal interests of the deceased person's family, heirs or other interested parties[2]

The Coroners and Justice Act 2009 introduced changes to the structure and appointment system for coroners, more flexibility between working areas of coroners and the mandate for all coroners to have held a legal qualification for 5 years. This was intended to standardize practice and ensure sufficient legal understanding of the processes. The new appointment of a chief coroner, with a senior legal background, reporting to the government, was recommended. The remit of this post included responsibility for establishing national training and governance standards for coroners and developing a charter for improving services to bereaved families.[2] The death certification system was modified to provide consistency whether the body is buried or cremated and to ensure that adequate scrutiny of the circumstances around the death happens and is documented. The introduction of a medical examiner to scrutinize all death certificates prior to burial or cremation replaced the previously medically unqualified registrar.

Structure of the coroner system in the UK

Coroners are responsible to the Chief Coroner, a senior legal practitioner who must have previously held the position of high court or circuit judge and, ultimately, is responsible to the Crown through the Lord Chancellor. There are approximately 148 coroner's districts throughout the UK and each district has a coroner and deputy coroner. Coroners are assisted in their duties by coroner's officers, who are commonly ex-police officers, and whose work is dedicated solely to coronial matters. This has probably arisen because of the significant proportion of cases in which police are the notifying agent. The nature of a coronial investigation requires knowledge about legal matters and skill in information gathering. From a practical viewpoint, the coroner's assistants may be responsible for performing such duties as attending the scene of a death, arranging transport of the body to the mortuary, notification of the next of kin and obtaining statements from relevant parties. Clearly, variation in the structure of the service between regions is inevitable and reflects the size, composition and workload within the district.[1,2]

The Coroners and Justice Act 2009 also included changes to the investigation process for certain deaths and reforms of the certification and registration of deaths. The need for reform was galvanized by several landmark cases including the Shipman Inquiry (2003), in which the system had not identified and isolated a pattern of criminal activities spanning many years by the UK general practitioner, Dr Harold Shipman, and the Fundamental Review of Death Certification and Investigation (2003), which revealed a number of problems and inconsistencies in the services available to bereaved relatives. Other findings prompting reforms included a perceived lack of leadership and training for coroners and a perceived deficiency of medical knowledge within the system. Changes to the process for issuing a death certificate include the replacement of a non-medically qualified registrar with a Medical Examiner, who scrutinizes and, if necessary, recommends investigation, following the issuing of the death certificate.

Upon notification of a death, the coroner makes initial inquiries and may direct a pathologist to perform a post mortem examination (PME). If it becomes clear at this early point that the death is a natural one and does not fall within the Coroners Act, no further investigation is required and a death certificate is issued. In other circumstances, further investigations occur and relevant information is gathered. If the coroner is subsequently satisfied that the death is natural, no inquest is required. In other cases, or in certain prescribed circumstances, an inquest is held. At the conclusion of an inquest, a finding or verdict is delivered. This verdict is not framed in a way that implies liability.

Reportable deaths

There is no statutory obligation in the UK for a doctor or any member of the public to report deaths to the coroner; however, an ethical responsibility exists and it is recognized practice to do so in particular circumstances. A 1996 letter from the Deputy Chief Medical Statistician to all doctors outlined these circumstances (Box 28.2.2).[5]

Each booklet of medical death certificates also contains a reminder of the deaths that a coroner needs to consider. The registrar of births and deaths in Scotland has a statutory duty to report certain deaths (e.g. those due to industrial disease and those occurring during surgery) to the procurator fiscal, and more specific guidelines

Box 28.2.2 Circumstances in which a death should be reported to the coroner

- The cause of death is unknown
- The deceased was not seen by the certifying doctor either after death or within the 14 days before the death
- The death was violent, unnatural or suspicious (including accident or suicide)
- The death occurred in custody or state detention
- The death may be due to self-neglect or neglect by others, or the result of a medical mishap
- The death may be due to an industrial disease or related to the deceased's employment
- The death may be due to an abortion
- The death occurred during an operation or before recovery from the effects of an anaesthetic
- The death may be a suicide
- The death occurred during or shortly after detention in police or prison custody

regarding deaths possibly related to medical mismanagement are provided (Box 28.2.3).

How to report a death

Having determined that a death is reportable, the emergency physician should contact the district coroner's office and notify the details of the deceased or if in doubt to discuss the matter further. The discussion and subsequent decision should be recorded in the patient's clinical notes. A death certificate should not be written at this stage.[4,5]

Handling the body

There are no official guidelines in place regarding handling of the body once death has been reported to the coroner; however, this aspect may be an important component of the subsequent investigation. Any therapeutic and monitoring devices, such as endotracheal tubes, intercostal catheters and intravascular catheters, should be left in situ, as determination of their correct placement or otherwise may be relevant to the death investigation. It may be important to isolate any equipment (e.g. intravenous infusion pump devices) suspected of being faulty and contributing to the death. In circumstances of suspicious or violent deaths in particular, the body should be not be handled unnecessarily, nor should the body be washed. Important trace evidence that may be crucial for subsequent criminal proceedings could be lost. For example, in deaths involving firearms, it may be useful for a forensic scientist to swab the deceased's hands for gunshot residue.

Box 28.2.3 Circumstances in which a death should be reported to the procurator fiscal in Scotland

- Deaths that occur unexpectedly involving fault or neglect on the part of another
- Some deaths of children including foster children, newborns, suffocation
- Deaths that are violent, suspicious, unexplained or due to poisoning
- Possible or suspected suicide
- Deaths that are apparently associated with lack of medical care
- Deaths as a result of a medical mishap or as a result of treatment, or absence thereof, including during the actual administration of general or local anaesthetic or which may be due to an anaesthetic
- Any death at work, whether or not due to an accident, or due to occupation or industrial disease
- Any death due to notifiable infectious disease including food poisoning
- Any death in legal custody
- Any death by drowning

Clothing removed from the deceased during resuscitation efforts should be set aside and preferably placed into individual paper bags. Any remaining clothing on the deceased should be left in situ. Blood taken during resuscitation attempts, regardless of whether it was processed or not, should not be discarded, but kept refrigerated and its existence indicated to the coroner. The examination of ante-mortem blood samples can provide valuable information; for example, electrolyte and glucose concentrations, drug concentrations and, in cases of anaphylaxis, a tryptase assay.[4] The autopsy process may also involve microbiology, virology, metabolic studies and electron microscopy. Post mortem imaging is a rapidly growing field of expertise which may augment, or replace the autopsy. Experience with post mortem computed tomography (CT), magnetic resonance imaging (MRI), angiography and 3D surface scanning may all be useful with different indications for different modalities. CT gives a detailed tissue and organ view with foreign body visualization, while 3D surface scanning gives a detailed digital view of the body surface.[5]

Documentation

The clinical record of the deceased will usually accompany the body to the mortuary and is scrutinized by the pathologist. Clinical information is crucial when considering the cause of death and may help direct the pathologist towards an appropriately detailed examination of the relevant system or organ. The guidelines for appropriate documentation in reportable cases are the same as those that apply to medical record-keeping in general. They should be made contemporaneously or as close to as is possible in a resuscitation environment. Each entry should be dated and the time recorded. They must be legible, objective and the sources of information identified. Any errors made should be crossed out, dated and signed. Likewise, if omissions are recalled or information comes to hand at a later date, that entry should be dated and timed. Finally, the author's name and designation should be clear and all entries signed.

The medical certificate of cause of death (MCCD) is usually written by the medical practitioner who cared for the deceased during their last illness and is then passed to a medical examiner attached to the relevant primary care department for scrutiny and investigation if required. The medical examiner may then, if satisfied, authorize burial or cremation or may request further investigation.[6]

Information for families

The 2009 Coroners and Justice Act sought to create a charter of rights for bereaved families in response to perceptions of non-uniform and sometimes inadequate, care and information given to relatives. The next-of-kin of the deceased must be informed that the death has been reported to the coroner and the requirement or reasons for doing so. It is important to inform them that police may be involved in the investigation of the death on behalf of the coroner, but that this does not imply a criminal wrongdoing. Many coroners have a process for meeting with bereaved families to share information and answer questions about the subsequent process. An information leaflet explaining the coroner's work and rights of the next-of-kin is available from the Home Office and should be available in every ED to pass on to bereaved families. Another useful publication written for bereaved families provides information regarding post mortems and is available from the Royal College of Pathologists.[6,7]

Post-mortems

The coroner may decide upon the initial report of a death that a post mortem is necessary in order to determine the cause of death or resolve an issue relevant to a coronial inquiry. In 2016, post mortem examinations were conducted in approximately 22% of cases by the coroner, which is decreasing steadily.[8] The Coroners Act states that, in fact, the coroner may 'direct any legally qualified medical practitioner' to conduct the post mortem; however, the Coroners Rules 1984 direct that they should be performed

'whenever practicable by a pathologist with suitable qualifications and experience' and, in practice, most are conducted by Home Office accredited forensic pathologists.[7,8] Clearly, if the standard of medical care provided by the hospital in which the death occurred is in question, it is inappropriate for a pathologist employed by that hospital to conduct the post mortem.

Consent from relatives to conduct the post mortem is not required in coroner's cases. If relatives object to the PME, the coroner may delay it to allow time to obtain legal advice. Post mortem imaging and minimally invasive endoscopic autopsy and tissue and organ biopsy[7,9] are becoming well used alternative methods. Post mortem imaging may be seen as more acceptable if the refusal for autopsy is made on religious grounds; however, if the death does fall within the coroner's jurisdiction and a post mortem is deemed to be necessary, their objection would be over-ridden. Relatives may also request a second post mortem, although this seldom occurs in practice, and the advantage of post mortem imaging is that it may be repeated if needed without the usual concerns of radiation exposure in a living person. Post mortem CT and MRI are both proving to be very accurate methods of PME.[3]

The coroner must notify certain persons, including the usual medical attendant of the deceased or the hospital in which the death occurred, of the time and date of the post mortem. In practice, this tends to occur when a desire to be represented at the examination has been expressed to the coroner and, in that instance, a nominated, medically qualified representative (not a doctor whose practice may be in question) may be present to observe the post mortem.

The issue of tissue retention at autopsy has received worldwide attention. The Human Tissue Act 2004 laid down guidelines around the process of tissue and organ removal, and the need for informed consent by relatives. Guidelines issued by The Royal College of Pathologists[7,9] recommend that, in coroner's cases, clear protocols between the coroner and the pathologist should exist, and the retention, or disposal, of tissues including slides, frozen specimens and other remains should occur with the consent of both the relatives of the deceased and the coroner.

Preparing a statement for the coroner

The coroner may request a statement from a doctor involved in the care of the deceased and, while there is no obligation to comply with this request, it is generally in the doctor's interest to do so. The coroner, otherwise, has no option but to compel the doctor to attend court and answer questions. A statement that has been carefully prepared with due thought to any issues identified may avert the need for an inquest or at least can act as a solid base upon which the examination in court will occur. It is important that the doctor writing the statement understands the circumstances of the death and access to the post mortem report is often vital. It is generally advisable, except where it is clear that simple, factual background information only is required, to seek legal advice early when requested to provide a statement or attend an inquest.

The statement should be printed and contain the author's qualifications, work experience and current employment post. The sources from which the report is prepared, including clinical notes and pathology reports, should be acknowledged and it should be set out in a logical manner, in chronological order. Technical terms should be qualified with an explanation readily understood by a layperson. It is advisable to have a senior colleague review the statement before submission to the legal representative for final review. The final statement should be dated and signed, and a copy kept for future reference.

Inquest

An inquest is a limited, public, formal inquiry in court at which the identity of the deceased and how, when and where the deceased died are to be determined. In 2016, only around 17% of reported deaths proceeded to inquest, with the remainder being examined 'in chambers'.[1] Inquests (or fatal accident inquiries in Scotland) are mandatory in certain prescribed circumstances, including deaths in prison or police custody, and deaths resulting from workplace incidents. In certain unusual circumstances, inquests are held with a jury that is responsible for the final verdict.

The inquest is inquisitorial in nature, rather than adversarial, and is not intended to establish liability but to answer the who, where, how, and when of the deceased. The court hears evidence by the pathologist and may be questioned by the legal team and coroner. If the coroner is satisfied with the evidence, a death certificate can be issued and the case closed. As with the preparation of a statement for the coroner, it is wise for a medical witness to seek legal advice and possibly representation prior to attendance at an inquest. The legal arena in which they are held is unfamiliar territory to most doctors and they frequently attract intense media scrutiny. Involvement in an inquest may be a daunting and stressful experience requiring support from colleagues and friends.

CONTROVERSIES AND FUTURE DIRECTIONS

- The coronial system in the UK was seen to be outdated, but took many years to revise. The Coroners and Justice Act 2009, the first major reform of the coroner's service in over 100 years, made changes to the structure, training and governance of the coronial system, and this is constantly evolving.
- Post mortem imaging is now considered a highly accurate alternative to autopsy.[9]
- The number of coroner autopsies performed is under continual review with debates around whether too many autopsies, with too few standard indications, are being performed.[10,11]

28.3 Consent and competence—the Australian, NZ and UK perspectives

Jane Terris • George Braitberg

ESSENTIALS

1 Informed consent is an essential process for medical treatment that has ethical, legal and administrative elements. Complexities of the practical situation may result in deviation from the theoretical ideal.

2 Consent may be implied, verbal or written, and should always be clearly documented.

3 Consent must be informed, specific and freely given, and must cover that which is actually done.

4 The patient must be competent or have the capacity to give or to refuse the consent, and the default assumption, until proven otherwise, should be that an adult patient has capacity. Patients who are minors or have serious mental health problems or impaired consciousness are examples of those who may not have the capacity to consent, although these are not absolute and exceptions may apply.

5 In life-threatening situations, it is often necessary to give treatment without waiting for consent, in which case the emergency physician must be able to demonstrate and document that they were acting in the patient's best interests.

6 The emergency department (ED) environment has unique challenges for the determination of capacity, including lack of privacy and time, lack of a pre-existing relationship with the patient and often lack of knowledge of the various factors that may influence patient choice.

7 Capacity is condition and decision specific. A patient may be deemed competent to consent to one procedure but may not fully understand the implications of another.

8 Assessing capacity and obtaining informed consent for ED treatment are core skills within emergency medicine and should not be delegated to non-ED colleagues although, in complex situations, a supporting psychiatric opinion may be useful.

9 Informed consent discussions must cover the diagnosis, proposed and alternative treatments, no treatment option and the risks and benefits of each. A clinician sufficiently knowledgeable in the area to do so should provide the information.

10 The informed consent process should be driven by the desire to enable and support appropriate treatment choice by a patient, rather than the fear of litigation.

Introduction

Consent is necessary for any clinical intervention performed on a patient and the higher standard of informed consent has become accepted.

Consent is an essential basis for any medical intervention and has ethical, legal and administrative elements.[1]

Historically, the need for consent may have been applied more variably than today. The American physician, Oliver Wendell Jones said in 1871 to his students: 'your patient has no more right to all the truth than he has to all the medicine in your saddle bags and should get only so much as is good for him'.[2] Self-determination was addressed in 1914 by Justice Cardozo who said: 'every human being of adult years and sound mind has a right to determine what shall be done with his own body'.[3] The pendulum has recently swung in the direction of person centred care, patient autonomy and informed choice to the extent that clinicians now need to go to extensive efforts to ensure that enough specific information is given to the patient prior to consent being obtained and the threat of successful litigation, although rare, serves as a potent stimulus to this.

Respect for patient autonomy is enshrined within consent law and to impose care or treatment on patients without respecting their wishes is illegal and unethical.

Consent serves to protect the patient from assault and battery, namely unwanted medical interventions. The more exacting standard of informed consent requires that the patient be given and understand adequate and appropriate information specific to the procedure or intervention to be performed. There is debate around what defines reasonable consent practice in different clinical circumstances. There is also debate around the ethical and legal interpretations of the principles underpinning informed consent, which may vary according to local jurisdiction, subjective interpretation and may, in practice, deviate from the theoretical ideal.

Legally, informed consent protects the patient from assault and protects the clinician from an allegation of assault. On an ethical level, the clinician should aim to facilitate autonomous decision making around treatment goals as jointly agreed with the patient. From an administrative point of view, consent documentation serves as proof of a systematic check that the patient received information concerning, and agreed to, the procedure undertaken. The consent form is only the documentation of consent having been obtained and should not be seen as equivalent to or a substitute for the consent process.

Consent

All medical treatment is based on legal and ethical principles. The four basic ethical principles in medicine are:

- Beneficence: the duty to do the best for the patient.
- Non-maleficence: the duty to do no harm to the patient.
- Autonomy: the right of individuals to make decisions on their own behalf.
- Justice: the fair distribution of resources, incorporating the notion of responsibility to the wider community.[4]

Resources may need to be rationed to ensure fair and equitable distribution, and no patient

has the right to demand treatment not felt to be indicated by the treating clinician.

There is a requirement that patients consent to the specific interventions proposed, provided they have sufficient information to make an informed choice and are competent to do so. It is the job of the emergency physician to ensure that the patient is sufficiently well informed to make the choices that best meet his or her own needs in the context of patient-centred care. Legal judgements have centred around the nature of the relevant material risks disclosed and whether the patient was actually given sufficient specific information to make an informed choice, in addition to the determination of whether a particular patient has competence in a specific situation.

The term 'informed decision making' is preferred by some to informed consent as it reflects consideration of patient autonomy and recognizes the importance of partnering with patients in making decisions about their health care.[5] Consent should be considered as a two-way process in emergency medicine, with an exchange of adequate and relevant knowledge between a patient and the emergency physician, or nurse in some circumstances, and the end goal should be to share the aims of treatment, although it has been suggested that the means of getting to the shared end could reasonably be guided by the clinician, if acting in the patient's best interests.

Failure to obtain informed consent can lead to prosecution. The risk of litigation is related to patient dissatisfaction due to perceived lack of clinician communication or rapport,[6] therefore this should serve to build in good communication skills as an essential part of the consent process.

Consent requires the clinician to take an active role in giving information and choice, while respecting the patient's wishes.[7] The concepts of competence, provision of adequate information and the voluntariness with which consent is given are crucial in the consideration of obtaining valid consent or seeking an informed decision. In Victoria, Australia, an adult patient is competent to provide informed consent if they are able to understand, retain, use or weigh up information about the general nature and effect of the proposed medical treatment and communicate their decision to consent to the treatment.[8] If the patient is not able to provide informed consent, his or her instructions regarding care can be communicated via a legally witnessed advance care directive. Recent legislation (Medical Treatment Planning and Decisions Act 2016) has specified two forms of statement a person may include in their advance care directive:

- An instructional directive, where a person may either consent to or refuse a particular medical treatment or form of therapy.
- A values directive, where a person may make more general statements about their preferences and values and what matters to them. If the person has not included a relevant instructional directive, then the clinician will need to obtain consent from a medical treatment decision maker to provide treatment.

Clinicians are required to make a reasonable to attempt to seek and follow the instructions in a directive. This is often difficult to validate in an emergency situation.

The recent changes to Victorian law enshrine the concept of autonomy and support of the person's rights in the following ways:

1. A person has the right to refuse medical treatment in most circumstances.
2. The medical practitioner must usually seek the person's consent prior to carrying out medical treatment.
3. A person's capacity to consent is assumed unless there are indications otherwise.
4. A competent person can refuse treatment in relation to a current or future condition by completing a valid instructional directive.
5. Likewise, the person's medical treatment decision maker can consent to or refuse treatment on their behalf if they no longer have the capacity to do so themselves.

Treatment without consent may be considered an assault, although the law is generally pragmatic, and as long as the clinician is able to demonstrate that they gave information in a manner that most reasonable patients would wish to know, acted in the best interests of the patient, and in a manner that most reasonable professionals of similar clinical background and seniority would have done. Judgements may take into account whether the treatment was carried out in an emergency rather than an elective situation, and documentation should aim to demonstrate the circumstances under which the decision was taken at the time. There has been debate in both Australian and UK law around what constitutes the reasonable standard of care around consent practices and whether the standard should be that which is thought to be reasonable by a responsible body of professional opinion, known as the Bolam standard.[9] The Bolam ruling was challenged in the Bolitho case[10] which ruled that even expert clinical opinion may be challenged if it was felt to be illogical and not to stand up to analysis. Legal discussion has also centred around precisely what information most patients in a particular situation would want or need to know in order to be considered adequately informed. This principle was the deciding factor in Rogers vs Whittaker,[11] in which consent given by the patient was held to be invalid on the grounds of a ruling that insufficiently detailed disclosure by the surgeon did not allow the consent to be informed. Judgements are likely to be subject to location-specific jurisprudence and to consideration of the urgency of the situation; however, it should be emphasized that there is a strong need to demonstrate, and to document, that the decision around gaining consent was taken in good faith, with the available evidence at the time, in the patient's best interests.

To present only a one-sided option may be seen as a form of coercion. However, there is much potential for debate on ethical and legal points of what defines full, relevant and expected. This is not surprising as the literature around informed consent comes from multiple disciplines including clinical, legal and ethical cases, and judgement is open to unique interpretation.

The clinician is encouraged to be open and transparent in their communication with patients, and that all relevant information pertinent to the procedure and outcome be disclosed in a manner that provides the patient with all the information needed to make an informed decision.

The patient has the right to self-determination. Consent lies at the heart of the medical contract between the clinician and the patient. Medical investigation and treatment are essentially voluntary acts, which the patient consents to the clinician performing.

Consent may be given in several ways: implied, verbal or written. If the patient voluntarily presents to the emergency department (ED) then some degree of consent is implied, although consent must be specific to the intervention proposed. Simply presenting to the ED with a severe headache does not automatically imply consent to lumbar puncture, for example. Such a procedure would usually need sufficient explanation in order that the patient understood what was to be done and the potential consequences of not doing the procedure, before the consent was given. One should consider the clinical context when contemplating the mode of consent. If a doctor says 'put your arm out straight because I need to take some blood for a test' and the patient cooperates by extending his or her arm voluntarily this can be taken as implied consent for venesection. Verbal consent is when the patient orally states agreement to the treatment or procedure (which usually does not carry a significant risk). Written consent is generally sought before more invasive, potentially complex or prolonged procedures, and where the treatment or procedure carries significant risk such as procedural sedation for hip relocation in ED and surgery under general anaesthetic. Written consent is not more valid than verbal consent that is documented, but it is easier to prove.

Adjuncts to written consent may serve to strengthen both the patient's understanding of the procedure and to protect the clinician. These

may include procedure-specific consent forms and patient information leaflets detailing what to expect after local anaesthetic or recovery from procedural sedation.

Consent must be sought after a full and relevant explanation of what is to be done and the expected results, risks and the consequences if it is not done. The explanation should, as much as possible, be balanced and realistic in describing the advantages and disadvantages of each option. Informed consent or decision making requires that clear, accurate and relevant information must be given to the patient. Legal judgements have defined the importance of considering what may be material or significant to that particular individual when disclosing information. Essentially, the patient should be provided with information regarding: (1) treatment options; (2) the foreseeable consequences and side effects of any proposed treatment or intervention; and (3) the consequences of not proceeding with the advised treatment. This information should be conveyed in unambiguous terms and in a manner that is likely to be understood by the patient. Language and other communication needs must be met and there must be an opportunity for the patient to ask questions and to reflect on the information given. It is important that the clinician is aware of their patient's level of health literacy. Health literacy is defined as the capacity of a person to access, understand and apply information to make effective choices about health and health care. People with low levels of health literacy are one and a half to three times more likely to have an adverse health outcome, and in 2006, the Australian Bureau of Statistics identified that almost 60% of adult Australians have low health literacy. Understanding the impact of language, culture, age, socioeconomic and educational advantage is relevant to any discussion on informed consent.

The information should be given by the clinician responsible for the intervention or a delegate who is suitably qualified and has sufficient knowledge of the proposed intervention. Hence in the public hospital system interns are discouraged from obtaining consent. It is appropriate for a doctor to give advice as to the best clinical options and for the reasons for this professional opinion. Such an opinion is frequently expected and desired by patients, and it cannot be considered as coercive unless the information has been presented in a manipulative fashion in order to elicit a particular choice. It is important to avoid subtle forms of information bias, for instance, presenting the patient with only the benefits of having a fracture reduced on an operative list under general anaesthetic in order to minimize workflow disruption in ED, without the relevant statistics of complications of general anaesthetic versus those of procedural sedation in the ED.

In Australia, it is common practice for hospitals to assist staff in making their communications contextual and understanding the unique needs and preferences of indigenous patients. Indigenous peoples experience disadvantage across a number of socioeconomic indicators and English is often a second language. Therefore indigenous people are at risk of lower individual health literacy. In New Zealand, the Treaty of Waitangi[12] creates a particular specification in relation to Maori, whereupon doctors may be expected to include the extended family in decision making and to allow the family to be present with the patient. Similarly, clinicians in Australia need to be aware of family and kinship within an indigenous community and how it may impact on the decision-making process. There are other cultures that may have similar expectations within the multicultural environments of both Australia and the UK.

Competence

The terms 'competence' and 'capacity' are often used interchangeably in the context of informed consent. The patient must be competent to give the consent or to refuse.

For consent to be valid, it must be given by a person who has the capacity to make that decision which, generally, will be the patient. The default assumption should be that the adult patient has capacity unless clinical assessment clearly finds otherwise.[13] Indicators that the patient may not have intact capacity and may need a more detailed assessment of capacity, include decisions at odds with the treatment advice without a rational explanation, decisions that change with no clear justification and decisions taken on the background of failure to understand the discussion around treatment options for any reason. Capacity may fluctuate in either direction, for instance, in a patient with altered cognition due to alcohol or recreational drugs, and it may be necessary to reassess capacity prior to performing the procedure. The assessment of the competence or capacity of adults to make decisions on their own behalf is a functional one that requires more than cognitive testing with a tool such as the mini-mental status examination, although this should be performed and documented as part of the assessment process. Assessment of competence should be sought and conducted by the doctor proposing the treatment or investigation and should not be delegated to other colleagues, although in complex situations of impaired capacity, a psychiatric opinion may be helpful and legally advisable.

Table 28.3.1 Questions for determining competence

Parameter	*Questions*
Comprehension	What is your present condition? What treatment choices have been suggested?
Belief	What do you think is wrong with you? Do you believe that you need treatment? What do you think the treatment will achieve? What do you think will happen if you have no treatment? Why has the doctor recommended this particular treatment for you?
Weighing	How did you reach the treatment decision that you have chosen and what factors helped you make that decision?
Choice	Have you decided whether to accept the treatment choice that was recommended for you? Have you made any other decision about your treatment?

The essential elements required to demonstrate competence are:

- the ability to maintain and communicate a choice
- the ability to understand the relevant information
- the ability to remember information relevant to the decision
- the ability to appreciate the situation and its consequences
- the ability to use or weigh the information in a rational fashion.

Questions that may be of assistance in assessing capacity are listed in Table 28.3.1. Third parties, such as relatives, are unable legally to provide consent (unless they have been appointed as a medical treatment decision maker under the Act), although it is frequently assumed that they are; however, it is a long-established practice and frequently a useful exercise to involve relatives in the process of determining what the patient would have wanted in a particular circumstance. They may also provide valuable information during the process of competence assessment regarding a person's set of values and beliefs, cultural considerations and usual behaviour.

Patients who may be incompetent to consent (Table 28.3.2)

Children and adolescents

The legal age of consent in Australia has changed in the last quarter of a century from 21 to 18 years and, in some circumstances, to 16 years or less. This has occurred against a background of differing ages at which persons may vote, buy tobacco or alcohol, drive cars or engage in sexual activity. There is ongoing debate in both Australia and the UK around the age at which a child may be considered competent to consent, as tested in the cases of Gillick[14] in the UK and Marion's case[15] in Australia (Table 28.3.3). In the UK, the principle of decision making by a proxy grants a parent or guardian, or a designated person or local authority, the right to give consent. If the proxy is unavailable in an emergency, the principle of necessity justifies treatment provided it can be demonstrated that any decision is taken in the best interests of the patient.

Table 28.3.2 Examples of patients who may not be able to give consent and who may consent for them

Patient	Proxy consent
Children	Parent, guardian, guardianship board, local authority
Serious mental illness	Parent, guardian, guardianship board
Toxic impairment (drugs and alcohol)	Patient when competent, guardianship board, medical director
Intellectual impairment	Guardian, guardianship board, local authority
Emergency situations	Patient, guardian, medical director, local authority

The most important factor to be considered is the competence of the patient to understand what is wrong and what the treatment entails. This has more to do with intellectual and emotional maturity than chronological age. It would be reasonable for a 14-year-old girl to consent to an appendicectomy, but quite unreasonable to expect the same person to understand the consequences of hysterectomy. In a genuine emergency, the care of the patient is the most important factor and the absence of a parent or guardian is not a bar to an emergency procedure. Should treatment of a minor be required and valid consent not obtainable, the steps taken to obtain consent and the reason why the treatment must be carried out must be clearly documented. If at all possible, the opinion of a second equally or more senior clinician should be documented. Many hospitals require that, in such circumstances, the hospital medical director or delegate give approval. This is simply a means of ensuring that the hospital is aware of the situation and accepts responsibility.

A special situation occurs for children whose parents hold religious beliefs that proscribe the administration of blood products. This creates a situation where the child is incompetent and the parents do not consent. There is now almost standard legislation that allows the attending doctors to certify that blood transfusion is required to sustain life and to then administer the treatment despite opposition from the parents in the best interests of the patient.

Intellectually impaired

For consent to be valid, the patient must be able to understand the nature of the condition, the options available and the treatment being recommended, plus the material risks and the possible outcome of any potential treatments.

The mildly intellectually impaired patient may be able to satisfy these criteria, but the more severely disabled will not be in a position to give valid consent. In the latter situation, in Australia, the guardian or regional Guardianship Board would have to be involved in all but the most urgent cases and there is legislation that covers the protection and administration of incompetent patients. The Board is available to give timely help and has the authority to conduct hearings, receive evidence and make decisions on behalf of incompetent persons. This provides protection for the patient and the doctor. Emergency physicians should ensure that they are aware of how to contact their local Board, both in and out of working hours.

Mentally ill

A diagnosis of mental illness does not automatically preclude a patient from giving consent. The attending doctor must decide on the competence of the patient to consent. The attending psychiatrist may be in a position to assist. If the patient is not competent then the relevant mental health legislation must be considered. Within Australia, the regional Guardianship Boards or Mental Health Tribunals should be consulted. In the UK, The Mental Capacity Act Deprivation of Liberty

Table 28.3.3 Examples of relevant landmark legal rulings

Case	*Australia*	*UK*
Bolam, 1957: Patient undergoing ECT was not given any muscle relaxant and sustained fractures. Not warned of this risk by psychiatrist.		Ruling that the psychiatrist acted in accordance with a reasonable body of psychiatric opinion in not disclosing small risks of injury. Concept became known as the Bolam test of what a reasonable professional opinion would do or say.
Bolitho, 1997 Case of whether a 2-yr-old boy with respiratory problems who died should have been intubated.		Bolam test challenged. Ruling that decisions had to stand up to logical scrutiny, whether or not other similar professionals would have taken that decision.
Gillick, 1986: Mother of five girls brought case in UK to prevent contraceptive advice being given to under 16s without parental knowledge.	Principles of Gillick case were accepted as part of common law in Australia.	Some forms of medical treatment (contraceptives in original case) could be prescribed to under 16s without parental consent or knowledge if the child had sufficient maturity and understanding. Ambiguity around what sufficient meant.
Marion's case, 1992: Request for sterilization of a girl with intellectual impairment.	Recognition of the requirement to respect the autonomy and bodily integrity of the individual.	
Rogers vs Whittaker, 1992.	Consent deemed invalid on grounds that surgeon had given insufficient detail to inform. View that courts, rather than medical professionals, should determine the relevant standard of care. Overturned Bolam standard.	

Safeguards protect patients in hospitals or care homes from harm.

In an emergency where life or quality of life is seriously threatened and time is of the essence, the facts should be recorded and treatment commenced. A sound knowledge of the mental health and guardianship legislation relevant to the region is essential.

Under the Mental Health Act Victoria 2014 the following guiding principles are provided[16]:

- Capacity to give informed consent is specific to the decision that needs to be made.
- A person's capacity to give informed consent may change over time.
- It should not be assumed that a person lacks capacity to give informed consent based only on their age, appearance, condition or behaviour.
- A determination that a person lacks capacity to give informed consent should not be made only because the person makes a decision that could be considered unwise.
- An assessment of a person's capacity should occur at a time and in an environment in which a person's capacity can be most accurately assessed.

Patient disabled by drugs or alcohol

When a patient is temporarily disabled by drugs or alcohol, the situation is less clear. Legal and medical opinions do not always agree, especially in respect of capacity and blood alcohol readings. The absolute legal position is unclear as to whether an intoxicated person can give consent, but there is no doubt that any clinician who acts in the best interest of the patient will always be on solid ground in the event of legal challenge.

Restraint may be justified in order to prevent patients taking their own discharge with adverse consequences. In these complex situations, it is worth considering whether it is better to be sued for assault and wrongful imprisonment or to be sued for the damage that followed to a patient who was allowed to leave. It may be possible to ask the regional Guardianship Board or Mental Health Tribunals for help in Australia and the hospital medical director for advice in both Australia and the UK, but there will be occasions in which immediate decisions must be taken and the best rule is to do whatever would be the best for the patient in the longer term. If the treatment is provided under duty of care and the rationale for doing so is considered reasonable and in the best interests of the patient at the time it is unlikely that an adverse finding against the clinician would be found. Again, documentation at the time and the signatures of witnesses will help if the court is involved.

The emergency patient

There has been little written about the patient who requires emergency care but is temporarily incapable of providing consent. However, the overriding common law principle is one of the duty of care owed by the clinician to the patient. For example, involuntary sedation of a patient with acute severe behavioural disturbance can be given in an emergency situation to save the person's life or to prevent serious danger to the health of others.[17]

(The clinician is under obligation to explain to the patient [and/or their medical treatment decision maker] what has been done as early as is reasonably possible in the recovery phase.)

The emergency physician must know the essentials of consent and the differences between implied, verbal and written consent. A sound knowledge of regional mental health and guardianship legislation is required. There must be adequate and contemporaneous documentation of decisions. If it is clear that the clinician was acting in the best interests of the patient and that the processes followed were deemed to have been logical and necessary in an emergency situation, it increases the chance that the law will be applied pragmatically.

Emergency physicians work in an environment of multiple simultaneous demands. With respect to critically ill and injured patients, detailed information regarding presentation, past history, cultural considerations and usual level of functioning is often lacking and may, in fact, be wrong. A clinician may have little time to make a detailed assessment before a treatment decision is required. Similarly, the information available at a point in time may be lacking or may change later. Emergency physicians often make complex decisions at short notice with little background information. In situations where decisions have been made on behalf of a patient who is felt to be incompetent, it is important to carefully document the information available at the time and the differential diagnosis and reasons for the course taken. It is good practice also to seek the assistance and advice of a senior colleague where the competence of a patient is in doubt and significant interventions are deemed necessary.

The informed consent process should be driven by the desire to enable and support an appropriate treatment choice by a patient, rather than the fear of litigation, and is a core skill within emergency medicine.

CONTROVERSIES AND FUTURE DIRECTIONS

- English medical law was influenced by the introduction of the Human Rights Act 1998, with courts having to take into consideration case law of the European Court of Human Rights. Decisions are made on a case-by-case basis and established precedents may not always guide future judgements. There is debate around the importance of medical expert opinion versus the logical legal argument.
- Case law on the issue of what is considered appropriate information to give to patients regarding treatment options points to the need to be as specific as possible during consent discussions.
- Computerized decision support tools have been suggested as an aid to improve patient understanding.
- The concept of what constitutes a minor, and in what situations, is changing with increased emphasis on the autonomy of the child in some situations.
- As health moves further towards person-centred care, clinicians must be prepared to ensure they provide clear, concise transparent communication with their patients, to ensure they provide information needed for an informed decision and to respect the choices that patients make even if they do not conform with best practice.

28.4 Privacy and confidentiality

Biswadev Mitra • De Villiers Smit

ESSENTIALS

1 Privacy and confidentiality issues can be related to the physical environment in which care is given or to the personal health information involved in the patient's care.

2 Breaching confidentiality of personal health information now breaks Australian and New Zealand legislation.

Introduction

An individual's right to privacy and confidentiality has gained increasing recognition over the past decade. In an emergency setting, where patients are more vulnerable because of illness or injury, staff are often provided with confidential family and legal information that would otherwise not be divulged, trusting that it would be used only to assist in the care of the patient. The law preserving confidentiality in public and private hospitals, day procedure centres and community health centres (called 'relevant health services' in the act) is to be found in the relevant sections of individual state and territory health services acts.[1] The section applies to the health service itself, the board of the service or a person who is or was a member of the board, a delegate to a board, a proprietor of such a service or engaged or employed in a service or performing work for it. These people are generally prohibited from disclosing information that could directly or indirectly identify a patient. In addition, the individual state or territory's health records act and the Privacy Act 1988 (Commonwealth) confer statutory privacy rights on patients whether they are treated in a public or private facility. Both acts set up complaint procedures for patients who believe that confidential information about them has been unlawfully disclosed to a third party. New Zealand has similar legislation.[2]

Physical privacy

Emergency departments (EDs) are necessarily designed in an open plan to increase efficiency, observation and communication, but these requirements do intrude on privacy, particularly if cubicles are separated by curtains rather than solid walls. Consultations may be overheard during history taking and when patients are being discussed with other medical staff or specialists, either directly or by telephone.

Patient privacy incidents occur frequently in an ED, risk factors being length of stay and absence of a walled cubicle. Patients who have their conversations overheard are more likely to withhold information and less likely to have their expectations of privacy met. Privacy and confidentiality are further challenged by the physical design of the department, crowding, visitors, film crews, communication and other factors.[3]

Emergency clinicians should take specific steps to mitigate the risk of privacy incidents. Prior permission should be obtained from the patient to allow students, nurses, other medical officers to be present during the history taking, examination and procedures. This applies both in public and private hospitals. Some aspects of privacy in health care in the ED relate to confidentiality while the patient is being assessed (being overheard, seen, exposed or embarrassed), which relate to ED design as well as staff awareness, sensitivity and care. ED staff may be unaware how their routine behaviour may infringe on patient privacy.

Enclosing staff bays with glass screens may be useful to prevent others from hearing the details of a patient's history or to prevent patients from becoming unnecessarily alarmed by discussion of serious differential diagnoses. However, this may also create an illusion of separation between clinical staff and patients and may cause patients to feel more isolated. It is of the utmost importance that staff at all times behave in the most appropriate and professional manner, seeing that patients will often observe staff very closely and that comments made by staff may be overheard.

In adolescent patients, privacy needs may exclude communication with a parent. An understanding of the relevant informed consent law relating to minors is required. The federal Privacy Act does not specify an age at which a child is considered of sufficient maturity to make his or her own privacy decisions. Doctors must address each case individually, having regard to the child's maturity, degree of autonomy, understanding of the circumstances and the sensitivity of the information being sought.

The white board for patient tracking has been replaced by computer screens in most EDs. Often, information on tracking screens is visible to everyone in the ED; therefore it is important to minimized this as much as possible. These problems are more common during the shift change-over period. Staff should be aware of such risks and mitigate them whenever possible. Specific steps include rapid and single sign-on/sign-off solutions, roaming Information technology (IT) profiles, the use of screen savers that activate with a short time lag, and preventing patients and relatives from gaining access to clinical screens.

Well-known people ('very important persons' [VIPs], politicians, media personalities, and sports stars) need even more privacy than others, and crowd control is often required, since they may be accompanied by support staff and, perhaps, a bevy of reporters who may be difficult to control. They cannot be restricted until such an individual is actually inside the hospital building, after which security is in charge. Even when outside the building, most of this retinue will accept advice to remain in a provided access zone where they may use their cameras or microphones without intruding on the privacy of other patients or their subject of interest. Hospital staff involved in the care of such patients may also wish to have their own privacy protected. Most hospitals now have media relations officers who can provide regular updated bulletins. It is also important that only those staff involved in the clinical care of these patients access their medical histories. For this reason, hospitals often provide these patients with aliases to protect their privacy.

In addition to the statutory offences of breaching confidentiality, doctors and other healthcare providers may be sued at common law if they divulge confidential information without a patient's consent. The patient may sue for breach of contract or because the doctor has been negligent in disclosing the information. It should be noted that it is lawful for a health professional to disclose information if

- some other law requires disclosure.
- it can be argued that the person has provided express or implied consent for the disclosure.
- it may be in the public interest for the information to be disclosed.

Mandatory reporting

Mandatory reporting overrides privacy laws where such reporting is for the purpose of protecting the health of individuals or communities. For example, mandatory reporting may take place in order to

- reveal to police or a court the presence of alcohol or any other drug in the breath or blood of a driver after a motor vehicle accident.
- report a reportable or reviewable death to the coroner.
- provide notification of a communicable infectious disease.
- report child abuse.
- report elder abuse.
- report domestic violence.

This becomes more difficult when there is merely a suspicion, but doctors are protected if they report on this basis only. The laws vary between jurisdictions.

Health care providers

There is also the important matter of privacy for health providers. Whether full names should be displayed on identity badges is debatable. Details of contact numbers and home addresses of consultants, medical staff and nurses must be kept confidential, as there are cases of disgruntled or mentally unstable patients harassing and stalking clinical staff. Even if the request for contact details is innocent, it is an invasion of a health care worker's privacy for that information to be released without consent.

Police and medico-legal reports

Assistance must be given to the police when a criminal offence has been committed. In such cases, patient name, date of birth, address, nature of incident, description of injuries and conscious state may be released. An opinion of causation must not be stated.

If an injured patient is suspected of being a crime victim or perpetrator and may be a danger to his own or another's life, it is the doctor's civic duty to inform police of the circumstances.[4]

If a police enquiry is made by telephone, it is important to record the name, station, contact number and, preferably, to call back the station, asking for the information after checking its validity. All police statements should be handled by the hospital's legal department, including requests and completion of statements by clinical staff.

The doctor should state his or her credentials and experience before giving details of a history and physical findings. It is important to be objective and to avoid venturing opinions outside the doctor's area of expertise.

Assistance is also given to help police seeking to identify missing or deceased persons.

Medical reports by treating clinicians or experts can be provided to lawyers or police officers acting on behalf of a prosecution or defending lawyer after written consent is obtained from the patient. Such reports are the intellectual property of the doctor writing the report. Although a patient has a right to view reports about himself or herself, there is no right for a copy to be supplied unless an appropriate fee for preparation of the report is paid.

Patient health information

Privacy of patients' health information refers to

- their medical and social conditions.
- their medical records.
- any images (still, video or diagnostic imaging).
- results of investigations.
- their treatments.
- their treating doctors.
- specialist and medicolegal reports.

Legislation

The confidentiality of health information has been the focus of legislation over recent years.

The Privacy Act 1988[5] applied only to the Australian Commonwealth public sector, but steps were taken early on to introduce it to the private sector, resulting in the Privacy Amendment (Private Sector) Act 2000, which became a law covering the private (and public) health sector in December 2001. Patients who have been treated in public hospitals are able to gain access to their medical records by means of the relevant state or territory freedom of information act (e.g. Freedom of Information Act 1982 [Victoria]). Patients treated in a private hospital, by a private doctor or other private health professional have a right to gain access under the relevant state or territory health records act (e.g. Health Records Act 2001 [Victoria]) and also under the Privacy Act 1988 (Commonwealth).

New Zealand's Privacy Act was enacted in 1993 and was used to develop the Health Network Code of Practice and Health Information Privacy Code 1994, which was further modified by the Health Information Standards Organization in 2005.

Australian privacy principles

The 13 Australian Privacy Principles (APPs) replaced the National Privacy Principles (NPPs) for organizations from March 12, 2014. The APPs are found in the Privacy Amendment (Enhancing Privacy Protection) Act 2012 (Commonwealth). The amendments to the Privacy Act introduce the concept of a 'permitted general situation' and a 'permitted health situation'. The existence of a permitted general situation or permitted health situation is an exception to various obligations in the APPs. A new section 16A outlines seven permitted general situations, where the collection, use or disclosure of personal information about an individual or of a government-related identifier will not be a breach of certain APP obligations.

New section 16B outlines five permitted health situations, where the collection, use or disclosure of certain health information or genetic information will not be a breach of certain APP obligations.

Australian Privacy Principle 1

APP1 requires hospitals or health care agencies to have ongoing practices and policies in place to ensure that they manage personal information in an open and transparent way. APP1 introduces a new requirement for agencies to have a clearly expressed and up-to-date policy about the management of personal information by the agency. APP1 specifies the minimum information that should be included in the agency's APP privacy policy. An agency needs to take reasonable steps to make its APP privacy policy available free of charge and in an appropriate form. The agency must take reasonable steps to provide the policy in a particular form if requested by an individual or body. APP1 also requires an agency to take reasonable steps to implement practices, procedures and systems that will ensure compliance with the APPs and any registered APP codes and enable the agency to deal with inquiries and complaints by individuals.

Australian Privacy Principle 2

APP2 deals with anonymity and pseudonymity and allows individuals to interact with agencies while not identifying themselves or by using a pseudonym. Both requirements are subject to certain limited exceptions, including where it is impracticable for the agency to deal with individuals who have not identified themselves or where the law or a court/tribunal order requires or authorizes the agency to deal with individuals who have identified themselves.

Australian Privacy Principle 3

APP3 outlines when and how an agency may collect personal and sensitive information that it solicits from an individual or another entity. An agency must not collect personal information (other than sensitive information) unless the information is reasonably necessary for, or directly related to, one or more of the agency's functions or activities. The APPs impose obligations on agencies regarding sensitive information for the first time. APP3 deals with the collection of sensitive information by agencies, which is not

permissible unless certain exceptions apply. An agency must collect only personal information from the individual unless an exception applies. It is sometimes difficult to obtain an accurate history in an ED due to the patient's anxiety about his or her presenting symptoms. More accurate information may become available after patients have had a chance to collect their thoughts or to affirm areas of their history with family or other witnesses. It is useful to re-check details that may not fit a working diagnosis.

Patients are not obliged to give their reasons for requesting access to their medical records. Patients do not have immediate right to investigation results. The doctor ordering the tests must be given the opportunity to assess and discuss the results; otherwise there is the risk of misinterpretation.

Australian Privacy Principle 4

APP4 introduces new obligations for agencies in relation to unsolicited personal information. Where an agency receives unsolicited personal information, it must determine whether it would have been permitted to collect the information under APP3. If so, APPs 5 to 13 will apply to that information. If the information could not have been collected under APP3 and it is not contained in a Commonwealth record, the agency must destroy or de-identify that information as soon as practicable but only if it is lawful and reasonable to do so.

Computerized patient data must only be accessible to authorized personnel by password-protected access.

Australian Privacy Principle 5

APP5 specifies certain matters about which an agency must generally make an individual aware at the time when, or as soon as practicable thereafter, the agency collects his or her personal information. Patients do have a right to access opinion as well as factual material, including a specialist's report, whether or not the report states that it is not to be shown to the patient without the patient's consent.

Australian Privacy Principle 6

APP6 outlines the circumstances in which an agency may use or disclose the personal information that it holds about an individual. If an agency collected personal information for a particular purpose, it must not use that information for any other purpose unless

- the individual has consented to the use for another purpose.
- the purpose is directly related to the purpose for which the information was obtained.
- In addition, disclosure is allowed if
- the agency believes that the use or disclosure is necessary to prevent or lessen a serious and imminent threat to the life or health of the individual or another person.
- the use or disclosure is required or authorized by or under law (e.g. the Road Traffic Act requiring disclosure of blood alcohol results).
- the use or disclosure is reasonably necessary for enforcement of the criminal law or of a law imposing a pecuniary penalty or for the protection of the public revenue.
- an agency uses or discloses the information for this purpose, a note of this should be made on the record.
- the agency has reason to suspect that unlawful activity or misconduct of a serious nature that relates to the agency's functions or activities has been, is being, or may be engaged in and the agency reasonably believes that the use or disclosure is necessary in order for an agency to take appropriate action in relation to the matter.
- the agency reasonably believes that it is necessary to assist any APP entity, body or person to locate a missing person and the use or disclosure complies with rules made by the commissioner.
- it is reasonably necessary for the establishment, exercise or defence of a legal or equitable claim.
- it is reasonably necessary for the purpose of a confidential alternative dispute resolution process.
- the agency reasonably believes that it is necessary for the agency's diplomatic or consular functions or activities.

Australian Privacy Principle 7

APP7 regulates the use and disclosure of personal information by organizations for the purpose of direct marketing.

Australian Privacy Principle 8

APP8 introduces an accountability approach in relation to an agency's cross-border disclosures of personal information. Before an agency discloses personal information to an overseas recipient, the agency must take reasonable steps to ensure that the overseas recipient does not breach the APPs (other than APP1) in relation to that information. In some circumstances, an act done, or a practice engaged in, by the overseas recipient that would breach the APPs, is taken to be a breach of the APPs by the agency. Hospitals may transfer health information to countries where similar privacy laws exist. Consent needs to be obtained from the patient when in doubt or when sending to countries where no such protection exists.

Australian Privacy Principle 9

APP9 prohibits an organization from adopting, using or disclosing a government-related identifier unless an exception applies. In some settings, such as counseling in HIV/AIDS or sexual health, there are instances where anonymity is requested and granted. In the case of public or private hospital EDs, for providing a safe health service and for billing and rebate purposes, doctors are required to record the identity of the patient.

Australian Privacy Principle 10

Under APP10, an agency must take reasonable steps to ensure that the personal information it collects is accurate, up to date and complete. An agency must also ensure that the personal information that it uses or discloses is accurate, up to date, complete and relevant having regard to the purpose of the use or disclosure.

Australian Privacy Principle 11

APP11 requires an agency to take reasonable steps to protect the personal information it holds from interference, in addition to misuse and loss and unauthorized access, modification and disclosure. APP11 imposes a new requirement on agencies to take reasonable steps to destroy or de-identify information if the agency no longer needs the information for any authorized purpose, unless

- it is contained in a Commonwealth record.
- the agency is required by or law or a court/tribunal order to retain the information.

Australian Privacy Principle 12

APP12 requires an agency to give an individual access to the personal information that it holds about that individual unless the agency is required or authorized to refuse to give access by or under the Freedom of Information Act 1982 or any other Commonwealth or Norfolk Island legislation that provides for access by persons to documents. Agencies must respond to requests for access within 30 days. Agencies must give access in the manner requested by the individual if it is reasonable and practicable to do so and must not charge for this access.

Australian Privacy Principle 13

APP13 requires an agency to take reasonable steps to correct personal information to ensure that, having regard to a purpose for which it is held, it is accurate, up to date, complete, relevant and not misleading.

New Zealand

New Zealand implemented its Privacy Act in 1993, with 12 principles that are similar to the Australian NPPs.[6] The Privacy Act has 12 information privacy principles:

Principles 1 to 4 govern the collection of personal information. This includes the reasons why personal information may be collected, where it may be collected from and how it is collected.

Principle 5 governs the way personal information is stored. It is designed to protect personal information from unauthorized use or disclosure.
Principle 6 gives individuals the right to access information about themselves.
Principle 7 gives individuals the right to correct information about themselves.
Principles 8 to 11 place restrictions on how people and organizations can use or disclose personal information. These include ensuring that information is accurate and up to date and that it is not improperly disclosed.
Principle 12 governs how 'unique identifiers' (such as Inland Revenue Department (IRD) numbers, bank client numbers, driver's licence and passport numbers) can be used.

In 2005, the Ministry of Health released the Health Information Strategy for New Zealand[2], with an emphasis on security of electronic data and maintenance of trust in and integrity of, communication. They developed a Privacy, Authentication and Security (PAS) guide, which brought all the existing relevant documents together.

Complaints and non-compliance

Doctors are advised to obtain their own independent legal advice and notify their medical indemnity/insurance company if they are investigated by the privacy commissioner as the result of a complaint that privacy may have been breached. Monetary fines or imprisonment may result from non-compliance.[5]

CONTROVERSIES

- Release of information on adolescents to parents is a difficult and controversial area.
- Protection of staff privacy is also an issue; should full names be displayed on identity badges?
- There is debate about the extent to which information may be provided to the police or other authorities. Many clinicians, when pressured, feel uncomfortable about providing information to police. It is best to involve the hospital's legal department for all requests.
- Controversy exists about whether the reporting of elder and domestic abuse should be mandatory in all regions.
- The security on current computer systems may not be sufficient to protect personal health information.

28.5 Ethics in emergency medicine

Michael W. Ardagh

ESSENTIALS

1 Ethics is about doing the right thing for the patient.

2 The morality of the doctor and the morality of the patient will influence decision making.

3 The two most common ethical dilemmas in emergency medicine concern treating patients who do not consent and stopping resuscitation.

4 When these dilemmas are being addressed, the application of pragmatic tools assists ethical decision making.

5 The first tool considers the four principles of Beauchamp and Childress, particularly respect for patient autonomy and the benefits and harms of the treatment options.

6 The second tool helps to determine whether the patient's expressed decision is autonomous by asking three questions:
- **a** Does the patient know enough?
- **b** Can the patient think clearly enough?
- **c** Is the patient free enough?

7 The third tool explores patient competence (can the patient think clearly enough?) by asking whether the patient understands
- **a** the problem.
- **b** the options for treating the problem.
- **c** the pros and cons of each of the options.

8 Subsequent tools reassure that the ultimate decision is the patient's true autonomous wish.

9 Resuscitation, like any other medical intervention, requires consent to proceed. Presumed consent using professional substituted judgement is a model that may be the best for honouring the patient's autonomy.

Introduction

To be ethical in emergency medicine is to do the right thing for the patient. However, this can be challenging in the context of urgency, uncertainty and impaired patient competence.

How do we know if we should let the intoxicated head-injured patient leave the emergency department (ED) without being fully assessed? How do we decide if the decision of the elderly lady with a fractured neck of femur not to have surgery should be honoured? How could we possibly know what the unconscious cardiac arrest patient wants?

The pragmatic tools described in this chapter, based on current popular bioethics, can guide clinicians who work among the ethical complexities of emergency medicine. In this area, standardized processes are popular, and this tool kit suggests a standardized approach to ethics. However, in practice, ethics must be individualized to the patient in front of us. Good clinicians need to superimpose their own morality and understanding of the patient and the patient's context. This involves a unique interaction with the person the patient is. Ultimately, the aim is to facilitate a process whereby the patient's true autonomous wishes are honoured. The nature of emergency medicine makes this challenging, but not impossible.

Ethics and law

The ethics methodology described here is a relatively simple approach, to be applied in specific cases, taking into account the peculiarities of the patient's medical condition and the patient's 'world view'. However, this methodology, and ethics in general, involves the struggle to arrive at indisputable, definitive answers. The law also intends to arrive at a definitive answer so that a determination can be made regarding the lawfulness of what was done. The law uses a combination of statute (written law) and precedents (previous interpretation of written law in specific cases) to come to this determination. It is a complex methodology that is best applied retrospectively once all the facts are known. In emergency medicine, ethics is an easier model to use as it can be applied prospectively while there is still uncertainty. However, from time to time the law is called upon to determine the 'rightness' of medical decision making. Good ethics, well documented, should see the law get behind the medical decision making. However, the decisions of emergency physicians must be consistent with local law. In reality, this places the emergency physician in a difficult situation, being required to act in keeping with the law yet with an incomplete knowledge of the law and, at the time of decision making, dealing with many unknowns. Generally the law is sufficiently consistent to enable the application of ethics with confidence. Furthermore, there are local differences, particularly regarding how consent might be obtained and who might give it (e.g. the acceptance of proxy consent – that is, consent from relatives), which should be well known in relevant EDs.

Ethical decision making – influences and processes

The words 'ethics' and 'morals' have origins in different languages, but they have similar meanings – 'the done thing' or 'the right thing to do'. The use of these words in the English language generally considers morals or morality as qualities of an individual and ethics as a description or study of those qualities. However, they both relate to doing the right thing.

What encourages us to do the right thing?

An individual's morality is a manifestation of the interactions of many influences, including belief, upbringing, culture, societal influences and professional obligations. Some of these are internal drivers of behaviour (for example, religious or other beliefs), others are 'internalized' (for example, societal codes of conduct which are learnt and become habit) and some are 'external' (for example, laws and professional codes, which are obeyed for fear of the consequences if not). The relative contribution of these influences varies from person to person and from context to context. Whatever that mix may be in an individual doctor, it is a prerequisite for ethical practice that the doctor be of good moral character.

The method of decision making we employ might be 'utilitarian' or 'deontological'.[1] A utilitarian approach considers the outcomes of actions and values in terms of the positive balance of good over bad (or benefit over harm). A deontological approach values actions that adhere to overriding moral principles.

Considering the influences on morality and the methods of decision making. We might, for example, be nice to our patients because we are nice people (internal morality), we have learnt that being nice is the right thing to do (internalized morality), the code of ethics of our professional body instructs us to be nice (external morality), we believe that being nice is a governing principle of behaviour (deontology) or we think that being nice means that patients are less likely to complain about us (utilitarianism). Of course these are not mutually exclusive; in practice, there is a mix of all of these influencing our behaviour.

In addition to the clinician's mix of morality and decision-making methodologies, patients' choices will be influenced by their own morality and 'world view'. Some individuals are influenced considerably by spirituality or religion and some cultures have a predominance of such individuals. A deontological approach has appeal in this context. Some individuals have no such influence and instead are influenced by a rational consideration of utility. Some cultures champion the individual's freedom to determine his or her own destiny. Other cultures consider a group, often a family group, as appropriate to make decisions on behalf of the individual. In some cultures, there is a relatively high level of respect for authority (power differential), so there might be a reluctance to question those of perceived authority, such as doctors. In other cultures, there is less of a barrier to questioning authority, potentially allowing for a better exchange of information.

These three dimensions help to define the context in which the patient considers ethical decisions: 'belief' versus 'rationality'; 'individualism' versus 'collectivism'; and 'high-power differential' versus 'low-power differential'. Current popular medical ethics tends to come from a Western context of rationality, individualism and relatively low power differential. It is appreciated that this context is not applicable to all. Of most importance, the individual patients we manage have varying positions on each of these three dimensions. Just as one model does not fit all contexts in the same ED, one model does not fit all patients. One of the challenges we face is to welcome the patient's perspective (context, values, world view) into the process of decision making.

The contributions to our morality and our processes of ethical decision making are a complex and variable mix, but that does not mean we cannot employ a standardized process for decision making. A song varies in sound depending on who sings it—the music does not change, it is the quality of the voice that makes the difference. So, with the 'tools' that follow—it is the quality of the individual's morality that makes these tools work to best effect.

An ethics tool kit for the emergency department

In emergency medicine there are many aspects of ethics relevant to our practice, including research ethics, professional ethics, ethical issues in resource allocation and so on. Although relevant, these are not peculiar to the ED. However, two dilemmas are common in EDs:

- Treating people who express a desire not to be treated (for example, the elderly lady with the fractured neck of femur who refuses

Box 28.5.1 An ethics tool kit for the emergency department

- Tool 1: The four principles
- Tool 2: Respecting autonomy
- Tool 3: Assessing competence
- Tool 4: Reassurance about competence
- Tool 5: Confirmation that the decision is the right one
- Tool 6: Stopping resuscitation

Box 28.5.2 Tool 1: The four principles of Beauchamp and Childress

1. Respect for patient autonomy
2. Beneficence
3. Non-maleficence
4. Justice

surgery and the intoxicated head-injured patient who insists on being discharged)

- Deciding to stop resuscitation efforts (as with the man in cardiac arrest)

The following 'tools' in ethical deliberation provide a structure for decisions in these two areas (Box 28.5.1).

Tool 1: The four principles (Box 28.5.2)

Beauchamp and Childress[2] combined the traditional principles of Hippocrates (try to help and do no harm) with a consideration of the rights of individuals to determine their own destiny and the rights of others who might be affected. In so doing, they described four principles that offer a pragmatic structure for deliberation. Although the 'principlism' of Beauchamp and Childress has attracted some criticism, it remains a popular and useful starting point.

Autonomy describes the patient's right to determine his or her own destiny. However, there are occasions in emergency medicine when respecting autonomy is difficult because the patient's competence is impaired or there are other influences undermining his or her autonomy.

Beneficence is the principle of acting in a way that benefits the patient. Non-maleficence, or the principle of avoiding harm, is attributed to Hippocrates. All medical interventions have the capacity to harm, and it is unrealistic to expect to 'do no harm'. Instead, we proceed if the benefit/harm balance is acceptable to the patient. When the benefits and harms are determined by the doctor without due consideration of, or in contradiction to, the patient's perception of benefits and harms, the action is termed 'paternalistic' (as a father might treat a child), although 'parentalistic' might be a more appropriate, less sexist term.

Ideally, the benefits and harms of our interventions are reasonably clear before we proceed. For example, the performance of gastric lavage on a non-consenting patient after a trivial overdose several hours earlier is ethically unjustifiable, as there is insufficient benefit to override the principles of respect for autonomy and non-maleficence. Research is an ethical necessity to provide the evidence of benefit and harm, upon which decisions must be based.

Justice, or the concept of fairness, is best addressed by questioning whether there are others who might be adversely affected by a particular action. It does not usually offer much to the deliberations when interventions for an individual in an emergency are being considered, but there are exceptions. For example, in a mass casualty incident, the performance of a hopeless resuscitation might be unjust if, in addition to harming the patient, it deprives another person with a greater chance of survival. Or if the intoxicated head-injured young man were to leave the ED with car keys in his hand and an intention to drive, then there is a potential injustice to other drivers, possibly sufficient to override his intention to leave.

In addition, there might be questions about the cost of life-sustaining and other emergency care in comparison to other care, such as hip replacements or immunizations. Although such considerations of 'distributive justice' are important, it is not appropriate for the clinician managing an individual patient to be influenced by such concerns at that time. However, it is very appropriate for clinicians to contribute to debate regarding healthcare funding and policy, but in a meeting room rather than a resuscitation room.

In applying this tool, it is necessary to discuss with the patient the clinical utility (the beneficence and maleficence, benefits and harms, pros and cons) of the therapeutic options and identify the preferred option or options. The patient is allowed the opportunity, as circumstances permit, to deliberate, discuss with others and then express a decision. Urgency and impaired patient competence might limit how much information can be provided to the patient, but these barriers should not be used as a reason not to try. Patients should receive the maximum information available under the circumstances. In many cases in EDs, the urgency is related to pressures of work rather than real clinical urgency.

Allowing, even encouraging, a discussion with an interchange of questions and answers will enhance the opportunity for the patient to understand what is available. For the patient, the belief that he or she has been able to maintain control, to take time, to say what he or she thinks and to be listened to is immensely fulfilling. Independent of the clinical outcome, this belief enhances patient satisfaction.

It is inevitable and appropriate, that clinicians have a preferred option based on their understanding of the utility of the interventions and their experience of what the average patient in similar circumstances—and the average clinician in similar circumstances—would choose.

The clinician's preferred option should not be stated 'up front' but may be better offered in the course of conversation. The patient might ask what the clinician thinks is best or the clinician may offer it if the patient appears to be struggling to make a decision ('would you like me to tell you what I think would be best?').

If the decision the patient has made is concordant with the clinician's preferred option, then it is appropriate to proceed with that option. If the patient has been given the best chance possible to make a considered, free and informed choice and that choice is the same as the clinicians' preferred option, then it is reasonable to assume that a true autonomous choice has been made and to get on with it. If the decision the patient has made is discordant with the clinician's preferred option (as might be the case with the elderly lady who refused surgery for her fractured neck of femur), then it is sensible to proceed to the next tool.

Some would argue that accepting a decision because it is concordant with the clinician's is a thinly veiled parentalism. However, it is unlikely that a concordant decision would be a wrong one; it is more likely that such a decision would lead to ongoing treatment (thereby keeping the options open). Owing to the practicalities faced by clinicians in an emergency context, the unravelling of such complex scenarios must be relegated to the fine print.

Although a discordant patient choice may well be a true autonomous choice and therefore would deserve to be honoured, discordance with the preferred choice is a trigger for a higher degree of scrutiny. The higher degree of scrutiny continues with the next tool.

However, prior to proceeding to that tool, it is important to explore (as part of the continuing interaction started earlier) the reasons for the patient's decision. There might be 'cons' or 'harms' of the preferred choice that could be addressed to the patient's satisfaction, thereby giving the patient a chance to choose again with a new perception of pros and cons. The clinician should not be coercive in content or in manner; however, if there are possibilities that would influence the patient's decision, they should be offered. An interaction such as this is permissive, not coercive: 'That's OK and we will respect your decision, but is there any particular reason you are against the operation?' 'OK, I see what you mean. Is there anything we can do so that this is less of an issue for you?'

For example, if it transpires that the elderly woman's main reason for declining surgery for her fractured neck of femur is an intense concept of privacy, with anticipated unbearable

Box 28.5.3 Tool 2: Respecting autonomy

1. Does the patient know enough? (information)
2. Can the patient think enough? (competence)
3. Is the patient free enough? (free from coercion)

Box 28.5.4 Tool 3: Assessing competence

Does the patient display an understanding of
1. The problem he or she has?
2. The options to address the problem?
3. The pros and cons of the options?

Box 28.5.5 Tool 4: Reassurance about competence

Does the patient have the capacity to understand?
- Indications that the patient might not have the capacity to understand:
  - Low level of consciousness (score on the Glasgow Coma Scale)
  - Intoxication (clinical assessment and/or levels)
  - Repetition (perseveration), suggesting short-term memory impairment
- Indications the patient probably does have the capacity to understand:
  - Listening, hearing, thinking and expressing a view
  - Understanding the reason behind a decision

embarrassment associated with being in a multibed room, having to use a bed pan and being examined by multiple people, then offering a single room and enforcing a rule of no visits by medical or other students may give her a new balance of pros and cons that changes her decision.

Tool 2: Respecting autonomy (Box 28.5.3)

We have arrived at tool 2, because at tool 1 the patient's expressed choice was discordant with the preferred option of the clinicians. The expressed choice of the elderly lady who refuses to consent to surgery is explicit. The expressed choice of the drunk young man insisting on his discharge is not articulated as clearly, but his violent and offensive behaviour and his self-initiated discharge represents a 'discordance' with the choice of the clinicians.

As part of tool 1, the reasons for the patient's decision have been explored (as opportunity allowed) and any possibilities of mitigating the cons of the preferred option have been explored and the options reconsidered. The patient's decision remains discordant.

There are two questions for the clinicians to consider at this point:

- Is this decision a truly autonomous decision?

If the answer to this question is 'no', then the next question is:

- Would the patient's truly autonomous decision be different?

If the answer to this question is yes, then respecting the patient's autonomy means disregarding the expressed wish of the patient and honouring the truly autonomous wish. It is an important concept that overriding the expressed wishes of a patient (which on the surface appear parentalistic) is done to honour the truly autonomous wishes of the patient (which have not been expressed due to influences undermining autonomy).

To answer the first question ('is this decision a truly autonomous decision?'), it is necessary to consider the elements of autonomy—information, competence and freedom—by asking three questions. (See Box 28.5.3, which describes tool 2: *Respecting Autonomy*.)

The first component of an autonomous decision is sufficient information to make the decision. A patient is at liberty to decline to be informed and to make a decision based on whatever information he or she considers sufficient. However, if a lack of information is clearly leading to a decision the patient would not make if sufficiently informed, then the decision is non-autonomous.

The second component of an autonomous decision is the ability to deliberate and express a decision. Some refer to this as *competence*, or *decision-making capacity* (although both of these terms may have wider definitions). For this chapter, the term *competence* is used. Is the patient cognitively impaired, thus impairing his or her competence? And, if he or she were competent, is it likely that he or she would make a different decision? Determining the patient's competence is challenging and is covered more fully in Chapter 28.3. However, a simple approach is outlined in tool 3.

Are there coercive influences leading the patient to make a decision he or she would not make if free from the influence? In the ED, the most common coercive influence is suicidal ideation secondary to depression. Occasionally other influences, from family or friends, may be present. The presumption in the ED is that someone who has attempted suicide has a depressive illness that is reversible and that their true autonomous wish (if the coercive influence of depression were reversed) would be to receive treatment to preserve his or her life. This presumption is not always correct, as some suicides might be considered to be 'rational,' 'autonomous' decisions (for instance, the patient with an advanced, incurable neurological disease). Determining that the patient's choice is free from a reversible coercive influence is very difficult for an ED clinician in a hurry. In this context, the most senior and qualified assessment should be called upon (the emergency physician or the psychiatrist, for example). However, if these are unavailable or still uncertain, then it is appropriate to default to the presumption that the patient's suicidality is reversible and that the truly autonomous wish would be to receive treatment to preserve life. This default keeps options open and allows further specialist assessment of psychiatric illness. As such, it is the lesser of two possible errors.

Tool 3: assessing competence (Box 28.5.4)

Tool 3 comes into play because it is believed that the patient's discordant decision might not be his or her truly autonomous one and the reason relates to possible impaired competence.

The initial test of competence in this step might or might not be definitive. If it is clear the patient 'knows what he are doing,' or it is clear he does not, decision making might be finished at this point. Otherwise, and if there is any doubt, reassurance might be required, as discussed in tool 4.

Competence is mostly about understanding. An initial assessment of competence can be made by asking if the patient displays understanding of three things. (See Box 28.5.4, headed, 'Tool 3: Assessing competence'.)

Does the patient display understanding of the illness or injury, the therapeutic options and the perceived or estimated benefits and harms of the various therapeutic options? If it is clear that she does, then competence can be assumed. If it is clear she does not, then competence can be assumed to be absent. If it is unclear whether or not she understands, reassurance can be gained, as described later.

Tool 4: reassurance about competence (Box 28.5.5)

Competence is mostly about understanding, but there will be supporting information concerning the patient's capacity to understand, which this tool explores.

Observations regarding the patient's score on the Glasgow Coma Scale (GCS) and intoxication are important, as they provide 'hard data' in the clinical notes (and should be recorded there). However, they are not absolute, as they indicate capacity to understand and not actual understanding. A GCS score below 9 (indicating that the patient is not interacting with the environment except in making non-communicative responses to painful stimuli) will clearly indicate impaired competence, as at that level no decision can be made or expressed. However, a GCS score of 14 out of 15 (or even 13 or 12 out of

15) does not necessarily mean that the patient does not understand. The head-injured man who insists on discharging himself and leaving the hospital might be drunk, with an initial GCS score of 14. This suggests that his competence might be impaired but does not define incompetence. Incompetence must be proven by a determination that an individual's understanding is impaired by reapplying tool 3.

Similarly, an early, humane and judicious dose of intravenous morphine for a painful condition (as for the elderly lady with a fractured neck of femur) does not necessarily render the patient incompetent. If she still indicates understanding, then competence should be assumed.

Perseveration is common in mild to moderate head injuries, often manifesting as repeating the same questions over and over ('Hey doc, what happened to me?' 'Why am I here?' etc.). If new information is not being stored, then competence to make important treatment decisions is unlikely to be present.

If the decision the patient makes is discordant with the preferred option, then we have already challenged his or her understanding: 'OK, we well respect your decision but can I please, for my own reassurance, ask you a few questions so that I am sure you understand the decision you are making? Can you tell me what you understand about what has happened to you? Can you tell me what you understand about the operation? Can you tell me what you understand about what will happen if you do not have the operation?' Then, the first part of tool 4 has asked us to note some potential indicators of impaired capacity to understand. The second part of tool 4 asks about 'reason' as an indicator of the capacity to understand. Reason ('I am making this decision because…') is a powerful indicator of a competent decision. The intoxicated head-injured patient might be asked why he wants to leave. He might answer, 'I left my friend at the nightclub. I'm worried about what s/he's up to.'

Although we might challenge his reason (and counsel him that, his friend is most likely safe), he has displayed reason and it is not our place to challenge 'what makes people tick' (their context, their values, their world view). Instead, we have the task of making sure that patients are making the right choices —their truly autonomous choices. Reason in a decision suggests the choice is a competent one; consequently it is probably an autonomous one.

Tool 5: confirmation that the decision is the right one (Boxes 28.5.6 and 28.5.7)

At this stage, one of two possible decisions about the patient's discordant decision has been made. A final confirmation for each of these decisions follows.

Box 28.5.6 describes tool 5a: Respecting the patient's refusal of care. It is important to emphasize that any of these three prove the case. In other words, the presence of any of these three disallows overriding of the patient's refusal of care.

Box 28.5.8 describes tool 5b: Overruling the patient's refusal of treatment. It is important to emphasize that all three are needed to justify treating a patient against expressed wishes. In this case, the truly autonomous wishes of the patient (to be treated) are being honoured.

In the case of the elderly lady who refused an operation for her fractured neck of femur, discussion might reveal that she had understanding of the consequences of her (discordant) decision. Further discussion might confirm the reasons (an intense sense of privacy). Both understanding and reason refute any allegation that she has impaired competence. Her decision is a truly autonomous one and should be honoured. However, there is the possibility of mitigating her reasons (redefining the pros and cons) by arranging greater privacy, as suggested earlier. Then her truly autonomous choice and the preferred option of the clinicians may become concordant.

The intoxicated young man became offensive and disruptive and then left the department. Was his refusal of care a truly autonomous one? If not, would his truly autonomous decision be to accept care? Applying tool 1, there might be concern that his worsening aggression in the context of a violent blow to the side of his head represents a deterioration consistent with an expanding extradural haematoma needing urgent attention (beneficence and non-maleficence) and that his discordant decision may be non-autonomous. Applying tool 2, there might be concern that he 'wasn't thinking clearly enough' (had impaired patient competence). Applying tools 3 and 4 might reveal that he did not know what day it was, he seemed to need reorientation about where he was and what had happened and, when asked if he understood how serious his injury might be and why he was refusing to cooperate with treatment, he was irrational and incoherent. A decision is made that his refusal of care should be overruled and if reassurance, persuasion, bargaining and threats did not allow treatment to proceed, then the clinical staff should consider the use of drugs and restraint to provide treatment. Tool 5 is used for confirmation that this decision is the right one. Finally, and of great importance, the clinicians must document carefully their reasons for intervention (beneficence and non-maleficence) and how they respected this young man's autonomy (the evidence of incompetence and a belief that his true autonomous wish would be to receive treatment).

Box 28.5.6 Tool 5a: Respecting the patient's refusal of treatment

Although the patient's refusal of treatment is discordant with our preferred choice, the refusal should be respected because

- there are no good, beneficent or non-maleficent justifications to override the patient's decision.
- the patient's choice to decline treatment seems to be his or her truly autonomous wish (the patient appears to know enough, be able to think clearly enough and is free enough).
- we are reasonably confident that *if* he or she knew enough, *could* think enough and *were* free enough, he or she would most likely give the same answer that he or she is giving now.

Box 28.5.7 Tool 5b: Overruling the patient's refusal of treatment

Despite the patient's expressed refusal of treatment, we believe that the patient's truly autonomous wish is to receive treatment, because

- there are good beneficent or non-maleficent justifications to treat the patient.
- the patient is non-autonomous because he or she does not know enough, cannot think clearly enough or is not free enough.
- it is believed that the patient's true autonomous wish is to be treated (*if* he or she knew enough, *could* think enough and *were* free enough).

Tool 6: Stopping resuscitation (see Box 28.5.8)

When a clinician is considering whether to stop a resuscitation, the tools listed earlier are relevant. But if the patient is unconscious, there is no expressed indication of his or her autonomous wishes. Respect for autonomy and consent may appear irrelevant, but consent should be obtained for resuscitation, as in all other medical interventions.

There is an assumption that resuscitation offers hope of a good outcome (which is true) but does not cause harm (which is false). Resuscitation is often provided with this 'no harm in trying' belief, but without due consideration of the harms of resuscitation or how the patient would perceive the balance of benefits and harms. The benefits of resuscitation include the avoidance of death and the restoration of health. However, resuscitation can cause unnecessary discomfort, indignity, false hope, a lingering death, financial and opportunity costs and survival with a poor quality of life.[3] If patients undergoing resuscitation were

Box 28.5.8 Tool 6: Stopping resuscitation

Presumed consent using professional substituted judgment involves the following:

Knowing what I know about the benefits and harms of this resuscitation,

knowing what I know about the patient and his or her possible and/or likely wishes

and if I could pause the resuscitation, sit the patient up and calmly talk to him or her, would he or she consent to resuscitation?

- If the answer is 'yes' then resuscitation proceeds.
- If the answer is 'no' then resuscitation stops.
- If the answer is uncertain, then resuscitation should usually continue (a 'trial of treatment') and the question repeated as resuscitation brings or fails to bring improvement or more information about the patient's likely wishes is forthcoming.
- As soon as the answer becomes a clear 'no', resuscitation must stop.

able to consider the potential benefits and harms of the resuscitation intervention received in a calm and rational state, just as a patient might when consenting for elective surgery, then it would not be surprising to find a number declining consent.

Consent, in relation to resuscitation, attempts to determine what the patient would want if able to consider the benefits and harms of resuscitation. Informed consent, as is appropriate for elective surgery, might be inappropriate during resuscitation owing to the urgency of the treatment and impaired competence of the patient. However, if informed consent is not relevant, other forms of consent still are.[4] The two most common forms of consent used in resuscitation scenarios where there is both urgency and impaired patient competence are presumed consent and proxy consent.

Presumed consent uses the concept that a reasonable patient under similar circumstances—or if this patient were able to—would consent to the resuscitation endeavours proposed. This form of consent has merit and is commonly employed, but it occasionally attracts criticism as being a form of medical parentalism in that it may be perceived to be respecting the principle of beneficence as the resuscitators perceive it rather than as the patient would perceive it.

Proxy consent involves obtaining consent for resuscitation from a family member or other person who is perceived to be able to speak on behalf of the patient. Proxy consent avoids the criticism of medical parentalism as the decision is taken out of the physician's hands; however, it suffers as a model because the decision maker may be unable adequately to receive information, understand it and deliberate during a hurried and rapidly evolving resuscitation.

In addition, the proxy might not reflect the views of the patient. There might be occasional circumstances where the proxy declines resuscitation because of some financial or other benefit that would accrue from the patient's death. More commonly, proxies have a tendency to demand more resuscitation than the patient would have wanted.[5,6]

A modification of proxy consent that better addresses the issue of respect for patient autonomy is proxy consent with substituted judgement. This involves not asking what the proxy would want done for the patient but instead what the proxy thinks the patient would want done. In other words, it attempts to see the resuscitation from the patient's perspective as the proxy understands it.

Similarly, a modification to presumed consent is presumed consent with professional substituted judgement.[7] In this model, the resuscitators gather as much information about the patient as they possibly can in trying to understand how the patient would view this decision. This usually involves speaking with the patient's loved ones. Then, with some knowledge of the likely outcome of the resuscitation proposed, based on previous experience and a knowledge of the medical literature, they can exercise their moral imagination by asking *'If I could pause the resuscitation, sit the patient up, talk to him and ask if he wants this resuscitation, what would he say*?' In this way the patient's autonomy is respected as best it can be under difficult circumstances by combining a knowledge of the harms and benefits of the resuscitation with an appreciation of this balance from the patient's perspective as best the resuscitators can appreciate it.

For example, in a cardiac arrest, the patient's primary care doctor might relay details of a conversation he had with the patient during which the patient expressed a desire not to be resuscitated from cardiac arrest. With that information known, asking the question mentioned earlier would bring a clear *'No, I do not want this resuscitation'*. With that response, the resuscitators have an obligation to stop.

The resuscitation should not proceed if presumed consent using professional substituted judgement is employed and the answer to the question is *no*. To resuscitate without regard for the patient's explicit or perceived wishes is a harmful disrespect for the patient's autonomy.

Often, and appropriately, a decision to proceed will be made on the basis of a perceived balance of benefit over harm and an uncertainty about what this patient would want. In this case, a 'trial of treatment' keeps options open (by keeping the patient alive) and allows time to gather a clearer view of the likely benefits and harms of resuscitation (as the patient responds or fails to respond to the resuscitation) and the likely desires of the patient (as information about the patient comes from relatives or others). The question is asked again—*'If I could pause the resuscitation, sit the patient up, talk to him and ask if he wants this resuscitation, what would he say*?—until a clear *yes* or *no* is apparent.

The resuscitators should recognize when the balance of benefit and harm becomes unfavourable from the patient's perspective by employing professional substituted judgement. When it is clear that the patient would say *'No'* to ongoing resuscitation, the resuscitators have a moral obligation to withdraw resuscitation as they can no longer presume the patient's consent.

The consent model used in resuscitation (proxy or presumed, with or without substituted judgement) will be influenced by the moral dimensions above (especially individualism versus collectivism) and by the legal jurisdiction in which the decision is being made (some may favour a stronger role of proxies in decision making). The law, like ethics, has the objective of ensuring the right things are done for the patient. Presumed consent using professional substituted judgement aims to achieve this, but clinicians should ensure the model they use is consistent with local law.

Summary

To be ethical in emergency medicine is to do the right thing for the patient. The right thing is what the patient would choose if given the ideal circumstances to exercise autonomy. The difficulty we have is determining what the right thing is. The clinician's morality and methods of weighing ethical issues form a platform for this determination. From this platform the clinician can then apply pragmatic tools, including the four principles, the three questions about autonomy and then the three questions about competence. Further consideration can reassure the clinician about competence and about decisions to treat or not treat patients without their consent. In the setting of the unconscious patient undergoing resuscitation, a presumption of consent using professional substituted judgement has the greatest potential to reflect the patient's truly autonomous wishes.

Having made a good ethical decision, the final task is to document it well. Considerations of the benefits and harms of interventions and how the patient's autonomy was respected should be well documented and should be concordant with the events that transpired.

SECTION 29

EMERGENCY AND MEDICAL SYSTEMS

Edited by *Peter Cameron*

29.1 Pre-hospital emergency medicine

Stephen A. Bernard • Paul A. Jennings

ESSENTIALS

1 **Ambulance call taking and dispatch is increasingly becoming computerized, which allows for the medical determination of the most appropriate response speed and skill set as well as telephone instructions for cardiopulmonary resuscitation and first aid.**

2 **Ambulance care of the critically ill or injured patient is similar to initial evaluation and management by an emergency physician, with emphasis on basic life-support measures.**

3 **The role of advanced life support measures such as endotracheal intubation and intravenous drug and fluid therapy in patients with severe trauma or cardiac arrest is uncertain.**

4 **Patients with chest pain and ST-segment elevation on a 12-lead electrocardiogram should be triaged to a centre with facilities for percutaneous coronary intervention. If this transfer cannot be achieved with 1 hour, then pre-hospital thrombolysis should be considered.**

5 **Paramedics have effective treatment for other common medical emergencies including cardiac arrhythmias, acute pulmonary oedema, narcotic drug overdose, seizures, hypoglycaemia and anaphylaxis.**

Introduction

Ambulance services have traditionally had the primary role of providing rapid stretcher transport of patients to an emergency department (ED). Increasingly, paramedics are also trained to provide emergency medical care prior to hospital arrival in a wide range of life-threatening illnesses with the expectation that earlier treatment will improve patient outcomes.

Dispatch

Many countries have a single telephone number for immediate access to the ambulance service in cases of emergency, such as 911 in North America, 999 in the United Kingdom and 000 in Australasia. However, the accurate dispatch of the correct ambulance skill set in the optimal time frame is complex. It is inappropriate to dispatch all ambulances on a 'code 1' (lights and sirens) response to all callers, since this entails some level of risk to the paramedics and other road users. On the other hand, it may be difficult to accurately identify life-threatening illnesses or injuries using information gained from telephone communication alone, especially from bystanders. Also, the dispatch of paramedics with advanced life support training to routine cases where these skills are not required may make them unavailable for a subsequent call to a patient with a time-critical emergency.

In order to have consistent, accurate dispatch of the appropriate skill set in the optimal time frame, many ambulance services are now using computer-aided dispatch programs. These programs have structured questions for use by call takers with limited medical training. Pivotal to accurate telephone dispatch is identification of the chief complaint, followed by subsequent structured questions to determine the severity of the illness. The answers to these questions allow the computerized system to recommend the optimal paramedic skill set and priority of response. This computer algorithm is medically determined according to local protocols and practices and provides consistency of dispatch.

Most ambulance services have at least four dispatch codes. A code 1 (or local equivalent terminology) is used for conditions that are considered immediately life threatening. For these, emergency warning devices (lights and sirens) are routinely used. The possibility of

lifesaving therapy arriving as soon as possible is judged as outweighing the potential hazard of a rapid response. In a code 2 (or equivalent) response, the condition is regarded as being urgent and emergency warning devices may be used only when traffic is heavy. In a code 3 response, an attendance by ambulance within an hour is deemed medically appropriate. Finally, a non-emergency or 'booked' call is a transport arranged at a designated time negotiated by the caller and the ambulance service.

Despite continuous developments in computer algorithms, accurate telephone identification of life-threatening conditions may be difficult. For example, identification of patients who are deceased (beyond resuscitation),[1] in cardiac arrest[2] or experiencing an acute coronary syndrome[3] has been shown to lack the very high sensitivity and specificity that might be expected.

The dispatch centre also has a role for telephone instructions on bystander CPR[4] and first aid. For conditions that are regarded as non-urgent, the dispatch centre may transfer the call to a referral service for the provision of a medical response other that an emergency ambulance.[5] This might include dispatch of a district nurse for a home visit, the provision of simple medical advice with instructions to see a family physician or advice to attend an ED if symptoms persist.

Clinical skills

Ambulance treatment protocols vary considerably around the world. Since there are few randomized controlled trials to provide high-quality evidence-based guidance for pre-hospital care, there is still much controversy and considerable variation in the ambulance skill set required by different ambulance services.

Many ambulance services provide a number of different skill sets, dispatching ambulance officers trained in basic life support (including defibrillation) to non-emergency or urgent cases (ambulance paramedics) and more highly trained officers (designated as advanced life-support paramedics or intensive-care paramedics) to patients with an immediately life-threatening condition for which advanced life-support skills may be appropriate.[6] In addition, ambulances services may co-respond with other emergency services (such as firefighters) to provide rapid-response defibrillation and assist with basic life support.

The evidence for some of the more common pre-hospital interventions is outlined in the following sections.

Trauma care

Pre-hospital trauma care may be considered as either basic trauma life support (clearing of the airway, assisted ventilation with a bag/mask, administration of supplemental oxygen, control of external haemorrhage, spinal immobilization, splinting of fractures and the administration of inhaled analgesics) or advanced trauma life support (ATLS), including intubation of the trachea, intravenous (IV) fluid therapy, decompression of tension pneumothorax and the administration of IV analgesia.[6]

Basic trauma life support

On arrival at the scene of the patient with suspected major trauma, paramedics are trained to perform an initial 'DR-ABCDE' evaluation (e.g. consideration of dangers, response, airway, breathing, circulation, disability and exposure), which is similar to the approach developed for physicians. Of particular importance in the pre-hospital trauma setting are dangers to paramedics from passing traffic, fallen electrical wires and fire from spillage of fuel.

The initial assessment of the airway and breathing includes the application of cervical immobilization in patients who have a mechanism of injury suggesting a risk of spinal column instability. Although decision instruments have been developed to identify patients in the ED who require radiographic imaging,[7] the accuracy of these guidelines in the pre-hospital setting is uncertain. Spinal immobilization of many patients with minimal risk of spinal cord injury is uncomfortable and may lead to unnecessary radiographic studies. Therefore the recommendation to immobilize the neck in all cases of suspected spinal column injury based on mechanism of injury alone is currently being challenged.[8] On the other hand, if spinal cord injury is suspected, patients should be transported with full spine immobilization.[9,10]

Accurate triage of major trauma patients is an important component of trauma care in cities with designated major trauma centres. Triage tools based on vital signs, injuries, and modifying factors such as age, co-morbidities and mechanism of injury are used.[11] Paramedic judgement may also have a role, although some injuries, such as occult intra-abdominal injuries, are difficult to detect on clinical grounds.[12]

Advanced trauma life support

The role of ATLS by paramedics, particularly intubation of the trachea in comatose patients and IV cannulation for fluid therapy in hypotensive patients, is controversial. Although these interventions are routinely used in critically injured patients after hospital admission, studies to date indicate that the provision of ATLS provided by paramedics may not improve outcomes.[6,13] On the other hand, few studies conducted to date have been sufficiently rigorous to allow definitive conclusions, and many were conducted in an urban setting with predominantly penetrating trauma rather than blunt trauma. Therefore many ambulance services continue to authorize advanced airway management and IV fluid resuscitation in selected trauma patients, particularly those who are injured some distance from a trauma service.

Intubation

Following severe head injury, many unconscious patients have decreased oxygenation and ventilation during pre-hospital care, and this secondary brain injury is associated with worse neurological outcome.[14] In addition, a depressed gag or cough reflex may lead to aspiration of vomit, which may cause a pneumonitis that can be fatal or result in a prolonged stay in an intensive care unit. To prevent these complications of severe head injury, endotracheal intubation may be performed. This facilitates control of oxygen and carbon dioxide, provides airway protection and is routinely performed in patients with a Glasgow Coma Scale score less than 9 following severe head injury after hospital arrival.[15]

Most patients with severe head injury maintain a gag or cough reflex, and successful intubation requires the use of drugs to facilitate laryngoscopy and placement of the endotracheal tube. The usual approach in the ED involves rapid sequence intubation (RSI), which is the administration of both a sedative drug and a rapid-acting muscle relaxant such as suxamethonium. It is unclear from the literature whether RSI should be performed pre-hospitalization by paramedics or, alternatively, be performed in an ED by appropriately trained physicians.

Pre-hospital RSI performed by paramedics has been reported as having a success rate as high as 99.4%.[16] However, it is uncertain whether this procedure is associated with improved outcomes.[17,18] The only prospective, randomized trial in adult patients with severe traumatic brain injury to date reported that paramedic RSI increased the rate of favourable neurological outcome at 6 months as compared with intubation in the hospital by physicians.[19] On the other hand, this study also showed a relatively high incidence of cardiac arrest in the patients who underwent paramedic RSI. Therefore some uncertainty remains regarding the efficacy of this procedure.

Intravenous fluid

IV fluid resuscitation has been shown to worsen outcome in patients with penetrating trauma and hypotension.[20] However, most major trauma in Australasia and Europe is blunt rather than penetrating and few patients require urgent surgical control of haemorrhage. Therefore the issue of pre-hospital IV fluid administration for the treatment of hypotension remains a subject of debate.

Supporters of pre-hospital IV fluid therapy suggest that this treatment is intuitively beneficial

and that any delay of this therapy increases the adverse effects of prolonged hypotension, which may result in end-organ ischaemia followed by multi-organ system failure and increased morbidity and mortality. On the other hand, opponents suggest that this therapy prior to surgical control in patients with uncontrolled bleeding increases blood loss due to increased blood pressure, dilution coagulopathy and hypothermia from large volumes of unwarmed IV fluid. Any additional blood loss would increase transfusion requirements and could be associated with increased morbidity and mortality.

There is no evidence from clinical trials for benefit of the administration of IV fluid to bleeding patients in the pre-hospital setting. Nevertheless, if IV fluid is given to patients with hypotension and severe head injury, crystalloid rather than colloid should be given, particularly in hypotensive patients with severe traumatic brain injury.[21] In some helicopter emergency medical services, blood transfusion is available as an adjunct to crystalloid fluid therapy.[22]

Analgesia

The administration of effective analgesia in the pre-hospital setting for traumatic pain remains a difficult issue for ambulance services. Many paramedics are not trained to administer IV therapy; therefore treatment options are limited to inhaled therapy.

Inhaled analgesic treatments include methoxyflurane and oxygen/nitrous oxide. However, although the former is reasonably effective,[23] there are concerns with the administration of this agent in an enclosed space such as the rear of an ambulance because of the perceived risk to the paramedics of repeated exposure to these analgesics.

Alternatively, the training of paramedics in the insertion of an IV cannula and administration of small increments of IV morphine is increasingly regarded as a feasible alternative to inhalation analgesia. Alternative routes of narcotic administration such as intranasal administration have been found to be effective; for example, the use of intranasal fentanyl has been shown to be equivalent to IV morphine.[24] Nerve blocks for some painful injuries have been trialed by paramedics with some success,[25] leading several emergency medical services to increase their paramedics' scope of practice to include the administration of nerve blocks.

An alternative analgesic agent for paramedic use is ketamine. Ketamine in addition to morphine has been shown to be superior to morphine alone for traumatic pain. In a randomized controlled trial, adult patients with moderate to severe traumatic pain were randomized to receive either 5 mg of morphine followed by ketamine or morphine alone.[26] Those who received morphine and ketamine reported a significantly reduced pain score compared with those who received morphine alone. However, the rate of adverse effects, such as nausea and dysphoria, was higher following ketamine compared with morphine.

Cardiac care

Cardiac arrest

In 1966, external defibrillation was introduced into pre-hospital care. This led to the development of 'mobile coronary care units' in many countries for the delivery of advanced cardiac care for the patient with suspected myocardial ischaemia.[27] This approach was subsequently extended to rapid response for the defibrillation of patients in cardiac arrest. Protocols for the management of pre-hospital cardiac arrest are based on the concept of the 'Chain of Survival', which includes an immediate call to the ambulance service, the initiation of bystander CPR, early defibrillation and advanced cardiac life support (ACLS) (intubation and drug therapy).

The patient in cardiac arrest represents the most time-critical patient attended by ambulance services. For the patient with ventricular fibrillation, each minute increase from time of collapse to defibrillation is associated with an increase in mortality of approximately 10%. However, most ambulance services have urban response times that average 8 to 9 minutes. Since there may be 2 minutes between collapse and dispatch and 1 minute between arrival at the scene to delivery of the first defibrillation, total time from collapse to defibrillation would usually be approximately 12 minutes. Therefore current survival rates for witnessed cardiac arrest are low.[28]

The most effective strategy to improve outcomes would be to decrease ambulance response times. However, this would require very significant increases in ambulance resources and would be an expensive strategy in terms of cost per life saved. Alternatively, response times to cardiac arrest patients may be reduced with the use of co-response by first responders, such as firefighters equipped with defibrillators. More recently, first responders trained in CPR may be dispatched using telephone Apps, such as GoodSAM.[29]

The role of ACLS during cardiac arrest remains controversial.[30] For example, in a randomized, controlled trial comparing a basic life support approach with an advanced life support approach, the rate of survival to hospital discharge was 10.5% for the ACLS group compared with 9.2% for the no ACLS group ($P = .61$).[28] This finding of a lack of efficacy of ACLS during cardiac arrest remained after adjustment for underlying differences between the groups in the rates of ventricular fibrillation, response interval, witnessed arrest or arrest in a public location.

Therapeutic hypothermia after resuscitation from cardiac arrest is used in many hospitals, particularly when the initial cardiac arrest rhythm is ventricular fibrillation. A number of more recent clinical trials have tested whether therapeutic hypothermia should be initiated by paramedics during resuscitation using a bolus of cold IV fluid[31] or intranasal cooling[32]; however, the results of these studies do not currently support this therapy prior to hospital arrival.

The use of mechanical CPR devices has been shown to have similar outcomes compared with manual chest compressions.[33] However, if the patient requires CPR to a hospital which can provide extracorporeal membrane oxygenation (ECMO), then mechanical CPR is required for paramedic safety. This strategy has been shown to be feasible in the pre-hospital setting and is associated with a relatively high survival rate.[34]

Acute coronary syndromes

Most ambulance services have protocols for the management of the patient with chest pain where the cause is suspected to be an acute coronary syndrome. These protocols usually include the administration of aspirin and sublingual trinitrates followed by rapid transfer to an ED for definitive diagnosis and management. In addition, pain relief using IV morphine may be given by advanced life-support paramedics. The role of supplemental oxygen in patients with ST-elevation myocardial ischemia (STEMI) but without hypoxia remains uncertain.[35]

Although these interventions may decrease symptoms, more recent strategies to improve overall outcomes involve triage by paramedics of patients with STEMI using 12-lead electrocardiography and referring them to centres for interventional cardiology.[36] For patients with STEMI who are greater than 1 hour away from a cardiac catheterization laboratory (i.e. rural patients), prehospital thrombolysis may be considered. In a recent European trial, patients with STEMI who presented within 3 hours after symptom onset but were unable to undergo primary percutaneous coronary intervention (PCI) within 1 hour were assigned to undergo either primary PCI or fibrinolytic therapy.[37] The primary end point of death, shock, congestive heart failure or reinfarction occurred in 12.4% of patients in the pre-hospital fibrinolysis group and in 14.3% of patients in the primary PCI group (relative risk in the fibrinolysis group, 0.86; 95% confidence interval, 0.68 to 1.09; $P = .21$). The rates of intracranial bleeding were similar in the two groups (after the dose of fibrinolysis was halved in patients aged over 75 years of age). These data suggest that pre-hospital thrombolytic therapy is appropriate if there is a delay of greater than 1 hour in transport to a definitive centre for PCI.

Cardiac arrhythmias

Some patients with an acute coronary syndrome develop a cardiac arrhythmia during ambulance care. Pulseless ventricular tachycardia is treated with immediate defibrillation, and amiodarone by slow IV infusion is recommended for ventricular tachycardia where a pulse is palpable and the patient is alert.[38] For supraventricular tachycardia, the use of verapamil or adenosine appears to be equivalent in efficacy,[39] and most pre-hospital systems will include treatment of supraventricular tachycardia in their clinical practice guidelines for use by intensive care paramedics.

Pulmonary oedema

During myocardial ischaemia, the patient may develop pulmonary oedema. In these patients the use of oxygen and glyceryl trinitrate is regarded as useful.[40] There is evidence that continuous positive airway pressure is feasible in the prehospital setting, may reduce the need for intubation and may reduce short-term morbidity[41]; and for this reason it is becoming the standard of care in most prehospital systems.

Other medical emergencies

Stroke

Early identification and effective management of stroke aims to promote optimal recovery. Ambulance services play an important role in stroke management by triaging patients with suspected stroke to an appropriate hospital. Use of a validated stroke screen tool has been shown to increase diagnostic accuracy in identifying stroke, thus facilitating transfer to a stroke centre. There are a number of published stroke screening tools for paramedic use, such as the Los Angeles Motor Score (LAMS)[42] and the Melbourne Ambulance Stroke Score.[43] Both of these have been shown to be effective in accurately identifying stroke. Patients suspected of having had a stroke should be managed as time-critical emergency cases and be preferentially transported to a facility capable of delivering reperfusion therapies as well as stroke unit care.[44] With the increase in number of sites able to perform the highly specialized procedure of endovascular clot retrieval (ECR), a challenge for prehospital care providers will be to identify those patients with stroke who are likely to benefit from ECR and transfer these patients preferentially to facilities where this can be achieved within the appropriate time frame.[45]

Hypoglycaemia

The patient with hypoglycaemia due to relative excess of exogenous injected insulin will suffer neurological injury unless the blood glucose level is promptly corrected. Treatment of the conscious patient involves orally administered dextrose. For unconscious patients, IV 10% dextrose should be administered. For paramedics who are not trained to insert IV cannulae or where IV access is not possible, the administration of intramuscular glucagon is also effective, although this is associated with an increase in the time to full consciousness.[46]

Patients who respond to treatment may refuse transport to hospital since they feel they have recovered. However, patients on oral hypoglycaemic agents may later develop recurrent hypoglycaemia.[47] Therefore transport to hospital in this patient group is recommended.

Narcotic overdose

Patients who inject narcotic drugs may suffer coma and respiratory depression, which is readily reversed by naloxone. However, the administration of IV naloxone by paramedics is somewhat problematic, since IV access may be difficult and the half-life of IV naloxone (approximately 20 minutes) may be shorter than the injected narcotic. If the patient awakens and leaves medical care, there may also be a recurrence of sedation. Therefore many ambulance services administer naloxone via the intramuscular or subcutaneous route. Whilst the absorption via this route may be slower, overall the time to return of normal respirations is equivalent. To avoid the use of needles, naloxone may also be administered via the intranasal route. This has an onset time equivalent to that of intramuscular naloxone.[48]

Anaphylaxis

Many patients with known severe anaphylaxis are prescribed adrenaline (epinephrine) by their physician for self-administration. The use of intramuscular adrenaline (epinephrine) by paramedics is a safe and effective pre-hospital therapy.[49] Generally, a dose of adrenaline 0.3 mg IM together with IV fluid therapy is recommended as first-line therapy for anaphylaxis, with IV adrenaline reserved for patients who become severely hypotensive. Children may also be effectively treated with epinephrine.[50]

Seizures

Out-of-hospital status epilepticus is also regarded as a time-critical medical emergency. The first-line treatment of this condition is usually a benzodiazepine. For many years this was provided using the IV or rectal route of administration. More recently, there are supportive data that intramuscular midazolam is just as effective as a benzodiazepine delivered intravenously.[51] Many ambulance services therefore now authorize midazolam 0.1 mg/kg in the adult patient with seizure, with a half dose considered in older patients.

Acute agitation

Presentations of patients with acute agitation and combativeness are commonly seen by paramedics in the pre-hospital setting, and such patients pose a risk to both themselves and their caregivers. Many ambulance services have introduced clinical practice guidelines to address such presentations. These include de-escalation strategies and a range of drugs with sedative properties, such as midazolam, droperidol, olanzapine and ketamine.

CONTROVERSIES AND FUTURE DIRECTIONS

- Computer-aided dispatch algorithms require further improvement to increase the sensitivity and specificity for the detection of life-threatening emergencies.
- Advanced life support—including intubation and IV fluid therapy by ambulance paramedics for the severe trauma and cardiac arrest patient—is unproven and expensive. Further randomized controlled trials are required to justify these interventions.
- Patients with chest pain and STEMI should be identified with 12-lead electrocardiography and transferred directly to a centre with facilities for interventional cardiology. There is a role for prehospital thrombolysis if time to a cardiac catheterization exceeds 1 hour.
- Routine application of cervical spine immobilization interventions on the basis of mechanism of injury alone is being challenged. The utility of clinical examination and decision support tools to accurately identify those at increased risk of spinal injury requires further research.
- Use of sensitive and specific diagnostic tools to identify patients who are likely to benefit from ECR may assist in determining most suitable destinations for patients following stroke. The use of prehospital 'CT ambulances' is likely to assist with such decisions.

29.2 Retrieval

Marcus Kennedy

ESSENTIALS

1 Mature retrieval systems act as a single point of entry for the referrer, preferably providing services by initiation of a single call to a systemwide phone number.

2 Retrieved patients are often unstable, at the margin of physiological compensation, and in need of specialized investigation and intervention. They are often at that phase of an emergency presentation where diagnosis is incomplete, treatment is problem-focused and risk is high. This setting therefore requires special expertise, risk-averse processes, and fail-safe systems characterized by anticipation, redundancy, rapid response and reliability.

3 The retrieval environment poses particular risk, and technical training regarding platforms, procedures, relevant legislation, communication methods, rescue and escape procedures and equipment performance characteristics is needed.

4 Retrieval crew members must be trained to critical care standard. The skill set they provide must meet the clinical needs of the patient.

5 It is likely that the most complex patients receiving the highest levels of support are also the most likely to be exposed to in-transit critical incidents or equipment failure. Clinical practice in this setting requires the anticipation of such events, vigilance to detect them, and rehearsed and standardized problem-solving algorithms to rectify them.

Retrieval systems

The definition of retrieval varies by jurisdiction; however, it includes the inter-hospital transfer of critical patients using specialized clinical staff, transport platforms and equipment. In most regions, this definition extends to the pre-hospital environment when medical staff crewing is deployed and, in this setting, is termed primary retrieval. In various systems, staff may include medical, nursing, advanced life support (ALS) paramedic or intensive care paramedic (or equivalents) in a range of combinations or crew-mix. Retrieval generally involves the transfer of patients with critical illness or life-threatening injury—situations where the patient requires the highest levels of clinical care and vigilance. Retrieved patients are often unstable, at the margin of physiological compensation, and in need of specialized investigation and intervention. They are often at that phase of an emergency presentation where diagnosis is incomplete, treatment is problem-focused and risk is high. This setting therefore requires special expertise, risk-averse processes and fail-safe systems characterized by anticipation, redundancy, rapid response and reliability.

Retrieval is a coordinated process that provides specialized assessment and management, prior to and during transfer of critically ill patients from situations where resources or services are inadequate, to a destination where definitive care can be provided. It aims to deliver the same or higher level of clinical care as that available at the point of referral, thus ensuring that the patient is not exposed to any reduction in the quality of clinical care, despite the inherent risks of the transport environment.

The need for retrieval is related to the limitations of health facilities and the geography of populations. It is a reasonable premise that rural communities have a right to equitable and timely access to critical care medicine; however, it is recognized that there is often an urban/rural divide in regard to the accessibility of health care generally and to specialized critical care in particular. Key clinical 'gap' areas exist at both urban and rural and regional levels in regard to trauma, neurosurgery, cardiac, and neonatal and paediatric critical care. Advances in medicine and technology are inevitably (at least initially) usually concentrated in major metropolitan centres, thus increasing the need for critical patient transport (e.g. coronary percutaneous procedures, interventional radiology, such as angio-embolization, major trauma centres and paediatric tertiary and quaternary care hospitals). Given that such divides exist and that critical-care transfer is inevitable, retrieval medicine aims to ensure quality of care in transfer.

Retrieval systems are often a product of their geography, and some services have evolved due to their unique environment. Examples include Nordic systems and alpine systems that have emerged from the demands of challenging altitude and temperature extremes, urban trauma service (such as HEMS London), and systems driven by the tyranny of distance, such as the Queensland retrieval system.

Retrieval systems vary by state and internationally. There are no uniform system designs or standards, and consequently, services vary in their use of transport platforms and crew types (nurse, paramedic, doctor). Staff may be employed by a health department or ambulance service, or by contract with a private provider, or a retrieval service may utilize hospital personnel. A state service may incorporate several retrieval service providers with central coordination; alternately, systems exist with local governance and responsibility at a district or area level. Transport platforms are generally state owned and operated or contracted; however, non-government-owned helicopters may be part of a state system (and have historically received both benevolent and state funding). In the past, such services were the mainstay of retrieval practice and were often initiated by passionate volunteers, being funded by community donations, corporate sponsorship and government grants. Governance systems for such services and their coordination and performance responsibilities were typically variable. Consequently, retrieval systems have evolved, leading to increased systematization and corporate and clinical governance, aiming at reduction in variation, greater accountability and increased reliability at the system level.

Most countries have progressively moved towards centralized state systems. These are characterized by central coordination centres that use nurses, paramedics and doctors who work together utilizing their complementary skills and experience. Neonatal, paediatric, perinatal and adult retrieval services may be integrated, co-located or separate; however, the trend of recent years is to co-locate these services with common governance, to allow synergies to be realized in regard to operational processes, infrastructure, management, education, research, response platforms and clinical staff.

Most retrieval services have developed similar systems for management of the generic

operational processes of: patient referral, case coordination, response and logistics, clinical intervention, and destination determination (Box 29.2.1). In addition, these are usually supported by a formal array of governance elements (Box 29.2.2).

In addition, states may legislate[1] or learned and academic bodies may publish guidelines and standards to promote safe systems of patient transfer, particularly in the critical-care sector.[2]

Retrieval processes

Retrieval coordination

Case coordination is at the heart of all retrieval systems. As a process, it commences with the initiation of contact from a referral site. Ideally, first contact with a retrieval service should be made prior to arrival at the first hospital—by the primary transport clinicians. It is important for referrers to understand the indications for retrieval and to have clear guidelines (both system and local) to encourage early referral and good decision making. Statewide trauma systems and neonatal paediatric care systems often have well established transfer criteria; however, processes for other clinical groups are often less developed and may be *ad hoc*. Mature retrieval systems act as a single point of entry for the referrer, preferably providing services by initiation of a single call to a system-wide phone number. Coordination staff are appropriately qualified senior clinicians, with specialized training and knowledge. Case coordination fundamentally answers: What are the needs of the referrer and their patient? Are the needs for clinical advice, for organization of transport and crew or for assistance in obtaining an appropriate destination for a critical patient? The coordinator must determine quickly and efficiently the planning and intervention priorities for each case. These may be for immediate care or advice, immediate response, destination planning or consideration of complex decisions involving logistics, crew or transport platforms. Coordinators need to display leadership while at all times taking a systems perspective and avoiding tunnel vision or task fixation.

Coordination must be provided through high-performance organizations and, typically, utilizes sophisticated communication technologies, such as multi-party conference calls, telehealth videoconferencing, case recording and comprehensive data management systems.

Coordination of retrieval also implies an ongoing process of communication and feedback with the referrer of case progress, estimated response times and knowledge of patient status changes. During the response and transfer phase, the coordination centre maintains communication with response teams, providing logistic support and mission oversight.

Transport platforms

Retrieval services generally use road, rotary wing (helicopter), or fixed wing aircraft response and transport platforms. For international retrieval missions, commercial larger jet transport is used, and in uncommon settings, aquatic transport platforms may be used. In consideration of platform selection for a mission, clinical factors must be factored first; these will include need for pressurization, need for space for specialized crew or equipment, and patient size. Further factors include urgency (of response or return leg or both outbound and return components), distance to referral hospital, availability of helipads at referral and destination hospitals, and need to minimize the out-of-hospital time for the patient. Heightened risk for patients in transit is experienced during platform transfers (from bed to trolley to ambulance to aircraft stretcher and so on) and, in general terms, in the out-of-hospital setting. Minimization of number of patient transfers and the out-of-hospital time for the critical care retrieval patient are important principles.

Road transport platforms should be specifically designed and fitted out for retrieval purposes to minimize variation (improving crew performance and safety) and the risk of *ad hoc* unsecured equipment placement. Use of helicopters (with crews of appropriate skill mix) in retrieval response has been demonstrated to improve patient outcomes,[3,4] particularly patients with severe trauma and others with a need for time-critical interventions. In general, helicopter transfer is considered for retrieval of patients approximately 75 to 175 km from base, with road response used for shorter transfers and fixed wing for longer. These broad recommendations vary depending on road, geography and climatic conditions, and on the performance characteristics and landing options for individual aircraft. Fixed wing transfers have the advantage of providing a (usually) pressurized aircraft, greater speed and comfort, more space and a controlled temperature. Rotary wing aircraft have advantages of door-to-door transfer where helipads exist at referral and destination sites, the primary response capability and the potential to avoid road transport legs, and multiple patient transfers. Road transfer offers spatial flexibility, door-to-door transfer and cost efficiency (Fig. 29.2.1).

Crew

Staff selected for roles in retrieval must meet required professional and personal standards. Critical-care capability is essential and medical staff specialist training in a critical-care specialty is desirable. Similarly, nursing and paramedic staff must be trained to intensive care practitioner level. In addition, all staff must have specific training in management of the retrieval environment, clinical care in transport settings and personal and crew behaviours.

The retrieval environment poses particular risk and technical training regarding platforms, procedures, relevant legislation, communication methods, rescue and escape procedures and equipment performance characteristics is needed. Training in clinical care during retrieval needs to ensure capability in management of the complete range of critical care, trauma and intensive care scenarios, and an ability to apply depth of clinical knowledge to the relatively compact window of patient care that the retrieval mission represents. Practitioners need to understand in a retrieval setting that an intervention may be possible and ideal while also being inappropriate and inefficient, or that an intervention may be desirable but not be possible or practical. Compromise and pragmatism have a role in pre- and interhospital transfer particularly, where priority exists for reaching a definitive care destination. Training in personal and crew behaviours is necessary to optimize the cohesiveness and functionality of the retrieval team—formal exposure to crisis resource management tools is a standard component of aeromedical and road-based retrieval education.[5] In interaction with referring practitioners and primary responders, the retrieval team needs to exhibit empathy, listening skills and professional behaviours—avoiding arrogance, premature

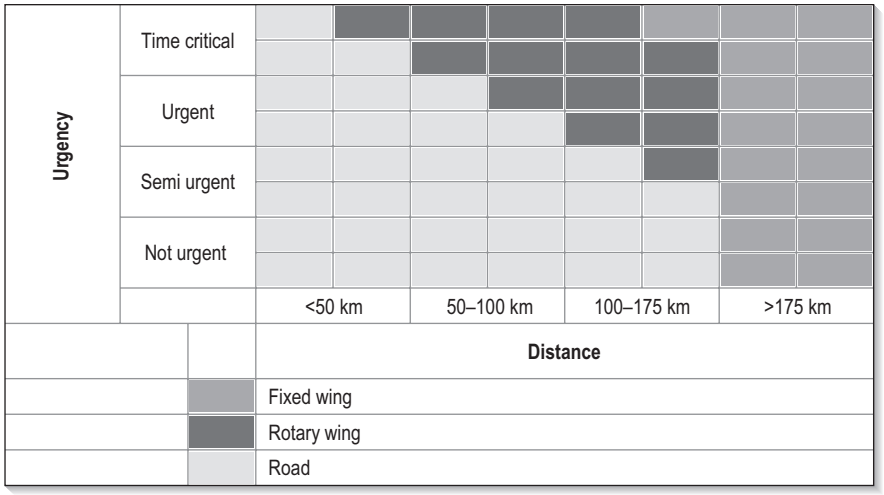

FIG. 29.2.1 Retrieval transport platform allocation grid for fixed wing, helicopter and road transport based on distance versus transport urgency of either the response leg or the patient transfer leg of the retrieval mission.

conclusions or judgmental behaviour. The training and knowledge base required is significant, therefore training processes must be formalized and must be supported by ongoing professional development and regular credentialing in addition to compliance with relevant regulations.

Crew safety is paramount, so personal protective equipment and clothing which meets aviation and ambulance service standards is mandatory. Safety risk arises also in long and overnight missions, and crewing must be adequate to allow sharing of clinical vigilance duties and patient interventions at times of fatigue and to allow for adequate breaks and rest.

Retrieval services play a major role in disaster response and management and generally provide a significant component of the early response to such incidents. Retrieval services and, in particular, their coordination processes are also key to the distribution and reception phase of the disaster response—providing system overview of capability and capacity of health services to receive victims. Retrieval staff must therefore be trained to expert status in this discipline.[2,6]

Skill sets

Retrieval medicine and primary response aeromedical settings provide the most challenging of all clinical environments, and therefore, choice of staff skill sets and professional team makeup is fundamental to optimizing clinical outcomes. The central tenets of this clinical environment are that a critical-care retrieval team must consist of (at least) two professionals.[6] They must be trained to critical-care standard and work within their core scope of practice. The skill set they provide must meet the clinical needs of the patient. In most national and international jurisdictions, blended medical practitioner and paramedic or nursing crews satisfy these tenets. Significant literature supports the role of medical practitioners in this environment due to the additional diagnostic capability, procedural range, extent of knowledge and depth of clinical understanding they contribute.[7] Such skills are complemented by the skill set of critical-care-trained nursing staff. Paramedic staff contribute substantial critical-care capability (depending on individual jurisdictional training levels) together with expertise in the transport and pre-hospital scene environments. Crews composed of paramedic or nursing staff paired in various combinations and without a medical crew member are inappropriate for high-risk critical-care transfers, intubated critical care transfers or patients requiring significant cardiovascular and/or respiratory support. This level of crewing creates unacceptable safety, quality, governance and risk exposure; retrieval systems must be designed to ensure continuity of standards or to increase the quality of care provided during transfer. Such system and governance design principles are not lost in hospital governance and quality frameworks and are equally applicable in the pre-hospital and retrieval setting. The skill set needs to match the requirements of the patient in the basic dimensions of clinical complexity and physiological stability, with the more unstable and complex patient clearly requiring a higher skill mix in the retrieval team. In rare situations, and where life-saving intervention may be possible, the transport of highly specialized clinical staff to the patient may be appropriate and should be considered—for example, transporting a surgeon to perform an infield amputation on an entrapped patient (Fig. 26.2.2).

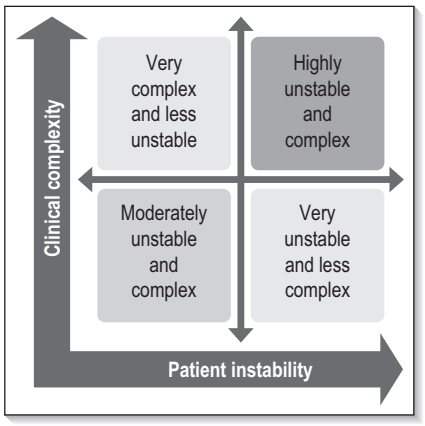

FIG. 29.2.2 Crew skill set matches the clinical requirements of the patient.

Equipment

Within a retrieval service, equipment should be standardized as far as possible. Response kits and platform layouts will then be familiar to all practitioners at all times, including at night and during uncontrolled clinical emergencies. Equipment must meet the needs of the patient population or therapeutic interventions and must consider the operating environment, mission duration, availability of electrical power in transport platforms, oxygen consumption and standard oxygen supplies available in vehicles. Stretchers and equipment bridges must meet aviation engineering standards, as must all electrical equipment that may be used in aircraft.

On all missions, the retrieval practitioner must have access to the complete range of airway management equipment including a difficult airway kit, cardiac monitor defibrillator pacer, multiple infusion pumps appropriate for inotrope infusions, a transport ventilator capable of complex respiratory support, invasive pressure monitoring, temperature monitoring, capnography and oximetry. All equipment must be maintained to the highest level of biomedical support and be fitted with appropriate auditory and visual alert systems. A comprehensive range

Box 29.2.3 General principles to be applied in preparation of patients for retrieval

Airway

1. Assess airway stability for all patients, particularly those with compromise in conscious state or risk of deterioration.
2. If an endotracheal tube is in place, record laryngoscopic grade during intubation; note any intubation difficulties and record ETT size and lip length.
3. Secure endotracheal tube.
4. Insert an orogastric tube unless there is a major contraindication.
5. Perform a CXR to confirm position of endotracheal tube.

Breathing

1. Observe respiratory rate and character.
2. Measure SpO_2 and $ETCO_2$.
3. Administer oxygen using the correct delivery device.
4. Check ABGs if indicated/possible.
5. Secure intercostal catheters if present.

Circulation

1. Insert two peripheral IV lines.
2. Secure all lines; ensure injection ports are accessible.
3. Prepare drug infusions in 50 mL syringes (or other standard as used by the regional retrieval or ambulance service).
4. For advice on standard infusion concentrations, discuss with the retrieval coordinator.
5. Record all IV fluids and consider insertion of a urinary catheter (mandatory in intubated patients).
6. Transduce all arterial and central lines.

Documentation

1. Complete standard referral forms if available.
2. Provide copies of all patient charts.
3. Investigation results—pathology and ECG.
4. Imaging—films/scan/MRI.
5. Advise any 'limitation of treatment' orders.
6. Notify any infectious disease risk/contagious disease risk or exposure.

Other priorities

1. Monitor and maintain body temperature.
2. Empty drainage bags prior to transport.
3. Administer antiemetic in conscious patients.
4. Maintain spinal precautions if indicated.
5. Splints and pressure care.
6. Remove possible contaminants, such as glass, dirt, etc.
7. Notify significant deterioration in conscious state, blood pressure, heart rate, respiratory status, oxygenation, or any major clinical developments, such as significantly abnormal diagnostic tests, new clinical signs or the need for major interventions prior to the retrieval team arriving (e.g. intubation, surgery).

ABG, Arterial Blood Gas; *CXR*, Chest Xray; *ECG*, Electrocardiograph; *ETCO2*, End Tidal Carbon-dioxide; *ETT*, Endotracheal Tube; *IV*, Intravenous; *MRI*, Magnetic Resonance Imaging; *SpO2*, Oxygen Saturation.

of drugs is necessary to cover the spectrum of clinical presentations and scenarios encountered in the retrieval setting. These should be maintained in sealed drug kits, with attention paid to expiry dates and to temperature control where relevant. The retrievalist will also require access to antivenoms, thrombolytics, blood and blood products and other specialized agents at times; systems must be in place to ensure timely access to uncommonly used pharmacological agents.

Clinical principles in retrieval and pre-hospital medicine

Preparation for transport

In many cases, the referral of a patient for retrieval is an uncommon event that may occur at one site perhaps once or twice each month and which may involve individual staff members only once or twice per year. Therefore clear understanding and communication of the needs of the critical-care patient for transfer must be in place. Common dilemmas are faced:

- Does the patient require intubation for transfer?
- If so, should the patient be intubated now, later or wait for the retrieval team to arrive to intubate?
- What IV access does the patient require? CVC? Arterial line?
- Drug and equipment compatibility—what will the retrieval team expect? What will they want to take with them?
- What if the patient's clinical status changes?

Airway management is perhaps the greatest risk in the critical-care retrieval setting. The need for intubation for transfer should be discussed between the retrieval coordinator, referring staff and the retrieval team. In general terms, the patient should be intubated if needed for respiratory failure or, if significantly aggressive, agitated or obtunded, or if their clinical condition makes it likely that they will deteriorate en route (e.g. large intracranial haemorrhage, complete cervical cord injury), or if they have threatened airway obstruction (e.g. burns, epiglottitis) which would present a high-risk in-transit intubation.

The general principles that should be applied systematically in the preparation of patients for retrieval are given in Box 29.2.3.

Monitoring

Monitoring equipment used in transport should be in accordance with recommended jurisdictional standards. Most patients require at least continuous ECG, pulse oximetry and blood pressure monitoring. In addition, capnography, invasive pressure monitoring, temperature, ventilation and other monitoring may be required. Equipment must be selected carefully and, where possible, be integrated. Sophisticated light, transport-specific, multimodal monitoring units are now available, which include the previously listed components plus defibrillation and external pacing capability. Display screens must be visible in daylight, and battery life must be appropriate for the duration of transport. Equipment alarms must be clearly visible, as auditory alarms are difficult or impossible to hear in moving vehicles, especially aircraft. A major component of any monitoring system is the observer, and in the retrieval setting, the need for vigilance is paramount; at all times at least one of the retrieval crew members must be absolutely focused on the patient and monitors, continually scanning measured parameters and clinical status (including temperature, peripheral circulation, urine output, conscious state and respiratory oscillation).

Environmental impacts

Transport environments are usually confined and limited in space, which may present hazards for all staff, the patient and equipment. Care, deliberate planned actions and vigilance are important, as is the need to ensure all equipment is secured (and equipment that is needed is accessible). Planned exercise, movement, nourishment, breaks and fatigue avoidance must be considered, depending on the mission characteristics. Aircraft retrieval presents particular challenges.[8] Altitude results in reduction in barometric pressure and associated reduction in partial pressure of oxygen and expansion of gas within enclosed spaces. Expansion of gas (such as in an undrained pneumothorax or in a distended bowel) may result in pain or significant worsening of

underlying pathology. In a normal person with sea level SpO_2 of 98% and without supplemental oxygen, SpO_2 decreases to about 90% at 3000 m altitude (10,000 ft). Most passenger jet aircraft are routinely pressurized to around 8000 ft; however, some aeromedical platforms may be able to be pressurized to sea level, while some (including most helicopters) cannot be pressurized at all. In patients with respiratory and cardiac disease, impacts are felt at lower altitudes. During descent, trapped gas will occupy less space causing contraction of flexible tissues, such as membranes and mucosal surfaces—this may cause pain, for example, when middle ear or sinus space pressures cannot be equalized with the rising external atmospheric pressure. Air transport of patients with decompression sickness requires particular planning and care, since the condition may be significantly worsened at altitude as gas solubility in blood decreases with altitude (due to reduced barometric pressure) and dissolved gas comes out of solution in the circulation, forming nitrogen bubbles with devastating consequences.

Other impacts of flight include those due to noise, vibration, humidity, gravity, acceleration and deceleration, third space effects (swelling) and fatigue.

Critical incidents

It is likely that the most complex patients receiving the highest levels of support are also most likely to be exposed to in-transit critical incidents or equipment failure. A component of clinical practice in this setting is therefore the anticipation of such events, vigilance to detect them, and rehearsed and standardized problem-solving algorithms to rectify them (Fig. 29.2.3). Examples include ventilator failure, unexpected hypoxia, high airway pressures, cardiac arrest in flight and so on. Such approaches are routine in the aviation industry, from which retrieval and pre-hospital medicine draws much at a cultural level, and have been applied commonly in anaesthesia.[9]

Respiratory support

Provision of appropriate oxygen therapy via correct delivery systems will be required for most retrieval patients. Oxygen supplies vary on different patient transport platforms, and these must be checked prior to transport. Assisted ventilation is a frequent intervention in critical-care retrieval and must be approached with discipline. A reliable and capable transport ventilator will provide suitable ventilation mode options, including intermittent positive pressure ventilation (IPPV), synchronized intermittent mandatory ventilation (SIMV) and pressure support. Non-invasive ventilation (NIV) methods are not commonly utilized in air transport; however, they may

EXTUBATION IN TRANSIT

Recognition

- Tube out
- Sound of air leak
- Falling CO_2
- Ventilator alarm: low MVe
- Dropping sats

- Differential
  - Isolated cuff leak: check pressure, reinflate
  - Circuit disconnection / kink

Communication

- Stop ambulance (consider urgent landing or diversion)
- Notify pilot
- Notify coordinator, Med ONE status

Action

- If isolated cuff leak (as long as oxygenation is okay): leave it in
- Rescue: bag-mask ventilation
- Attempt re-intubation
- Consider
  - LMA
  - Surgical airway

- Systems issues/risk avoidance
  - Secure ETT, circuit and ensure cuff working before moving
  - Controlled patient movements

be valuable in road transfer and in retrieval of patients in whom intubation and assisted ventilation may be undesirable or contraindicated or in patients for whom short-term assisted ventilation is indicated. Ventilators are almost universally power dependent so back-up ventilation systems (manual self-inflating bag/valve system) must be available at all times in the patient cabin to allow management of power, gas or mechanical failure.

Circulatory support and infusions

Intravenous infusions are best delivered using simple and compact syringe drivers. These are available in various sizes and configurations, including banks of multiple syringes. Each retrieval service and, preferably the jurisdiction in which it operates, should maintain standard infusion protocols for preparation, labelling and administration of therapeutic agents and, in particular, inotropes. Use of syringe systems that have error reducing software and programs integrated in them reduces risk of adverse events and patient harm. The retrieval environment is dynamic, and attention must be paid to maintenance of infusion rates during transfer and power interruption. Critical patients are often highly dependent on inotropic support, and brief periods of interruption of infusions may be associated with catastrophic circulatory collapse. Adequate fluid volumes and spare syringes which are pre-prepared for longer transfers must be planned for, as must the availability of blood and blood products, which may need significant coordination.

Infectious risk

The proximity of the retrieval environment means that patients with infectious diseases may present hazards to medical crew, flight crew including pilots and other patients or passengers. Clearly, the application of universal precautions against infectious diseases is applicable as in all clinical settings. However, other measures may be important, such as use of ventilator expiratory filters, avoidance of use of nebulizers which may, for instance, aerosolize influenza, use of prophylactic medications, such as rifampicin, after prolonged exposure to meningococcal disease, barrier precautions in patients with vancomycin-resistant enterococci (VRE) and so on.

Highly specialized retrieval

Neonatal, obstetric and paediatric specialized retrieval systems have been a part of many health systems for decades. While the clinical demands of these systems require particular sets of knowledge, the retrieval frameworks required are complementary and intersect with the larger and higher volume world of adult retrieval and pre-hospital care. Consequently, blending, collocating or integrating retrieval services are seen as a sustainable model and have become more common. Technical advances in critical care, such as increased use of extracorporeal membrane oxygenation (ECMO) support in severe respiratory failure, for example, in influenza, have promoted the development of specialized retrieval systems to manage these highly fragile patients.[10] Interestingly, in response to these needs, technology has evolved rapidly to offer lighter, smaller, less invasive and simpler ECMO systems.

CONTROVERSIES/EMERGING ISSUES

- Increased centralization is a consistent feature in Australian retrieval (and internationally). Where states and regions previously may have had multiple systems for retrieval, it is more common now to see single coordinated systems with improved governance. Building on relevant interfaces which are a strong part of retrieval work is a common theme so that movement of retrieval services into management of critical and

acute care bed flow and access management, outreach and support, telehealth and education is being seen. As rural and remote populations face increasing challenges with burden of disease and clinical workforce availability, outreach services require appropriate growth and development.

- Retrieval and pre-hospital medicine around the world is moving quickly to specialist or sub-specialist status within academic colleges and has fully reached this point in some countries. Formal training systems and qualifications are evolving in both the tertiary education sector and in specialist medical college settings.

29.3 Medical issues in disasters

Jonathan Abrahams • David A. Bradt • Richard J. Brennan

ESSENTIALS

1 **The incidence of globally reported disasters from natural and technological hazards increased exponentially from 1960 to 2000 and has fallen slightly in the period 2006 to 2015 after a peak in 2005.**

2 **Deaths due to natural hazards has steadily declined over the past five decades—largely due to improvements in multisectoral emergency risk management—but numbers of affected populations continue to rise, encompassing 25% of the world's population in the decade to 2015.**

3 **The average annual economic losses associated with natural hazards are approaching $US300 billion.**

4 **Effective health emergency and disaster risk management requires knowledge of a community's major hazards, exposures, vulnerabilities and capabilities, event history and hazard-associated patterns of morbidity and mortality. Disaster response planning is 80% generic for all hazards, 15% hazard-specific and 5% unique to the event.**

5 **Public health interventions are high priorities following events that disrupt environmental health infrastructure (e.g. water supply, sewerage), events that result in significant population displacement (e.g. conflict), epidemics and pandemics and events that involve the unintentional or deliberate release of chemical, biological or radiological agents.**

6 **Emergency physicians and other health professionals have a vital role in health emergency and disaster risk management including prevention, mitigation, preparedness, response and recovery operations.**

7 **Increasing frequency and severity of climate-related events as well as continuing losses from other types of events have led to calls for community resilience as a cornerstone of national emergency risk management strategies.**

8 **The events most likely to confront emergency physicians are domestic transportation incidents with trauma-associated multiple casualties.**

9 **Effective management of mass casualty incidents requires knowledge of local and regional emergency response plans, scene assessment issues, site management, communications, casualty flow plans, field triage and the clinical management of hazard-specific conditions such as crush injury and blast injury.**

Introduction

Health emergency and disaster risk management, encompassing related terms such as emergency management and disaster management, involves a complex, multidisciplinary system of which emergency medicine comprises one component. Domestically, fire fighters, law enforcement, ambulance services, civil defence, State Emergency Services, Red Cross national society, defence forces and other aid organizations commonly play major roles. Internationally, governmental and nongovernmental organizations, International Federation of the Red Cross and Red Crescent Societies and United Nations agencies are frequently involved. The health and medical management of hazardous events, which includes mass casualty incidents, community emergencies and disasters, can also cut across healthcare disciplines, requiring contributions from emergency medicine, public health, primary care, surgery, anaesthetics and intensive care.

From the health perspective, certain types of events are usually associated with well-described patterns of morbidity and mortality. The clinical and public health needs of an affected community therefore also vary according to the type and extent of the event. Emergency physicians should understand the public health and medical consequences of the various types of events in order to determine their own roles in preparedness and response. In practice, emergency physicians are most actively involved in the response to acute-onset events that involves multiple casualties, such as transportation incidents. Other types of events, including floods, are generally associated with few casualties. The health and medical needs in these

settings usually involve augmenting public health and primary care services. Emergency physicians should be familiar with disaster epidemiology and local emergency management arrangements and understand the medical response to events involving multiple casualties.

The differential effects of events on communities in all countries are associated with risk factors which make some communities and subpopulations more vulnerable and less capable of dealing with the risks than others. A defining feature of disasters is the level of impact and disruption to the functioning of society which is often widespread and long term. Apart from health and medical issues, disasters can cause significant social, economic and environmental losses that may have devastating effects on the general well-being of the affected community. They may set back years of development progress in poorer countries, including the disruption of health systems, such as in the Haiti earthquake of 2010, Pakistan floods of 2010 and Hurricane Irma in the Caribbean of 2017. Their effects may be felt well beyond the borders of the first affected country. Epidemics may be prone to widespread international spread, with broad range economic and sociopolitical consequences, for example, the Ebola outbreak in Sierra Leone, Liberia and Guinea of 2014 to 2016, the Zika virus epidemic in Latin America of 2015 to 2016 and the H1N1 pandemic of 2009. It is estimated that a global influenza pandemic could result in tens of millions of deaths and cost the global economy up to $US4 trillion.

Definitions and classification

In February 2017, the United Nations General Assembly endorsed a set of terms to support the implementation of the Sendai Framework for Disaster Risk Reduction 2015 to 2030 which included a definition of a disaster as 'a serious disruption of the functioning of a community or a society at any scale due to hazardous events interacting with conditions of exposure, vulnerability and capacity, leading to one or more of the following: human, material, economic and environmental losses and impacts'. The annotation provides further clarification: 'the effect of the disaster can be immediate and localized, but is often widespread and could last for a long period of time. The effect may test or exceed the capacity of a community or society to cope using its own resources, and therefore may require assistance from external sources, which could include neighbouring jurisdictions, or those at the national or international levels.' The term 'emergency', while sometimes used interchangeably with the term 'disaster', does not usually have the connotation of a serious disruption nor that the local capacity is overwhelmed by the event.[1]

The Australian Emergency Management Glossary defines disaster as: 'a serious disruption to community life which threatens or causes death or injury in that community and/or damage to property which is beyond the day-to-day capacity of the prescribed statutory authorities and which requires special mobilization and organization of resources other than those normally available to those authorities'.[2]

The Center for Research on the Epidemiology of Disasters (CRED), which compiles the data behind the annual World Disasters Report of the International Federation of Red Cross and Red Crescent Societies, stipulates a quantitative surveillance definition involving one of the following: 10 or more people killed; 100 or more people affected; declaration of state of emergency; or an appeal for international assistance.[3] Thus international data tend to be focused on large-scale events.

Disaster risk management is 'the application of disaster risk reduction policies and strategies to prevent new disaster risk, reduce existing disaster risk and manage residual risk, contributing to the strengthening of resilience and reduction of disaster losses'.[1] Disaster risk management activities are designed to establish and maintain control over disaster and emergency situations and to provide a framework for helping at-risk populations avoid or recover from the impact of an event. It addresses a much broader array of issues than health alone, including a multisectoral approach to hazard identification, vulnerability analysis, risk assessment, risk evaluation and risk treatments.[4]

Disaster medicine can be defined as the study and application of clinical care, public health, mental health and disaster management to the prevention, preparedness, response and recovery from the health problems arising from disasters.[5] This must be achieved in cooperation with other agencies and disciplines involved in comprehensive health emergency and disaster risk management. In practice, emergency medicine and public health are the two specialties most intimately involved in disaster medicine.

A mass casualty incident is an event causing illness or injury among multiple patients simultaneously through a similar mechanism, such as a major vehicular crash, structural collapse, explosion or exposure to a hazardous material. A complex emergency (CE) is an event complicated by civil conflict, government instability, macroeconomic collapse, population migration and an elusive political solution. Events are commonly classified as natural versus human induced (Box 29.3.1).[6,7]

Box 29.3.1 Classification of hazard events

Natural

Geological

- Earthquake
- Ground shaking
- Tsunami
- Mass movement (dry)
- Liquefaction
- Volcanic activity

Hydrological

- Floods (e.g. riverine, flash, coastal flood, storm surge)
- Mass movement (wet) (e.g. avalanche, mudflow)
- Wave action (e.g. seiche)

Meteorological

- Storm (e.g. cyclone, tornado, wind, rain, hail, sand/dust)
- Extreme temperature (e.g. heatwave, coldwave)
- Fog

Climatological

- Drought
- Wild fire (e.g. land, bush, forest)

Biological

- Air-borne diseases
- Water-borne diseases
- Vector-borne diseases
- Insect infestation
- Foodborne outbreaks

Extraterrestrial

- Airburst
- Space weather (e.g. geomagnetic storms)
- Near-earth objects (e.g. asteroid)

Human induced

Technological

- Industrial hazards (e.g. chemical spills, gas leak, radiation)
- Structural collapse (e.g. building, dams, bridges)
- Transportation (e.g. air, road, rail, water)
- Fires/explosion (e.g. building)
- Air pollution (including haze)
- Power outage
- Hazardous materials in air, soil, water
- Food contamination

Societal

- Armed conflicts
- Civil unrest
- Terrorism (e.g. conventional, chemical, biological, radiological, nuclear and explosives (CBRNE))
- Financial crisis

Events may also be classified according to other characteristics, including sudden versus slow onset, short versus long duration, unifocal versus multifocal distribution and primary versus secondary. Classifications of event magnitude exist for selected natural hazards, such as earthquakes and cyclones; however, there is currently no standard classification of severity of disaster impact.

Epidemiology

Globally, the types of events associated with the greatest numbers of deaths are CEs. These are crises characterized by political instability, armed conflict, large population displacements, food shortages and collapse of public health infrastructure. Because of insecurity and poor access to the affected population, aggregate epidemiological data for CEs are somewhat limited. However, between 1998 and 2007 in the Democratic Republic of Congo, it is estimated that 5.4 million people lost their lives due to the consequences of the major humanitarian crisis afflicting that country.[8] This was four times the United Nations Office for Disaster Risk Reduction (UNISDR) estimate of deaths globally due to natural and technological disasters during the 20 years between 1992 and 2012. During the Syrian conflict that started in 2011, some sources indicate that up to 350,000 people may have been killed. This does not include excess deaths due to other causes linked to the deterioration in the health system.[9]

According to information reported by the International Federation of the Red Cross, there has been a significant increase in the total number of natural and technological disasters worldwide during the past 50 years. From 1960 to 2010, the annual number of disasters rose from 50 per year to approximately 700/year peaking at 810 in 2005. The annual average number of disasters was 609/year for the decade 2006 to 2015. While the total number of people killed by natural and technological disasters was approximately 77000/year (for the decade 2006 to 2015), there was a wide annual range (14,389 in 2014 to 314,503 in 2010 due to the Haiti earthquake and the Russian heatwave). Moreover, the total number affected has almost quadrupled over the past three decades. It is estimated that approximately 190 million people are directly affected on an annual basis.[3] Selected data are presented in Figs. 29.3.1 and 29.3.2.[3]

The commonest types of disasters across the globe are: transportation incidents, floods, windstorms, industrial incidents, building collapses, droughts, and earthquakes/tsunamis (see Fig. 29.3.1). Asia is the region of the world most prone to natural and technological disasters, recording 40% of such incidents between 2006 and 2015. It is followed by Africa (24%), the Americas (20%), Europe (13%) and Oceania (3%). Compared with other regions of the world, Australasia and Oceania have a relatively low incidence of disasters.[3] Nonetheless, the World Risk Index (WRI) Report of 2016 included Vanuatu, Tonga and the Solomon Islands among the 10 countries most at risk for natural hazards.[10]

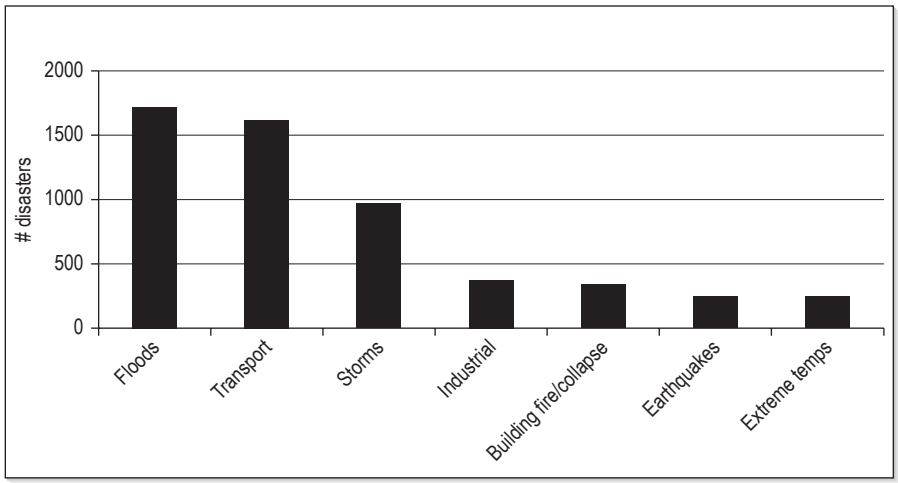

FIG 29.3.1 Global disasters incidence by hazard 2006 to 2015. (From International Federation of Red Cross and Red Crescent Societies. *World Disasters Report 2016*. Geneva: International Federation of Red Cross and Red Crescent Societies; 2016.)

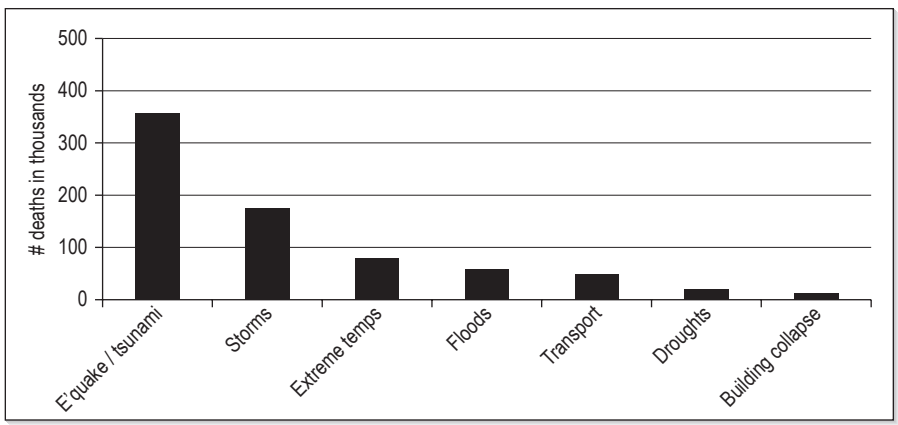

FIG 29.3.2 Global disaster deaths by hazard 2006 to 2015. (From International Federation of Red Cross and Red Crescent Societies. *World Disasters Report 2016*. Geneva: International Federation of Red Cross and Red Crescent Societies; 2016.)

Over the past 10 years, the commonest causes of disasters in Australia have been severe storms, transportation events and bushfires. Historically, the leading cause of death from disasters due to natural hazards in Australia have been heatwaves (438 killed in 1939, 404 killed in 2009), followed by cyclone and bushfire. Human-induced disasters resulting in multiple casualties have occurred more frequently in Australia in recent years. The commonest causes of mass casualty incidents have been bus crashes, structural fires, mining incidents, aviation incidents and train crashes. The impact of disasters in New Zealand over the period 2001 to 2010 was dominated by the Christchurch earthquake that caused 185 deaths. The incidence of disasters also differs from Australia, with the commonest major events being transportation disasters, industrial disasters and earthquakes.

Data reporting on the incidence of armed conflict is complicated by varying and changing definitions and political motivations of the reporting agencies. The Uppsala Conflict Database Program identified 49 ongoing conflicts on five continents in 2016.[11] As of December 2017, it was estimated that 135.6 million people require humanitarian assistance—the highest on record.[12] This need is largely driven by conflict. The number includes 65.6 million people who have been forcibly displaced from their homes—also the highest on record. In spite of the overwhelming needs, the humanitarian community will target 105.1 million people (67%) for assistance in 2018, due to pervasive operational constraints including insecurity, limited local capacities, lack of funding and bureaucratic constraints.[13]

The countries recording the highest number of terrorist attacks in 2016 were Iraq, Afghanistan, India, Pakistan and the Philippines, although data on terrorist attacks in Syria has been difficult to capture. Iraq, Afghanistan, Syria, Nigeria and Pakistan accounted for 75% of all deaths due to acts of terrorism. Slightly more than half of the attacks in 2016 did not cause any deaths while 5 percent of attacks caused more than 10 deaths.[14] Overall, the number of deaths due to terrorism is just a very small fraction of the total number deaths attributed to natural and technological disasters and CEs.

Disaster epidemiology globally, including the Australasian region, is being affected by climate change. Global warming has already been associated with an increase in the frequency, severity, and unpredictability of weather-related disasters, such as heatwaves, wild fires, floods and droughts. Rising temperatures have been implicated in the spread of infectious disease, such as malaria and dengue, through increases in vector populations, such as mosquitoes. Other important diseases are also sensitive to changing temperatures and rainfall, including malnutrition and diarrhoea. The health-related and other impacts of climate change will not be evenly distributed. Disasters associated with global warming are particularly likely to threaten the lives and livelihoods of coastal communities, those living on low-lying islands (e.g. due to rising sea levels) including in the Pacific Ocean and in arid and high mountain zones.

Socioeconomic impact

Disasters have the potential for major socioeconomic impact of direct damages plus economic losses, costing the host countries and international community billions of dollars annually. In developing countries, years of development work and investment can be devastated by a single disaster. Economic losses from disasters such as earthquakes, tsunamis, cyclones and flooding are now reaching an average of $US250 billion to $US300 billion each year.[15] These losses are taking greater account of minor but regularly occurring events. Windstorms and earthquakes were the costliest types of natural hazard over the decade led by the Great Eastern Japan earthquake which also triggered a tsunami and the Fukushima nuclear incident. Terrorist attacks on major financial centres, such as the World Trade Center in New York, have demonstrated the potential for tens of billions of direct economic impact, enormous social consequences and political repercussions. These figures may be overshadowed by pandemic disease, such as from avian influenza, for which economic cost estimates range to upwards of $US1 trillion.[16] In Australia over the past 30 years, floods, storms, then cyclones have caused the greatest disaster-related economic losses with an average of approximately $AUS1 billion annually. The most economically costly disaster was the 2010 to 2011 Queensland floods exceeding $AUS7 billion in damages and losses.

Economic estimates, of course, are unable to reflect the true scale of human suffering associated with different types of events. While the documentation of mortality, morbidity and financial losses associated with disasters remains challenging, it is impossible to quantify all of the associated personal, psychological, social, cultural and political losses.

Emergency and disaster risk management

As emergency physicians play a vital role in the medical aspects of emergency and disaster risk management, they should be familiar with the underlying concepts on which these arrangements are based.[17]

Integrated approach

The basis for the Australian system for managing emergencies and disasters is a partnership between the Commonwealth, State/Territory local governments, the private sector and the community. Under legislation, State and Territory governments have the primary responsibility for coordinating emergency and disaster risk management activities and maintaining government and statutory agencies that provide emergency services to the community. Local governments play an active role in risk assessments, land-use planning, public education and awareness, local emergency planning and providing local resources in emergency relief and recovery. The major roles of the Australian Federal Government are to support State and Territory governments in coordinating national strategic policy, to assist with emergency and disaster information and knowledge management (e.g. meteorological and geological data to support risk assessments and early warnings), to provide financial resources on a cost-sharing basis with States and Territories and to provide operational support in the event that a disaster exceeds the affected State or Territory's response capability.[18] Federal assistance in the area of health would most likely be medical resources provided by the Australian Defence Force (ADF). The ADF also has special expertise in the management of incidents involving chemical and biological agents.

Comprehensive approach

The comprehensive approach to emergency and disaster risk management encompasses prevention, preparedness, response and recovery. The traditional view is that health and medical professionals contribute most significantly to emergency preparedness and response. A broader appreciation of the factors that enable communities to be more resilient would further recognize the role of the health sector in prevention and mitigation—specifically, by improving overall health, immunization rates and nutritional status of individuals—as measures to reduce vulnerabilities and strengthen resilience. The disaster equivalent of primary prevention activities includes regulatory and physical measures that prevent or mitigate the effects of hazards and to reduce community exposure and vulnerabilities to these hazards. Emergency preparedness involves arrangements to ensure that resources and services that may be needed can be rapidly mobilized and deployed. Response activities are those actions taken during and immediately after impact to ensure that the event's effects are minimized. Recovery involves strategies and services that support affected communities in reconstructing their physical infrastructure and restoration of their social, economic, physical and emotional well being, and reducing the risks of future events.

All-hazards approach

Different types of events can cause similar problems. Therefore emergency and disaster risk management arrangements, including response plans, are based on a core set of arrangements and measures that can be applied to all hazards. Many risks, however, including acts of terrorism, also require specific prevention, preparedness, response and recovery measures.

The prepared community

The prepared (or resilient) community is the foundation of Australia's emergency management arrangements. Local governments, voluntary organizations and individuals all play a critical role in this area. Individuals can reduce their own risks by being aware of the local hazards and taking appropriate precautions. Experience has demonstrated that individual and community self-help can often provide the most immediate, decisive and effective relief following an event, as it cannot be assumed that assistance from external sources always arrives promptly, particularly in remote area communities.

Risk management

From 1996, following the endorsement of the National Emergency Management Committee, the principles and processes of the joint Australian and New Zealand Standard for Risk Management have been adopted by the Australian emergency management community. The risk management methodology embraces the key approaches identified above and ensures a greater focus on reducing vulnerability of communities, as well as hazard prevention, emergency preparedness, response and recovery measures.[19]

Disaster resilience

Against the background of disasters, climate change and a myriad of social, economic and environmental factors, the Council of Australian Governments adopted the National Strategy for Disaster Resilience in 2011. The Strategy emphasizes the shared responsibility of individuals, households, community organizations, businesses and governments to enhance Australia's capacity to prepare for, withstand and recover from disasters. According to the Strategy, a disaster-resilient community has the characteristics of: functioning well while under stress, successful adaptation, self-reliance and social capacity. The Strategy provides high-level direction and guidance on how to achieve disaster-resilient communities through a long-term commitment to a broad range of measures including understanding risks, communicating and educating about risks, reducing risks and supporting capacities for resilience.[20]

Emergency response planning

Emergency response planning is the process by which a community, jurisdiction or organization develops a comprehensive strategy effectively to manage and respond to emergencies and disasters. At community level, emergency response planning is a collaborative effort that requires cooperation among government agencies, community services and private organizations. The objectives of the planning process include identification of the main hazards facing the community; clarification of the capabilities, roles and responsibilities of responding agencies; and the strengthening of emergency networks. Other operational issues, such as emergency communications and public warning systems, should also be addressed.

All-hazards planning for response and recovery remains fundamental to emergency preparedness. To that end, experience to date reveals a generic set of issues that emergency response planners must address in the management of any hazard. These include risk assessment, incident management, on-scene and overall disaster command, control and coordination, relief operations, risk communication and media management, reconstruction, and community recovery. By contrast, the nature of the hazard imposes specific implications for epidemiology, search and rescue, medical care and consequences of contamination and communicable diseases. To this end, governments have elaborated all-hazards emergency response planning including hazard-specific disaster subplans (e.g. mass casualty management for burns). Finally, the circumstances of time, place, climate, geography, politics and security are unique for each event and challenge planners to anticipate the issues arising from those specific circumstances.

Several high-profile terrorist events (e.g. in Australia [Lindt Café, Sydney], Belgium, France [Paris and Nice], Norway, Spain, United Kingdom [London and Manchester] and the United States) and important gatherings (e.g. Olympic Games, Commonwealth Games) have highlighted the need for specific planning for terrorist events. Such planning frequently involves collaboration with relevant military, security and intelligence agencies and a consideration of the tactics used by terrorists. The majority of terrorist attacks have employed conventional weapons, including explosives and small arms. Other terrorist tactics include assassinations, hijacking and kidnapping. Unconventional attacks, including those using jet airliners as weapons of mass destruction, or chemical, biological and radiological weapons have constituted only a tiny fraction of international terrorist attacks.

Exercises must be conducted regularly to test the response and recovery aspects of the plan. Exercises range from desktop simulations to realistic scenarios with moulaged patients in the field. If conducted appropriately, they demonstrate strengths and weaknesses of the plan and highlight any need for an updating of response procedures. They are also considered to provide the most practice-based form of disaster response training. Emergency response planning is a continuous process and plans need to be regularly reviewed and updated.

Planning and responding for international disasters has become more relevant for Australasian health professionals after the terrorist attacks in Bali (2002 and 2005), the Indian Ocean tsunami (2004), the earthquake in Pakistan and India (2005) and the Pakistan floods (2010), including through the deployment of Australian medical response teams (Australian Medical Assistance Teams [AusMATs]).[21] In recent years AusMAT deployments have included Papua New Guinea earthquake in 2018 Tropical Cyclone Winston in Fiji 2016; Nepal earthquake 2015; Tropical Cyclones Pam, Vanuatu 2015; Solomon Islands flooding 2014; Typhoon Haiyan, Philippines 2013; and Solomon Islands dengue fever outbreak 2013.[22]

Such planning and response can be advised by the internationally recognized Sphere Minimum Standards in Disaster Response[23] and in collaboration with important international agencies, such as the World Health Organization's Emergency Medical Teams Initiative and the United Nation's Office for Coordination of Humanitarian Affairs. A revision of the Sphere Minimum Standards published in 2018 will specify standards in four sectors of disaster response: water, sanitation and hygiene promotion (WASH); food security and nutrition; shelter and settlement; and health action.[24] These standards are relevant for all events and represent an extremely useful reference to guide planning and response for domestic incidents as well.

A major reform of the international humanitarian system was initiated at the end of 2011 under the leadership of the UN's Office for Coordination of Humanitarian Assistance (OCHA) and involving all major relief agencies through the UN's Inter-Agency Standing Committee (IASC). This reform process, known as the IASC Transformative Agenda, includes a broad range of policy and procedural measures to improve the leadership, coordination, predictability and effectiveness of international disaster response. It also aims to increase the accountability of responding agencies, especially to the affected populations.

Domestic emergency response activities

Emergency management is increasingly seen as a cardinal sign of good governance in civil society. Health care systems have become mandated

to undertake a range of health emergency and disaster risk management actions, with a focus on emergency preparedness, including emergency response planning, training and exercises and response. Specific to emergency medicine, mass casualty management is the subject of well-developed training packages, such as Emergotrain, Major Incident Medical Management and Support (MIMMS), Basic Disaster Life Support (BDLS) and Advanced Disaster Life Support (ADLS).

Incident management

Scene assessment and stabilization

The initial scene assessment is conducted by first responders, such as police, fire or ambulance personnel. It is important for the first medical responder, generally an ambulance officer, rapidly to report findings to the Ambulance Communications Centre. An accurate, timely assessment is critical to initiating an appropriate and effective response. Key information that should be relayed from the scene includes the nature and magnitude of the event, the presence of ongoing hazards, the estimated number of deaths and injuries, the need for further assistance and the most appropriate routes of access to the scene. In large-scale disasters that affect entire populations, such as cyclone or earthquake, a rapid multisectoral assessment followed by broader epidemiological assessments is required, including an evaluation of the impact on the health infrastructure, health services, public utilities and shelter.

Site security and safety procedures must be observed to ensure that rescuers and bystanders do not become victims. This is particularly relevant in chemical and radiological incidents or when a terrorist incident is suspected, because of the threats posed by a secondary attack on responders or the potential use of weapons of mass destruction. The police should establish a perimeter around the scene of a multiple casualty incident and allow access only to authorized personnel. If a hazardous material is involved, rescuers may be required to wear specialized personal protective equipment (PPE) to protect their airways, eyes and skin. Electrical hazards, fires, explosions, leaking gases and unstable structures may all pose significant threats to rescue personnel. These hazards must be eliminated or controlled prior to initiating rescue operations.

Hazard-specific issues

While the all-hazards approach remains fundamental to emergency and disaster risk management, a unifying approach for undifferentiated hazards has been developed for the management of incidents involving chemical, biological or radiological agents. Basic principles of awareness include: recognition of potential terrorist events, avoidance of the affected area, isolation of the affected area, and notification of proper authorities. Basic principles for first responders include the four don'ts: don't become a victim; don't rush in; don't taste, eat, smell, touch (TEST) anything; and don't assume anything. Only properly trained and equipped hazardous material personnel should be in contaminated areas.

Site arrangements

Regardless of the nature of the incident, a Forward Command Post should be set up at or near the disaster site at the beginning of the emergency operation. The Command Post has representatives from the major responding services and reports back to the regional or State Emergency Operations Centre. The function of the Command Post is to coordinate the activities of the various services during the rescue operations. It also provides a central point for the submission of requests for assistance by each of the responding services. Medical and ambulance commanders are located at the Command Post to direct and coordinate medical care to victims at the scene, patient transportation, hospital communications, provision of medical supplies and medical air operations.

Communications

Good communications are vital to ensure appropriate command, control and coordination during response to major incidents. Communication problems are often cited as a major cause of suboptimal emergency response. There are many factors that may contribute to poor communications at the scene. Damaged equipment and overloaded telephone systems indicate the need for backup systems, including reserved cellular phone lines. The use of different radio frequencies by different agencies may lead to poor coordination and an inability to communicate vital information. Compatible frequencies need to be identified and utilized. Megaphones may be required to overcome noise at the scene due to heavy extrication equipment, helicopters and general rescue activities. Information overload may also hamper the rescue effort. Radio and telephone reports should be kept brief, relevant and succinct. Professional jargon is frequently misunderstood or misinterpreted by other agencies and is best avoided.

Hospitals must also have reliable communications systems. Designated phone lines, cellular phones and backup radio networks may augment the existing system during a disaster. It is essential for hospitals to remain in regular contact with the incident medical director, to provide information regarding medical capabilities, bed capacity and bed availability.

Medical management

Personnel

Provider roles in emergencies continue to evolve. Dedicated emergency and disaster medical response teams have been extensively studied. These teams form an integral part of national response plans in many developed countries notwithstanding lack of data attesting to any reduction in disaster-associated mortality associated with their deployments.[25] At international level, standards and procedures for emergency medical teams have been developed, after the poor experiences with many clinical teams following the Haiti earthquake in 2010.[26]

Emergency responders generally respond best when their roles are similar to their daily professional practice. Medical and nursing personnel are best suited to staffing emergency rooms and hospitals, where they have the advantage of working in a familiar, more stable environment. Ambulance personnel have more experience in prehospital settings and are usually responsible for conducting the initial on-site medical assessment and triage. In situations where there are multiple casualties, it may be appropriate to send a hospital team to the scene of a disaster, where their main functions are to perform primary and secondary triage and to provide medical care at the Patient Treatment Post. The science and practice of disaster medicine has progressed substantially. Therefore only doctors and nurses specifically trained to work in the field environment and familiar with the relevant best practices and standards should be deployed to the scene, as inexperienced personnel may well hinder the medical response.

Prehospital mass casualty management

Disaster epidemiology has refined the expectations of casualty flow plans. Current epidemiological evidence indicates that 50% to 80% of people acutely injured in a mass casualty disaster arrive at the closest medical facilities generally within 90 minutes after the event.[27] Moreover, the vast majority of event-affected patients self-evacuate without benefit of prehospital triage, transport or decontamination. A casualty-flow plan remains crucial to optimize patient care and transportation of those remaining at the scene.

A Casualty Collection Area should be established at a site that is close enough to the disaster scene to allow easy access, but far enough away to ensure protection from potential hazards. Patients are assembled and triaged here prior to transfer to a nearby Patient Treatment Post, where they are once again triaged and basic medical care provided. An Ambulance Loading Point and Ambulance Holding Point also need to be clearly marked so that patient transportation is conducted efficiently and to ensure that scene convergence and congestion is minimized.

Landing zones for helicopters are established away from the incident site for safety reasons, to limit noise and to reduce down-wash from rotor blades. A temporary morgue may need to be established in a nearby area when many fatalities have occurred.

Triage

The aim of triage is to allocate medical resources, including personnel, supplies and facilities, in a manner that provides the greatest good to the greatest number of patients. The emphasis is not on providing optimal care to each individual patient, but rather on directing limited medical resources to those who are most likely to benefit. Triage is the single most important medical activity at the scene of the event. It is a dynamic, ongoing process that occurs at every stage of patient management, from the disaster site, to the Casualty Collection Area, Patient Treatment Post and again at the hospital. Patients are rapidly assessed and categorized according to priority of treatment and transport. The condition of patients frequently changes and repeated examinations are required so that patients may be moved up or down in the order of priority. Triage is a learned skill and should be conducted by the most experienced medical or ambulance officer at the scene.

Different triage systems have emerged in different parts of the world. In British and Australasian health systems, 'sieve and sort' triage processes have become the preferred approach through MIMMS training courses.[28] In North America, 'start and save' triage processes have become incorporated into the National Disaster Medical System.[29] In the USA, a National Disaster Life Support Consortium has promulgated a triage approach based on 'move, assess, sort and send'.[30] These different systems rely on different assessment approaches with different vital sign thresholds to assign triage priority.

In general, most systems recognize that there are categories of patients who require immediate care, delayed care, minimal care and those that are expectant or unsalvageable. Patients requiring immediate care are individuals in critical condition, but to whom simple life-saving procedures may be successfully applied, such as the manual clearing of the airway. Patients classified as requiring delayed care may have significant injuries, such as major fractures, but are likely to survive if treatment is postponed for several hours. Minimal care patients are generally ambulatory and their treatment may be delayed until other patients have been appropriately treated. Expectant or unsalvageable patients are those that have acutely life-threatening injuries requiring advanced resuscitation, or those that have nonsurvivable injuries, such as massive head trauma. Advanced life support measures, such as cardiopulmonary resuscitation, are rarely indicated at a scene with multiple casualties. Instead, these patients generally receive palliative care, but only after patients in the immediate category have received appropriate treatment.

Stabilization

Following triage of the affected patients, rapid stabilization of airway, breathing and circulation is provided to those with the greatest potential for survival. Definitive care is not generally provided at the scene. On-scene medical care concentrates on securing the airway, administration of oxygen, external pressure to control haemorrhage and insertion of intravenous catheters for volume expansion prior to hospital transportation. Medical care should generally be provided at the Patient Treatment Post but, during prolonged rescues, resuscitative procedures may be required prior to extrication. Appropriate use of analgesia, including parenteral narcotics and regional nerve blocks, may assist with the extrication of trapped individuals. Special on-scene procedures are sometimes required for those with crush injury, blast injury, burns or hypothermia. Amputation of a mangled limb, although rarely indicated, may be a life-saving procedure for an entrapped patient.

Decontamination

Chemical, biological, radiological and nuclear (CBRN) agents have the potential to contaminate individuals, property and the general environment. In practice, industrial accidents represent by far the most common cause of exposure to hazardous materials that may require decontamination. A small number of high-profile chemical–biological terrorist incidents over the past 20 years have also prompted medical as well as lay attention to this potential threat. Regardless of the cause, the principles guiding the process of decontamination remain consistent.

Decontamination is the process of removing or neutralizing a hazard from the victim or environment. Fundamental principles involve:

- staff and site preparation with establishment of hot/warm/cold zones;
- casualty, staff and crowd protection;
- decontamination procedures;
- clinical treatment of contaminated patients and transport to definitive care;
- recovery of environment.

Removal of contaminated clothes should be conducted as a matter of urgency. Rapid decontamination of the skin is especially necessary following exposure to the liquid or aerosolized form of an agent. It is most useful when conducted within 1 minute of exposure but, in practice, this is rarely possible. When indicated, decontamination should be conducted close to the scene (i.e. in the 'warm zone') and, ideally, prior to transportation. Commonly used agents for decontamination include soap and water and hypochlorite (household bleach) in concentrations of 0.5% to 2.0%. Steps must be taken to ensure that emergency responders, health personnel and other patients are not at risk of secondary exposure to the chemical agent. Decontamination after exposure to a biological agent is less important, as most biological agents are not dermally active. But decontamination may be an effective way to limit the spread of the agent from potential secondary aerosolization.

Transportation

Efficient and rational transportation of patients to appropriate health facilities is dependent on good communications between hospitals and the incident Transport Officer. Capabilities of the affected community's hospitals should be identified and documented in the regional emergency response plan. Hospitals are required regularly to update the Incident Commander and Transport Officer of their bed availability status. The closest hospitals may be flooded by 'walking wounded' who have made their own way from the scene and by victims transported by well-meaning civilians. This has the potential of overwhelming local emergency departments and the Transport Officer must take this into consideration when determining the appropriate distribution of patients. It is essential that the complications of the emergency scene not be relocated to the nearest hospitals.

A number of factors need to be considered when determining the most appropriate hospital for a particular patient, including the patient's triage category, the hospital's capabilities (e.g. trauma, burns), transportation times, distance from the scene and the available transportation modalities. Medical helicopters may be able to transport patients to more distant hospitals, to relieve pressure on nearby facilities.

Health facility management

Guidance on hospital planning for disaster management has become widely available from the World Health Organization[31] as well as domestic stakeholders. Emergency physicians are expected to be familiar with their own hospital disaster plan and have contributed significantly to its development. The plan should address both internal and external disasters. Surge strategies for hospitals and emergency departments are generally well defined.[32]

The emergency department needs to be cleared of noncritical patients and steps taken to expedite appropriate discharge of stable ward patients, so that bed capacity may be optimized. The emergency department should be well stocked with supplies and have arrangements with suppliers for rapid replenishment. A recall system

for additional medical and nursing staff mobilized in a disaster needs to be incorporated into the plan. Extra security staff should be on standby to assist with the management of patients, families, friends, onlookers and the media.

Patients require re-triage by a senior medical officer as they arrive at the emergency department. Those with acutely life-threatening injuries are immediately resuscitated. Less severely injured patients need to be regularly reviewed while awaiting definitive care, to monitor for a potential deterioration in their condition. Expectant, unsalvageable patients are provided appropriate palliative care and their condition clearly explained to their relatives. Documentation is kept succinct and should generally be limited to the essential points about each patient's condition and treatment. Any forensic investigations are likely to require the cooperation of emergency physicians and other health personnel. Cultural and religious needs associated with the management of dead bodies and in communication with relatives should be respected at all times.

Urban search and rescue

Urban search and rescue (USAR) is the science of locating, reaching, treating and safely extricating survivors who remain trapped following a structural collapse. Search and rescue response capabilities have increased significantly, due to advances in rescue technology and in emergency services.

In the period immediately following a structural collapse, many survivors are rescued by uninjured bystanders. Those who remain trapped generally require the assistance of specially trained and equipped units from fire, ambulance or police services in order to be safely extricated. Medical members of search and rescue teams are tasked to provide medical care to the victims and medical support to the rescuers. They are not usually involved in the actual extrication process. Potential hazards to victims and rescuers are numerous and scene safety is of critical importance. The identification and extrication of victims following a major structural collapse is one of the most physically and emotionally challenging tasks of any rescue operation. The shock of dealing with scenes of carnage and mutilation may render some rescue personnel ineffective. These teams must therefore be trained and prepared to deal with the emotional strains of working in such a demanding environment.

Mental health

It is easy to overlook the mental health needs of affected individuals during the emergency response, when rescue and life-saving interventions receive top priority. Emergency physicians should be aware of the significant psychological impact of events on victims, families and rescue personnel. Psychological support is recommended as first-level assistance to affected communities and personnel.[33] Mental health consequences, such as depression, anxiety states and post-traumatic stress syndrome, are well described following disasters and need to be considered when developing the disaster plan. Crisis counselling may play an important role in the overall medical care provided to patients following a disaster. In addition, rescue personnel may well suffer psychological consequences from their own involvement in the disaster response and should therefore be provided with access to appropriate support and services.

Mass gatherings

Social and cultural events can result in the gathering of many people in one place at a particular time, sometimes over several days. Common examples include religious events, music festivals, sporting events, fairs and parades. The organization of medical services for mass gatherings is generally designed to address minor medical needs, but must also take into consideration medical emergencies, such as cardiac arrests, and disaster planning, for incidents such as extreme weather, fire, structural collapse or terrorism. Medical services developed for the mass gathering must be linked to local emergency medical systems. Public health and occupational health regulations, including food safety and environmental health measures, must be observed.

Public health issues in emergencies and disasters

Public health professionals are involved in all phases of health emergency and disaster risk management and it is important for emergency physicians to understand the role of public health in disaster medicine and emergency risk management. Epidemiological studies that have identified risk factors for illness and injury following hazardous events have contributed greatly to emergency risk assessments, prevention, mitigation, preparedness (including planning), response and recovery. These investigations have been central to the development of the science of disaster medicine. They have led to key strategies that have been effective in reducing event-related morbidity and mortality.

Public health interventions become high priorities following disasters that disrupt the social infrastructure (for instance, cyclone, flooding, earthquake) and disasters that result in significant population displacement (such as CEs). Priorities for the affected population include the provision of adequate water quantity and quality, sanitation, food, shelter, infectious disease control and disease surveillance. The role of public health following a mass casualty incident includes injury control, occupational health and safety measures for responders and injury surveillance.

The interface between emergency medicine and public health becomes increasingly important following technological events or terrorist events involving biological, chemical or nuclear agents. The terrorist attacks with anthrax in the USA during 2001 and their aftermath demonstrated the vital importance of key public health tools, such as disease surveillance and outbreak investigation and control. Following incidents with chemical or radiological agents, public health officials may be required to provide guidance on issues, such as evacuation of the public, mass decontamination and the mass distribution of iodine. Emergency physicians should become more familiar with the skills, roles and responsibilities of their public health colleagues, especially as they relate to disaster management and infectious disease control.

Conclusion

State-of-the-art in contemporary health emergency and disaster risk management emerges from interdisciplinary, interagency and international best practices. Curative medical skills and public health skills are both fundamental to the comprehensive management of a community affected by hazardous events of all scales. Emergency physicians contribute most significantly to the preparedness and response aspects of emergency and disaster risk management. Emergency physicians should plan and build capacities for emergencies and disasters based on an assessment of the major risks that their communities face and those which are most likely to result in multiple casualties. These include the risks associated with natural, technological, biological and societal hazards. The increased risks posed by climate change and terrorists require the continuing review and revision of disaster risk-assessment processes and disaster planning. Events associated with multiple casualties provide unique challenges to the health and medical communities. Short courses in emergency and disaster risk management are widely available and should be part of every emergency physician's training.

Likely developments

- Increasing frequency, severity and unpredictability of events due to natural hazards, exacerbated by climate change.

- Increasing standardization in international response mechanisms, including emergency medical teams.
- Increasing accountability of health factors for clinical interventions and their outcomes in emergencies and disasters.
- Strengthened mechanisms for the leadership, coordination and effectiveness of international disaster response, in line with recent reform measures.

CONTROVERSIES AND FUTURE DIRECTIONS

- The fields of emergency and disaster risk management and disaster medicine continue to professionalize. There are updated standards, best practices and training for most aspects of emergency response. There has also been significant progress in managing the risks posed by various hazards prior to events occurring. Emergency physicians should familiarize themselves with these developments so that they are better able to respond to both small- and large-scale disasters.
- Planning for emergency preparedness and response must address the most common hazards and vulnerabilities within a community, while still including a prudent approach to high profile events that have low probability and high consequences, such as terrorist attacks. The all-hazards approach provides appropriate guiding principles for such planning.
- The threat of pandemic influenza and other potential epidemics must also be considered in planning for emergency preparedness and response. Emergency physicians should increase their familiarity with important concepts, such as infectious disease surveillance, case detection and outbreak investigation and response. They should also become more familiar with the skills, roles and responsibilities of their public health colleagues, especially as they relate to disaster management and infectious disease control.
- Australian medical response teams (AusMATs) provide opportunities for civilian specialists, including emergency physicians, to be deployed to countries experiencing or emerging from emergencies due to natural hazards or conflict. Opportunities also exist with a range of nongovernmental organizations and UN agencies. Emergency physicians wishing to take advantage of these opportunities need to be familiar with specific clinical and public health issues, security considerations and international emergency response architecture and procedures.

29.4 Triage

Drew Richardson

ESSENTIALS

1 **Triage is the ongoing process of sorting patients on the basis of the urgency of their need for medical care.**

2 **Urgency is distinct from both severity and complexity.**

3 **Triage categorization has been found to relate strongly to both resource use and patient outcome in the near term.**

4 **The five-level Australasian Triage Scale (ATS) forms the basis of emergency department triage in Australasia.**

5 **The ATS is also used in case mix funding models and important performance measures.**

6 **The 'treatment strategy' by which the next patient to be seen is chosen from the various treatment queues continues to evolve in the face of increasing demand and 'streaming' according to patient characteristics and likely therapeutic need.**

7 **Similar triage scales have been developed and adopted in other jurisdictions.**

Introduction

Provision of high-availability quality medical care is expensive and has been traditionally limited to the very wealthy or to situations of great demand, such as the military in battle. Even today, well-organized emergency medical systems are concentrated in societies sufficiently affluent to spend 5% or more of Gross Domestic Product (GDP) on health. Some form of rationing is required whenever an expensive resource is coupled with fluctuating demand. Price, queuing and denial are all used in different areas of medicine. Simple application of any of these methods in emergency medicine would not be efficient nor equitable, so the majority of emergency medical systems use a triage process to sort patients into a number of queues.

Triage, the sorting of patients on the basis of urgency, is an ongoing process that nevertheless requires formal structures at different points within the continuum of care. In the emergency department (ED) setting there is considerable evidence that urgency can be assigned reliably and distinctly on a five-level scale and that this categorization is applicable and useful beyond the concept of 'urgency' into other aspects of hospital care.

Origins of triage

The word 'triage', arising from the French 'trier' meaning 'to sort' has its origins in Latin. It has entered English at least three times: from the 18th century wood industry, the 19th century coffee industry and from 20th century emergency medicine. The process understood today as triage was first described by Baron Dominique Jean-Larrey (1766–1842),[1] the surgeon to Napoleon, who also developed the ambulance volante, the first field ambulance. This delivered large numbers of injured but salvageable cases to medical units, mandating a more efficient system than treatment in order of military rank. Jean-Larrey's 'order of dressing and arrangement' by urgency was also in keeping

with the egalitarian spirit of the French revolution, although there is no evidence that he actually used the word triage. His concept was embraced and refined by military surgeons over the next 150 years, usually with the primary intent of returning soldiers to battle in the most efficient manner.

Civilian triage developments

There was certainly some sorting of patients from the moment 'casual wards' opened in 19th century hospitals, but the first systematic description in civilian medicine was in Baltimore in 1966. Since that time, there has been a huge growth in emergency medicine as a specialty and a number of workers have undertaken formal investigation of triage, particularly in Australasia. The Australasian experience formed the basis of ED triage development in Canada and the UK, while some other jurisdictions have developed systems independently.

Process of triage

The underlying principles of triage are those of equity (or justice) and efficiency. EDs experience potentially overwhelming demand from patients with an enormous range of conditions. Equity demands that the distribution of resources for treatment is fair in the broadest sense. The concept of urgency is well understood by the population who generally accept that it is fair to treat those in the greatest need ahead of those who arrived before them. Efficiency demands that best use is made of available resources. In the setting of ED, cost and resource pressures prevent all demand being satisfied simultaneously. The overall philosophy of 'doing the greatest good for the greatest number' requires resource allocation on the basis of need which, in turn, requires a process to identify and prioritize the needs of the presenting population.

In the ED, urgency is distinct from severity, prognosis, complexity and case mix, although a correlation exists. Some urgent problems (for example, upper airway obstruction) have a poor outcome without rapid intervention but are not severe in the sense of requiring long-term care; other severe problems (for example, life-threatening malignancy) may not require any treatment in the ED time frame. Complexity is reflected in the number of interventions, such as investigations or consultations required, whereas case mix is an indication of the resources required to provide care. Developments in medical care, particularly time-critical interventions, for example radiological procedures for intravascular thrombus in stroke, mean that the urgency of some presentations has changed over time.

Triage is an ongoing process that may change in response to alterations in patient status and resource availability, but it is efficient to undertake a formal process once, early in the patient's encounter, and then review only as necessary. ED triage is normally undertaken by trained nursing staff at the time of arrival and the assigned urgency is then used to guide treatment order. 'Triage', used as a noun, is now regarded as the first point of patient contact in EDs.

The overall efficiency and effectiveness of such a system depends not only on the allocated priority but also on the treatment strategy, that is, the way in which the next patient is chosen from the different queues. A more urgent case should wait less time than a less urgent case but, when resources become available to treat the next patient, choice may still be required between a new arrival and a slightly less urgent patient who has already been waiting for some time.

It may also be a more efficient strategy in terms of both waiting time and patient care time to 'stream' particular patients to particular providers or groups of providers. Common streaming approaches include division by expected outcome (admission and discharge streams), division by complexity (acute and 'fast track' streams), and division by age (separate paediatric stream).

Australasian triage development

The first Australasian description was of the Box Hill Triage Scale by Pink and Brentnall in 1977.[2] They used verbal descriptions without time consideration and classified patients into five categories: immediate, urgent, prompt, nonurgent and routine. Fitzgerald modified this scale in 1989,[3] to produce the Ipswich Triage Scale. This used five colours to categorize patients according to the question: 'This patient should under optimal circumstances be seen within…'. The five categories were seconds, minutes, an hour, hours and days. The scale had interobserver reliability on formal testing and was a practical predictor of ED outcome and length of Intensive Care Unit (ICU) stay, but a poor predictor of outcome at hospital discharge.

Jelinek[4] investigated the relationship between the Ipswich Triage Scale and case mix, observing a strong correlation between triage categorization and overall use of resources in the ED and validated possible funding models. He proposed two possible case mix classifications: urgency and disposition groups (UDGs—12 groups) and urgency related groups (URGs—73 groups) based on urgency, disposition and diagnosis. After trimming for outliers, these were found to account for 47% and 58% of the cost variance in large hospitals.

In 1994, the Australasian College for Emergency Medicine formalized the National Triage Scale,[5] derived from the Ipswich Triage Scale. This used colours, names or numerical categories to represent five groups, based on the answer to the question 'This patient should wait for medical care no longer than…'. The categories were immediate, 10 minutes, 30 minutes, 1 hour and 2 hours. The definition document also proposed Jelinek's concept[4] of performance indicators based on the proportion of patients whose care fell within the desired time threshold and audit by means of admission rates and sentinel diagnoses. It influenced treatment strategies by indicating the need to achieve performance indicators in a high proportion of patients in every category (higher in the more urgent) and it clearly established the need for EDs to employ systematic, accountable and audited triage processes.

Over the next few years, the National Triage Scale was widely accepted and recognized by all Australian State Governments as an appropriate measure of access to emergency care. It was also adopted in the performance indicators promulgated by the Australian Council on Healthcare Standards.

The Australasian Triage Scale

The Australasian Triage Scale (ATS)[6] is the current refinement of the National Triage Scale (NTS). It has been jointly developed by the Australasian College for Emergency Medicine, emergency nursing organizations and other interested parties. For practical purposes, the scale concept itself is unchanged, but the ATS uses numeric classification only, better defines waiting time and includes associated implementation guidelines and educational material, partly derived from work on the NTS in areas such as mental health triage. Further training packages have subsequently been developed,[7] secondary to concerns about variation in triage training.

The ATS categorizes patients presenting to EDs in response to the question: 'This patient should wait for medical assessment and treatment no longer than…' (Table 29.4.1).

Other triage scales

The concept of desirable waiting time must include some subjective component and

Table 29.4.1 The Australasian Triage Scale categorization of patients presenting to emergency departments

ATS category	*Treatment acuity (maximum waiting time)*
ATS 1	Immediate
ATS 2	10 min
ATS 3	30 min
ATS 4	60 min
ATS 5	120 min

ATS, Australasian Triage Scale.

achievement of ATS waiting times is a useful performance indicator, but this remains a measure of process rather than ED outcome. Concerns have been expressed in some jurisdictions about the medicolegal implications of a time-based threshold which will not always be met but most have developed five-level triage systems along the Australasian model. Major validated triage scales include:

- Canadian Emergency Department Triage and Acuity Scale (CTAS): derived from the ATS but using a 15-minute threshold in category 2.
- Manchester Triage Scale: uses an algorithmic approach to the UK Triage scale, similar to the ATS but with longer thresholds for lower acuity.
- Emergency Severity Index (ESI) Triage Algorithm: developed in the USA without any time thresholds, but using a simple approach to classifying complexity and urgency.

Use beyond waiting time

Triage is based on a brief assessment and an individual triage categorization can reflect only the probability of certain outcomes. Large populations of triaged patients, however, exhibit predictable patterns. There is a very strong, almost linear relationship between triage category and total rate of admission, transfer or death, ranging from 80% to 100% in ATS1 to 0% to 20% in ATS5.[8] This pattern is repeated across hospitals of different size and different patient mix. Admission rates by triage category follow the pattern of overall admission rates in relation to age, giving a flattened 'U-shaped' distribution. The inter-rater reliability studies performed using the Ipswich Triage Scale have been repeated using the NTS/ATS, which has been found to be slightly better.[9]

The NTS/ATS has been extensively studied as a case-mix tool. ED outcome (admission/transfer/death versus discharge) accounts for the largest variance in cost, but triage categorization comes a close second, with age third. UDGs, described by Jelinek using the Ipswich Triage Scale, have been validated using the National Triage Scale on large samples.[10] Age has been included to derive urgency, disposition and age groups (UDAGs—32 groups), which account for 51% of the cost variance and are not susceptible to different diagnostic approaches. The relativities derived in these studies should no longer be considered valid in the era of access block, because staff costs for admitted patients reflect length of time in the ED, which may now be driven by outside factors. Further, the costs for discharged patients are becoming skewed by increased pressure to keep complex patients out of hospital.

Triage categorization is a very strong predictor of ED outcome, a good predictor of utilization of critical care resources, and a relatively poor predictor of outcome at hospital discharge. Many patients with chronic or subacute conditions that frequently cause death are triaged to less urgent categories because there is no benefit from earlier treatment within the time scales available in the ED.

Triage staff are well able to assess complexity and so initial triage is also the appropriate point to start streaming decisions. Although streaming can be seen as decreasing equity because the less urgent patients achieve shorter waiting times than more urgent, in practice, this is compensated by the gain in overall efficiency. Like the triage process itself, changes to the treatment strategy can and should be ongoing, reflecting not the urgency of the patients, but the best distribution of the resources available at that moment. For example, one common treatment strategy is to treat ATS1 and 2 in order of urgency (always most urgent waiting first) and ATS3 to ATS5 in order of time of arrival within each stream. In a large tertiary triage mix, this approach slightly increases waiting time for ATS3 with the benefit of markedly reducing excessive waits for ATS5. A strictly urgency-based treatment strategy might otherwise cause ATS5 patients to 'never be seen' because there is always at least one ATS4 waiting.

Structure and function of a triage system

The exact requirements for triage vary, but effective systems share a number of important features, mostly derived from experience:

- A single point in the ED near the entrance where triage is undertaken so that all patients will be exposed to the nurse(s) undertaking triage.
- Appropriate facilities for undertaking brief assessment and limited treatment (first aid) including relevant equipment and washing facilities for staff and patients.
- A balance between competing concerns of accessibility, confidentiality and security.
- A computerized information system to both record assessment and triage categorization that will 'follow' the patient through their time in the ED and provide contemporary data on the state of the ED and the expected patients.

Prehospital triage

The principle of making best use of available resources to maximize patient outcome remains the basis of triage in any setting. Relatively less therapeutic options are available to prehospital providers and patient disposition is generally limited to transport and sometimes choice of hospitals. The initial travel to the patient must be undertaken on the basis of minimal information. Most prehospital systems are strongly protocol driven and tend towards three- or four-level assessment: rapid response (lights and sirens), immediate response, routine response or no transport. Once the patient is assessed in the field, there is patient benefit in triaging to the most appropriate hospital for tertiary-level conditions, such as major trauma or ST-elevation myocardial infarction.

Military and disaster triage

In situations of overwhelming imbalance between resources and demand, triage remains critical in ensuring that available resources are used to achieve the greatest good. The principles of rapid assessment, documentation and multiple queues for care remain the same, but competing demands on resources may mean triaging cases to receive minimal or no care or treating first those who can return to work or duty. The need for both human and physical resources for more important tasks may profoundly limit individual patient care.

Military and disaster triage require seniority and experience (which by definition is rarely available), the ability to make and defend rapid decisions and a successful liaison with other players outside the medical or nursing hierarchy. Senior personnel with significant experience and preferably with additional training should be chosen for this role if possible. Formal triage and documentation must be brief and will use different scales from those appropriate in the ED.

CONTROVERSIES AND FUTURE DIRECTIONS

- Revision and improvement of the ATS will continue. Further study is likely on issues including:
- variation in implementation between sites, particularly hospitals of different role delineation
- different appropriate 'treatment strategies', that is, how the next patient to be treated is chosen from the various queues, in both normal and overcrowded conditions and between different patient mixes
- variation associated with activity or overcrowding—there is evidence of consistency in some hospitals but changes in others
- variation in approach to paediatric triage, especially between mixed and paediatric EDs and to psychiatric triage
- use of triage as a case-mix or funding tool, particularly since there have been dramatic changes in population, age and access block since the last major studies.

29.5 Emergency care in a humanitarian crisis

Angela Jackson • Mark Little

ESSENTIALS

1 **The worldwide problem of refugees, internally displaced and stateless persons is significant and likely to increase.**

2 **Overall responsibility for internally displaced persons (IDPs) lies with the governments of the country in which they reside. The international community, including many of the United Nations (UN) agencies, can assist through collaboration and diplomacy (http://www.ohchr.org/EN/Issues/IDPersons/Pages/Issues.aspx). Refugees, on the other hand, have crossed an international border and therefore are protected under the mandate of the United Nations High Commission for Refugees (UNHCR), although numerous other organizations assist.**

3 **During times of mass displacement, people establish homes using whatever structures are available, commonly tents. They generally live in close proximity to each other thus increasing the risks of disease, violence and social dislocation.**

4 **In 2005 the UN undertook humanitarian reform and introduced the cluster system to improve communication and coordination within sectors so UN, non-UN, government and local actors could work together to achieve common goals.**

5 **The World Health Organization (WHO) Emergency Medical Team (EMT) initiative is identifying minimum standards and best practice guidelines for medical teams with the overall aim to produce a more reliable and well-trained medical response to a humanitarian crisis.**

6 **The basics of nutrition, shelter, clean water and sanitation are always the most important. The Sphere Handbook sets out agreed minimum standards for the provision of care.**

7 **The four major health threats in a humanitarian crisis are malaria, measles, diarrhoeal illness and respiratory tract infections.**

8 **For those who are displaced, the durable solutions are resettlement in their country of origin, integration into the new host country or resettlement into a third country.**

9 **The ultimate solution to solving global displacement is political stability and a strong rule of law.**

Introduction

Increasingly over recent years, Australian health professionals, including emergency medicine clinicians, have responded to humanitarian crises due to conflict or natural disasters within our region. Caring for displaced persons is not a new problem. Since World War II up to 100 million civilians have been forced to flee their homes due to unrest. The major factors that cause people to flee their country include conflict, political repression and persecution, and are as old as humanity. In 1573, the term 'refugee' was first used for Calvinists fleeing political repression in the Spanish-controlled Netherlands.

Until the end of the World War I, the response to refugees was from philanthropic sections of the community. In 1921, a High Commission for Refugees was established with a mandate to look after refugees fleeing the Russian and Armenian wars. Its first commissioner was Fridtjof Nansen, who established a special identity document, the 'Nansen Passport', as refugees frequently had no means of identification.

In the wake of World War II, the United Nations (UN) established the International Refugee Organization (IRO) to assist the millions of displaced persons in Europe. Between 1947 and 1951, it helped 1.6 million people, mainly Germans and Austrians.

The United Nations High Commissioner for Refugees (UNHCR) replaced the IRO in 1951 and the *Convention Relating to the Status of Refugees* came into being. This key legal document defines who is a refugee, what rights they can expect and what the legal obligations of the host nations are. It has been widely ratified to date and, notably, was signed by the President of Nauru, Marcus Stephen, on 17 June 2011. With some fine-tuning over the years it remains the cornerstone of International Refugee Law. It defines a refugee as:

A person who owing to a well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group or political opinion, is outside the country of his nationality and is unable or, owing to such fear, is unwilling to avail himself of the protection of that country; or who, not having a nationality and being outside the country of his former habitual residence as a result of such events, is unable or, owing to such fear, is unwilling to return to it…

The UNHCR encourages countries to receive refugees and to provide them with assistance

and protection. One of the major protections provided for in the *Convention* is the principle of 'non-refoulement', which means refugees cannot be forcibly returned to their countries of origin, if to do so would threaten their life or freedom.

Unlike refugees, and because of the element of sovereignty, governments of countries where IDPs reside are responsible for their protection because these people have not crossed an international border. IDPs are commonly fleeing situations such as internal armed conflict, communal violence and other human rights violations. In many instances, state authorities may not only be the cause of displacement but may lack the will or capacity to address issues and the needs of the IDPs. This includes not only humanitarian relief assistance, but also protection. Where a state lacks capacity, it can request humanitarian relief assistance from UNHCR and other agencies. Since 1992, UNHCR has been focusing more efforts toward the protection of IDPs and, since 2007, has taken the lead in complex emergencies.

In 2017, according to UNHCR, there were 65.6 million people displaced worldwide (up by ~23 million in 6 years). Of these, 22.5 million were refugees and 43 million were internally displaced persons (IDPs). Turkey is hosting 2.9 million and Pakistan 1.4 million refugees. Up to 93% of all refugees were being hosted within the region of the country they had fled. The major sources of refugees in 2017 were Syria (5.5 million), Afghanistan (2.5 million), and South Sudan (1.4 million). Of all these refugees, 46% are less than 18 years of age.

In 2017, China, the Philippines, Syria, the Democratic Republic of the Congo (DRC), Cuba, the United States, India, Iraq, Somalia and Ethiopia had more than one million new displacements each. At the height of the crises in 2010, the floods in Pakistan saw 20 million people displaced. The worldwide problem is clearly significant.

Sadly many nations are restricting border access and assistance to refugees fleeing crises.

The solution to any displacement problem is ultimately nonmedical because the underlying issue is commonly based on political instability. Even in the acute phases of refugee movement, the most urgent needs are food, shelter and clean water. Access to health care is important. Emergency physicians should have an understanding of the issues at hand and possible solutions including links to appropriate information and organizations where necessary. Of particular importance is that at all stages of relief assistance, the displaced population, sometimes referred to as 'the beneficiaries', must be actively involved in planning and delivery of aid. Affected communities themselves know what they need, who their leaders are, what the cultural norms are and they speak the local language.

Coordination in a humanitarian crisis

A number of reforms have been introduced in recent times to address problems of poor planning and coordination. After the Great Lakes Disaster in the early 1990s, it was agreed in 1997 to establish a set of minimum standards and rights to which refugees were entitled. The collaborative project, called Sphere, was initiated in 1997 by a group of humanitarian nongovernment organizations (NGOs) and the International Red Cross and Red Crescent Movement with the overall aim of improving the quality of their actions and accountability during disaster response. The Sphere Project produced a manual that is available free from the website www.sphereproject.org. The Sphere Handbook is widely known and sets out common principles and universal minimum standards for humanitarian response. The Sphere Handbook was first published in 2000 and the newest edition was published in November 2018. Other organizations, such as Médecins Sans Frontières (MSF), UNHCR and the World Health Organization (WHO), also have several excellent manuals describing in detail the approach to humanitarian emergencies.

In partnership with national and international actors, the Office for the Coordination of Humanitarian Affairs (OCHA) is the UN agency responsible for mobilizing and coordinating effective and principled humanitarian action. In 2005, OCHA initiated a review of its coordination processes. This resulted in the introduction of the UN clusters with the aim of building sufficient response capacity, improving humanitarian coordination and leadership and building effective partnerships. Table 29.5.1 shows the current clusters and their lead agencies.

Global cluster leads develop partnerships, humanitarian preparedness and set standards and policy. At a field level, the cluster lead, together with the affected country's government representatives, ensures collaboration and coordination and are accountable to the senior UN representative, the Humanitarian Coordinator, as well as the host country government authorities. The cluster lead is the 'provider of last resort', which means they must do their utmost to ensure an adequate response. Where that response is lacking, it is their responsibility to seek assistance from others, such as the Humanitarian Coordinator or the host government. Any organization responding to a humanitarian crisis and working in a specified area of response (e.g. health) is welcome to attend any relevant cluster meeting.

Table 29.5.1 Clusters and cluster lead agencies

Technical clusters	
Nutrition	UNICEF
WASH	UNICEF
Health	WHO

Telecommunications	WFP
Sector	**Organization**
Refugees	UNHCR FAO
Agriculture[a]	UNICEF/SCF UK
Education[a]	WFP
Food security	FAO WFP

[a]Agriculture and education were the newer clusters established.
FAO, Food & Agriculture Organization; *IFRC*, International Federation of Red Cross; *IOM*, International Organization of Migration; *OHCHR*, Office of the High Commissioner for Human Rights; *SCF UK*, Save the Children Fund UK; *UNDP*, UN Development Program; *UNHCR*, UN High Commissioner for Refugees; *UNICEF*, United Nations International Children's Emergency Fund; *WFP*, World Food Program; *WHO*, World Health Organization.

Emergency Medical Teams

The medical response to the earthquake in Haiti resulted in many issues, particularly regarding variable standards of care. As a result, the WHO in collaboration with others developed the 'Emergency Medical Team (EMT) Initiative'. This sets out a series of minimum standards for various levels of medical team response and includes clinical care, waste management and logistics. Teams may be civilian or military. EMTs are verified to meet the WHO standard, and agree to work with the WHO and the government's Ministry of Health in responding to a health crisis. Nations experiencing sudden onset disaster can be confident any EMTs who have successfully undergone WHO verification who are deploying to their country will meet preset minimum standards of health care and will provide well-trained and self-sufficient medical teams. Australian and New Zealand Medical Assistance Teams (AusMATs & NZMATs) have been verified for type I (primary health care both fixed and mobile) and AusMAT type II (field hospital) levels of care.

Before you go

The Internet and electronic media are increasingly being used in innovative ways by humanitarian agencies. It is now possible to follow evolving disasters on several websites, such as UN affiliated sites, Red Cross sites, major NGOs and MSF sites and explore what each particular organization is doing. OCHA has an excellent website called Reliefweb (www.reliefweb.int) which gives regular updates on all crises. Relevant data can also be sourced from gapminder (www.gapminder.org). In most humanitarian crises, the health issues are predictable (e.g. orthopaedic injuries with earthquakes). It is important to be aware of the literature and to scan previous reports of health issues within the region where you are intending to travel before you leave. As soon as clusters are operational, they will report recent data for the affected region, as will the local Ministry of Health. Where possible, it is preferable to be in contact with these organizations prior to departure. WHO publish on the internet some excellent manuals on diagnosing and managing cases in humanitarian crises and have prepacked medical kits (Interagency Emergency Medical Kits). WHO also publish the EMTs guideline often referred to as 'the blue book' which is available online. The Sphere guidelines are another essential resource and the Australian Medical Assistance Team training manual is also helpful.

Personal attributes

Working under difficult conditions imposed by a humanitarian crisis demands special qualities. It is certainly not glamorous and often much of what has been learned from training and practice in the West is either irrelevant or needs modification to suit local conditions and resources. In general the main requirements are:

- flexibility, versatility and ability to improvise;
- appropriate qualifications and sufficient clinical experience along with the ability to work independently in extreme conditions;
- cultural awareness and sensitivity;
- good interpersonal and communication skills and the personality to get along with all types of people;
- willingness to follow leadership and direction;
- good predeployment preparation, including appropriate vaccinations and insurance arrangements;
- acceptance of security and health risks both by the individual and their family.

Camps for refugees and internally displaced persons

Persons fleeing war or persecution escape in a variety of ways. They may be integrated within the local community or be accommodated by friends and relatives. Typical, however, is the mass movement of populations either across a country or a border into temporary accommodations or camps. It is under these circumstances that the displaced are most at risk, as they are not accommodated in isolation. There are generally interactions with a local population, which are not necessarily cordial. There may also be important political and ethnic factors within the displaced population themselves, which can lead to tensions or even violence within camps. This scenario was tragically demonstrated in the post-Rwandan holocaust camps in 1994. Camps themselves can sustain conflict in some areas, for example, the West Bank and the camps on the Thai–Cambodian border that were used as refuges by Khmer Rouge and became a platform from which they could carry on the war.

Responding to a crisis

Emergency phase

As a result of a crisis, due either to war or acts of nature, large populations can be displaced from their normal environment. This often results in large numbers of people, with minimal to no basic life needs, descending upon a region. Where they stop is generally where a camp evolves. Most population movements into such camps occur in developing countries that already have limited resources with which to deal with such influx. Preplanning by the UN, aid agencies and host governments is essential to ensure a rapid and well-coordinated humanitarian response. Considerable expertise in responding to refugee emergencies has been gained and the main priorities are now well recognized. In accordance with Sphere guidelines the main priorities are as follows.

Initial assessment

A rapid assessment of the population structure, their medical and other needs, is essential in the very early stages to prioritize planning and allocate resources appropriately. It is essential to involve local leaders and population in assessing needs and planning priorities.

Measles immunization

Conditions in refugee camps can facilitate large-scale measles epidemics that, in an at-risk population, can have devastating consequences. In 2011, the UNHCR reported that in one of the Dollo Ado camps in Ethiopia—host to mainly Somali refugees—up to 10 children per day were dying, mainly due to measles and malnutrition. Combined with malnutrition, measles can have a case fatality rate as high as 33%. The detection of one case of measles in a camp is a public health emergency and requires urgent intervention. Mass vaccination of all children from 6 months to 15 years is essential and should be done as soon as possible. To increase vaccination efficacy, WHO recommend combining measles vaccination with the administration of vitamin A. According to WHO, vitamin A has been shown to reduce the burden of disease mortality and morbidity, particularly in children less than 5 years, by improving immune response. The dosing schedule for vitamin A administration is available from the WHO website and is age specific.

Water and sanitation

Poor water supply and sanitation play a major role in the spread of diarrhoeal diseases. Well-defined standards that can be checked with simple kits now exist for acceptable water quality. The Sphere guidelines stipulate minimum quantities of water in the emergency phase of a disaster are 5 L/person per day initially and rising to 15 L/person per day when possible. Sphere also set standards for the location, type and number of latrines and washing facilities per person in camp situations.

Food and nutrition

Malnutrition is common in refugee populations and particularly in the at-risk young and elderly groups. The initial food ration recommended is 2100 kcal/person per day. It is also important to undertake surveys to assess for specific micronutrient deficiencies, such as scurvy or pellagra, and treat accordingly. Measurement of mid–upper arm circumference (MUAC) in children between 6 months and 5 years is a common quick way to assess the overall nutritional status of a population.

Assessment of nutrition in the population is an ongoing process and special feeding programmes may need to be set up for at-risk groups. Generally, there are specific agencies, such as the UN World Food Program, that specialize in this area. It is therefore important that adverse findings are reported to the health cluster to determine who will be responsible for targeting the at-risk population.

Shelter and site planning

Proper shelter and adequate clothing are essential early priorities. Overcrowding can lead to or worsen disease outbreaks and may affect the mental health of the camp population. Protection from the elements is essential for well being and particularly so in extreme climates. When planning camps, it is important to consider the size, terrain, security, access in and out, nearby water supply, distance to host community, etc. Again, well-defined standards for living space and shelter construction are available in the Sphere Handbook and other resources.

General healthcare

Organizing a system to deal with the health needs of a population is essential. Medical needs of a population are rapidly assessed and endemic diseases taken into account. There may be numerous organizations involved in health delivery activities. To avoid duplication and the waste of valuable resources, it is important for all providers to participate in ongoing communication and health planning. In disaster situations, this is best achieved by reporting to the health cluster, which has overall responsibility to coordinate the health response. Accurate data collection and reporting is necessary to monitor response progress. There are manuals and guidelines available to assist and WHO have created medical kits intended to cover the needs per 1000 refugees for a 3-month period.

Control of infectious disease

The four most frequent infectious diseases in the emergency phase are diarrhoea, malaria, respiratory infections and measles. The provision of good basic living conditions will help decrease the burden of these and other illnesses. If an outbreak does occur, there is potential for high mortality rates. Aggressive treatment and decisive public health interventions are therefore essential. As diarrhoea is a major cause of death, the early establishment of oral rehydration centres is essential.

Public health surveillance

Collecting epidemiological data on a daily basis provides essential information to those in charge of a camp so that interventions can be planned and disease outbreaks rapidly recognized. The most useful health indicator is the daily crude mortality rate (CMR), which is normally expressed as deaths/10,000 population/day. The Sphere manual gives baseline CMRs for different regions worldwide. Double the baseline CMR is an indication the emergency threshold has been reached. If the baseline CMR is unknown then a CMR of over 1/10,000 per day for adults (or 2/10,000 per day for children less than 5 years) is an indicator of an emergency situation. Disease-specific mortality rates may also be useful.

Human resources and training

Administering a refugee camp is complex and requires a variety of skilled personnel who include doctors, nurses, water/sanitation experts, nutritionists, logisticians and others. The need for different types of personnel should be determined followed by appointment of appropriate personnel which will ideally be selected from the local population where possible.

Post-emergency phase

This phase begins when the basic needs of the population are met (food, shelter, water and so on) and the CMR is either back to the baseline or less than 1 per day/10,000 for the adult population and 2 per day/10,000 for the under–5-year-olds. The situation in the post-emergency phase is complex and fluid. Some of the displaced persons may become quite settled and start to work locally or farm some land. The health and nutritional status of refugees can even surpass those of the local population because of the availability of overseas aid. This may lead to resentment and the rise of complex political issues. Where a large population remains in place, descent back to the emergency phase is an ongoing possibility and may occur with epidemic outbreaks or fresh influxes of newly displaced people. In general, however, the post-emergency phase is concerned with consolidating earlier achievements, preparation for possible new emergencies and future sustainability. The continuation of water quality monitoring, public health surveillance and nutritional status assessment is important for early detection and intervention.

Healthcare delivery in the post-emergency phase is complex. Some issues that warrant consideration for planning purposes include:

- standardization of training, supervision and delivery of health services;
- curative healthcare services;
- reproductive health care, including antenatal and delivery, postnatal and family planning, sexually transmitted infections (STIs) and HIV/AIDS;
- child health activities, such as expanded programmes of immunization (EPIs);
- specific HIV/AIDS/STI programmes;
- tuberculosis programmes;
- addressing psychosocial and mental health issues.

Permanent 'durable' solutions

There are three possible solutions to any displaced situation—repatriation, integration or resettlement in another country. Many displaced populations reside in countries neighbouring their own country and are thereby the responsibility of the UNHCR. Repatriation is the preferred option but is often quite complex. In 2016, UNHCR reported that 189,300 refugees were voluntarily repatriated. This will generally only occur where there is a solution to the problem that caused the refugees to leave initially. This can take years. People returning need a lot of extra support in order to rebuild their lives. At the time of repatriation, some families have lived in refugee camps for years and children and grandchildren have been born in camps in the host country. The newborns may have no link to the original country they fled and have more of a relationship with the host country and hence, some refugees remain in the host countries and integrate into local communities. In the past, particularly amongst African nations, integration into host communities were commonplace. More recently however, this has become increasingly difficult, particularly when African governments see their Western counterparts' reluctance to accept refugees.

The minority of refugees who cannot return are resettled in third (mostly Western) countries. Many countries have quotas and will only admit those refugees determined by UNHCR as having a valid claim.

Past problems

In the past, there have been important problems with the response to a refugee crisis. These are in many instances due to poor coordination between agencies responding to a particular crisis. It is well documented that poor coordination has in the past led to inappropriate interventions and even frank competition. Often, in a dramatic disaster, such as an earthquake which has considerable media coverage, there is a frenzy of intervention as agencies attempt to get their image across to international viewers to assist in fundraising.

CONTROVERSIES AND FUTURE DIRECTIONS

- There is often a lack of coordination and communication between agencies involved in responding to a humanitarian crisis. The challenge is to coordinate the response and maximize efficiencies and outcomes.
- The development of the EMT initiative is fairly recent but it is ongoing and with time more teams will be verified.
- The numbers of displaced populations are exploding. Developing durable solutions for the world's displaced population that currently stands at 65.6 million is challenging. Part of this is to change the attitude of many developed countries towards accepting these people for resettlement.
- Instead of spending millions of dollars each year on international staff to assist in humanitarian crises, would this money be better spent if given directly to those affected by the crisis?
- Although the UN cluster system has been established, there is a need to build resilience in this system. This includes working to support and strengthen disaster-affected governments to improve emergency systems including response and coordination.
- Disaster risk reduction and mitigation is more important than humanitarian response and, in the long term, will be more effective.

29.6 Emergency department short stay units

Carl Luckhoff

ESSENTIALS

1 Emergency department short stay units play a key role in modern emergency departments.

2 Staffing is ideally by emergency department staff with defined admission criteria and a plan for disposition within 24 hours.

3 They offer time-limited intensive treatment with clear treatment and follow-up guidelines.

4 They have an increasing role in improving patient flow while maintaining quality of care and safety in the era of time-based targets.

5 Emergency short stay units reduce length of stay and cost compared to inpatient ward admissions.

Introduction

Emergency department (ED) short stay units have evolved to become an integral part of modern emergency medicine service provision. The exact function and benefit to patient care varies according to hospital demand and patient needs, but in general ED short stay units allow for safe decision making and management whilst a final disposition decision is reached. It provides a further option for medically complex patients who require more diagnostic testing and therapeutic intervention in a short time frame, and also facilitates effective patient flow through emergency departments.

ED short stay units augment hospital bed access through prevention of hospital admissions for <24 hours and have proved to be a safe and cost-effective alternative to hospital admission for various conditions including chest pain, asthma, syncope, atrial fibrillation, dehydration, infection and other conditions requiring initial work up and stabilization.

Terminology around short stay units is inconsistent and these wards are sometimes referred to as observation wards or clinical decision units (CDUs). The emergency short stay unit is characterized by specific admission and discharge criteria, whereas the term of 'observation ward' can be considered for patients with more undefined clinical presentations. In contrast to these, some units are referred to as CDUs, implying that patients require a period of medical management prior to a final disposition decision being reached. The CDU has defined admission and discharge criteria, but generally, the focus is on medically unwell patients, potentially for admission, as opposed to patients being discharged home with potentially surgical conditions. No consensus definitions exist.

In contrast to the above the concept of a medical assessment and planning unit (MAPU) has also emerged over the past years. These units are short stay medical inpatient wards with an expected length of stay <72 hours.

Emergency short stay units are defined by the following general characteristics[1–5]:

- discrete wards with 4 to 20 beds, located adjacent to or in close proximity to the main body of the emergency department (ED)
- designed for short term observation or stay <24 hours
- staffed and run by ED personnel
- specific admission and discharge criteria and policies

These wards provide evidence-based short-term observation and treatment for specific patients as clinically indicated. The average length of stay is dependent on a variety of factors unique to each facility, but a length of stay of 10 to 15 hours is common.[6,7] Any length of stay for >24 hours should be the exception. In the era of focus on patient flow and time targets (e.g. 4-hour rule or National Emergency Access Target [NEAT]), the emergency short stay unit provides a degree of control and flexibility to emergency physicians to extend investigation and care beyond the 4-hour targets.

The benefits of having a short stay unit as part of the emergency department include[1–5]:

- allowing patients to access investigations before leaving the emergency department, ensuring accurate diagnosis and formulation of a discharge plan;
- admission to the correct inpatient service once an accurate diagnosis has been made;
- provides an alternative to inpatient hospital admission as a way to improve efficiency, clinical care and patient satisfaction, while minimizing costs[3,4];
- reducing inpatient admissions[1–4];
- temporary accommodation for patients (e.g. elderly or those with acute situational crisis) where immediate discharge, especially after hours, would place the person at risk;
- safeguard for junior medical staff who require assistance;

Table 29.6.1 Cost and length of stay comparisons for observation ward versus inpatient care

- shorter length of stay and cost compared to inpatient stay (Table 29.6.1).[3]

Observation ward policies and protocols

The general function of the observation ward varies depending on the needs of the individual hospital and department; nonetheless, there are some common characteristics that are essential to the efficient functioning of these wards.

These include guidelines around leadership, criteria for admission and discharge, responsibility of care and escalation of concerns, and documentation and transfer of care upon discharge from the unit whether that be to an inpatient unit or community-based service. Operational and clinical protocols, a policy manual and a quality improvement program with measures that evaluate performance are essential to the safe and efficient functioning of these units.

Admission and care process

There must be clear medical governance and responsibility for the patient at all times. Strong administrative leadership is essential and this should come from both medical and nursing leadership structures.[8] Handovers during the patient's journey through the observation ward should be kept to a minimum as this reduces medical errors. The aim is to have a senior clinician making key decisions, minimizing handovers and ensuring nursing staff are aware of who to contact in the event of patient deterioration.

Admission and discharge criteria

The emergency doctor should have admission rights to the unit and admission criteria need to be clear. Suitable patients should have an expected length of stay of no more than 24 hours and at the time of admission to the observation ward have well-defined reasons for observation, and a clear management plan. This should include immediate treatment goals, expected outcomes/response and clear instructions around monitoring, food/fluid intake, medication scheduling and the need for ancillary/allied health service review. All patients within the emergency short stay unit should be handed over in the clinical handover rounds.

Many units function within strict protocol-driven guidelines for admission and care, as well as clear exclusion criteria.

It is useful to have pre-negotiated referral pathways to other inpatient teams in the event of failed discharge planning. This will vary depending on the available resources of each department. Admissions and discharges should be monitored and audited to ensure adequate utilization of the unit with expected discharge rates between 80% and 90% of all patients admitted to the unit.[7,9]

The provision of discharge summaries cannot be overstated. These documents should include salient clinical findings, investigation results and the provisional/final diagnosis, with a clear follow-up plan.

The practical utilization of observation units varies greatly between health services.

The conditions listed below have been studied in more depth to establish safety of care within an emergency observation ward setting[1–5,10–12]:

Conditions requiring observation +/– further investigation after initial review and treatment:

- Undifferentiated abdominal pain
- Syncope

Time-limited intensive treatment:

- Renal colic
- Mild to moderate asthma
- Dehydration as a result of a known cause likely to resolve within 24 hours, i.e. gastroenteritis
- Migrainous headache
- Soft-tissue injuries, i.e. back pain after a fall
- Commencement of therapy that will be continued out of hospital by hospital in the home services, general practitioners or home care nurses (e.g. intravenous antibiotics for cellulitis)

Patients requiring a longer ED stay before a disposition decision can be made:

- Requiring investigations before disposition planning (e.g. clinical decision unit for undifferentiated pain syndromes)
- Postprocedure observation (e.g. lumbar puncture or Bier block)
- Alcohol and drug intoxication
- Minor head injury assessment and observation
- Envenoming requiring a period of investigation and treatment

Patients requiring input from allied health, psychiatric services or where discharge after hours is not appropriate:

- Elderly or other vulnerable patients, to ensure safety for discharge
- Acute situational crisis where patients would benefit from psychiatric input where the risks are low and the patient is likely to go home within 24 hours

Other uses of an observation ward

- Chest pain assessment unit—for low-risk chest pain patients[13,14]
- Toxicology unit—providing care for envenomed patients, acutely poisoned patients not requiring intensive care procedures or after intensive care unit (ICU) admission for a toxicological indication and after intensive care unit (ICU) admission. Such units may be run by clinical toxicologists where present and have been demonstrated to be efficient, particularly in post-ICU care, reducing length of stay in the ICU.[9]
- Psychiatry unit—the need for dedicated areas that facilitate care of the psychiatrically unwell patient are an increasing area of focus. These units may either be low stimulation areas for distressed patients, or secure areas with a strong focus on staff and patient safety. Models of care may either involve

short-term emergency admission, as appropriate under an emergency short stay unit model of care, or a psychiatric assessment and planning unit (PAPU), where governance and care is dictated by the psychiatry unit of the specific hospital.

Emergency staff should be very cautious in using the short stay admission unit for patients allocated to an inpatient bed to create flow in the emergency department. These behaviours result in ineffective use of beds and poor utilization of resources.

Exclusion criteria

Some general themes around exclusion criteria include the following:

Patients who clearly require >24-hour admission:

- Patients who have more than one or complex medical problems, especially the elderly
- Patients without clearly defined treatment plans
- Patients who require intensive nursing care
- Patients who are a heavy nursing load, e.g. those who are immobile, requiring full care with all their activities of daily living (ADLs)
- Patients who are violent, psychotic or disruptive

Some patients are admitted to the emergency short stay unit pending review and opinions from inpatient teams where the expectation is that the patient will be discharged. It is important that inpatient treatment is not delayed unnecessarily.

Efficiency of patient care

The emergency short stay unit is an area of rapid patient turnover within a defined time frame. There are a number of factors that assist with the efficient running of the ward[1–5]:

- Senior clinician input is required for rapid decision making and referral as necessary. Ward rounds and presence of the senior decision maker should not be affected by weekends or public holidays (as may be the case with other inpatient teams).
- Defined clinical pathways and referral process to facilitate patient disposition. This improves and streamlines the referral process. As an example, the management of renal colic should be a straightforward process with analgesia and imaging, and referral to urology as per a pre-agreed protocol.[11] Efficiencies can be gained by negotiation with radiology for a streamlined process for appropriate imaging.
- Access to allied health professionals with the skills and knowledge to provide early interventions and discharge planning is essential. This ensures safe discharge, reduces the number of admissions and can expedite care in the community, especially in the elderly age group. Allied health team members include physiotherapists, occupational therapists, social workers and psychiatry liaison services.
- Nonclinical staff such as ward clerks should strongly be considered. They facilitate patient and family reception and are responsible for clerical and administrative duties related to the unit.

Access to storage, a kitchenette or beverage bay and single rooms for patients with infectious diseases should also be considered as essential elements in the design of an emergency short stay unit. A desk for nursing and medical staff and a general layout similar to an inpatient ward should be considered, including separate shower and toilet facilities for patients.

Ten to 20% of patients in the observation ward will be referred to inpatient teams for admission. This is a key performance indicator in most departments. For this group of patients, it is important to negotiate priority admission to inpatient wards so as not to impact on the efficiency of the ward.

Audit and feedback

As the function of the emergency short stay unit evolves and matures, it is important to have some form of monitoring and auditing process. Some key performance indicators have been established, but it is also important to monitor other measures of quality provision of care. These may include utilization of observation ward beds, adherence to guidelines and patient satisfaction. Examples of key performance indicators include:

- number of observation ward patients transferred to the care of inpatient teams (internationally 10% to 20% is acceptable)
- occupancy rates
- length of stay
- discharge to home rate
- representation rates within 48 hours
- adverse events and outcomes
- complaints

Conclusions

The emergency short stay unit is an integral extension of the emergency department. Its value is in improved clinical decision making and improved flow, especially in an overcrowded emergency department. There is increasing evidence for various discrete conditions where the role of the emergency short stay unit reduces hospital admission rates and length of stay.

Emergency short stay units have taken the role of a defined diagnostic and therapeutic unit with clearly defined measures of quality care.

29.7 Overcrowding

Drew Richardson

ESSENTIALS

1 Overcrowding is the situation where emergency department (ED) function is impeded primarily by the excessive number of patients needing or receiving care.

2 Access block is excessive delay in accessing appropriate inpatient beds and, in Australasia, is defined as the proportion of patients with longer than 8 hours total ED time.

3 Access block is the principal cause of overcrowding but overall demand is also increasing.

4 Although multiple different definitions have been used in studying overcrowding and access block, there is clear evidence that both are associated with diminished quality of care and worse patient outcomes including mortality.

5 Changes to ED structure and function including senior staffing, increased size, fast-track observation units and multidisciplinary discharge procedures can to some extent improve the function of the ED in the face of overcrowding, but do not address the underlying causes and are easily overwhelmed by increasing access block.

6 The causes of overcrowding and hence the solutions lie largely outside the ED and require a hospital-wide response, especially in managing hospital bed stock in such a way that inpatient beds remain available.

Introduction

Wherever human beings gather there are fluctuations in number and, without outside control, numbers occasionally exceed the efficient maximum for a given purpose. Emergency departments (EDs) are designed largely for ongoing flow of patients rather than gathering, but even in systems designed purely for flow (such as roads) there are peaks and troughs of activity and occupancy sometimes exceeds the number able to move safely and smoothly.

Overcrowding to the point of dysfunction has gradually become the norm in Australasian EDs and has been widely reported since the mid-1990s. The greatest contributing factor has been access block, the inability of patients requiring inpatient admission to access appropriate beds in a timely fashion, a phenomenon which is generally called 'boarding' in North America. There has additionally been increase in demand on EDs in both number and complexity of patients resulting from the enlarging, ageing population, the growth in diagnostic and therapeutic choices and changing expectations of medical availability and service. This has not been matched by growth in other services, especially outside office hours, increasing the burden on EDs.

Theoretical basis of overcrowding

Queuing theory indicates that the length of a queue and hence the waiting time to treatment is determined by the arrival rate, the treatment rate and the baulk rate (did not wait to be seen rate, which is usually dependent on the length of the queue). An individual patient's access to emergency care is dependent first on their urgency (assuming the patient is triaged to the correct queue), secondly on the number of similar patients already waiting ahead and thirdly, on the rate and strategy of treatment. Treatment rate is dependent on staffing and on the number of patients already being treated (occupancy), which determines physical availability of resources and the competing demands on staff. On a daily basis, patient flow is significantly dependent on occupancy because even a small decrease in treatment rate has a cumulative effect: it further increases the number waiting ahead of each new arrival.

EDs can be considered as overcrowded when normal pathways of clinical care cannot be followed due to total patient load, that is, the treatment rate is reduced or the treatment quality suffers. Some authorities believe that an ED can be purely overcrowded with patients waiting to be seen while the treatment function remains optimal; others regard this situation as a 'surge'—a subset of disaster medicine, rather than an overcrowding problem.

Definition of overcrowding

The Australasian College for Emergency Medicine (ACEM) defines ED overcrowding[1] as the situation where ED function is impeded primarily because the number of patients waiting to be seen, undergoing assessment and treatment, or waiting for departure exceeds either the physical or the staffing capacity of the ED. Access block is quantified as the proportion of admissions to hospital, transfers to other hospitals and deaths that have a total ED time of greater than 8 hours.[1]

The American College of Emergency Physicians defines crowding[2] as occurring when the identified need for emergency services exceeds available resources for patient care in the ED, hospital, or both, a definition deliberately closer in spirit to that of disaster medicine. Most research on the subject, however, is concerned with the balance between daily fluctuations and ED occupancy, rather than the response to mass-casualty surges.

'Crowding' might be the more descriptive term, but 'overcrowding' is in common use and researchers have used multiple definitions in attempts to quantify the phenomenon. All major recognized definitions incorporate occupancy with patients under treatment, but many also include subjective factors and outcomes, such as ambulance bypass, which are not applicable to all EDs.

Retrospectively identified episodes of overcrowding tend to be reliable for research but are of only strategic significance in ED management. Real-time assessments may be correlated with patient service (number of patients waiting correlates well with waiting time for new arrivals) but are only useful if there is a managerial commitment to intervening. Predictive algorithms based on the number being treated suffer from false positives and again are only justified if interventions exist to prevent deterioration in flow.

Causes of overcrowding

The single most important factor affecting ED overcrowding is the availability of inpatient beds. Bed availability depends not only on the number of physical beds but also on the way the bed stock is managed. Modelling of extensive hospital datasets has identified the importance of

discharge practice, patient complexity and even admission practice at off-peak times to ED flow at peak times. ED overcrowding is best seen as a marker of whole-of-hospital dysfunction which requires a whole-of-hospital response.[3]

Hospitals providing a local service in areas of significant demographic change, such as a large ageing cohort or rapid growth, may experience ED overcrowding simply through the pressure of presenting numbers exceeding appropriate increases in ED capacity. Although locally, hospitals may close when demand falls, overall ED demand continues to increase worldwide at rates well above population growth, reflecting both changing patient expectations and demographics. This will likely be exacerbated among Western cohorts with a large ageing 'baby boomer' population.

Development and adoption of new diagnostic and therapeutic approaches and therapies has contributed to increases in total ED time in some groups. Chest pain 'rule-out' protocols using delayed marker measurements and increasing use of computed tomography (CT) scans for conditions such as abdominal pain are two examples. These are only partly mitigated by shorter, protocol-driven care of other conditions, for example routine CT for minor head injury with immediate discharge after a normal result rather than observation. Substitution of hospital admission by longer ED stays is likely contributing to an increase in ED 'practice intensity' but admission numbers are also rising.

Consequences of overcrowding

Adverse effects of hospital overcrowding have been described since the birth of modern medicine and ED overcrowding has been seen as undesirable since before the recognition of emergency medicine as a specialty. In Australasia, access block was recognized as a quality issue from 1998,[4] first shown to be associated with decreased ED function in 2000, and defined by ACEM from 2002.[1] Worldwide, properly conducted research started in 2001 and, since that time, multiple studies in different centres have found an association between overcrowding and reduced access to care, decreased quality measures and lesser outcomes, including increased subsequent inpatient length of hospital stay. This relationship is robust and applies both to patients who experience delay in obtaining an inpatient bed and to those who present to, or are unlucky enough to already be in, an overcrowded department.

The most important studies are those linking overcrowding with excess patient mortality. The first well-controlled studies were Australian[5,6] and they have been followed by multiple, large, well-designed international studies linking mortality with ED overcrowding in specific disease processes, patients who 'board' in ED, admissions, discharges and in populations served by potentially overcrowded EDs. Demonstration of the link with quality measures, widespread similar results and a dose–response effect have removed any doubt that the relationship between overcrowding and mortality is at least partly causative. There exists good evidence of a degree of reversibility in performance metrics and patient satisfaction when overcrowding is reduced and some evidence of a corresponding reduction in mortality.[7,8]

Strategies to deal with overcrowding

EDs have an obligation to reduce overcrowding and to mitigate its effects. Multiple successful strategies have been described at an individual ED level, although systematic reviews have tended to be critical of the quality of the evidence. There is no doubt that overcrowding can be reduced, but single interventions may not be easily transferrable between different EDs. International experience in system-wide approaches includes the British 4-hour rule, the Western Australian 4-hour rule, the Australian National Emergency Access Target (NEAT, 4 hours) and the New Zealand Shorter Stays in ED target (6 hours). Many of these mandated key performance indicators are no longer enforced or have been modified to form part of a suite of indicators and some hospitals have undertaken interventions without central government funding. It is worth noting that hospital commitment to aiming at such a target appears to have beneficial effects on ED function even if the target is not fully achieved. Targets enforced by jurisdictions (i.e. 'top down') usefully engage hospital management but risk driving a 'target culture' where achieving numerical results is seen as more important than quality of care.

Despite likely publication bias, research from these interventions shows that it is definitely possible to significantly reduce ED overcrowding given the right mixture of incentives.[9] Successful strategies to address overcrowding feature executive leadership involvement, hospital-wide coordination, data-driven management, and performance accountability.[10]

Increases in the number and seniority of ED staff are associated with improvements in process measures and are a widely used initial response to overcrowding. Physical rebuilding is used to increase patient care spaces but changes in flow dynamics are highly dependent on the rest of the hospital. Analysis of flow and system redesign can allow better use of existing resources. Use of senior medical staff earlier in the patient's journey, triage nurse ordering of investigations and streaming of selected patients through a rapid assessment ('fast track') area are all effective interventions in the ED. None of these responses can be used indefinitely if access block keeps increasing.

Evidence is accumulating in favour of hospital enforced 'overcapacity protocols' which distribute the overcrowding burden between ED and inpatient areas. Discretionary, low-complexity presentations by patients who might reasonably be managed elsewhere, often incorrectly called General Practice 'GP-type' patients, constitute a significant number but an insignificant workload in most EDs. Such presentations have a short assessment and treatment time and do not need fixed capacity spaces, such as resuscitation rooms, so their contribution to occupancy with patients under treatment is low. However, being of lower triage urgency their contribution to the number waiting at any given time is relatively high.

Telephone advice services have not been shown to reduce ED workload in Australasia but are highly regarded by the public. Dedicated ED fast-track areas address the management of low-complexity patients in an efficient manner and thus tend to improve overall waiting time performance and staff and patient satisfaction. Their contribution to reducing occupancy with patients under treatment in fixed spaces, and hence improving ambulance offload, is low.

EDs also themselves have a small but significant role in reducing hospital occupancy. Observation medicine within the ED is a useful adjunct or alternative to formal inpatient admission. Multidisciplinary assessment and discharge is effective at reducing representation at least in the elderly.

Conclusions

Overcrowding has changed the nature of emergency medicine practice. Access block represents a useful simple description of overcrowding because the fundamental issue is the availability of inpatient beds. There is a causal relationship between overcrowding and worse patient outcomes including mortality. Emergency physicians have a role to play in maintaining patient care function in the face of overcrowding, but most of the solutions lie outside the ED.

Future research

The relationship between overcrowding and adverse patient outcomes is accepted to be at least partially causal. Large, well-designed studies of hospital- or system-wide interventions to reduce overcrowding, with adequate follow-up to detect improvements in outcome, especially mortality, are now being undertaken and will assist in clarifying barriers and enablers in improving ED overcrowding.

CONTROVERSIES/FUTURE DIRECTIONS

There are medicopolitical, financial and ethical controversies related to ED overcrowding.

- Political dimension: ED overcrowding is the product of hospital overcrowding, that is, lack of available inpatient beds. Hospital overcrowding is likely to continue while hospital funding schemes favour elective surgery over emergency cases and utilization over efficiency. Politically driven funding incentives can improve this situation but sufficiently robust change is not yet widespread.
- Financial dimension: demand for healthcare is effectively unlimited, but demand for current levels of care will grow as the cohort of 'baby boomers' age, meaning significant rationing is inevitable if health spending remains contained. Although EDs have a role to play in reducing admissions, the major change needs to be in increasing early discharges, as the inpatient bed-day is the largest driver of acute hospital costs.
- Ethical dimension: emergency physicians are comfortable with rationing on the basis of need—it is the foundation of the triage system. However, rationing by queuing becomes fundamentally inefficient once the time in the queue starts to approach the time course of the disease. The current institutional culture of the majority of hospital units does not accept rationing of care to ward inpatients even when other patients with clearly greater medical needs are waiting for immediate access. These differences partly reflect ethical conflict between the principles of justice for all patients and beneficence for individual patients.

29.8 Rapid response systems and the emergency department

Julie Considine • Daryl A. Jones

ESSENTIALS

1 **Serious adverse events (SAEs), including cardiac arrest were previously common in hospitalized ward patients.**

2 **SAEs were often preceded by signs of physiological derangement for up to 24 hours prior to the event.**

3 **Rapid response systems (RRSs) are designed to enable early recognition of, and response to, clinical deterioration.**

4 **Three systematic reviews show that RRSs reduce in-hospital cardiac arrests, and one demonstrates a reduction in all-cause hospital mortality for ward patients.**

5 **Increasing literature suggests that patients in the emergency department (ED) can experience clinical instability, which predicts subsequent development of adverse events.**

6 **ED-specific RRSs are a patient safety strategy, particularly given the undiagnosed, unstable and undifferentiated nature of ED patients.**

7 **Future research needs to validate activation criteria and response for an ED-specific RRS, to optimize systems for escalation of care within the ED, and to assess the potential benefits of such a system for deteriorating patients in the ED.**

Introduction and definitions

Predicting and managing the risk of deterioration is fundamental to emergency care. This process commences at the point of initial triage and continues for the duration of the emergency care episode.[1] Over the last three decades, emergency departments (EDs) have developed systematic approaches to the assessment, risk management and clinical care of specific patient groups including trauma, stroke, sepsis and acute coronary syndrome that have improved patient outcomes.[2–6] Rapid response systems (RRSs) are well established for patients who deteriorate on hospital wards. Such systems provide a framework to assist staff in the identification of a deteriorating patient, as well as guidelines for the expected response when deterioration occurs. In Australia, national standards mandate that all acute care facilities have an RRS for the recognition and response to deteriorating ward patients.[7,8] However, a

similar systematic approach for the recognition and response to deteriorating ED patients following their initial triage have only emerged in recent years.[1,9,10]

The term RRS describes an entire system. The major components of RRS are the afferent limb to detect clinical deterioration, an efferent limb (the responding team), and audit and governance limbs.[11] The 'afferent' limb provides clinicians with an objective definition of deterioration, largely based on vital sign derangement or clinician concern (Table 29.8.1). Most RRSs also enable activation for clinician concern, thus allowing RRS activation for deteriorating patients in whom the vital signs are not deranged.[12] The 'efferent' limb describes the structured and expected response to RRS activation. Rapid response teams (RRTs) are composed of staff who manage deteriorating hospital patients with the preventing SAE.[11,13] When the team leader is a doctor, the RRT is called a medical emergency team (MET). A MET should have a number of competencies, including abilities in the following areas[13]:

- prescription of therapies
- advanced airway management skills
- insertion of invasive vascular lines
- commencement of intensive care level of care at the bedside.

Table 29.8.1 Commonly used rapid response system calling criteria[61]

System	*Criteria*
Airway	Stridor
	Threatened airway
Breathing	Acute change in respiratory rate <8 or >30 breaths/min
	Acute change in saturation <90% despite oxygen
	Difficulty breathing
Circulation	Acute change in heart rate <40 or >130 bpm
	Acute change in systolic blood pressure <90 mm Hg
	Uncontrolled chest pain
	Uncontrolled bleeding
Neurology	Acute change in conscious state
	Agitation or delirium
	Seizures
Other	Staff member is worried about the patient
	Uncontrolled pain
	Acute change in urine output to <150 mL in 6 h or >500 mL in 1 h

The most common type of response in Australia is the MET; however, other types of review team include the nurse led RRT and critical-care outreach team, which differ in their staff composition, skill set and mechanism of activation.[13] Additional components of the RRS include quality improvement and clinical governance arms, which permit the audit and evaluation of SAEs and the implementation of hospital-wide strategies to prevent recurrence.[13] Quality systems that enable collection and analysis of RRS data are important to establish 'dose' or frequency of activation, the causes of deterioration and to track patient outcomes.[11]

Principles underlying rapid response system

Historic studies demonstrated that in-hospital cardiac arrest or unplanned intensive care unit admission were often preceded by abnormal physiological signs in the hours before these events. Further, there is a well-documented relationship between abnormal vital signs and mortality.[14–18] The intent of RRSs is to prevent SAEs, and thereby improve patient outcomes by the early recognition of, and response to, deteriorating patients.[19–22] Most Australian health services have a two-tiered RRS comprising the cardiac arrest team (CAT) and the MET. There are now three systematic reviews demonstrating that the introduction of an RRS is associated with a reduction in in-hospital cardiac arrests, and one revealed a reduction in all-cause hospital mortality.[19,20,23] Benefit has been observed for both adult and paediatric patients. The in-hospital mortality of patients who have an RRS review is as high as 34%,[24–26] suggesting that recognition and response to clinical deterioration should occur earlier than RRS review.[27] As a result, a number of Australian health services have added a third 'pre-MET' tier to their RRS, whereby the thresholds for escalation of care are lower and care is escalated to the parent unit.[28,29]

Clinical deterioration in emergency department patients

The epidemiology of clinical deterioration in ED patients is an area of developing knowledge. Approximately 20% to 25% of ED patients exhibit one of more abnormal vital signs during ED care.[30,31] Between 1.5% and 23% of ED patients experience clinical deterioration that fulfils ED-specific or hospital-wide RRS activation criteria at some stage during their ED care.[9,10,30,32–34] By way of contrast, one or more abnormal observations are reported at any point in time in 3% to 14% of ward patients.[15,35–38] It may be expected that a considerable number of ED patients will have vital sign abnormalities by virtue of the fact their illness or injury has resulted in ED attendance. There are 7.8 million attendances to Australian EDs annually[39]: if 1.5% to 23% of ED patients have abnormal vital signs, as many as 1.8 million ED attendances may have physiological abnormalities making physiological instability an issue of significant concern.

Interpreting the results of studies of ED patient deterioration has been challenging in part due to the variable patient populations included: all ED patients in treatment spaces (so excluding waiting room patients)[33]; patients with specific presenting complaints (abdominal pain, chest pain, shortness of breath and febrile illness)[9,30]; and patients in general treatment areas of the ED (so excluding patients in resuscitation and fast track areas).[32] Recent Australian studies show that the most common vital sign derangements fulfilling hospital MET criteria during ED care are tachypnoea, tachycardia and hypotension.[9,10,30,32,34]

Abnormal vital signs during emergency department care and patient outcomes

Several studies have investigated the relationship between physiological status in the ED and patient outcomes. There is evidence that vital sign abnormalities present during ED care increases the risk of hospital admission,[40] in-hospital death,[40,41] the need for critical care admission[41] and RRS calls in the early stages of hospital admission.[34,42]

In-hospital mortality

A number of studies have shown that ED hypoxaemia,[31] hypotension,[31,40,43,44] tachypnoea[31,40] and altered conscious state[31,40] are predictive of in-hospital mortality. Vital sign predictors of hospital admission in ED patients include systolic blood pressure ≤100 mm Hg, pulse rate >130 beats per minute, respiratory rate >30 breaths per minute, temperature >38.5°C and altered conscious state.[40]

Hospital admission

Experienced clinicians can accurately identify the need for hospital admission in ED patients from the point of triage,[45,46] and early warning scores also have predictive value in determining the need for hospital admission, particularly during the ED episode of care. Burch et al.[40] showed that an increased Modified Early Warning Score (MEWS) score was associated with higher rates of hospital admission in medical patients, so MEWS may be used to identify

medical patients who require hospital admission and who are at increased risk of hospital death. Similarly, Groarke et al.[41] examined the predictive value of an EWS calculated on hospital presentation in medical patients. For each increase in score category, there was increased risk of intensive care unit (ICU) admission, critical care unit (CCU) admission, death and hospital length of stay.[41] Groarke et al.[41] concluded that the early warning score is a potential triage tool for ED medical patients and that improved serial early warning score (EWS) within 4 hours of hospital presentation may be used to predict clinical outcomes.

Intensive care unit admission

Clinical factors evident on ED arrival predictive of critical care admission (ICU and CCU) in patients triaged as low-to-moderate acuity were chief complaints of nausea, vomiting and diarrhoea on ED arrival; heart rate or temperature abnormalities at triage; and respiratory rate or heart rate abnormalities at first ED nursing assessment.[47] Tachypnoea,[48] hypoxaemia, tachycardia and altered conscious state during ED care also have been shown to predict ICU admission from the ED.[31] In patients with sepsis, respiratory compromise, systolic blood pressure <100 mm Hg and heart rate >90 beats per minute were the vital sign derangements present in ED that were predictive of ICU admission.[49] Known predictors of unplanned ICU admission in patients admitted to hospital wards through the ED are older age, male sex, higher acuity triage category and a history of comorbid conditions.[50] Further, diagnostic groups associated with higher incidence of unplanned ICU admission included sepsis, acute renal failure, lymphatic–haematopoietic tissue neoplasms, pneumonia, chronic obstructive pulmonary disease and bowel obstruction.[50]

The association between emergency department instability in hospital ward rapid response team review

As many as one-quarter of hospital-wide RRT or CAT activations occur among patients admitted to medical or surgical wards via the ED during the first 24 hours of emergency admission[51] and up to half of RRT activations occurring in the first 24 hours of emergency admission occurred in the first 8 hours.[52] Tachypnoea or hypotension fulfilling hospital RRS activation during ED care was associated with an increased risk of RRS activation on the wards within 72 hours of admission, and a subsequent increase in-hospital deaths, unexpected in-hospital deaths, ICU admissions and longer length of hospital stay.[34] ED patients who had an RRS activation within 24 hours of admission to the ward were more likely to have respiratory rate abnormalities at triage, and heart rate abnormalities in the ED prior to ward transfer.[42] Patients who experience an RRS call within the first 24 hours of admission also have higher in-hospital mortality than patients who did not have an RRS call (21% vs 6%, $P = .0003$).[42]

The results of these studies demonstrate relationships between mortality and morbidity and ED patient characteristics; physiological abnormalities present on ED arrival; or physiological abnormalities that occur during ED care, and may be used to inform ED systems for recognition of, and response to deteriorating ED patients. Further, parameters currently absent from inpatient MET criteria, such as advanced age and temperature abnormalities, have been linked to critical-care admission and death, and therefore may have a place in the increasing recognition of deteriorating ED patients and warrant further investigation.[47,53]

Table 29.8.2 Similarities and differences between medical emergency team services and trauma teams

Variable	*Trauma team*	*MET*
Location of patient	Emergency department or trauma centre	Hospital ward
Team leader	Typically the emergency department doctor	Typically the intensive care unit registrar
Patient profile	Young with few co-morbidities	Elderly with multiple co-morbidities
Presenting problem	Trauma	Hypoxia, hypotension and tachycardia
Need for early intervention	Concept of 'golden hour'	Shown for sepsis, myocardial ischaemia, stroke

MET, Medical emergency team.

The case for more structured recognition and response to emergency department deterioration

The ideal response to deteriorating ED patients is unknown and for many deteriorating patients, the ED response will be appropriate, but can be clinician and ED dependent. However, the advantages of a structured and consistent approach to escalation of care include the further development of already positive multidisciplinary relationships and enhanced inter-professional communication, particularly for new or transient ED staff.[1,54] A systematic and ED-led approach to recognizing and responding to deteriorating ED patients is a logical progression, building on other patient safety systems, such as triage and systematized approaches to ED care of critically ill or injured patients (Table 29.8.2). There is a need to further develop and test ED-specific approaches to improve the sequential detection, recognition and timely escalation of care for all patients located in the ED (including boarding inpatients) who have deteriorated after initial triage and assessment.[1,54]

Emergency-department-based rapid response systems

One of the tenets underlying the MET principle is that early intervention in the course of critical illness is associated with improved outcome. This observation also has been made in ED patients suffering trauma,[2,55] acute coronary syndrome,[4,56] sepsis[3] and stroke.[5,6] The MET was originally described in 1995 when Lee et al. reported the introduction of a MET service into Liverpool Hospital in Sydney, Australia.[57] In the original description of the MET system, the ED was one of the hospital areas serviced by the MET and, in fact, was the area that attracted the highest number of MET activations. MET was modelled on rapid detection and correction of abnormal vital signs that were occurring with trauma teams in that era.[57] Although EDs have the capability to manage deteriorating patients, the principles of the MET system can be locally adapted within EDs, to enhance the recognition and response to deteriorating patients. Local systems should ensure that there is:

1. a common definition of deteriorating patients, so deterioration is recognized by even the most inexperienced doctor or nurse and they know when to escalate care;
2. a clear process of escalation of care to senior medical and nursing staff that is robust and consistent and not dependent on how confident the clinician identifying deterioration feels to escalate care, or the characteristics of the clinicians to whom care will be escalated (typically the nurse in charge and the emergency physician); and
3. an expected response when care is escalated, in terms of who will respond and in what time frame.

If the ED is functional and well-staffed, then these things should happen as a matter

of course. However, if the ED is not functional due to poor staffing, access block or overcrowding, the risk of unrecognized, unreported or under-treated deterioration increases, so a safety net for patients becomes more important. As highlighted above, coordinated teamwork and early interventions have been shown to improve outcomes in patients with specific clinical problems where the clinical diagnosis is rapidly determined and algorithmic- or guideline-based therapies exist.

One Australian ED-specific RRS model is a single trigger approach with escalation of care to the emergency physician and nurse in charge to ensure timely review of the patient by senior personnel and mobilization of ED resources as required by personnel who have a global overview of ED activity.[10] This model resulted in two to three early warning system activations per day, so it did not overburden ED clinicians and simple interventions (e.g. intravenous fluids and supplemental oxygen), and restored physiological normality in most patients within 1 hour.[10] This study highlights that local ED-specific systems have patient safety benefits and can ensure that senior ED medical staff are notified of deteriorating patients in a timely manner. Although there are many senior medical and nursing staff in EDs who can accurately identify the deteriorating patient, they need to see and examine the patient. Structured and consistent systems are particularly important if patients are cared for by less experienced nursing and medical staff who are working in areas of the ED that are geographically separate, or have only intermittent input by senior clinicians. This same model also showed that nurses were well placed to identify deteriorating patients and to rapidly escalate care within 5 minutes[10]; the incidence of unreported clinical deterioration decreased from 86.7% to 54.0% in the first 4 years of its implementation.[9]

A recent study of systems for recognition and response to clinical deterioration in Victorian EDs showed that of the 16 participating EDs, 14 had an ED RRS.[54] Of the EDs with an RRS in place, 8 had one tier, single-trigger RRS and 5 had a two-tier, single-trigger RRS. There was variability in the activation criteria, but at 11 sites the ED RRS activation criteria were the same as ward MET activation criteria. Also, there was some variability in the members of the responding team: the ED RRT was composed of ED-specific staff at 8 sites, staff external to the ED responded at 2 sites and the remaining 4 sites did not have a predetermined responding team. Two-thirds of sites ($n = 11$) collected data regarding the clinical deterioration of ED patients.[54]

Future developments

There is now level 1 evidence for the effectiveness of RRSs, and such systems have been introduced into thousands of hospitals worldwide to manage deteriorating ward patients. RRSs are an integral component of The Australian National Safety and Quality Health Service Standards.[8] For these reasons, it is unlikely that further randomized controlled trials will be conducted to assess the effectiveness of METs in improving the outcome of acutely unwell hospitalized patients, including those located in the ED.

The most important questions that need addressing regarding RRS for both ED and ward patients in the near future include:

- Why do patients need RRS calls? (Clinical, disease state and system factors.)
- What is the outcome of RRS calls?
- What are barriers to RRS activation?
- How can RRS be most effectively used to review patients most likely to benefit from RRS service intervention?

From an ED perspective, there is also a need to better quantify the point prevalence and consequences of clinical instability and to validate ED-specific activation criteria.

CONTROVERSIES

There are a number of actual or potential controversies that have arisen from the implementation of RRS on hospital wards. How these controversies will play out as EDs implement RRS is yet to be understood. There have been claims that RRS carry a risk of deskilling ward medical and nursing staff; however, to date, there is no evidence to support this contention.[58,59] It has also been proposed that RRS result in inappropriate patient management because the MET is unfamiliar with the patient, and communication failures are a leading cause of adverse events in health care.[8] Most ward RRS require the involvement of the parent unit; however, this issue is a challenge for EDs when a boarding admitted patient deteriorates in the ED. Commonly the ED team will respond to ensure the patient is safe but how and when to involve parent units in managing the acute deterioration of their patients located in the ED is an area requiring further development. There are concerns about resourcing, and that RRS divert critical care staff from their usual duties; these concerns are valid for both ward and ED RRS responders. There needs to be a balance between patient safety and early recognition and response to clinical deterioration, and managing the burden and cognitive load on already overworked clinicians.[1] There is also considerable literature reporting that up to one-third of ward patients have end-of-life care issues during the RRT call.[60] It has been suggested that clinicians on the ward may not reliably recognize the fact that some in-hospital patients are at risk of dying during that admission. Further work is needed to improve advance care planning to reduce the administration of non-beneficial therapies to hospitalized patients, and to provide optimal conditions for a comfortable and dignified death.

29.9 Public health and emergency medicine

Diana Egerton-Warburton • Jennie Hutton • Peter Aitken • Hilary Tyler

ESSENTIALS

1 **Public health is a key component of a sustainable health system.**

2 **Emergency medicine has a mandate to advocate for public health initiatives.**

3 **Acute health care has limited opportunity to affect health care outcomes compared to public health.**

4 **Screening, brief intervention and referral for treatment are the cornerstone of emergency department (ED) prevention.**

5 **Disease and injury surveillance is an important function for emergency departments including identification of emerging infectious diseases.**

6 **Emergency medicine can take a leadership role in highlighting and addressing socially determined health inequalities, particularly the health care gap of indigenous and other vulnerable populations.**

7 **EDs can improve health care outcome and experience for Indigenous patients by increasing the cultural competency and safety of their staff.**

Introduction

Public health (PH) is an organized attempt by society to ensure a healthy population. It is recognized as key to a sustainable and effective health care system. The UN Universal Declaration of Human Rights (1948) states that all people are equally entitled to good health and decent living conditions and it is this humanistic ideal that drives much of PH.

Emergency medicine (EM) is an important but is an under-recognized and -utilized player in PH. While at first glance it may appear non-core to EM, PH and EM interact over a number of domains. These include disease surveillance, health care access, disease and injury prevention and advocacy. The International Federation for Emergency Medicine provides a clear mandate for PH in its definition of EM as: 'A field of practice based on the knowledge and skills required for the prevention, diagnosis and management of acute and urgent aspects of illness and injury'.

Emergency departments (EDs) in Australia and New Zealand see over 8.7 million attendances annually. This population is receptive to PH intervention in a concept described as the 'teachable moment'. This has been described as a brief opportunity to intervene to change behaviour. This is particularly pertinent when patients present as a consequence of risky health behaviour. The large majority of emergency physicians (EP) see PH as part of their role as a health care advocate and ED clinician.[1] PH intervention in the ED setting is challenging. EDs have limited resources and strive to provide safe and timely acute care. PH roles may be seen as simply adding to the burden.[1]

Increasingly, the social determinants of health affect individuals' opportunity to have a healthy life. Examples include access to safe and affordable housing, education and exposure to violence. Many ED patients have poor social determinants and limited access to alternate health care options. EM should, through its surveillance and advocacy role, help to highlight and address these issues at a community and policy level. Social and environmental factors can be influenced by advocacy both at a local and national level. EP and the Australian College of Emergency Medicine (ACEM) are credible and persuasive health care advocates to provide effective PH and policy messages.

Disease and injury surveillance

EDs play an ongoing and pivotal role in injury prevention through surveillance. ED surveillance plays an important role in injury campaigns, such as alcohol harm, child drowning and road safety. With regard to alcohol harm, EM has advocated for changes to access to alcohol though 'early closing', sport sponsorship and drink driving legislation.

Based upon figures from the World Health Organization, the health profile of many countries is changing. The burden of non-communicable diseases has risen and will increase further with ageing populations.

The Australian Institute of Health and Welfare, Australian Burden of Disease Study 2011,[2] found that cancer, cardiovascular diseases, mental and substance use disorders, musculoskeletal conditions and injuries account for almost two-thirds of all disease burden.

Almost one-third of the total burden of disease could be prevented by addressing modifiable risk factors including: tobacco use, high body mass, alcohol use, physical inactivity and high blood pressure.

Emerging infectious diseases (EID) are increasing and becoming a significant burden on global economies and health.[3] The Institute of Medicine defines EID as: 'infections whose incidence in humans has increased within the past two decades or whose incidence threatens to increase in the near future'. These may be new pathogens, such as severe acute respiratory syndrome (SARS) or bat viruses; old pathogens expanding in range and incidence, such as dengue or Ebola; and multidrug-resistant tuberculosis strains. The majority of EID originates in wildlife and is correlated with socioeconomic, environmental and ecological factors.[3] Increasing temperatures, associated with climate change, may contribute to malaria and dengue extending to more temperate zones.[4]

Increased global travel, coupled with the incubation periods of some diseases, such as SARS (2 to 10 days) or avian influenza (2 to 10 days), also means travellers may not become ill until returning home. Monitoring increases in ED visits for key 'chief complaints' has been shown to provide timely indicators for outbreaks, and ED staff should be aware of EIDs and what tests to request. They should be suspected in patients aged up to 49 years, those with life-threatening illness of potentially infectious aetiology and with no cause for illness identified by preliminary testing.[5]

Both screening and diagnostic tests are needed. Screening tests help detect a disease early, often in relatively asymptomatic patients. They are sensitive but often less specific. Screening tests correctly identify those individuals who may have a given disease but often require more specific diagnostic testing to confirm or exclude this.

The ED is part of a system with integrated management and communication strategies needed rapidly to identify EID. Collaboration

needs to occur locally, regionally, nationally and globally as well as between the ED and multiple disciplines.

Disease prevention and control

EDs are overcrowded and resources scarce, we are challenged to deliver the principal role of acute care. However, ED patients are often those that most need to be targeted for preventive measures and are least able to access it by other means. These populations include the homeless, people on low incomes, people living with a disability, people with mental illness, refugees, migrants and Indigenous populations. These populations may also have poor health literacy.

There is a growing body of evidence that can guide us as to the optimum way to target our time and resources in the ED setting to deliver effective, efficient preventive care. Bernstein suggests that any intervention should be considered by asking the following questions.[6] Is the PH purpose clear? Is the screening appropriate and accurate? Will the intervention be effective and is this the best approach? The intervention needs to be rigorously assessed.

Prevention in the ED setting can be divided into primary, secondary and tertiary measures. Primary prevention involves intervention in a population prior to illness occurring. In the ED, this would include the routine vaccination of patients with the tetanus immunization and post-exposure prophylaxis for diseases such as HIV.

Secondary prevention involves an intervention in an at-risk population, early in the course of the disease. A good example in the emergency setting is that of screening for alcohol harm.

Tertiary prevention involves an intervention in a population that is at risk and has experienced a resulting illness. This is treating an established disease which is core EM practice.

Screening, brief intervention and referral for treatment

Screening, brief intervention and referral for treatment (SBIRT) has been described as the cornerstone of EM preventive care. There is some evidence that supports the use of SBIRT in the ED in family violence, risky alcohol use and smoking cessation. Much of this evidence comes from North America.[7]

Traditionally, the methods used for SBIRT include paper-based, computer questionnaire, video and a computer-based intervention. Innovations including the use of new technology and social media, will provide many opportunities.

SBIRT need not be resource intensive for EDs, but additional resources are required to make them sustainable.[7] Both the setting and the provider of the prevention activity may vary. It can occur at any opportune time in the patient's journey though the ED and by all health workers in the ED.

The cost to Australian society of alcohol, tobacco and other drug misuse in 2004–05 was estimated at $56.1 billion, including costs to the health and hospital system, lost workplace productivity, road crashes and crime. Of this, tobacco accounted for $31.5 billion (56.2%), alcohol accounted for $15.3 billion (27.3%) and illegal drugs $8.2 billion (14.6%).[8]

The act of quitting smoking involves five stages of which a number can occur in an ED. A single physician encounter results in 2% of patients quitting. Routine physician screening and counselling may increase cessation from 3% (usual care) to 8% to 11% at 6 to 12 months.[9] Smoking cessation interventions are more cost effective than other interventions, such as treatment of blood pressure or cholesterol and Pap smears. In one investigation, it was found that EPs were likely to gather information about smoking but not to counsel or educate patients to quit; 56% of discussions with current smokers contained advice to quit; 16% an assessment of readiness to quit; and only 13% a referral to quit. Smoking was more likely to be discussed when the patient presented with a smoking-associated condition.[9] Smoking interventions in the ED, even if low efficiency, will have high reach due to the absolute number of smokers attending. This results in a high impact intervention, which is cost effective.

Almost 1 in 10 Australian and New Zealand ED presentations are alcohol related. This equates to more than half a million ED attendances every year in Australia alone.[10] Alcohol related presentations are more likely to be male, high acuity and arrive by ambulance or correctional services than non-alcohol-related presentations.

Alcohol-related occupational violence and aggression is common in the ED, with a survey of ED clinicians indicating that 9 out of 10 have experienced it in the last year.

EDs are well placed to recognize patients with both binge and chronic drinking problems. Validated screening tools can be used. The general efficacy of brief alcohol interventions in these settings has been recognized, although the evidence has been mixed.[7] The effectiveness of brief interventions varies with patient populations and treatment contexts.[7] Ultra-brief interventions that take less than 10 minutes to perform or that are technology driven and allow patients to self-administer, have been demonstrated to have a small effect size on reducing alcohol consumption. This type intervention may overcome some of the feasibility issues for use in the ED and may have a measurable population affect given the number of alcohol-related presentations.

Many ED-based SBIRT are disease or risk behaviour focused rather than patient centred. They fail to recognize that many risk behaviours interact and are synergistic. They also have limited capacity to consider health literacy and social and cultural determinants of health. Thus, paradoxically, the most vulnerable populations may be least likely to benefit from them. For example, a smoking intervention is not likely to be effective in a person with low health literacy and alcohol dependence. While a role exists for simple effective interventions, future research should be patient centred and take into consideration the social and cultural context. More rigorous multicentred research is required in the Australasian context to determine the effective of SBIRT before widespread introduction can be recommended.

Health of Indigenous people and cultural safety

The first peoples of Australia and New Zealand have not fared well from the respective colonisation and this is apparent from their health status. The Australian Institute of Health and Welfare emphasises the benefits from connections to culture and country. Overall, Australia's Aboriginal and Torres Strait Islander people have poor health outcomes, resulting from limited access to resources such as adequate housing, education, employment, municipal infrastructure, health services and an enforced dismantling of cultural practice and community governance. Low socioeconomic status has been estimated to account for one-third to one-half of the gap in life expectancy between Indigenous and non-Indigenous Australians. Many chronic diseases are the direct result of overcrowding and poverty. Recurrent streptococcal skin infections resulting in renal disease occurring at an early age is the direct result of poor living conditions. The risk and severity of type II diabetes is a consequence of limited access to affordable healthy food. Issues of alcoholism can be linked to dislocation, homelessness, experiences of racism and despair. Aboriginal people living in poverty often access health care infrequently. Although many co-morbidities may appear to be peripheral to the prime reason for attendance, an opportunistic approach with this group of people can have long-term health benefits.

Addressing issues of cultural safety and competency in EDs in Australia and New Zealand has the potential to improve health care and thus outcomes. EDs can improve their service for Indigenous patients by increasing the cultural competency of their staff, ensuring that barriers for Indigenous patients accessing EDs are minimized and that environments are culturally appropriate, employing Indigenous

staff including Indigenous health workers and Indigenous liaison officers, and developing networks with Indigenous health services.

Australian Indigenous Aboriginal and Torres Strait Islanders

According to the Australian Bureau of Statistics, in 2014–16 the median age of death for Indigenous Australians was 58.8 years, compared to 82 years for non-Indigenous Australians. While there has been a decline in mortality rates for both Indigenous and non-Indigenous Australians since 1998, there has been no significant change in the gap. Chronic diseases are responsible for 64% of the total disease burden for Indigenous Australians, with an onset at an earlier age compared to non-Indigenous Australians. Cardiovascular, respiratory, chronic renal disease and diabetes are common and often present in Indigenous patients presenting to EDs. Infectious diseases, including tuberculosis, hepatitis and sexually transmitted diseases including HIV/AIDS are common.

Mental health and substance use disorders combined are the leading cause of disease burden for Indigenous Australians. Overall, fewer Aboriginal and Torres Strait Island people drink alcohol than non-Aboriginal people; however, of those who do drink, more of them drink at harmful levels.[11] Injury is the second leading cause of disease burden in Indigenous Australians, with (in order) suicide and self-harm, road traffic accidents, and homicide and violence accounting for more than 50%. Diseases of poverty and overcrowding, such as rheumatic fever, post-streptococcal glomerulonephritis and childhood bronchiectasis, have reported rates in Indigenous Australians amongst the highest in the world, and need to be part of differential diagnoses.

New Zealand's Indigenous Māori people

New Zealand government figures suggest that while Māori health has improved over the last decade, serious disparities exist in comparison to non-Māori. Life expectancy for Māori people has improved and the gap is narrowing; however, it is still not level with non-Māori in New Zealand (gap 7.1 years in 2012–14). Cardiovascular disease is the leading cause of mortality for Māori, with rates twice those of non-Māori. Māori and non-Māori have twice the rate of self-reported diabetes prevalence, but there are concerning disparities in developing complications, such as renal failure (five times) and lower limb amputation (three times). Māori cancer mortality rates are 1.5 times higher than that of non-Māori. Smoking rates are three times higher in this population with an estimated 42% of Māori adults smoking. Māori and non-Māori adults are equally likely to have consumed alcohol in the last year; they are twice as likely to consume large quantities and put themselves at risk of acute harm. While engaging in physical activity is similar between Māori and non-Māori, Māori adults were more than 1.5 times as likely to be obese. The problem is worse in Māori children, being twice as likely to be obese compared to non-Māori.

New Zealand has moved to a focus on reducing inequality across all ethnicities by addressing the issues and barriers, and by placing cultural safety training high in health workforce priorities. Sir Mason Durie[10] gives wise guidance on the three principles that can be gained from the New Zealand experience and applied in Australia: integrated solutions, indigenous pathways and empowering relationships

Cultural safety and competency

To be able to have a positive impact on health status, practitioners working in Australasian EDs must be able to work in a culturally safe manner. This requires an understanding of the social, political, historical and cultural influences on the health of indigenous people.

While indigenous cultures are diverse, themes such as the importance of customary law, the extended family and kinship obligations; the notion of reciprocity and a differing worldview are common. Identity is complex and it is essential that ED staff do not perpetuate notions of racial percentage and skin colour as determinants of someone's identity.

It is critical for health professionals to understand and acknowledge the existence of racism and how it has affected the health of Indigenous people.

Cultural competence is 'a set of behaviours and attitudes and a culture within business or system that respects and takes into account the person's cultural background, cultural beliefs and their values and incorporates them in the way health care is delivered to that individual'.[13]

Cultural safety is defined as a way of practicing; it is importantly measured from the patient's perspective and is when the health professional undertakes a process of reflection on their own cultural identity and recognises the impact of that culture on their professional practice. Unsafe cultural practice is any action that diminishes, demeans or disempowers the cultural identity and well-being of an individual.[14] A culturally safe health professional is one who knows what culture is, values their own culture, reflects on the interface between power and practice and acts to change unequal power relationships.

The ACEM has developed a set of educational tools and resources to enhance culturally competent communication and overall care for Aboriginal and Torres Strait Islander patients in the ED.

CONTROVERSIES/EMERGING ISSUES

- New technologies and social media provide new opportunities in preventive health initiatives in the ED.
- SBIRT should be rigorously evaluated prior to introduction.
- PH interventions in the ED will require additional resources in order to be feasible and sustainable.
- Smoking cessation and addressing risky alcohol use are priorities for EM.
- Developing cultural competency and practising in a cultural safe manner is vital for EPs.

SECTION 30 ADMINISTRATION

Edited by *Peter Cameron*

30.1 Emergency department staffing

Julie Considine • Sue Ieraci

ESSENTIALS

1 **An emergency department staff structure that is appropriate in numbers and skill mix is required to provide high-quality and timely clinical care, while maintaining sustainable working conditions for staff.**

2 **Senior medical and nursing staff have clinical roles that include direct patient care, as well as supervision and teaching of junior staff, coordination of patient flow and liaison with other clinicians.**

3 **The senior clinical staff profile should provide protected time for administrative, educational and research roles.**

4 **In calculating the staff numbers required, it is essential to consider not only the hours of extent of senior cover required, but also the volume of the direct clinical and clinical support workload.**

5 **Precise numbers and types of staff required depend on individual and institutional work practices and hospital roles.**

General principles

There are over 7.8 million attendances to Australian emergency departments (EDs) each year.[1] Patients requiring emergency care have the right to timely care by skilled staff. The aim of staffing an ED is ultimately to provide safe, high-quality emergency care in an acceptable time according to the patient's clinical urgency (triage category). Staff working in the ED also have the right to safe and manageable working conditions and reasonable job satisfaction.

As the activity of an ED fluctuates in both volume and acuity, a threshold level of staffing and resources is required in order to be prepared for likely influxes of patients. In addition, the staffing number and mix needs to take into account the important teaching role of EDs.

The precise numbers and designation of medical, nursing, allied health and other staff employed will be determined by the local work practices (which tasks are carried out and by whom). This chapter discusses staffing requirements under the current Australasian model of ED work practices. This includes a major supervisory and teaching role for consultants and a significant proportion of specialist trainees and junior medical staff in the medical workforce, with a range of tasks, including venipuncture, test requisitioning and documentation. In addition, roles are expanding into wider realms, such as toxicology, ultrasound and academic and observation medicine. Emergency nursing roles are focused on patient assessment, initiation of interventions and investigations, monitoring the response to therapies, escalation of care if required, and prevention of complications. In addition, there are a number of advanced practice roles for emergency nurses that include the initiation of tests and treatment, and emergency nurse practitioners who can independently manage the patient's episode of ED care.

Estimating medical workload

ED case mix and costing studies have sought to measure the medical time commitment for various clinical conditions. In addition, various

reviews have explored models of medical staffing based on factors such as ED activity and complexity of care.[2–4]

The following general principles apply:

- The direct clinical workload can then be calculated from census data, modified by other descriptors such as measures of acuity and complexity and local models of care.
- The workforce should be resourced and organized so that patients are treated within the benchmark times for their clinical acuity (triage category), as well as meeting standards for quality and safety. The Australasian College for Emergency Medicine (ACEM) has defined benchmarks for waiting time by triage category.[5,6]
- In addition to matching direct clinical care needs, staffing models should also provide for the various clinical and clinical support medical roles that supplement direct patient care (as outlined below).

Structure of medical staff

The medical workforce of Australasian EDs currently includes the following categories:

- consultants (specialist emergency physicians), including a medical director and Director of Emergency Medicine Training
- emergency medicine trainees (both advanced and basic)
- senior non-specialist staff: experienced hospital medical officers
- junior medical staff: interns and resident medical officers who have not yet started specialty training.

The specialist practice of emergency medicine includes clinical support roles (including departmental management and administration, planning, education, research and medico-political activities) as well as clinical roles. The clinical support workload of an individual department varies with its size and role, the structure of its staffing and the other management systems within the institution. For senior staff, clinical work generally includes the coordination of patient flow, bed management and supervision, and bedside teaching of junior staff in addition to direct patient care. Some emergency physicians may have other particular roles, such as retrieval and hyperbaric medicine or toxicology services. The increasing number of academic staff may have major research and teaching commitments. To cover these roles, the ACEM recommends 30% clinical support time for consultants (more for directors of departments and directors of emergency medicine training) and 15% clinical support time for registrars.

Throughout Australasia, EDs are experiencing increasing levels of activity. The calculation of medical staff numbers required for a particular department must include not only the extent of consultant cover required, but also the clinical workload and performance, local work practices and the nature of clinical and clinical support roles. Because of variations in roles and work practices between sites, it is not possible to devise a staffing profile that is universally appropriate. Other recent changes in staffing patterns include employment across a network, increasing part-time work and sessional contract arrangements. Many emergency physicians are diversifying their practice profile to achieve a balanced and sustainable career, combining salaried and contract work, different types of hospitals and part-time work with a range of other interests.

Estimating nursing workload

Australia has been a world leader in nurse staffing and the legislation of Nurse-to-Patient Ratios, which are now in place in a number of states. The Nurse-to-Patient Ratios started in Victoria in 2000 have most recently been introduced in Queensland in 2016[7,8] but not all Australian States have these ratios. ED Nurse-to-Patient Ratios are typically one nurse for every three treatment areas plus the nurse in charge of the shift and triage nurse(s). It is then up to the ED Nurse Manager to configure those staff: enabling 1:1 Nurse-to-Patient Ratios in areas like the resuscitation cubicles may then mean that nurses working in lower acuity areas of the ED will care for more patients. Additionally, a minimum skill mix is required to manage the acute and complex workload. In addition to the bedside nursing workload, there are requirements to provide for education and training, patient flow, and both clinical and departmental administrative roles.

Nurse staffing structure

In Australia, there are three levels of nurses registered with the Australian Health Professionals Regulation Agency:

- enrolled nurses
- registered nurses
- nurse practitioners.

Enrolled nurses work under the supervision of registered nurses and their scope of practice is generally limited to general adult or paediatric areas. Current practice standards do not enable enrolled nurses to be supervised or delegated to by medical officers. One of the major changes to enrolled nurse scope of practice in recent years is their ability to administer medications, and all enrolled nurses graduating since 2015 may administer oral or parenteral (including intravenous) medications. The majority of nurses working in EDs are registered nurses who have completed a 3-year bachelor degree typically followed by a 12-month graduate nurse programme. In many states, 6 to 12 months transition programmes to specialty practice in emergency nursing are offered to nurses wishing to pursue a career in emergency nursing, and are often a precursor to postgraduate studies in emergency nursing. Australian emergency nurses have one of the highest standards of education worldwide with the majority holding a graduate certificate or graduate diploma in emergency nursing. Postgraduate qualifications are the industry standard for complex emergency nursing roles, such as resuscitation and triage. Triage assessment is a nursing role in Australia and emergency nurses are often responsible for advanced patient assessment, initiation of investigations and symptom relief care prior to medical assessment. Emergency nurses are also primarily responsible for ongoing surveillance and escalation of care in the event of deterioration. Advanced emergency nursing roles for postgraduate qualified emergency nurses are widespread in Australia, and nurse-initiated pathology, x-rays and analgesia are among common examples. There are also a number of master's and PhD prepared emergency nurses in Australia working in various advanced clinical roles, joint clinical–academic appointments, nursing education and nursing management.

At the time of writing, there were over 1500 endorsed nurse practitioners in Australia, and emergency nursing has the largest cohort of nurse practitioners.[9] In Australia, to be endorsed as a nurse practitioner, nurses must complete a clinically based master's degree or a specific nurse practitioner master's degree, demonstrate experience in advanced nursing practice in a clinical leadership role in emergency nursing and have undertaken an approved course of study for prescribing scheduled medicines as determined by the Nursing and Midwifery Board of Australia. Nurse practitioners form a key workforce strategy in managing demand for emergency care and are able independently to manage specific patient groups within their defined scope of practice, including prescribing medications, ordering diagnostic tests, referring to specialists and discharging patients home. Published research shows that emergency nurse practitioners can provide safe, efficient and timely care, and are valuable members of the ED team.[10,11]

Allied health, clerical and other support staff

Allied health, clerical and other ancillary staff are essential to the efficient provision of

ED services. Clerical staff have a crucial role encompassing reception, registration, data entry and communications within and outside the department, as well as the maintenance of medical records. Dedicated allied staff, including therapists and social workers, are important in providing thorough assessment and management of patients, including participating in disposition decisions and discharge support. Other staff, such as porters and ward assistants, play an important role in releasing clinical staff from clinical support roles as well as movement of patients within and beyond the ED.

Optimizing work practices

Traditional hospital work practices involve systems and tasks that are inefficient for the smooth running of modern, busy EDs. In a work environment with a rapid patient throughput and large numbers of staff, efficient work practices are crucial in optimizing clinical performance as well as job satisfaction. A review of staff numbers and seniority cannot provide maximum benefit without consideration of how work practices are managed, which tasks are performed and by whom.

A review of ED work practices can encompass the following principles:

- re-allocation or deletion of inefficient tasks
- optimal use of the specific skills of all staff
- use of communication technology and data systems.

As the ED workforce develops greater seniority and specialization, and the demands of patient care increase, it is no longer possible to justify outdated work practices. Local research has shown that it is possible to improve clinical service provision by reorganizing roles and tasks in a sustainable way.[12–14] The opportunity exists to create a work environment that both delivers good clinical service and is rewarding and satisfying for staff.

CONTROVERSIES AND FUTURE DIRECTIONS

- Burnout is a real issue for staff working in the high-pressure ED environment. This is made more acute by rotating rosters, workplace violence and bullying, pressure to move patients through the system, and the constant fear of error. It is essential to good emergency patient care that staff are fostered within the ED and feel valued within the organization.
- The role of junior medical staff in Australasian EDs continues to evolve in the effort to balance clinical care and service provision with teaching and training. The ratio of senior to junior staff is crucial to maintaining safety and performance.
- Many urban and rural EDs rely on experienced doctors who have not completed specialist training in emergency medicine. As trained specialists begin to be employed in these EDs, hospitals should also aim to retain the expertise of other senior doctors.
- There are moves to increase numbers of enrolled nurses and to introduce a third level of health care worker, such as assistants in nursing or patient care attendants in EDs. Any redesign of the emergency nursing workforce needs to be evidence-based and take into account the needs of patients seeking emergency care and the key role emergency nurses play in patient safety. There is debate regarding the utility and safety of enrolled nurses within the ED. Recognizing that ED patients are becoming more complex, it is essential that team members have the widest possible scope of practice.

30.2 Emergency department layout

Matthew W.G. Chu

ESSENTIALS

1 **The layout of the emergency department should functionally promote efficacy of care, safety and efficient patient flow by maximizing access to every space with the minimum of cross-traffic.**

2 **The triage location should enable staff directly to observe and gain access to both the ambulance entry and the patient waiting areas.**

3 **The acute treatment area should be open, with all spaces directly observable from the staff station.**

4 **Supporting areas, such as the clean and dirty utilities, the medication room and equipment stores, should be centrally located.**

5 **Areas poorly planned include office, clinical support areas, clinical spaces and tutorial rooms. Storage space and future information and communication technology requirements are often underestimated.**

6 **Planning should consider the implications on night staffing when minimal staff are on duty.**

7 **The security of staff and patients is paramount in planning an emergency department.**

Introduction

The emergency department (ED) is a core clinical unit within a hospital. The experience and satisfaction of patients attending the ED are significant contributors to the public image of the hospital. Its primary function is to receive, triage, stabilize and provide emergency care to patients who present with a wide range of undifferentiated conditions, which may be critical to semi-urgent in nature. The ED may contribute between 15% and 75% of a hospital's total number of admissions. It plays an important role in the hospital's response to major incidents and trauma, and in the reception and management of disaster victims. To optimize its core function, the department should be purpose-built, providing a safe environment for patients, their carers and staff. The physical environment includes an effective communication and appropriate wayfinding system, adequate ambulance access and clear observation of relevant areas from triage. There should be easy access to the resuscitation area and quiet and private areas should cater for patients and their relatives. Adequate staff facilities and educational areas should be available. Clean and dirty utilities and storage areas are also required.

Design considerations

The design of the department should promote rapid access to every area with the minimum of cross-traffic. There must be proximity between the resuscitation and the acute treatment areas for non-ambulant patients. Supporting areas, such as clean and dirty utilities, the pharmacy room and equipment stores, should be centrally located to prevent staff traversing long distances. The main aggregation of clinical staff will be at the staff station in the acute treatment area. This is the focus around which the other clinical areas should be grouped.

Lighting should conform to national standards and clinical care areas should have exposure to daylight whenever possible to minimize patient disorientation. Climate control is essential for the comfort of both patients and staff. Each clinical area needs to be serviced with medical gases, suction, scavenging units and power outlets. The minimum suggested configuration for each type of clinical area is outlined in Table 30.2.1.

Medical gases should be internally piped to all patient care areas, and adequate cabling should ensure the availability of power outlets to all clinical and non-clinical areas. Although patient and emergency call facilities are often considered, frequently there is inadequate provision for telephone and information technology access. The availability of wireless technology to support equipment, such as workstation on wheels (WOWs), is desirable. Emergency power must be available to all lighting and power outlets in the resuscitation and acute treatment areas. Computer terminals should have access to emergency power, and emergency lighting should be available in all other areas. Electronic and computer equipment should be electrically surge protected, while physiological monitors and other patient care areas be cardiac and body protected, respectively.

Approximately 35% to 45% of the total area of the department is circulation space. An example of this would be the provision of corridors wide enough to allow the easy passage of two bariatric hospital beds with attached intravenous fluids. Although circulation space should be kept to a minimum, other aspects that also need to be considered are functionality, fire, and work health and safety requirements. The floor covering in all patient care areas should be durable and non-slip, easy to clean, be impermeable to water and body fluids, and have properties that reduce sound transmission and absorb shocks. Administrative areas, and interview rooms utilized to counsel and support distressed relatives, should be carpeted.

Size and composition of the emergency department

The appropriate size of the ED depends on a number of factors: the census, casemix, admission rate, defined performance levels manifested in waiting times, the length of stay of patients in the ED and the role delineation of the department. Departments of inadequate size are uncomfortable for patients; they often function inefficiently and impair patient care. Overcrowding of patients increases mortality and morbidity, enhances the risk of infectious disease transmission and increases harmful cognitive stimulation for patients with mental disturbance. For the average Australasian ED with an admission rate of approximately 25% to 35%, its total internal area (excluding departmental radiological imaging facilities and the Emergency Short Stay Unit) should be approximately 50 m^2/1000 yearly attendances. The total number of patient treatment areas (excluding interview, plaster and procedure rooms) should be at least 1/1100 yearly attendances, and the number of resuscitation

Table 30.2.1 Configurations for clinical areas

	Resuscitation	*Acute treatment adult/paediatrics*	*Specialty plaster/ procedure*	*Consultation room*
Oxygen outlets	3	2	2	1
Medical air outlets	2	1	1	—
Suction outlets	3	2	2	1
Nitrous oxide	1	1	1	—
Scavenging unit	1	1	1	—
Power outlets	16	8	8	4
Data outlets	6	4	6	4

areas should be at least one for every 15,000 yearly attendances. It is recommended that physiological monitoring be available to acute treatment bays.

Clinical areas

Individual treatment areas

The design of individual treatment areas should be determined by their specific functions. Adequate space around the bed should be allowed for patient transfer, assessment, procedures and storage of commonly used items. The use of modular storage bins or other materials employing a similar design concept should be considered.

To ensure privacy and minimize cross infection, each area should be separated by solid partitions that extend from floor to ceiling. The entrance to each area should be able to be closed by a movable partition or curtain.

Each acute treatment bed should have access to a physiological monitor. Central monitoring is recommended and monitors should ideally be of the modular type, with recording and print capabilities. The minimum monitored physiological parameters should include oxygen saturation(SpO_2), non-invasive blood pressure (NIBP), electrocardiogram (ECG) and temperature. Monitors may be mounted adjacent to the bed on an appropriate pivoting bracket or be movable.

All patient care areas, including toilets and bathrooms, require individual patient-call and emergency-call facilities. In addition, an examination light, a sphygmomanometer, ophthalmoscope and otoscope, and waste disposal unit should all be immediately available. Alcohol-based hand rub and hand washing facilities should be easily accessible.

Resuscitation area

This area is used for the resuscitation and treatment of critically ill or injured patients. It must be large enough to fit a standard resuscitation bed, allow access to all parts of the patient as well as allowing staff and equipment to move around the work area. The spatial requirements for equipment, monitoring, storage, wash-up and disposal facilities would necessitate a minimum size of 35 m^2 (including storage area) or 25 m^2 (excluding storage area) for each bed space in a multi-bedded room. The area should also have visual and auditory privacy for both the occupants of the room and for other patients, their carers and relatives. The resuscitation area should be easily accessible from the ambulance entrance and the staff station and be separate from the patient circulation areas. In addition to standard physiological monitoring, invasive pressure, capnography and temperature probe monitoring should be available. Other desirable features include a ceiling-mounted operating theatre light, a radiolucent resuscitation trolley with cassette trays, overhead x-ray and lead lining of walls, and partitions between beds.

Acute treatment area

This area is used for the assessment, treatment and observation of patients with acute medical or surgical illnesses. Each bed space must be large enough to fit a standard mobile bed, with adequate storage and circulation space. The recommended minimum space between beds is 2.4 m and each treatment area should be at least 12 m^2. All of these beds should be positioned to enable direct observation from the staff station and easy access to the clean and dirty utility, procedure room, pharmacy patient shower and toilet.

Single rooms

These rooms should be used for the management of patients who require isolation, privacy or who are a source of visual, auditory and olfactory distress to others. Deceased patients may also be placed there for the convenience of grieving relatives. These rooms must be completely enclosed by floor-to-ceiling partitions but allow controlled visual access and have a solid door. Each department should have at least two such rooms. The isolation room is used to treat potentially infectious patients. The isolation room should be located in an area that does not allow cross infection to other patients in the ED. Each isolation room should be self-contained with ensuite facilities, have negative-pressure ventilation and an ante room with change and scrub facilities. A decontamination area should be available for patients contaminated with toxic substances. In addition to the design requirements of an isolation room, this room must have a floor drain and contamination water trap. The decontamination area should be directly accessible from the ambulance bay and be located in an area that will prevent the ED from being compromised in the event of a chemical or biological incident. Single rooms should otherwise have the same requirements as the acute treatment area bed spaces.

Acute mental health area

This is a specialty area designed specifically for the assessment, protection and containment of patients with actual or potential behavioural disturbances. Ideally, each unit comprises two separate but adjacent rooms allowing for interview, behavioural assessment and treatment functions. Each room should have two doors large enough to allow a patient to be carried through and must be lockable only from the outside. One of the doors may be of the 'barn door' type, enabling the lower section to be closed while the upper section remains open. This allows direct observation of and communication with the patient without requiring staff to enter the room. Each room should be squarely configured and be at least 16 m^2 in size to enable a restraint team of five members to contain a patient without the potential of injury to a staff member. The examination/treatment room will facilitate physical examination or chemical restraint when indicated. The unit should be shielded from external noise, located as far away as possible from external sources of stimulation (e.g. noise, traffic) and must be designed in such a way that direct observation of the patient by staff outside the room is possible at all times. Services, such as electricity, medical gases and air vents or hanging points, should not be accessible to the patient. It is preferable that furniture be made of material that would prevent it being used as a weapon or for inflicting self-harm. A smoke detector should be fitted and closed-circuit television may be considered as an adjunct to direct visual monitoring. Psychiatric Emergency Care Centres or Behaviours of Concern areas, have been introduced in some hospitals. They are located within or adjacent to an ED and consist of four to six rooms with the configurations previously mentioned. Governance is dictated by the local operational policies.

Consultation area

Consultation rooms are provided for the examination and treatment of ambulant patients with non-complex conditions. These rooms have similar spatial requirements to the acute treatment area bed spaces. In addition, they are equipped with office furniture, a computer terminal, a radiological viewing panel and a basin for hand washing. Consultation rooms may be adapted and equipped to serve specific functions, such as ear, nose and throat or ophthalmological treatment, or be part of a fast-track model of care. When used in conjunction with an adjacent subwaiting area where patients are observed or are waiting for results of investigations, this model of care promotes the efficient use of the available floor space.

Plaster room

The plaster room allows for the application of splints, plaster of Paris and for the closed reduction of displaced fractures or dislocations, and should be at least 20 m^2 in size. Physiological equipment to monitor the patient undergoing procedural sedation or regional anaesthesia is required. Specific features of such a room include a storage area for plaster, splints and bandages; x-ray viewing panel/digital imaging systems facility; provision of oxygen and suction; a nitrous oxide delivery system; a trolley with plaster supplies and equipment; and a sink and drainer with a plaster trap. Ideally, a splint and crutch store should be directly accessible in the plaster room.

Procedure room

A procedure room(s) may be required to undertake procedures, such as lumbar puncture, tube thoracostomy, thoracocentesis, peritoneal lavage, bladder catheterization or suturing. It requires noise insulation and should be at least 20 m^2 in size excluding a storage area for minor equipment and supporting sterile supplies. Physiological equipment to monitor the patient undergoing procedures, a ceiling mounted operating theatre light, x-ray viewing panel/digital imaging systems facility, provision of oxygen and suction, a nitrous oxide delivery system, a waste disposal unit and hand washing facilities should all be available.

Staff station

A single central staff area is recommended for staff servicing the different treatment areas, as this enhances the co-ordination and communication between staff members. The staff station in the acute treatment area should be the major staff area within the department. The staff area should be in the centre of an 'arena' or 'semi-arena' design to directly observe the main areas of clinical activity. The station may be raised. In larger departments, interlocking pods—each involving a centrally located staff station overseeing an acute treatment area—may be arranged to maximize patient visibility. The staff station should be constructed to ensure that confidential information can be conveyed without breach of privacy. Sliding windows and adjustable blinds may be used to modulate external stimuli and a separate write-up area may be considered. Sufficient space should be available to house an adequate number of computer terminals, printers, data outlets and digital imaging systems, dangerous drug/medication cupboards, emergency and patient call displays, under-desk duress alarm, valuables storage area, police blood alcohol sample safe, photocopier and stationery store, and write-up areas and workbenches. Direct telephone numbers, bypassing the hospital switchboard, should be available to allow staff to receive admitting requests from outside medical practitioners or to participate in internal or external emergencies when the need arises. A dedicated line to the ambulance and police service is essential. A pneumatic tube system for the transport of specimens, drugs and medical records also may be located in this area.

Short-stay unit

Many EDs possess an ED short-stay unit (EDSSU) or emergency medical unit, which is managed under its governance and operates as an extension of the department. The purpose of these units is to manage patients who would benefit from extended observation and treatment but have an expected length of stay of less than 24 hours. This is in contrast to a medical assessment and planning unit, or medical assessment unit, which is managed by the inpatient service and may either be co-located or built near an ED. The minimum functional unit size of an EDSSU is eight beds. It is configured along similar lines to a hospital ward with its own staff station. The capacity is calculated to be 1 bed per 4000 attendances per year and its size will be influenced by its function and case mix. As short-stay units manage a significant caseload of psychosocial health issues, appropriate space should be allocated to allow allied health services to operate effectively.

Clinical support areas

The clean utility area requires sufficient space for storing clean and sterile supplies and procedural equipment with bench tops to prepare procedure trays. The dirty utility should have sufficient space to house a stainless-steel bench top with sink and drainer, pan and bottle rack, bowl and basin rack, utensil washer, pan/bowl washer/sanitizer and sluice sink with storage space for testing equipment (such as for urinalysis). A separate store room may be used for the storage of equipment and disposable medical supplies. A common pitfall is underestimating the amount of necessary storage space. A pharmacy/medication room is required for drug and vaccine storage and being readily accessible to all clinical areas. Entry should be secure with a self-closing door, and sufficient space should be allowed to house a refrigerator for heat-sensitive medications and vaccines. Other design features should include spaces for linen trolleys, mobile radiology equipment, patient trolleys and wheelchairs. Refreshment facilities for patients and relatives, blanket-warming cupboards, disaster equipment storage, a cleaners' room and shower and toilet facilities also need to be accommodated. An interview room allows for interview and counselling in private. It should be acoustically treated and removed from areas of high-volume traffic. A distressed relatives' room should be provided for the relatives of critically ill or deceased patients. Consideration for the provision of two rooms should be given in larger departments to allow the separation of relatives of patients who have been protagonists in violent incidents. They should be acoustically insulated and have access to beverage-making facilities, a toilet and telephones. A single-room treatment area in close proximity will enable relatives to be with dying patients and should be of a size sensitive to local cultural practices.

Non-clinical areas

Waiting area

The waiting area should provide sufficient space for waiting patients and those accompanying them. It should be open and easily observed from the triage and reception areas. Seating should be comfortable and adequate space should be allowed for wheelchairs, prams, walking aids and patients requiring assistance. There should be a dedicated waiting and play area for children and entertainment facilities, such as television, should be available. Easy access from the waiting room to the triage and reception area, toilets and baby change rooms and light refreshment should be possible. Public telephones and dedicated taxi lines should be accessible. The area should be monitored to safeguard security and patient well-being. The waiting area should be at least 5 m^2/1000 yearly attendances and should contain at least one seat per 1000 yearly attendances.

Reception/triage area

Ambulance and ambulant patients should access the department via separate entrances. Each entrance should have a separate foyer with security doors which may be closed by remote activation. Security doors should restrict access treatment areas. Both entrances should direct the patient flow towards the reception/triage area,

which should have clear vision to the waiting room and the ambulance entrance. The triage area should have access to a vital signs monitor, computer terminal, hand basin, examination light, telephones, chairs and desk and patient weighing scales. There should be ready access for minor medical disposables, equipment and stationery.

Reception/clerical office

Patients who present to the reception counter initially, will be directed to the triage area. After triage assessment, the patients will generally be directed back to the reception area, where clerical staff will conduct registration interviews, collate the medical record and print identification labels. Clerks may interview patients or relatives at the bedside but return to the reception area to finalize the administrative details. The counter should provide seating and be partitioned for privacy for interviewing. Planning should allow for direct communication between the reception/triage area and the staff station in the acute treatment area. The design should optimize staff safety. This area should have access to an adequate number of telephones, computer terminals, printers, facsimile machines and the photocopier. It should also have sufficient storage space for stationery and medical records.

Education and training area

Formal staff and student education and training are undertaken in this area. It should be in a quiet, non-clinical area near the staff room and offices. Provision should be made to accommodate webcasting, web conferencing, simulation and procedural skills training allowing for large- and small-group teaching. Technological support systems integrating computer projection broadband access electronic picture archiving and communication systems are essential. Equipment to support traditional teaching methods utilizing a whiteboard, a tube x-ray viewer system and examination couch must also be available.

Telemedicine area

Telemedicine is becoming increasingly important, particularly for EDs in hospitals that are either remotely located or have limited access to subspecialty support. In these EDs, the telemedicine equipment may be located in the resuscitation area or in a dedicated room where patient encounters, such as mental health assessments, may be undertaken or the transmission of images, such as burns or digital x-rays, expedited. A dedicated facility with appropriate power and communications cabling is necessary. For facilities that receive the telemedicine transmissions, the room should be of a suitable size to allow simultaneous interactions by members of the consulting service teams. It should be in close proximity to the staff station.

Offices

Offices provide space for administrative and managerial functions, quality and safety initiatives, and education and research activities. The number of offices required will be determined by the size of the ED. Typically, a large department will require offices for the director, deputy director, nurse manager, academic staff, specialists, trainees, nurse consultants/practitioners, nurse educators, secretary, allied health professionals, information and general support officers, research and projects officers and a clerical supervisor. A general meeting room is also important.

Staff amenities

A room should be provided within the department to allow staff some time out from the intensity of their clinical work. A preparation and storage facility for food and drink, and appropriate table and seating arrangements should be provided in a bright and attractive environment. There should be natural lighting and appropriate floor and wall coverings, located away from patient care areas. A staff change area with lockers, toilets and shower facilities should also be provided.

Likely developments over the next 5 to 10 years

EDs continue to face significant challenges. There continues to be a steady increase in demand. The work environment has become increasingly pressured. This has been paralleled by resource constraints and workplace changes such as the adoption of electronic information management technology. Care provision has increased in complexity. Advances in medicine have resulted in the ED managing greater numbers of patients who would previously have required hospitalization. As hospitals continue to face increasing fiscal constraints, the importance of the ED has grown considerably and modern departments have significantly expanded their care-giving role. Future design considerations will continue to centre upon advances in information and communications technology, telecommunications and newer non-invasive diagnostic modalities. A greater emphasis will be placed on developing ED design configurations to maximize efficiencies in work practice and to minimize the number of patient moves, while ensuring patients receive timely definitive care and time-critical interventions. Computerized patient tracking systems using electronic tags and built-in sensors will provide additional information that may further improve operational efficiency. The electronic medical record is already implemented in many EDs and allows immediate access to detailed medical information to facilitate the provision of timely care, quality, safety and research activities. Digital radiography, personal communication devices, voice recognition systems, wireless technology, portable computers and expanded telemedicine facilities will make the ED of the future as reliant on electricity and cabling as it is on oxygen and suction. Consideration of back-up systems in the event of interruptions to supply, such as blackouts and disasters, is essential.

The increase in the ageing population will impact upon ED design. Older patients have multiple co-morbidities leading to impaired mobility, visual and balance disturbances. They are at increased risk of delirium from their underlying disease or hospitalization. They require greater space because of mobility aids and require greater shielding from sources of cognitive overstimulation. Standard hospital trolleys pose a falls risk and contribute to the development of pressure areas. Strategies, such as the use of alternative hospital beds with pressure-relieving mattresses and more comfortable 'reclining lounge chair' style seating, are being adopted for this group of patients. Maximizing natural lighting and maintaining a normal diurnal 'night–day' light pattern will be factored into the design to cater for the elderly patients who may spend prolonged periods of time in the ED.

Faced with an increasing number of bariatric presentations, ED design will need to be flexible and appropriately modified to cater for this subgroup of patients as well.

CONTROVERSIES

- Expert opinion varies in approaching the design of security features. Some feel that the use of physical barriers, which are commonly seen in the reception/triage areas to isolate potentially violent people, may cause further aggravation to those people and this may have the paradoxical effect of increasing the incidence of violence. Others argue that protective physical features are of significant benefit, as staff may feel less vulnerable to physical attack and therefore are better able to diffuse potentially violent situations. Each potential solution has its own drawbacks.
- Another area of debate centres on how to protect patient privacy while still maintaining the ability to closely monitor patients within the department. Advocates of the direct observation approach believe that the resultant loss of privacy is a small price to pay to prevent the deterioration of a small number of patients with unrecognized severe illness.

Opponents of this view believe that a significant number of patients in EDs do not require constant observation and that 'open-plan' departments inhibit good communication and create a noisy and distressing environment. A satisfactory solution that meets the requirements of each group can be obtained by the use of solid partitions between treatment areas while the entrance is enclosed by a glass partition that may be opened when indicated. Ceiling baffles installed in the staff station significantly reduce noise transmission. If the treatment areas are also arranged in such a way that they surround the staff base, direct observation of each area is still possible.

30.3 Quality assurance and quality improvement

Kim Hansen

ESSENTIALS

1 Quality improvement offers the tools to translate knowledge into improved patient care.

2 The six key aims for improvement are safety, effectiveness, patient-centeredness, timeliness, efficiency and equitable care.

3 The commonly used quality cycle known as 'plan, do, study, act' involves planning a test, carrying out a change, observing the consequences and putting in place modifications.

4 Standards provide a consistent and uniform set of measures to benchmark safety and quality, and are utilized as a tool for accreditation.

5 Quality indicators are structure, process or outcome measures used to assess, compare and determine the quality of care.

Introduction

Quality in the emergency department (ED) can be defined as consistently providing optimal care to patients. There is often a gap between best practice and the care provided in a health care setting due to a variety of factors, independent of the will, skill, and attitude of the people who work in that system.[1] To improve the system, quality management must be applied to the system requiring leadership, commitment to change management processes, effective communication, staff engagement and accountability. Patient engagement is another fundamental aspect of quality management so that improvement aligns with their needs, preferences and values.[1] The six key aims for improvement in health care are:

1. Safety—reducing the likelihood of patient harm by medical errors.
2. Effectiveness—avoiding the underuse and overuse of services and resources.
3. Patient-centeredness—provision of a service that relates to patients and their families, accommodating their needs when making decisions.
4. Timeliness—the reduction of waiting times.
5. Efficiency—reducing waste and cost.
6. Equity—the closure of racial and income gaps in health care.[2]

Ideally, a quality culture exists where health care workers, leaders, patients and carers are continually focussed on improving processes and are empowered and resourced to do so.

Definitions

Quality Assurance (QA) is the monitoring of the system for detecting emerging problems, taking steps to address them and ensuring stability over time. QA processes used in EDs include morbidity, mortality and complaint audits, infection control, credentialing and standard setting.

Quality Improvement (QI) is a formal and systematic approach to the analysis and efforts to enhance performance. The difference between QA and QI is that QA ensures compliance with standards by means of measurement and inspection, with a focus on finding deviation from agreed standards. It is often externally driven and relies on monitoring. QI offers tools to focus on processes and systems that translate the ideal patient management into the care that happens every day. It is often driven internally by clinicians; however, to be successful requires the support of management.

Health care providers can use QI to hypothesize process change that will result in improvement. Key activities involved in the QI process include:

- multi-disciplinary collaboration within working groups
- patient involvement
- review of existing processes

- identification of performance measures
- implementing a change
- data collection and analysis
- communication of outcomes, with incorporation of key learning into process redesign, education and training.

When gaps are detected between expected and observed performance, a QI approach may be undertaken to close the gap. In QI, a variety of methods and tools are used to develop, test and implement changes. Following successful improvement, QA can then be used to monitor the redesigned process to ensure it performs at the expected level. Measuring and monitoring performance is essential to demonstrating effectiveness and provision of the best service possible. The difference between research and QI is that QI provides enough data to show improvement in common clinical situations, whereas research requires a large amount of data in ideal conditions to create new knowledge; however, convergence can occur.

Continuous QI is a management approach that focuses on processes that review, critique and implement positive change to achieve QI in a health care setting, therefore continuously improving the quality of patient care.

Benchmarking compares performance with others with the use of best practice as a marker for improvement.

Credentialing is a formal process to recognize and verify and individual's qualifications to assess their capacity to safely perform a task.

PDSA and other QI tools

QI requires the systematic use of improvement models or tools, of which the most commonly utilized is the Plan-Do-Study-Act (PDSA) model. The PDSA cycle is a process to improve quality based on the scientific method. It involves:

1. Plan—developing a plan to test the change
2. Do—carrying out the test
3. Study—observing and learning from the consequences
4. Act—determining which modifications should be made to the test.[3]

It is vital for success that the aims of a QI project are selected and articulated carefully, for example, using the SMART acronym—specific, measurable, attainable, relevant and timely. Multiple change cycles may be required by refining the intervention to lead to sustained improvement. The PDSA provides a set of proven, reliable and repeatable steps that all clinicians can use to improve confidence and minimize resistance when the change is implemented.[3]

Other commonly used QI tools include:

- Process mapping, which visually displays how various activities relate to one another in a timeline from start to end. This helps to identify the bottlenecks, redundancies and variation in practice, and therefore highlights opportunities for standardization and efficiencies
- Ishikawa diagram (also known as cause and effect or fishbone diagram), to organize the potential contributing causes of a clinical problem into categories
- Pareto chart is a bar chart of contributory various factors are arranged in order according to the magnitude of their effect, which helps concentrate efforts on the factors that have the greatest impact
- Stakeholder analysis involves identification of those that are affected by or have influence over the QI project's conclusion into groups, and the development of an engagement strategy with those stakeholder groups
- Run charts are a simple tool utilized to display data by plotting outcome measures against a time scale to determine if a system is demonstrating trends or sustaining change

The Institute for Healthcare Improvement has led the way championing QI and its tools in health care.[3] The typical process change for a QI project is redesign of processes, simplification, reminders or introducing interventions. Importantly, the improvement needs to be an evidence-based change addressing a practice gap.[4] QI is most powerful when a capable workforce is empowered by management to set bold aims, measure progress, redesign processes, and test changes rapidly and informatively.[1]

Benchmarking

National standards

In 2013, National Safety and Quality in Health Service Standards (known as the 'National Standards') became mandatory across all Australian public hospitals. The National Standards provide a nationally consistent and uniform set of measures of safety and quality for application across a variety of health care services. They were developed to provide a statement about the level of care consumers can expect and to drive implementation of safety and quality systems.[5]

In 2017, a second edition with eight standards was published, which cover:

1. Clinical governance
2. Partnering with consumers
3. Preventing and controlling health care-associated infection
4. Medication safety
5. Comprehensive care
6. Communicating for safety
7. Blood management
8. Recognizing and responding to acute deterioration[5]

Areas in EDs with a higher prevalence of adverse events are addressed in the National Standards, for example, clinical handover, aseptic technique in procedures, the use of high-risk medications and the response to clinical deterioration. These standards are used for accreditation of hospitals by the Australian Council of Healthcare Standards.

In New Zealand, the Ministry of Health sets the Health and Disability Services Standard. In the United States, the Joint Commission on Accreditation of Health Care Organisation plays a similar role.

Quality standards

In 2015, the Australasian College for Emergency Medicine (ACEM) published a comprehensive set of Quality Standards to provide guidance and set expectations for the provision of equitable, safe and quality emergency care in Australian EDs.[6]

The ACEM Quality Standards encourage a proactive focus on quality and safety, provide defined processes to continuously review and improve quality of care and to illustrate optimal requirements for running a quality emergency care service.[6]

The structure of the ACEM Quality Standards was based on the ACEM Quality Framework,[7] consisting of five domains:

1. Clinical pathway focuses on the patient care pathway through the ED, from first communication with the ED to admission, discharge or transfer, and aims to maintain a patient-centred approach.
2. Administrative domain describes the overall management of an ED within the whole of hospital context as the interface between acute care and the community. It focuses on ensuring that the workforce are suitably trained and supported through the physical environment, facilities and resources.
3. Professional domain focuses on the professional attributes of the ED team as well as the legal and ethical obligations encountered in the provision of care within the ED.
4. Education and training domain describes those components of practicing emergency care that are related to ongoing maintenance, supervision and development of knowledge, skills and professional attributes.
5. Research domain focuses on the conduct of research within the ED that complies with ethical requirements and good clinical practice guidelines, as well as encouraging the collaboration and participation in research to ensure the ED provides high quality, contemporary and evidence-based care to patients.[7]

In addition, the International Federation of Emergency Medicine has developed a consensus document outlining a framework for measuring quality.

Quality indicators in the emergency department

There is an increased emphasis on the quality of care provided to ED patients, from patients, families, health care organizations, governments and the community at large. This has led to an increasing number of quality measures, otherwise known as Quality or Clinical Indicators.

Quality Indicators are designed to monitor, compare and highlight potential issues that may require redress, by identifying variations within results. They are tools to identify areas for improvement, to assess whether a predetermined standard in patient care is reached, or to provide evidence for accreditation.[8]

The selection of ED Quality Indicators should be dictated by local needs as well as benchmarking against comparable departments and best practice. Qualities that guide selection of indicators include relevance, level of evidence, ability to abstract data, presence of a clinically significant gap between the care provided and best practice (practice gap), barriers to change and applicability.[8,9]

Quality Indicators can be divided into structure, process and outcome measures.[10] Structure indicators provide information about the organization's environment such as human resources, physical resources, physical layout and organizational framework. Process indicators measure the provision of care, supplying quantitative data regarding the effectiveness of policies, procedures and systems. Outcome indicators refer to the result of care, and provide quantitative data related to the outcomes of performance, typically including mortality, morbidity and quality of life.[8,9]

In recent years, Quality Indicators for ED have focussed on time-based measures. The National Emergency Access Target is a time-based target that reports the percentage of patients who leave the ED within 4 hours. It measures efficiency and accessibility of patient care, and highlights access block, but is heavily reliant on processes in other areas of the health care system. Other common quality indicators used to measure the standard of clinical care in EDs include:

- Time to Percutaneous Coronary Intervention or thrombolysis (known as 'door to balloon', 'door to needle')
- Time to analgesia
- Time to antibiotics in specific conditions, for example sepsis, febrile neutropaenia and the febrile neonate
- Waiting time by triage category
- Unplanned re-attendance rates
- Did not wait rates

Broader measures that reflect common ED activities are also used as quality indicators, including:

- Research output
- Exam pass rates
- Patient and staff satisfaction
- Staff turnover[8,9]

The future for quality

If staff and management recognize the value of QA and QI, invest resources to achieve improvements and work together to improve process, a culture of quality can be established. With increasing use of data from sophisticated electronic medical records, the ability to gather data multiplies exponentially. However, accelerating improvement will require strategies for developing the health care workforce as QI champions, and developing a quality culture.[1] It is essential that health care workers are involved in the selection of standards and quality indicators to ensure they are evidenced based, applicable and represent a potential gap in care.

Ultimately, health care is only as good as the change that can be affected at the individual clinician–patient level. With a focus on QI, appropriate benchmarking and quality indicators, the quality and consistency of care provided in EDs can be optimized.

30.4 Business planning

De Villiers Smit

ESSENTIALS

1 **Organizational business planning describes the strategies an organization will take to achieve the goals of the strategic plan.**

2 **The emergency department (ED) business plan is an important multipurpose document and informs the organization about the agreed performance dimensions of revenue and expenditure, activity, efficiency and quality of services proposed for the next financial year.**

3 **Once the business plan is approved by the hospital executive, the ED management group should regularly monitor actual outcomes against the targets and take remedial action where necessary.**

Introduction

Health care is an ever-changing environment, so it is critical for health care organizations to plan ahead for the next 5 to 10 years. A strategic plan for an organization is a vital document outlining how organizations propose to address changes in the health care industry, including changes in regulatory platforms, technology, demographics and funding. Typically, strategic plans will include a number (or all) of the following domains:

1. Improving quality and safety
2. Leadership in education and research
3. Financial effectiveness
4. Organizational environment improvement
5. Workforce sustainability

A strategic plan of any health care organization therefore provides an overview of the future direction of the organization. Organizational business planning describes the strategies an organization will take to achieve the goals of the strategic plan. The business plan for the organization therefore explains in more detail how the organization is planning to get there.

Units, wards, departments, programs or services within an organization are often required to develop a business plan. The value of a business plan is that it ensures that every service and department is progressing in the same direction.

Business planning help executives, managers, teams and staff by:

- Providing coordination and direction
- Motivating employees and creating a culture of team engagement, ownership and achievement
- Supporting better decision making by helping anticipate and address future problems and risks before they arise, and considering alternatives and evaluating the implications of decisions
- Creating confidence about the direction the organization is taking, how they will get there and what success will look like
- Meeting service expectations by identifying timeframes for action and aligning resources appropriately
- Reducing uncertainty and helping teams prepare for desired changes

Emergency department business planning

Business planning is especially important in the often unpredictable milieu of the emergency department (ED). ED efficiency directly affects the efficiency of the health care process in the hospital and hospital executives are therefore particularly interested in the performance of emergency medicine services. Reporting on the performance of the department is essential to justify their level of current resourcing and may influence future budget cycles.

The ED business plan is usually developed by the ED management team, which includes the medical director, the nurse manager and the finance or business manager. Input from other professionals, such as legal and allied health, also may be required from time to time. Engagement and consultation with the rest of the ED staff is important prior to finalization of the business plan. Final sign-off of the business plan is usually at clinical service/program level prior to submission to the executives of the organization.

Business plan development

The following are useful steps to take in developing a business plan.[1]

Step 1: Establish a small planning team to lead the planning process

The medical director or nurse manager will usually be appointed as the planning team leaders. The team usually consist of around three to five staff members. Their purpose will be to gather and review information, to clarify the purpose of the business plan, to identify key stakeholders and to confirm the planning process and timelines.

Step 2: The planning team considers the current environment

It is important to list major changes impacting on the department, including internally (e.g. patient-related and staffing) and externally (e.g. State and/or Federal Government). The team will review all relevant documents to identify actions, targets or key performance indicators. They will also consider organizational strategic plans, service development plans and previous business plans. Furthermore, it is important to include relevant aspects of hospital accreditation and the end results of clinical outcome review processes such as root cause analyses and Morbidity and Mortality meetings.

Step 3: Consult with staff and other stakeholders

A planning meeting with stakeholders is important to provide an overview of the meeting aims, to identify further issues and to brainstorm key actions.

Step 4: The planning team finalizes priorities from steps 2 and 3

A review of preliminary priorities against strategies identified in Steps 2 and 3 should be conducted and finalized based on organizational goals. It is important not to include any doubtful strategies at this stage.

Step 5: Draft the plan using the organizational business plan template

Incorporate about 10 strategies into the template. These strategies should be realistic and the language used should be clear, objective and concise. This should include how success will be measured, who will lead each of the strategies, and a timeline for completion. Be clear how you will monitor progress and report back to all those involved (staff and hospital executives).

Step 6: Circulate the draft business plan to obtain feedback

The draft should now be circulated to committee members initially and then to other stakeholders via team or executive meetings, for example. Feedback especially regarding timeframes and responsibilities should be sought.

Step 7: Finalize and distribute the plan

Based on feedback, the business plan will now be finalized and released to staff and the hospital executive.

Content of the emergency department business plan

The ED business plan should consider the organization-wide drivers and strategic goals. Typically, this should include aspects of the following as applicable to the ED environment:

- Hospital Accreditation and National Standards
- Quality Patient Care
- Hospital Risk Register
- Budgetary Targets
- Performance Targets
- Quality and Safety Parameters
- Service and Master plans
- Infrastructure Development
- Occupational Health, Safety and Wellbeing

Various templates are being used for business plans, but in general it will include a brief introduction stating the mission and objectives of the department, and an executive summary providing an overview of the business plan and highlighting certain critical issues. Box 30.4.1 illustrates a typical template of a business plan.

Specific considerations

Budget

The projected financial outcomes for the current financial year should have been carefully

Box 30.4.1 Typical business plan index

1.0 Introduction
Mission, role, objectives
2.0 Executive summary
3.0 Projected outcomes 2012/2013
3.1 Budget—revenue and expenditure
3.2 Budget variance analysis
3.3 Staffing profile
3.4 Activity
3.5 Quality and efficiency key performance indicators
Efficiency indicators
Clinical indicators
Consumer indicators
4.0 Budget estimates 2013/2014
5.0 Special issues 2013/2014
Equipment—clinical and non-clinical
<$5000
>$5000
Facility maintenance
Projects
Information system replacement
Short-stay unit expansion
Head-injury research

Smithfield Hospital emergency department business plan 2013/2014 table of contents.

estimated. This projected end-of-year position should be shown in a tabular format against the agreed targets from the previous year's business plan, as well as the actual outcomes of the previous year. In government organizations, adherence to the budget is of highest priority and it is therefore expected that these details are presented first.

In some jurisdictions, hospitals are funded based on activity, including ED activity, and it is incumbent on the ED to gather accurately and completely all necessary information to optimize this revenue. Similarly, privately insured patients must be identified as well as individuals for whom special funding or revenue premiums apply.

Activity

The activity of the ED may be shown as total attendances, attendances by category of the Australasian Triage Scale and the admission rate by triage category. All values should be tabulated against the previous year's activity levels. Additional data presented may include short-stay or observational unit occupancy, plus length of stay and case-mix index.

Quality and efficiency

Waiting time by triage category is a key quality and efficiency indicator for an ED. The average waiting time per patient in each triage category should be shown, together with the percentage of patients in each triage category who are seen within the timeframe specified by the Australasian Triage Scale. In addition, the percentage of all ED patients seen and admitted, discharged or transferred within 4 hours (Australia: National Emergency Access Target) must be reported against the target. These data should be benchmarked against the previous year's performance and, ideally, also against benchmarking data from similar hospitals elsewhere. Performance against clinical indicators recommended or required by government and other central agencies also should be reported. Additional access indicators may include patient off-stretcher time and admission access block (percentage of total admitted patients spending longer than 8 hours in the ED) should be provided.

It is appropriate in the section on 'quality' that research and educational achievements and plans should be succinctly reported, together with any innovative projects.

Projections

Having summarized the current year's performance, the remainder of the business plan should be used to present the ED's projections and estimates for the next financial year. Again, the projected budget should be presented first. Periodically, circumstances will dictate that a hospital vary the desired quality of services, perhaps as part of a strategic initiative to develop the ED or the volume of services in response to changing demographic projections. Particular attention also should be paid to high-cost areas of pathology, radiology and pharmacy with evidence-based utilization being regularly assessed.

Equipment

It is important that the totality of clinical and non-clinical equipment needs is understood and equitably prioritized in order to optimize the efficiency of the whole department. Apart from tabulating the need for equipment, a few lines of narrative about each item often assists the executive in ensuring the reasonableness of the request. The table should indicate whether the equipment is new or a replacement.

Facility maintenance

All but the newest departments will require some expenditure on maintenance each year. An inventory of departmental maintenance needs and costings should be developed in collaboration with the hospital engineering services and external contractors.

Projects

This final section can be used to describe and cost small or large projects to enhance the ED facilities, infrastructure or services. This is best presented in a project format, including a clear description of the business need (supported by all available, relevant data), a business case outlining all the costs and benefits and, if possible, additional material, such as architects' sketches and a project implementation plan, including a project timetable. Professional advice in preparing this documentation is essential.

Private emergency departments

The overview of business planning presented above is equally relevant to EDs in private hospitals. However, private EDs also need to develop a more robust revenue budget and marketing plan appropriate to their circumstances. The marketing plan will usually be a part of the hospital's overall arrangements, but the ED should be in a position to report on any changes in referral pattern or on any opportunities to expand the business.

Business plan implementation and monitoring

Soon after the hospital receives its global budget, activity targets and key performance indicators from the government, a short process of negotiation between the hospital executive and the ED management group should take place. This will fine-tune the business plan and, ultimately, permit authorization of the plan and the appropriate delegation for its implementation.

The ED management group should meet at least monthly to review actual performance against the outcomes predicted by the plan. Any variance from the budget in particular should be studied and understood. Remedial action should be taken wherever possible to maintain budget integrity. In many places, the ED management group would meet with the hospital executive at least quarterly to review department performance and to deal with any variation that may have occurred.

30.5 Accreditation, specialist training and recognition in Australia

James Collier • Barry Gunn

ESSENTIALS

1 Specialist training in emergency medicine (EM) in Australia and New Zealand is the responsibility of the Australasian College for Emergency Medicine (ACEM).

2 Specialist international medical graduates require recognition from either the Australian Medical Council or the Medical Council of New Zealand.

3 Specialist training in EM under the ACEM is a 5-year program. Trainees must complete certain training requirements, including workplace-based assessment, the ACEM primary examination and the fellowship examination.

4 ACEM training accreditation is awarded to sites if they meet all accreditation requirements.

5 Accreditation requirements are set by the ACEM within a framework of accreditation domains, standards and criteria.

6 Hospitals are inspected at regular 5-year intervals to determine whether standards are being maintained and thus to allow continuation of accreditation. This is supplemented by regular monitoring via trainee placement surveys and an annual census.

Specialist recognition and registration

Specialist recognition in New Zealand and Australia is handled by the respective medical councils in each country—the Medical Council of New Zealand (MCNZ) and the Australian Medical Council (AMC). In New Zealand, the MCNZ handles both specialist recognition (termed *vocational registration*) and general medical registration. In Australia, the AMC has responsibility for specialist recognition of specialist international medical graduates (SIMGs) and the accreditation of specialist medical colleges. Medical registration (both general and specialist where applicable) is the responsibility of the Medical Board of Australia, which is supported in this role by the Australian Health Practitioner Regulation Agency (AHPRA). Full general medical registration is required for those who wish to undertake specialist training via the ACEM. Prospective trainees with the ACEM must apply through a standards-based selection process.

Specialist training in emergency medicine

Specialist medical training is the responsibility of the various specialist medical colleges. Most of these organizations cover both Australia and New Zealand. They are accredited by the AMC. Specialist training in EM is covered by the ACEM.

The college provides the framework, standards and requirements for specialist training in EM, and successful trainees are granted fellowship in the ACEM (FACEM).

Training occurs in hospitals and rotations approved by the ACEM. Each accredited emergency department (ED) is required to have an appointed director of emergency medicine training (DEMT). This is the college fellow responsible for facilitating the delivery of the FACEM training program in a given department and hospital. The description of the training program that follows reflects the situation in January 2018.[1] This training program undergoes regular review and revision.

Specialist training in EM is divided into four stages:

- Provisional training
- Advanced training—stage 1
- Advanced training—stage 2
- Advanced training—stage 3

The ACEM curriculum framework describes the learning outcomes expected at the completion of each stage of training. There are eight domains within the framework: medical expertise; prioritization and decision making; communication; teamwork and collaboration; leadership and management; health advocacy; scholarship and teaching; and professionalism.

Provisional training

This usually occurs in the third postgraduate year or beyond. There are three requirements of provisional training:

- Completion of 12 months of training in approved rotations. At least 6 months of this must be in an accredited ED. Each term, which must be of at least 2 months' duration, is assessed via a structured in-training assessment (ITA) by the DEMT and or local supervisor for non-ED rotations.
- Successful completion of the ACEM primary examination. This is an integrated basic science examination with written and oral components covering four subjects: anatomy, pathology, physiology and pharmacology. The written component must be passed before the oral component can be attempted. The written exam involves two 180-minute papers consisting of select choice questions, multiple choice questions and extended matching questions. Candidates must achieve a global pass score across the two papers combined. The integrated oral examination comprises four 10-minute sections each assessing across the four science subjects as well as a clinical building block. The latter is an abnormal pathology result, radiological image or ECG that candidates are expected to describe and interpret. The standard of the clinical building blocks is at the level expected for a provisional trainee. Many of the questions in the written and oral examinations are linked by a clinical scenario to demonstrate the clinical relevance of the topic.
- Provision of three structured references. Each trainee must obtain three structured references as supplied by the ACEM from their DEMT and two other fellows who have supervised 6 months of their ED provisional training time. These seek to identify strengths and weaknesses in a number of areas of practice and serve as indicators of the trainee's suitability to progress into advanced training.

Advanced training

Advanced training consists of three stages across 48 months. The main elements are core EM training, non-ED training, critical care training, discretionary training, the paediatric requirement, the research requirement and completion of the fellowship examination.

Core emergency medicine training

Trainees must complete 30 months of training in accredited EDs. Each 3-month term is assessed via a structured ITA by the DEMT.

Trainees must complete at least 6 months in a major referral hospital and 6 months in either an urban district or rural/regional hospital.

During core EM training, trainees are required to complete a suite of Emergency Medicine Workplace-Based Assessments (EM-WBAs). These involve a FACEM undertaking short periods of observation and/or discussion with a trainee in clinical practice, followed by structured feedback and a rating of the trainee's performance. Types of EM-WBAs include mini-clinical evaluation exercises, direct observation of procedural skills, case-based discussions and shift reports.

Non-emergency department training

Trainees must complete a minimum of 6 months of training in approved non-ED rotations. These are usually in hospitals accredited for training by the respective college for that specialty. Experience can also be gained in the ACEM accredited special skills terms, such as pre-hospital and retrieval, trauma, toxicology, rural/remote health, ultrasound, research, medical education, simulation, safety and quality and medical administration.

Critical care training

Trainees are required to complete a minimum of 6 months in critical care medicine, either in an intensive care unit or an anaesthetics unit (or 3 months in each) approved for training by their respective colleges.

Discretionary training

Discretionary training is 6 months of advanced training time that can be utilized at the discretion of the trainee in either an ED or non-ED rotation, in addition to the previously mentioned core EM and non-ED training requirements.

Paediatric requirement

This can be gained by two pathways: completion of a 6-month term in an accredited paediatric ED or via completion of a paediatric logbook. With respect to the logbook, this can be utilized during ED and non-ED advanced training involving paediatric (aged 15 years and under) patients. Trainees must log at least 400 substantive encounters with paediatric patients, of which 200 must occur within an ED setting and 100 of these must be from Australasian Triage Scale categories 1, 2 or 3. EDs are given specific accreditation for the use of a paediatric logbook.

Research requirement

The mandatory learning objectives of the research requirement of training can be met by completing one of the following to the satisfaction of the ACEM Trainee Research Executive Panel:

- Publishing or presenting a research project
- Two postgraduate units of study at an Australian or New Zealand University
- A thesis as part of a university qualification involving research

Fellowship examination

The examination consists of written and clinical components. The written component consists of select choice questions (multiple choice and extended matching questions) and short answer questions. Both the select choice and short answer question papers must each be passed to achieve an overall pass in the written component and to be eligible for the clinical examination. The clinical component is an objective structured clinical examination (OSCE).

Progression through training

Trainees' ITAs and EM-WBAs are reviewed by the ACEM at pre-determined points of accrued training time to determine whether a trainee may progress to the next stage of training or requires a period of remediation (of 3 or 6 months' duration) to meet the required learning outcomes.

Variations in training

Recognition of prior learning and credit transfer can be applied for in line with regulations and upon registration. Up to 12 months of advanced training (excluding core-EM time) can be gained overseas with the prior approval of the ACEM.

Training can also be completed on a part-time basis (at least 50% of the time and conditions of a full-time post) and can be interrupted for up to 2 years. All requirements of the training program must be completed within 12 years of commencement of training.

Joint and dual training

There is a joint training program in paediatric EM (in conjunction with the Royal Australasian College of Physicians) and a dual training program in intensive care medicine (in conjunction with the College of Intensive Care Medicine) available to EM trainees.

Recognition of specialist training obtained outside of the ACEM

SIMGs in EM applying for specialist recognition in Australia are required to submit an application for primary source verification via the AMC. SIMGs in New Zealand apply via the MCNZ. In both cases, following this application, the SIMGs may then apply to the ACEM for specialist assessment. The ACEM reviews the applicant's training, qualifications and experience on paper and determines the comparability to a FACEM and the requirements for the SIMGs to be elected to fellowship. If the SIMG appears substantially or partially comparable to a FACEM, the ACEM conducts a structured interview for further clarification. The three senior FACEMs on the interview panel review the applicant's qualifications and experience and determine his or her level of confidence in the following areas: undergraduate training, basic training, advanced training, postgraduate experience, research and publication profile, education and training experience and administration. Additionally, a number of topical issues in EM are discussed.

The ACEM then makes a recommendation to the AMC or MCNZ for the requirements for each SIMG to obtain specialist recognition in Australia or New Zealand. This may include a period of supervised practice including the completion of WBAs. SIMGs may be required to complete the research requirement, fellowship written and fellowship clinical examinations. The exact requirements will vary with each SIMG and are determined by the Council of Education.

The ACEM has a comprehensive website (http://www.acem.org.au) that provides up-to-date information on all aspects of training and other college matters. The AMC (http://www.amc.org.au) and MCNZ (http://www.mcnz.org.nz) also have websites with useful information for overseas-trained doctors wishing to work in either country.

Accreditation

Hospitals seeking accreditation for defined purposes, such as service provision or training, must comply with set standards determined by external institutions which oversee the criteria applicable to such hospitals.

In the case of hospitals overall, the Australian Council on Healthcare Standards (ACHS) determines the service standards of patient care provided by a hospital and its individual departments.[2] The ACHS has included the 10 National Safety and Quality Health Service Standards within its framework and integrated these with standards concerning service delivery, provision of care, work force planning and management, information management and corporate systems and safety.

The ACEM separately accredits hospital sites as training providers for the FACEM training program.

Accreditation requirements

The ACEM utilizes a framework of accreditation domains, standards and criteria accepted by all specialist medical colleges in Australia[3]:

Domain 1 promotes the health, welfare and interests of trainees
- Standard 1.1 Governance, safety and quality assurance
  - Criterion 1.1.1 The training site has clear governance structures which supports:
    - (a) Education and training
    - (b) Workplace health, safety and welfare of trainees
    - (c) Trainee participation in governance
    - (d) Improved safety and quality
  - Criterion 1.1.2 Trainee management structures are effective
  - Criterion 1.1.3 There are appropriate quality assurances in place
- Standard 1.2 Infrastructure, facilities and educational resources
  - Criterion 1.2.1 There are appropriate educational resources and these are available to trainees
  - Criterion 1.2.2 The training site provides a physical environment that supports trainees

Domain 2 Ensures that trainees have the appropriate knowledge, skills and supervision to deliver quality patient care
- Standard 2.1 Department specialist staffing and supervision
  - Criterion 2.1.1 There is appropriate staff to ensure effective supervision of trainees at all times.
  - Criterion 2.1.2 Supervisory staff understand their roles and responsibilities and are supported in their supervisory roles.
  - Criterion 2.1.3 The designated director(s) of EM training is supported in the role and is available to trainees.
- Standard 2.2 The provision of clinical experience and work is relevant.
  - Criterion 2.2.1 The training site provides the appropriate breadth and volume of experience.

Domain 3 Supports a wide range of educational and training opportunities aligned to the curriculum framework requirements
- Standard 3.1 Education, training, teaching and learning opportunities
  - Criterion 3.1.1 Teaching and learning opportunities in the workplace are targeted and enable exposure to the breadth of experience in the learning environment.
  - Criterion 3.1.2 Structured education programs and continuing medical education sessions are accessible to the trainees.
- Standard 3.2 Multidisciplinary clinical support services and equipment
  - Criterion 3.2.1 Information on relevant supporting services and specialties supports the delivery of the specialty service.
  - Criterion 3.2.2 Equipment is available to provide the specialty service.
- Standard 3.3 Research opportunities are promoted and facilitated.
  - Criterion 3.3.1 The training site facilitates and supports specialty specific research.
- Standard 3.4 Accreditation by others where required.
  - Criterion 3.4.1 The facility is accredited by other recognized accreditation bodies

Within this framework, the ACEM has 54 craft-specific accreditation requirements.[4] These requirements are applicable to all types of departments (i.e. adult, paediatric, and mixed adult and paediatric) and all requirements must be met.

In general, these mandatory accreditation requirements describe specific outcomes as they relate to trainee welfare, the delivery of the FACEM training program and the environment in which the trainee works and trains.

Rationale for the accreditation requirements

The objectives of a formal process of accreditation and re-accreditation is to ensure that defined acceptable training and education standards are provided at the site.[5] In particular, the accreditation process seeks to ensure that trainees are provided with the necessary support and resources to enable them to meet the requirements of the FACEM training program. The process also assists accredited sites by identifying factors that may be adversely affecting their capacity to deliver effective and supportive training. The ACEM adopts continuous quality improvement principles in the assessment of sites and works collaboratively with sites to ensure all requirements are met.

Accreditation cycle

The ACEM utilizes a 5-year accreditation cycle. In the intervening years, the ACEM monitors the accreditation of sites through the review of trainee placement surveys, examination reports, and workplace-based assessment reports. Accredited sites are also required to submit annual census information updating the ACEM on departmental resources and patient casemix.

With respect to an accreditation inspection, the department completes an accreditation application in which the site provides justification and evidence supporting their meeting of each requirement. The application and accompanying documents are reviewed in detail by the inspection team prior to the inspection. The inspection team comprises one or two FACEMs from the ACEM panel of inspectors and may also include a trainee representative, an ACEM staff member and a health jurisdiction representative. The inspection involves confirming or clarifying the information provided in the application via interviews with hospital executives, the director of EM, the director(s) of EM training, other FACEM staff, trainees and the nurse manager.

Accreditation findings

The inspection team aims to make balanced and objective assessments of a site's performance against the accreditation requirements. Upon completion of an inspection, the team provide a requirement rating of 'met', 'partially met', or 'not met' for each requirement. 'Commendation' or 'suggestion for improvement' may also be provided for requirements that have been 'met'. Where a rating of 'partially met' or 'not met' has been determined for a requirement, an accreditation condition will be imposed. This provides a period of time for the site to address the condition identified via a quality improvement plan. Sites are required to have satisfactorily addressed all accreditation conditions within a maximum 12-month time frame. Failure to do so results in removal of accreditation from the training site.

Accreditation outcomes

Where accreditation is approved, the following outcomes are defined to the site:

- Approval of accreditation as either an ED, a paediatric ED, or a linked ED. Linked accreditation is provided to a small site that utilizes formal linkages to an accredited host site to meet all the relevant accreditation requirements.
- If applicable, accreditation as an Emergency Medicine Training Network (EMTN). An EMTN is a group of accredited sites that have formally agreed to provide a coordinated education and training program for trainees.
- Duration of advanced training time (6, 12, 18 or 24 months) that stipulates the maximum amount of training time a trainee may spend at a site. The assessment of the site-specific accreditation time limit is based on the level of fellow clinical coverage and the number, breadth, acuity and complexity of the case mix available at the site.
- If applicable, accreditation for paediatric logbook status.
- Designation of the ED as either major referral, urban district or rural/regional.

Implications

The accreditation requirements specify what must occur, not how, in order that sites may evolve and develop novel methodologies in the delivery of the FACEM training program having regard to local circumstances, including resources. The ACEM accreditation process is designed to be open and accountable, with an ongoing process of review to ensure that required changes are implemented and sites are given adequate opportunity and support to implement these changes effectively.[5]

Future directions

- The ACEM continues to undertake initiatives that better aligns training with the learning outcomes of the ACEM curriculum framework. Further evolution of training requirements to increase the time trainees spend in an ED environment under the guidance of FACEM supervisors has the potential to improve the training experience and its outcomes.
- The evolving models of care within health regions, hospitals and EDs are potentially changing what has been defined as a major referral hospital experience for trainees. Further defining the patient cohorts trainees require exposure to may better delineate which facilities trainees need to work in.
- Although the accreditation of sites in rural/regional areas has increased, the ongoing pressure to have trainees rotate to rural/regional areas must be reconciled with the ability of such facilities to meet the accreditation requirements and thus provide a beneficial education and training experience. The options of forming EM training networks, becoming a linked ED, or gaining a rural health special skill term provides rural and regional facilities with the ability to optimize training opportunities.

30.6 Specialist training and recognition in emergency medicine in the United Kingdom

Jason Long

ESSENTIALS

1 **Postgraduate medical training in the United Kingdom has become increasingly regulated and controlled by the General Medical Council (GMC).**

2 **Changes to immigration rules have occurred in response to insufficient training opportunities for UK and European graduates. This is one of the contributory factors in the deficit in the number of doctors in training in emergency medicine (EM). Nevertheless it is relatively easy for graduates from Australia, New Zealand, Hong Kong, Singapore, South Africa and the West Indies to undertake postgraduate training in the United Kingdom.**

3 **The GMC sets standards for the curricula and training programmes of the royal colleges and faculties.**

4 **The route to specialist recognition in the United Kingdom is by completing a full GMC-approved programme of training or for relevant college and GMC approval of training, qualifications and experience gained elsewhere.**

5 **EM training lasts for 6 years and comprises a 3-year core programme followed by a 3-year specialist programme and exit examination leading to a fellowship in the Royal College of Emergency Medicine.**

Introduction

The changing landscape of postgraduate medical training in all specialties in the United Kingdom that has occurred within the past decade is set to continue. The changes to the structure of training and recruitment have become embedded, and large-scale changes to the regulatory systems have occurred. The system to fund, control and manage postgraduate medical education (PGME) has undergone large-scale changes following legislation relating to health and social care in England. These systems have developed differently in Scotland, Wales and Northern Ireland.

An understanding of UK training in EM requires some knowledge of the regulatory bodies and systems—relating to the regulation of training, the shape of training and the content of training—that have been put in place since 2003.

Regulation of training

General Medical Council

Anyone who wishes to practise medicine in the United Kingdom must be registered with the GMC, which introduced a new registration framework in October 2007. This framework simplifies registration to either 'full' or 'provisional'. Provisional registration allows newly qualified doctors to undertake general clinical training in the United Kingdom as a Foundation Year 1 doctor (see later) in posts specifically approved for this purpose. Full registration allows doctors to undertake unsupervised medical practice.

Those new to full registration or those who have been away from UK practice for 5 years or more must work for 1 year in an 'approved practice setting'. A list of these placements can be found on the GMC website. They meet defined standards for the training, support and management of doctors.

For either provisional or full registration, non-European Economic Area (EEA) applicants must demonstrate to the GMC that they

- hold an acceptable primary medical qualification.
- have the requisite knowledge and skills for registration.
- have no impairment to their fitness to practise.
- have the necessary knowledge of English, such as a valid International English Language Testing System (IELTS) certificate. This can be done by
- passing the test offered by the Professional and Linguistic Assessments Board (PLAB)
- obtaining sponsorship from a medical royal college (or other approved sponsoring body)
- obtaining an acceptable postgraduate qualification
- becoming eligible for entry to the specialist or general practitioner (GP) register

Doctors applying for full registration must also supply evidence that they have had a period of post-graduate experience equivalent to the general clinical training of Foundation Year 1.

Detailed guidance is available at www.gmc-uk.org.

The GMC has taken over the role of independent regulator of PGME; it is now responsible for approval of curricula, training programmes and certification of completion of training.

Approval of curricula

The GMC has approved the curriculum for training in EM in the United Kingdom. The curriculum includes the syllabus, assessment methodology (including workplace-based assessment and examinations) and the required training programme. There is also an approved curriculum for subspeciality training in paediatric EM. The GMC has approved speciality training programmes in intensive care medicine and pre-hospital EM, thus extending the length of the training period for those doctors who wish to achieve dual training in EM and one of these specialties.

Specialist registration

Doctors who are fully registered with the GMC and who wish to practise as a substantive consultant or GPs in the National Health Service (NHS) must be on the specialist or GP register. The usual route for registration is to complete a full approved programme of training. Such doctors may then apply via their royal college for a Certificate of Completion of Training (CCT).

A second route, Certification of Eligibility for Specialist Registration (CESR), is available to doctors who have not completed a full approved training programme but who wish their training, qualifications and experience, wherever gained, to be considered for eligibility to be entered on to the specialist or GP register. Application forms, portfolios and other documentary evidence of what the doctor has achieved are sent by GMC to the relevant college for consideration and for a recommendation to be made with regard to registration. It is important to note that GMC is not bound by that recommendation.

If successful, such doctors are issued a CESR, which entitles them to apply for inclusion on the UK register but does not confer EEA registration privileges. The process tends to be slow and an application currently costs £1600. Fees to be included on the Medical Register are in addition to this.

Applicants for entry to UK-approved training posts who wish to have training in non-approved posts count toward their EM programme and enter at a level higher than the first year (CT/ST1) can do so on the CESR-CP (Combined Programme) route. Trainees who successfully complete the programme are issued a CESR.

Immigration rules

Immigration rules restrict access to UK PGME for international medical graduates (IMGs). This was driven by the concern that there may be insufficient training opportunities for UK and EEA graduates. A points-based system has been introduced to control immigration. EM is currently a 'shortage occupation' in the United Kingdom. Hence, applicants who meet the requirements for registration with the GMC are highly likely to achieve the points total required under a Tier 2 application for a visa for consultant posts or non-training junior doctor posts. CT3 and ST4 to ST7 specialist training posts in EM are also included on the shortage occupation list. Further details and up-to-date information is available at www.ukba.homeoffice.gov.uk/visas-immigration.

Medical training initiative

EM training in the United Kingdom for non-EEA doctors is also available for a period of 6 to 24 months under the medical training initiative. At the end of this period, trainees must return to their home country. Trainees are sponsored by the Royal College of EM and the Academy of Medical Royal Colleges under a government-authorized exchange programme. From April 2017, new applications for the MTI scheme from countries not considered Department of International Development priority countries or World Bank low-income and lower-middle-income countries will be placed on a revised waiting list and be processed only if and when there is capacity. It has been reaffirmed by the Department of Health, Health Education England and the Academy of Medical Royal Colleges that the priority focus of the MTI is to provide training opportunities for doctors in Department for International Development (DfID) priority or Low Income (LI) & Low middle income (LMI) countries and have therefore stated that although applicants in countries not considered DfID priority or LI&LMI are not barred from making an application, they can have no guarantee or expectation of receiving an MTI Certificate of Sponsorship (CoS). Further details are available at http://www.aomrc.org.uk/medical-training-initiative/

Successful applicants are exempted from the PLAB test (but are excluded from applying if they have previously failed this test).

To be eligible for sponsorship, the doctor must be one of the following:

- a current trainee in a non-EEA EM training programme with the support of the training programme director for the plan to spend a period of time training in the UK
- a consultant who has completed a specialist training programme in EM with the support of the employer for the plan to spend a period of time training in the UK
- a consultant who has trained in a specialty other than EM with at least 12 months of experience in EM with the support of the employer for the plan to spend a period of time training in the UK

The individual requirements for the MTI are that the doctor must

- not (normally) hold EEA citizenship or EEA rights of residency.
- hold a primary medical qualification acceptable to the GMC for full registration (and from June 2018 be independently verified by the Educational Commission for Foreign Medical Graduates).
- be able to provide a certificate of good standing (CGS) from each licensing and regulatory body in which they have been registered within the last 5 years. The GMC requires that doctors must provide a CGS from the country in which they obtained their primary medical qualification and each of the countries they have worked in during the 5 years immediately preceding an application for registration.
- have completed at least 3 years post-graduate training, including an internship.
- have an institutional sponsor in their home country specifying the post to which they will return.
- provide evidence of satisfactory progression through training. Acceptable evidence would be documentation of passing any required postgraduate exam, a logbook or training portfolio (if applicable), evidence of clinical governance activity, or appraisal documentation. Evidence should cover both generic EM and acute specialties. Any evidence should be validated by the overseas sponsor.

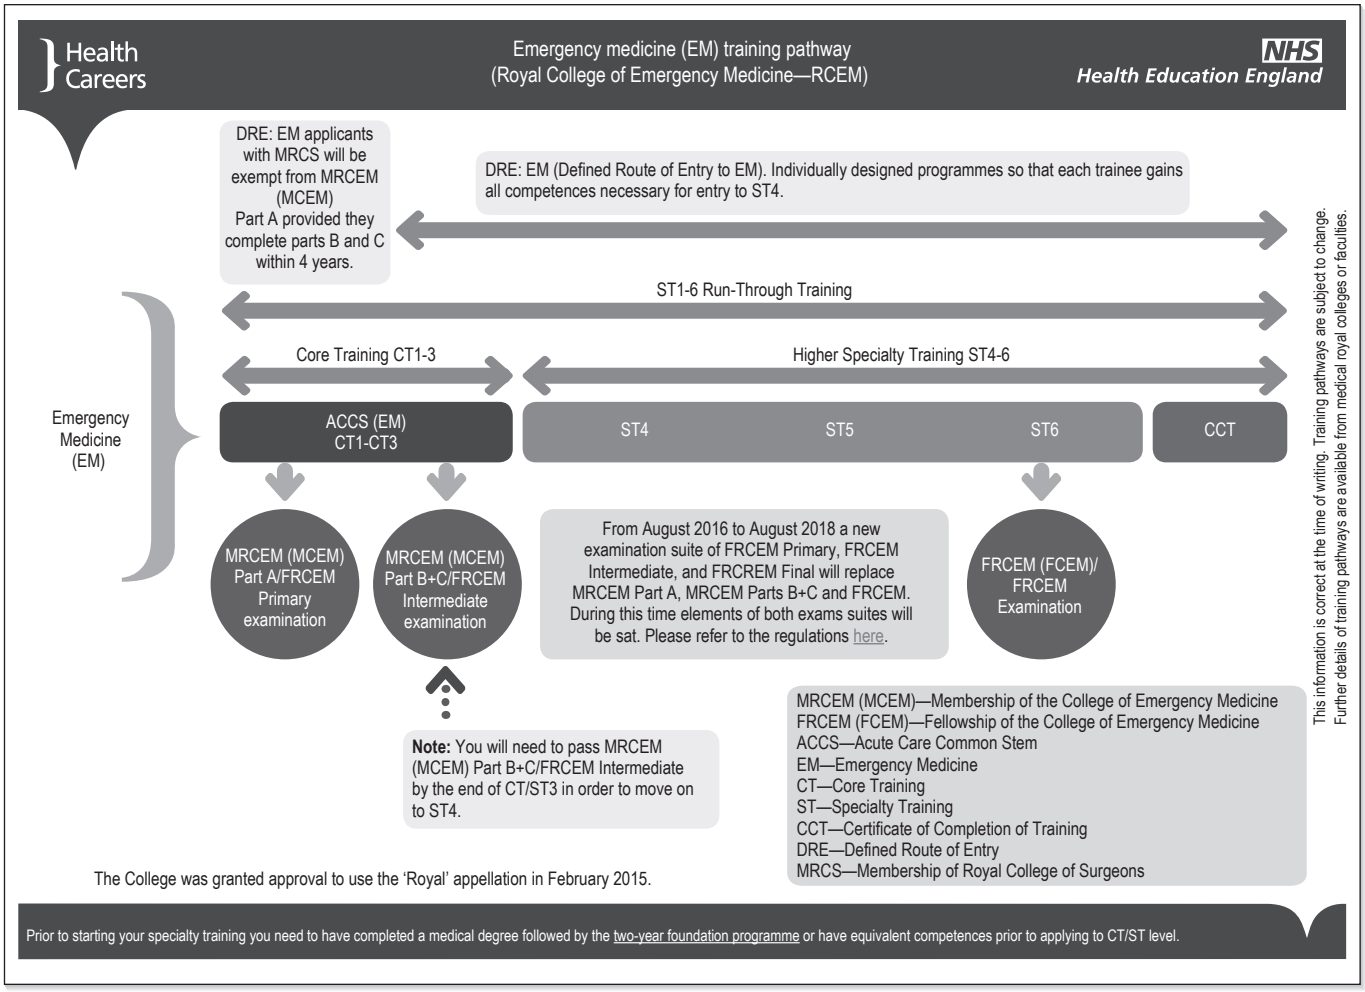

FIG. 30.6.1 Emergency medicine training programme flow chart. (Reproduced with permission from NHS Health Careers. https://www.healthcareers.nhs.uk/.)

- be certified in at least one life support course—ATLS, APLS or ALS (or accepted equivalent).
- have achieved a score of 7.0 in each section (speaking, listening, reading and writing) and an overall band score of 7.5 of the academic module of the IELTS within the last 2 years. If the doctor is practising in a country where the first language is English, he or she may apply to the GMC for exemption from the IELTS.

Postgraduate training in the United Kingdom

Following graduation, doctors enter a 2-year foundation programme that delivers general clinical training, a broader experience and the acquisition and verification of generic competencies. Thereafter, those who have successfully completed such programmes and those from other countries who can provide evidence of equivalent experience and competence (and who satisfy immigration rules) can apply for specialist training programmes. These programmes vary in their duration and pattern according to the specialty but lead to the award of a CCT.

Training in emergency medicine in the United Kingdom

The EM training programme in the United Kingdom lasts for 6 years. Acute care common stem (ACCS) training plus a further year in EM form the first 3 years (core training). During ACCS, trainees undertake posts in EM, acute medicine, anaesthesia and intensive care medicine. This is followed by a year working in EM, with a particular focus on gaining paediatric competences and the non-technical skills to be able to lead and supervise others. During this period trainees must pass the FRCEM intermediate certificate or previously have passed the membership examination of the Royal College of EM. This is followed by a 3-year specialist training programme leading to a fellowship in the RCEM to those who pass the exit examination. EM training is a run-through training programme, so that trainees no longer have to reapply for higher training. Trainees can choose to complete only ACCS training and then reapply to higher specialty training (ST) (Fig. 30.6.1).

A further route of entry into emergency training is the Defined Route of Entry into EM (DRE-EM). This allows entry to ST3 via two routes:

- From surgical training: Following 2 years of UK core surgical or run through surgical training. Leads to a CCT in EM.
- From ACCS specialties: Following completion of 24 months at core trainee level in any ACCS specialty (anaesthesia, EM, Intensive Care Medicine (ICM), acute medicine), of which at least 12 months is EM. Leads to a CESR-CP in EM.

ST years 4 to 6 are spent in a series of EDs. Year-to-year progression is dependent on satisfactory assessment and appraisals, mostly conducted in the workplace. In the final year of training, candidates who are supported by their local programmes are eligible to sit for the final FRCEM examination, successful completion of which is necessary to receive a CCT.

Many higher training posts are unfilled. The reasons for this are widely debated but include the unsocial nature of the work, the intensity of work, terms and conditions of service compared with elective specialties and primary care, changes in the specialty as a consequence of the emergency care standard ('4-hour target') and changes in immigration rules. Currently, these pressures are not adequately compensated by the rich and rewarding aspects of the work. RCEM, in conjunction with other bodies, is striving to correct this imbalance.

Subspecialty training

EM has two sub-specialties: paediatric EM (shared with paediatrics); and pre-hospital EM (shared with anaesthetics, AM and ICM). EM trainees who choose to sub-specialize must apply for such posts and, if successful, have their CCT date extended by 1 year, as neither sub-specialty is a part of the main EM curriculum. Trainees who successfully complete their sub-specialty and parent ST are recommended by RCEM to the GMC for inclusion on the specialist register for EM, with PEM or PHEM as a sub-specialty.

Conclusion

The training programme has been through a period of marked transition as a result of forces from within and outside the specialty. There has been a period of stability upon which further refinement, rather than wholesale change, will be likely. ACCS is very popular with trainees with significant competition for places. There is much less competition for higher training posts. Anyone interested in EM training in the United Kingdom is advised to make frequent visits to the websites of RCEM, GMC and the UK Border Agency.

CONTROVERSIES AND FUTURE DIRECTIONS

- Today's junior doctors are not attracted to working in EM in the United Kingdom in high enough numbers. Major steps are being taken to address the imbalance of work and reward. The future success of EM is dependent on continuing to attract and retain doctors of the highest quality.
- EM has always been a broad church. Constraining EM training in the United Kingdom previously to a single core training programme resulted in many benefits but limited the diversity of additional skills within the consultant workforce. The introduction of alternative routes of training within EM in the United Kingdom will hopefully reverse this trend.

30.7 Complaints

Fatima Rahman

ESSENTIALS

1 **Complaints occur in every emergency department. They can be considered useful feedback.**

2 **Good complaints management involves being open to complaints and seeing them as an opportunity for improvement.**

3 **The majority of complaints are at least partly justified when properly investigated.**

4 **An acknowledgement, apology, commitment to investigate and truthful response are expected.**

5 **Resolution is by conveying the facts, any corrective actions done and expressing regret.**

6 **Staff should be supported throughout and confidentiality upheld.**

7 **Lessons learnt should be integrated into risk management and quality improvement processes.**

Introduction

Complaints are inevitable in the setting of busy emergency departments (EDs). They may arise from poor quality of service or unmet patient expectations. Most senior ED staff are aware of what constitutes optimal care. Unfortunately, EDs are areas where there is little control over timing, volume or case presentations; that, combined with a mixture of staff with different levels of experience, long waits and multiple other reasons (Box 30.7.1), means that complaints are common.

Advances in emergency medicine (EM) and nursing clinical care have resulted in new standards with which the public have become familiar. Patients and their relatives have much higher expectations of EDs than previously. They are better informed, more litigious and encouraged by marketing from legal firms. Nevertheless, most patients who may have legitimate cause for complaint do not formally complain; hence the frequency of complaints is not an accurate gauge of patient satisfaction.

Incidence

Complaint rates about ED care vary from 0.26 to 3.8 complaints/1000 patients.[1,2] Some hospitals record only written complaints, whereas others also include verbal complaints in their data. Often the complaints refer to multiple issues. More complaints relate to paediatric patients and more are made by females and the literate.[3]

In an analysis of complaints lodged by patients attending Victorian hospitals between 1997 and 2001; in comparison to other hospital departments, ED complaint rates were significantly lower (1.9/1000) than those in general wards (6.2/1000) and intensive care (5.9/1000).[3]

In a further study of 2419 ED-related complaints from 36 hospitals over 5 years, 37% were made by the patient and 48% were from relatives. Friends accounted for 3%, and the rest included General Practitioners (GPs), specialists, government representatives and lawyers. ED

Box 30.7.1 Contributing factors and reasons for complaints

- Unpredictability of case mix and case load
- Variation in attendance rates
- Long waiting times
- Insufficient staffing for unexpected peaks
- Junior staff with variable experience and supervision
- Deficiencies in treatment (real or perceived)
- Inadequate assessment and missed diagnosis (real or perceived)
- Poor attitudes, lack of professionalism
- Poor communication, lack of information or consent
- Interruptions, multiple concurrent tasks
- Delays in investigations, consultations
- Access block to inpatient beds
- No appropriate follow-up
- Inappropriate or premature discharge
- Unmet expectations
- Invasion of privacy
- Fees in private hospital emergency departments
- Litigation for compensation

complaints were 14.3% of the total 16,901 hospital complaints.[1]

Reasons

In this study, there were four main categories for complaint: problems relating to care (inadequate treatment, diagnosis or follow-up—33%), communication (relaying information, rudeness and discourtesy—31%), access (26%) and administrative deficiencies (incorrect documentation, inability to obtain previous records, lack of privacy or confidentiality and loss of property—7%).[1] In most other studies, communication is by far the highest category.[2] In private hospitals, fees are an increasing source of complaint.

Clinical care

Approximately 50% of complaints claiming inadequate medical assessment and treatment are substantiated.[2] Inadequate physical examination followed by a missed or delayed diagnosis is a frequent complaint and can only be refuted if good medical documentation exists.

Medicine is not an exact science, and early clinical features may be atypical. Explaining this to the anxious patient who wants a quick diagnosis and symptom relief can pose difficulties for a busy doctor.

Missed fractures are the most frequent 'misdiagnosis'. Some 'misdiagnoses', as perceived by patients, result from poor communication, with lack of explanation by the treating doctor of the possible causes or what to do if there is no improvement.[2]

Lack of treatment includes insufficient or no analgesia, lack of investigations or antibiotics (where an initial presentation, particularly in a child, may have suggested a viral illness with eventual progression to a bacterial infection) and lack of a splint for a 'soft tissue injury', which is subsequently diagnosed as a fracture.

Rough, unskilled or incompetent treatment still occurs despite advances in training of both doctors and nurses. A heavy workload is not an acceptable excuse. With the reduction in allowable weekly labour hours for hospital-employed doctors, EDs may rely to some extent on junior staff and locums under variable levels of senior supervision on some rosters.

Unprofessional conduct and refusal to refer to a specialist or to a previous treating doctor are unacceptable causes of complaint. Cases of sexual misconduct are very rare in EDs and should be referred to a medical board.

Communication

Effective communication is fundamental to good health care services. Poor or inadequate communication with consumers is the reason behind many complaints.[4] Failure of doctors to introduce themselves and to explain the reasons for examination, investigations, treatment, disposition decisions, referrals or delays are all avoidable causes of complaints.

Abruptness, rudeness, discourtesy, insensitivity, absence of caring and other aspects of poor attitude used to be the main reason for complaints, but, perhaps as standards in general society have changed, this is no longer the case. However, in EDs, when people are rightfully anxious about their medical condition, such attitudes should not be tolerated. Lack of formality, addressing older patients by their given name, casual dress standards and incomplete identification have become the accepted norm in many Australasian hospitals but may still upset some of our senior citizens and immigrants.

Failure to obtain consent in the case of minors or to gain informed consent for procedures and to warn about risks occurs commonly in EDs, where it is assumed that attendance implies consent, but this can be challenged if the patient is brought to hospital by ambulance or other means.

Doctors may miss significant clues if they ignore aspects of a patient's history which do not fit with a presumptive diagnosis. This may also occur if the history is rushed and overly brief. Incorrect documentation and poor clinical handover are common sources of complaint, particularly when it results in the wrong treatment.

Reliance on referring letters or ambulance sheets without interviewing the patient can result in transcribing incorrect past history, medication charts and allergies. It cannot be assumed that referral details or old case histories are correct. Objective evidence of diagnoses should be sought.

It can be difficult to identify a 'source of truth', when people do not have a regular physician. This can be compounded by 'doctor shopping', where patients attend the most convenient bulk-billing family medicine clinic, where their past history is unknown, hoping for a quick cure for acute problems, while reserving attendances at their usual general practitioner for more complicated ongoing illnesses.

Clinical staff in EDs are commonly faced with excessive communication loads. The combination of interruptions and multiple concurrent tasks resulted in 36 communication events an hour in one study, and this may produce clinical errors by disrupting memory processes.[5]

Delays

Difficulty with access to health care is a worldwide problem, even in first-world countries, where economic rationalism and changing government policies have resulted in closure of hospital beds, mental health institutions and community resources. Lifestyle and industrial issues have decreased the numbers of medical and nursing staff in hospitals, particularly after hours.

Diminished outpatient services may mean that patients need to be referred to private consultants' rooms where appointments may not be readily available. Fewer general practices open in the evenings or weekends. Some patients want a one-stop service for their medical consultation, their laboratory tests and their radiology. These social reasons make unnecessary use of scarce resources, despite strategies, such as telephone triage services and hospital-run after hours GP clinics. All the aforementioned have contributed somewhat to increased ED attendances.

Delays in triage, time seen by doctor, treatment, investigations, consultations, admission or discharge may therefore occur. Measures to decrease these are only partially successful because there is generally no excess of staff or resources to call upon when there are unexpected peaks in workload. Steps to improve waiting times, increase throughput of short-stay patients and decrease misdiagnosis of fractures have resulted in fewer complaints.[6]

Particularly in the case of children and distressed patients, long delays cannot be easily tolerated, and a significant number 'walk out' without being seen. The elderly are less likely to complain but suffer in silence, such that any pain they have may be unrecognized and untreated until late in the management.[7]

Administration

Incorrect documentation by clerical, nursing or medical staff, lack of privacy or confidentiality, loss of valuables, poor cleaning or other

environmental issues and queries regarding billing in private hospitals comprise the majority of administrative complaints.[1,2]

Errors can be made by doctors in giving advice regarding a patient's right to claim compensation, because the full circumstances cannot easily be ascertained at the time of consultation. Doctors should not advise patients regarding entitlements to compensation but should complete the necessary documentation objectively.

Poor department design, lack of an accessible staff room or little adherence to departmental policy may cause complaints about staff socializing, eating or drinking. Their laughter may be seen by some patients as inappropriate but by others as a sign of good staff morale.

The Federal Privacy Act gives patients a general right of access to information held about them (see Chapter 28.4). Although patients have right of access, they must obtain consent from the doctors for further reproduction of the material, because the doctor still has ownership of clinical notes and specialists have legal rights over their reports. Relevant material must be made available to another doctor. Refusal of access must be based on reasonable grounds, such as that access would pose a serious threat to the life or health of any person. Conversely, information held by the doctor on the patient must not be divulged to third parties without patient consent, unless compelled by law, such as with mandatory reporting of child abuse.

Unmet expectations

Patient satisfaction surveys have ranked waiting times, symptom relief, a caring and concerned attitude and correct diagnosis as priorities when attending an ED. However, there is a mismatch when compared with staff who agree with the priorities but rank waiting time fourth.[8]

Patients expect ED doctors to identify serious or dangerous conditions and to treat these appropriately. Explanation and reassurance are needed.

Responding to a complaint

Effectively responding to a complaint minimizes the likelihood of adversity and escalation. An effective response is early, supportive, open, even-handed and constructive. It should be backed up by a clear, accountable and outcome-driven complaints management process that is supported by hospital administration (Box 30.7.2).

Immediate response

When a verbal complaint is made, the person to whom it is made has a responsibility to respond at the time, as well as notify the appropriate manager of the service. This response should be immediate, genuine and supportive of the complainant's right to raise issues. The more immediate and active the response, the less likely that the complainant will feel alienated or aggrieved and the more likely that anger will be rapidly defused.[9] If a consultation is not going well or there appears to be dissatisfaction brewing, rather than avoid the issue and escape from the situation, it can help to ask if there is anything on the patient's mind or ask a colleague or senior to assist by consulting. In both the public and private sectors, most unsatisfied patients may not complain immediately but will spread their disapproval more widely via contacts or media, which can ultimately have an adverse effect on staff morale and future interactions.

Box 30.7.2 Suggested procedure for response to complaints

Accept the complaint
Apologize for the complainant's dissatisfaction
Defuse any anger
Record the details
Undertake to investigate
Arrange follow-up
Investigate
Discuss with staff
Inform administration
Consider legal implications
Follow up with complainant
Resolve complaint
Lessons to be learnt

Diffusing dissatisfaction and conflict

To move towards resolution and to help minimize conflict, it is important to be empathetic and recognize the person's feelings. The interview should occur in a private place or office away from distractions and listened to in an open and supportive way, without interruption, and avoiding defensive postures and interjections. Early excuses, uninformed speculation or a defensive response without appearing to look into the matter will be seen through easily and regarded as dismissive and arrogant. If the person is rude or abusive, it is wise not to mirror this or terminate the meeting prematurely but to state that one still wants to help and understands that he or she is upset, in the knowledge that showing anger will make it harder to work together to get an appropriate outcome. If an 'independent' support person is available, such as a social worker, interpreter (or even a neighbour), for emotional, psychological or other support, this can help both doctor and patient.

Support of the complainant

The person has a right to alert the doctor of his or her concerns and be heard and to receive reassurance that he or she will be taken seriously. It helps to let the patient know what the doctor intends to do with his or her complaint, what the patient's rights are and that he or she has alternative routes to raise issues. Some experienced doctors are confident enough to thank the person for his or her complaint, on the basis that it provides an opportunity to improve services. A person who cares enough to report a problem in a department has great potential later to become a satisfied client. If some complaints may seem trivial, any underlying reasons or causes should be explored because failure to address their underlying concern may perpetuate the correspondence. It can help to encourage the patient to bring a support person because the presence of a less emotional witness improves recall and can moderate the experience.

Expressing regret

An expression of regret acknowledges the complaint and does not admit error or that the complainant is correct. The more serious the issue being complained about, the more relevant the apology is to establishing empathy and creating an open and honest relationship with the person.[4]

Documenting and investigating

As part of receiving the complaint, it is important to document clearly the complainant's perception of the issues, as well as the name, relationship to patient and correct contact details. At the end of the meeting it is a good exercise to summarize their perception of the issues and outline what actions will be next and the timelines for response.

In the information-gathering process, it pays to cross-check facts meticulously because any sloppiness in this phase will damage the process later. Take the time to interview involved staff, check medical records and do not be surprised if early assumptions are incorrect.

Determining the issues

Determining what the person wants may not be straightforward because he or she may not have crystallized it yet or be willing to articulate it. People would reasonably expect respect, an understanding of point of view, an immediate investigation of the true facts, early feedback and/or resolution and assurance that the problem will not recur to them or others. These are

reasonable and deliverable aspirations, and any department should have a system that supports this.

Some complainants want 'someone' to be reprimanded or punished (particularly if rudeness or lack of compassion featured), and some may feel they need some financial recompense. The desire for censure can be mitigated by a genuine apology for their experience by the involved staff or by their senior and, if relevant, explanation that contributing systemic issues were involved and will be addressed. If a complaint about unprofessional conduct is upheld, the option of escalating the complaint to a professional body should be available. There may be some scope in private hospitals to renegotiate costs if these contribute to a complaint.

Supporting staff and confidentiality

Most doctors and nurses are devastated when a complaint is made and might feel the need to justify what the patient perceived, disagree with recall and may feel anger towards the complainant. It should be sensitively explained that any complainant is voicing dissatisfaction with a perception and that everyone's views are being sought to investigate the facts fairly and openly and it may have value in improving the service.

It helps to reassure all that the principles of natural justice will be upheld and confidentiality of the staff and patient will be maintained.

If staff are distressed by the process, support and counselling should be offered, because many doctors and nurses have left the profession as a result of complaints, even though they were not directly responsible for the outcome.[10] Most jurisdictions currently operate a 'systems approach' to what we used to call 'human error', and part of this is accepting personal fallibility (it's normal to be human) and concentrating on identifying what systems issues require action. Any competence or conduct issue should be addressed by the director of training or supervisors and may form part of a regular 'performance appraisal'.[4]

Resolution

Once the facts have been established, ideally, corrective actions are identified that will prevent the event that provoked the complaint from recurring. Assess what the most appropriate resolution approach to take is. Facts laid out in a non-judgemental way, any corrective actions proposed and perhaps a repeat of the expression of regret form the basis of the follow-up interview or letter. Address all the issues raised. Rarely, it is advisable to refer to an external investigator or mediator, and there should be hospital policy available on this.

In the Victorian study, most complaints (75%) were satisfactorily resolved by explanation of facts and/or apology.[1] Changes in policy occurred in 2%, and remedial action took place in 5%. Very few complaints went to the legal system (<1%). The remainder were not upheld, not pursued or found to be frivolous. This is similar to the experience of the state health complaints commissions or ombudsmen, where most complaints are resolved by free and open investigation, explanation and conciliation and very few are seeking censure.

Integrating with risk management

An effective complaints handling process should integrate with risk management processes, by identifying areas for improvement. A complaint may highlight unusual patterns of practice, deficiencies in protocols and guidelines and areas for further training and even provide the objective evidence needed for development of an ED business case. Complaints and compliments should be included in the risk management discussion of any senior staff meeting.

If the complaint has medicolegal or adverse publicity implications, the medical director and/or executive officers need to be informed to allow a considered response. Systems might exist that facilitate or enforce this, such as incident monitoring systems, sentinel event monitoring or the formal open disclosure process.

Prevention

System design

A well-equipped ED with adequate numbers of senior medical and nursing staff supervising junior staff, all aware of their scope of practice, will likely have fewer complaints. The department's design can enhance safety, with good waiting area and resuscitation area visibility, patient privacy maintained and temperature and noise levels comfortable, and can provide sufficient space, easy access to rest rooms and refreshment and education areas for staff close by.[6] Analgesia or x-ray protocols should be considered and prioritizing pathology requests.

Verbal and printed information on the frequently complained about areas of triage system, assessment and investigation turnaround times, can be provided to waiting patients. High-risk groups that poorly tolerate prolonged waits, such as children and psychiatric patients, can be triaged to be seen earlier.

Systems and procedures to follow up abnormal pathology and imaging results should exist and be audited because one in six missed diagnoses are related to follow-up processes. Having protected and formalized clinical handover processes to effectively transfer information and responsibility should be standard clinical practice.

People

A polite well-groomed doctor who introduces himself or herself, makes eye contact, shakes hands and uses the person's title and surname can help to avert complaints. Talking out loud any examination findings as they conduct the examination can minimize accusations of inadequate examination because stressed patients have poor recall and distorted perception of the interaction.

Adequate documentation of the encounter may provide the only means of refuting or resolving a complaint and, although complaint-specific proforma, computerized decision support and discharge instructions can help documentation, preserving time to complete documentation is still important. Records must not be altered after a complaint.

A proactive approach to complaints handling as part of a wider incident reporting system can result in higher patient and staff satisfaction. Specific training on how to relate to people in the pressured ED environment and how to handle complaints effectively should be incorporated into orientation and undergraduate education for nurses and doctors.

Managing specific aspects

Written formal complaints

Acknowledging the notification as quickly as possible, ideally within 3 days, together with an apology that they have experienced dissatisfaction is an expectation in many jurisdictions. This early response, along with the commitment to investigate and act on any findings, may be satisfactory for many complainants. If the matter is clinically significant or may escalate, an early phone call in advance of the written response, perhaps to invite more information or, better, a managed face-to-face meeting. The Australian Council for Safety and Quality in Health Care has published examples of letters and responses.[4]

Catastrophic adverse events

If the complaint is about a serious adverse event, such as a deterioration or death, many hospitals advocate the open disclosure model, an initiative of the former Australian Council for Safety and Quality in Health Care. The elements of open disclosure are acknowledgement that

an adverse event has occurred, an expression of regret, a factual explanation of what happened, information about further treatment required, the potential consequences and the steps being taken to manage the event and prevent recurrence. There is an early informal phase where the treating clinician informs the patient of what has occurred and expresses regret for the harm caused or adverse outcome, with follow-up in the form of formal open disclosure, which is about facilitating more consistent and effective communication between the patient, the senior clinician and the organization using a *trained* team in response to the most serious adverse events.[4]

Grief reactions

Manifestations of grief and the desire to know all the circumstances should be respected but clinicians should avoid providing explanations that are unverified. Sometimes, a need to blame is part of the grieving process. Again, it is useful to offer support[8] (pastoral care, social worker, external counsellors or psychologists), and some open disclosure systems approve financial support to facilitate supportive acts (transport for a family member to come, accommodation close by).

Unreasonable requests or expectations

Although the ultimate outcome may be a negative, it can help to start with a positive assertion and try to establish a working relationship. A two-way communication allows the complainant to vent and prevents missing any important information. 'Yes, I can see why you are worried about taking John home. Let's talk through what the problems are and the early and longer-term solutions to this'.

'Pests' or persistent complainants

A small number of complainants are unwilling to accept decisions, continue to demand further action, insist on outcomes that are clearly not appropriate or demand things they are not entitled to. They may constantly change the complaints, complain about the process, complain to multiple bodies simultaneously or make inappropriate freedom of information (FOI) requests. Although it is tempting to pass them quickly up the chain, this can reinforce their behaviour and create more work. Try to own the complaint, manage their expectations early of what is going to happen and what is possible. Focus your attention on the conduct, not the person, and, similarly, separate the conduct from the complaint. Be firm and clear about what is not going to happen, that some complaints have no further avenues and that re-raising the complaint will not be responded to.[11]

Delays

Frequent and realistic communication by all staff can help, explaining what delays are occurring, that triage times are revised, why repeated consultations occur, why tests are being done and what the likely outcome of the wait is. It is useful to avoid unrealistic promises like 'I'll be back in a minute' or 'they said they'd be down from theatre straight away'.

Summary

Complaints are a source of stress and concern for both emergency physicians and their patients. They are inevitable, part of our responsibility and should not be avoided. An understanding of the public's expectations from their attendance will assist in prevention of complaints.[11]

Poor complaints management can damage a department. A good complaints management process can help by saving time, avoiding escalation, restoring the trust and confidence of patients, improving the safety and quality of the service and creating a more satisfactory working environment for staff.

Good complaints management can be easily learnt, but it sometimes requires a change in attitude; the most influential factor in changing attitudes and culture in an organization is senior leadership.

CONTROVERSIES

Areas where clinicians vary in their acceptance of best practice as proposed by complaints and conflict experts include:

- The first person to field a complaint has a responsibility to acknowledge and respond to the issue.
- An expression of regret or an apology is not an admission of liability.
- Staff members should be notified of complaints against them to allow a right of reply/natural justice.
- A vexatious, time-wasting or 'difficult' complainant who is avoided or 'passed up the chain' is encouraged by this behaviour.

30.8 Patient safety

Peter Sprivulis

ESSENTIALS

1 Approximately 1 in 10 hospital patients experiences an adverse event, of which half may be attributed to clinical error and one-third results in significant harm or death.

2 Emergency medicine faces particular challenges to safe patient care due to the undifferentiated and potentially unstable patient case mix, high staff turnover, staff inexperience and fatigue and distractions, noise and overcrowding in the clinical care environment.

3 Clinical errors in emergency medicine may include errors of patient identification, hospital-acquired infections due to poor procedure asepsis and patient isolation procedures, medication errors, misdiagnosis and failure of follow-up of investigation and imaging abnormalities, communication errors, physical care errors and mistriage.

4 Improving patient safety in emergency departments (EDs) requires an understanding of the ED environment and a methodical stepwise approach to improving safety based upon:

- **a** fostering reporting of clinical incidents, including 'near misses'
- **b** evaluating reported incidents using accepted methodologies such as root cause analysis
- **c** treating the risk: this is rarely achieved by exhorting staff to 'try harder' or removing the offending individual. Rather, risk reduction usually requires process redesign to make the 'right' thing easier to do and an error less likely.

5 Patient safety should be monitored proactively in order to ascertain risks and assist assessment and refinement of interventions to improve patient safety.

6 An open, communicative culture that promotes reporting and minimizes blame supports patient safety improvement.

Introduction

Patient safety, or the freedom from accidental injury due to medical care or from medical error, is increasingly being recognized as a critical consideration in the delivery of acute and emergency health care.[1] Several Organisation for Economic Co-operation and Development (OECD) countries have examined the proportion of acute care admissions during which an adverse event is identifiable. Typically 1 in 10 admitted patients experiences an adverse event, of which half are considered preventable with the current state of medical knowledge (i.e. are due to medical error).[1] Typically, one-third of adverse events leads to moderate or greater disability or death.[1] An important consideration for the emergency care of admitted patients is that the day of greatest risk of an adverse event is usually the first day of admission to hospital. This is when knowledge of the patient's clinical condition is often incomplete, the clinical condition is least stable and most patients experience the greatest number of procedures and interventions.[2]

Specific emergency department factors that may compromise patient safety

Safe patient care is challenged by several specific emergency department (ED) factors that include:

- *Staff factors*: ED staffing profiles, particularly in public EDs, typically include a high proportion of junior medical and nursing staff who are still in training. Safety improves with experience. In addition, there is usually a scheduled high turnover of staff, as staff are rotated between alternate training positions. These high levels of rotation can corrode 'memory' of safe and desirable processes and systems of care. ED staff are usually rostered to work shifts spanning 24 hours a day. Poorly designed rosters may contribute to fatigue.[3,4]
- *Clinical factors*: ED patients have an inherently high severity of illness, placing them at greater risk of serious adverse sequelae if a medical error occurs. In addition, the undifferentiated nature of illness and injuries cared for, often coupled with the incomplete clinical information, creates clinical uncertainty, increasing risk.[4,5]
- *Physical environment*: EDs are noisy, busy work spaces, with frequent intrusions from alarms, pages, telephone calls and personal consultations, all of which create distractions, increasing the risk of error.[6]
- *Linkages to other care systems*: emergency care is reliant upon a complex set of relationships between the ED, referring practitioners, prehospital carers, other hospital services and other services responsible for aftercare or following up after discharge from the ED. Poor linkages or communication between the ED and any of these other services can result in errors or omissions in information transfer that compromise patient safety.[7]
- *Overcrowding*: EDs have little control over patient attendance and, increasingly, suffer overcrowding as a consequence of poor access to beds downstream of the ED for admitted patients. This is associated with overcrowding and increased mortality, most likely due to a combination of resource effects (incorrect or insufficient resources or attempting procedures or monitoring in inappropriate locations) and delays in time to critical care.[4,8]

Common safety problems encountered in emergency departments

The factors described earlier interact to create a wide range of risks to patients needing emergency care.[4] Some of the errors observed in the emergency setting include:

- *Patient identification errors*: errors in patient identification, incorrect labelling of laboratory requests and mislabelled samples may result in delays, misdiagnosis and incorrect treatment, such as transfusion errors.
- *Hospital-acquired infection*: the conduct of simple procedures, such as peripheral intravenous line and urinary catheter insertion, by inexperienced staff using suboptimal asepsis techniques in inappropriate or crowded locations, increases the risk of hospital-acquired infection. Poor screening or compromise of isolation procedures due to overcrowding can pose genuine life threats to other patients.

- *Incorrect interpretation or failure to follow up pending imaging or laboratory investigations*
- *Medication errors*: illegible, incomplete and verbal drug prescriptions, dosing errors (particularly in children) and compromise of medication administration procedures increase the risk of adverse drug events.
- *Communication errors*: omissions in the handover of care between clinicians within the ED at the change of shift, upon transfer to inpatient teams or upon discharge/transfer may cause serious delays in both diagnosis and the follow-up of urgently needed investigations or treatment.
- *Physical care errors*: the care of elderly patients for extended periods in a bright, noisy environment, in the era of access block, increases the risk of confusion and falls.
- *Triage errors*: triage is known to be an imperfect art; however, in the era of overcrowding, which may result in significant delays in care for low-priority patients, a triage error may result in significant delays in diagnosis or initiation of treatment.

Improving safety in the emergency department

Specific actions to improve patient safety should be undertaken in the context of a comprehensive organizational framework for clinical governance and quality improvement.[1] The development of a programme of safety improvement for an ED should be undertaken methodically, in accordance with existing Australasian and international standards that usually encompass the following process elements:

- *Understand the environment*: initially, it is essential that the specific environment of emergency care, including the characteristics of EDs and emergency patients that impair safety and the types of errors encountered in emergency care, is fully understood.
- *Identify specific risks*: risk identification is usually undertaken with the aid of clinical incident reporting systems that encourage the structured reporting of clinical incidents that resulted, or could have resulted, in unexpected harm to the patient (e.g. the Australian Incident Monitoring System). These reports are usually collated both at the ED level and also at the hospital or organization level and even at the jurisdictional or national level.
- *Near misses:* For every 1000 prevented or no-harm incidents there may be 100 of the same type that cause minor to moderate harm, 10 that cause severe harm and 1 that causes death. Therefore it is important to learn from the prevented or no-harm incidents to reduce the chance of the single death incident happening. Often, employees are more willing to report near misses. The importance of including near misses in the incident reporting systems cannot be overemphasized.[1]
- *Analyse and evaluate the risks*: risk analysis should be undertaken using an accepted methodology with the support of staff trained in its use. Two common forms of analysis are root cause analysis and failure modes and effects analysis. Root cause analysis is conducted 'after the event' and aims to identify what happened, why and what can be done to prevent it in the future by attempting to identify systems problems that contributed to the clinical event. Failure modes and effects analysis can be conducted in the absence of specific clinical events. It uses a proactive, systematic approach to evaluate clinical processes and workflows in order to identify how they might fail and to assess the relative impact of different failures in order to identify the parts of the process/workflow that are most in need of change. This approach is particularly useful in evaluating a new process prior to implementation and in assessing the impact of a proposed change to an existing process.
- *Treat the risks*: common preconceptions that can stand in the way of an effective remedy include the 'perfection myth'—if we try hard enough, we will not make any errors—and the 'punishment myth'—if we punish people when they make errors, they will make fewer of them. In reality, at least 80% of errors may be attributed to poorly designed care systems, workflows and processes that fail to account for human fallibility. Unfortunately, the mere publication of a new clinical guideline rarely results in a sustained change in practice. The preferred approach to reducing risk is to use the principles of reliability engineering and process redesign that substitute clumsy, unreliable and dangerous processes or systems with standardized and sustainable processes that make errors more difficult to perform, make the 'right' thing to do the easiest thing to do and aid the detection and correction of errors if they do occur (e.g. replacement of vials of similar appearing drugs with well-labelled, prefilled syringes on a resuscitation trolley).[1] Increasingly, digital solutions incorporating clinical decision support are recommended to reduce specific clinical risks (e.g. electronic prescribing and medications administration).[9]

At all times:

- *Monitor and review*: the improvement of patient safety is a continuous process, and information concerning safety should be collated systematically and routinely and evaluated at scheduled intervals in order to detect changes in patient safety trends as early as possible. In addition, the impact of any changes to processes to improve patient safety should be monitored and evaluated in order to determine the effectiveness of the changes in reducing errors and to identify any unintended consequences that necessitate further refinement.
- *Communicate and consult*: patient safety is a team activity that requires communication of the approach to improving safety and its high priority to all members of an ED's staff. An open and fair culture, rather than a blame culture, must be promoted in order to yield the benefits of reporting systems. Participation in wider hospital and regional or national reporting systems offers the opportunity to learn from the mistakes of others. Expert help should be sought in attempting to evaluate patient risks or design interventions to improve safety. In the event of an adverse event, being open and honest with patients and with other staff improves the prospect of learning and the prevention of further errors.

Conclusion

Patients seeking emergency care are at significant risk of harm, in part due to their clinical situation and in part due to the challenges of delivery of emergency care itself. Improving patient safety in the ED requires a systematic approach to risk identification, risk analysis and evaluation and the implementation of safer processes of care. Monitoring is an essential component of patient safety improvement. An open, communicative culture that promotes reporting and minimizes blame supports patient safety improvement.

30.9 Wellness, resilience and performance in emergency medicine

Bethany Boulton • Melanie Rule • Alex Markwell

ESSENTIALS

1 Wellness is integral to performance and the ability to provide high-quality patient care.

2 Emergency physicians are at high risk of poor physical and mental health, including compassion fatigue and burnout.

3 Work-related distress is common. There is a need to move towards open discussion and encouragement of physicians to seek help when necessary.

4 Wellness interventions should include both individual and organizational strategies.

5 Peer support, mentoring, debriefing and access to trained counsellors can be of value.

6 Career longevity is identified as a significant issue for emergency physicians, and there is a need for ongoing research into workforce sustainability.

Introduction

A career in emergency medicine can be both rewarding and challenging. The combination of relentless shift work, high clinical acuity, challenging patient presentations and a real or perceived lack of control over the work environment creates a perilous milieu predisposing to poor physical and mental health, compassion fatigue and burnout.

Although literature reveals that doctors usually enjoy better physical health than the general population, emergency physicians suffer the highest level of burnout of all specialties.[1] The 2016 Australasian College for Emergency Medicine (ACEM) Workforce Sustainability Survey report revealed up to 75% of respondents had moderate to high degrees of the components of burnout (emotional fatigue, depersonalization and perceived lack of accomplishment).[2] To ensure career longevity, focus needs to be placed on well-being and maintaining meaning and joy in medical practice.

There is strong evidence that links physician health to workplace performance, which then directly relates to quality patient care. Happy workplaces with engaged staff are more productive, with better patient outcomes. The converse is also true, because patients treated by physicians with poor health suffer greater morbidity and mortality.[1]

Critical incidents, medical error and event debriefing

Emergency departments are high-risk environments for critical incidents, adverse events and medical errors. Witnessing major physical trauma, emotional trauma and death are everyday occurrences for staff. Their cumulative effect places individuals at risk of psychological impacts such as anxiety, depression and posttraumatic stress disorder. Involvement in an adverse event or medical error also has considerable impact on the well-being of staff involved.

After a critical incident or medical error, clinicians report experiencing ongoing feelings of sadness, guilt, shame, diminished confidence and anxiety about their ability to treat future patients, even years later. These clinicians are recognized as being *second victims*. Impact on their future practice includes a tendency to over-investigate and over-admit patients to avoid future adverse outcomes.[3]

Support for clinicians involved in critical incidents and medical error is imperative in order to prevent harm. Peer support networks and critical event debriefing have been proposed as workplace strategies that can be useful to support clinicians after these events. Formal critical event debriefing programmes, ideally facilitated by trained staff, are encouraged; however, this is not yet widely practised within emergency departments. Evidence of the long-term outcomes of these programmes and who should facilitate them is an ongoing source of controversy.[4] Many health care organizations provide access to trained counsellors through external employee assistance programmes, although these are often under-utilized.

It is important to accept that error is inevitable in complex human systems such as health care. Adopting a *just culture* in an organization, where reporting and systematic review of adverse events and near misses are encouraged, helps to anticipate and prevent errors. In a just culture, individuals are assured that any actions or omissions will not be subject to punitive or disciplinary actions, as long as they are within acceptable standards of practice.

Building individual strategies for dealing with failure can assist when inevitable adverse events occur during a career. Cultivating a growth mindset, where mistakes are not seen as failure but as an opportunity for improvement is protective when dealing with incident or medical error. Learned optimism and cognitive reframing are strategies based in positive psychology. Negative thoughts regarding an event are restructured and encouraged towards positive ones. Having a strong sense of identity outside that of clinician can also be effective in coping with failure when it occurs.

Compassion fatigue and compassion satisfaction

Individuals working in health care or emergency services are recognized as being at high risk for compassion fatigue. This is the emotional, moral and physical distress which occurs as a consequence of caring and bearing witness to the suffering of others. Compassion fatigue occurs through vicarious trauma, and repeated exposure compounds this, particularly when the individual loses perspective and the ability to access the usual protective mechanisms. Paradoxically, many health care workers also have high rates of the protective experience, compassion satisfaction, which is the positivity and growth resulting from caring for others and the ability to receive gratification and reward from the care–giving role.[5] Compassion satisfaction is not the antithesis to compassion fatigue, and somewhat counterintuitively the two conditions may co-exist.[5]

Distressed and impaired doctors

The demands of working in emergency medicine can take a physical, mental and emotional toll on physicians. It is imperative that doctors prioritize looking after themselves, as well as their professional colleagues. Physicians and managers must be trained in both recognizing and sensitively dealing with doctors in distress, including knowledge of the resources available to assist them.

Many doctors struggle to admit they are experiencing difficulty or to take time off to access help. Potential barriers include a fear of showing vulnerability, stigmatization, career consequences and mandatory reporting. Harmful behaviours observed in these doctors may include self-medication, alcohol and drug use.

Ideally, doctors in distress will seek care from their own general practitioner. Most health services also provide an employee assistance programme. Confidential advice and support is available in every Australian state and territory, as well as in New Zealand, with contact details accessible via the Australian Doctors' Health Network (adhn.org.au). These services operate 24/7 and are staffed by doctors and trained counsellors. In the United Kingdom, the British Medical Association offers a Counselling and Doctor Advisor service to support doctors in distress. Each province in Canada offers a Physician Health Program, and many states in America offer support via their Federation of State Physician Health Programs.

Mandatory reporting

Medical practitioners, employers and education providers are required by law to make a notification if they have a reasonable belief that the behaviour of a health care practitioner constitutes notifiable conduct or a notifiable impairment. This requirement aims to prevent the public being placed at risk of harm. Notifiable conduct includes:

- Practising whilst intoxicated by alcohol or drugs;
- Sexual misconduct in the practice of the profession;
- Placing the public at risk of substantial harm because of a health impairment; or
- Placing the public at risk because of a significant departure from accepted professional standards.

A mandatory notification is a serious event, and the threshold to trigger one is high. Due to recent concerns about the effect of mandatory reporting on the help-seeking behaviour of physicians, governments have agreed to review the existing legislation. If the risk is to the practitioner alone, with no risk to the public, the threshold for notification would not be reached. In addition, in a case where risk is being addressed by the physician seeking and participating in appropriate clinical management, mandatory notification is not required.

Any member of the public may raise a complaint or concern about a registered health practitioner, with notifications most commonly made to the Australian Health Practitioner Regulation Agency (AHPRA) in Australia or the Health and Disability Commissioner or Medical Council in New Zealand. Greater than 50% of notifications are dismissed without further action, but regardless of the outcome, the effect on the practitioner is often long-lasting.

Self-care and individual resilience strategies

Well-being can be considered as the sum of several components of health: physical, emotional, spiritual, intellectual, financial, social and occupational. Both the individual and the organizational contributions to these components are important.

Doctors who maintain preventative health strategies are more likely to recommend these same interventions to their patients. Importantly, their patients are more likely to follow this advice. To be able to provide safe and efficient medical care, physicians need to ensure that their basic physiological needs are met, including good nutrition and minimizing fatigue. Having an established relationship with a nominated general practitioner enables both preventative and therapeutic care.

Participating in activities that refuel or revitalize is essential for developing resilience. These may include physical exercise, hobbies, socializing with friends or family and meditation or mindfulness practice. In addition to the positive health benefits, practising mindfulness in the workplace (for example a few moments of mindful breathing whilst performing tasks such as handwashing or urine analysis) has been demonstrated to improve communication and lead to better patient outcomes.[6]

Identifying what brings an individual meaning and purpose both personally and professionally is fundamental. Physicians who spend 20% of their time on activities they find meaningful have lower levels of burnout and higher levels of satisfaction in their work.[7]

Ikigai (reason for being) is a Japanese philosophy that integrates one's talents and passions with more pragmatic concerns:

- That which you love;
- That which you are good at;
- That which the world needs;
- That which you can get paid for.

Reflecting on these components and defining what brings meaning across the work–life continuum can contribute towards an individual's engagement and satisfaction.

Organizational strategies

Addressing the issue of physician health is a shared responsibility between the individual and the organization. In addition to providing adequate resources and streamlined processes to deliver safe patient care, of prime importance is the organizational responsibility to assist in redefining medical culture, which has traditionally been one of perfectionism, stoicism, isolation and shame. Implementation of effective wellness programmes, such as the embedded mindfulness programme, oneED[8] and other practical options as described by Braganza et al.[9] have been shown to be feasible in busy emergency departments.

At an organizational level, physician burnout and distress represent a huge financial burden in the form of sick leave, staff turnover and reduced productivity. These factors contribute to increased rates of medical error and reduced quality of patient care.

Doctors' well-being is currently recognized as a missing quality indicator.[10] With tools that have been developed to assess several dimensions of physician well-being (burnout, stress, work–life integration, satisfaction), it is recommended that organizations both acknowledge the problem and measure these metrics routinely as institutional performance indicators. Collected data can be used to track interventional changes, benchmark against other institutions and national averages and should be published to add to the evidence base surrounding physician health initiatives.[7]

Leadership has a profound effect on staff well-being. A respectful, participatory management style of leadership has been shown to improve both burnout and satisfaction parameters.[7]

Effective leadership strategies include:

1. Keeping the team informed of changes in the workplace;
2. Seeking suggestions for workplace improvements and acting collaboratively towards solutions;
3. Acknowledging individual contributions and achievements;
4. Facilitating the professional development of others;
5. Having a safe environment for providing feedback and disclosing concerns.

Mentorship and peer support

Mentorship has been demonstrated to be an important influence on personal and professional development of doctors and helps to build a culture of support and collaboration.

It is paramount that mentoring be separated from the supervision processes within the workplace in order for trusting relationships to be built between mentors and mentees. Formal workplace mentoring programmes make mentorship accessible to all staff and can overcome some of the barriers to finding a professional mentor.

Co-worker support helps to buffer the negative effects of work demands.[10] Organizations should commit resources to peer support programmes because these have been shown to reduce symptoms of burnout and improve meaning at work.[7]

CONTROVERSIES AND FUTURE DIRECTIONS

- The value of critical event debriefing, who facilitates this and when.
- The impact that real or perceived concerns about mandatory reporting has on physician help-seeking behaviour.
- The relative responsibility of the individual versus the organization in optimizing physician wellness and healthy working environments.
- The focus on physician wellness continues to sharpen as more regulatory and accreditation bodies require this to be a priority for both individuals and workplaces.

Acknowledgements

The authors acknowledge the contributions of Dr Allison Fifoot and Dr Shahina Braganza to this chapter and additionally to cofounders of WRaP-EM, Dr Una Harrington, Dr Ashwini Amaratunga, Dr Suneth Jayasekara, Dr Charley McNabb, Ms Tracy Churchill and Ms Kate Jurd for their work on this important topic.
